This is consistent with patients' viewpoint who most frequently reported improving gait (f=6, n=5, 50%), memory (f=3, n=3, 38%), and balance (f=2, n=2, 25%) as their primary goal to increase their quality of life. In addition, patients reported being more active (f=1, n=1, 13%), increased functional abilities (ie, cooking; f=1, n=1, 13%), increased strength (f=1, n=1, 13%), or remaining independent in ADLs (f=1, n=1, 13%) as training goals:

> *It is mainly the memory. It is memory because it affects a lot of other things.* [P-01]

> *It would be wonderful, if I could go for a walk in the forest again without falling down.* [P-02]

> *I really want to remain independent. I definitely don't want to become dependent on others.* [P-05]

> *That I can keep things better in my head. That has diminished. That would be nice!* [P-06]

> *I want to have more strength again to increase stability and be able to walk longer.* [P-08]

T5: Exergame and Training Components

Location

Regarding training location, the experts reported that the patients would either prefer individual training at home (f=3) or in a mixed setting, including training at home combined with training at a clinic (f=4). None of the experts stated that patients would prefer exercising at a clinic or training facility in general, as this is often associated with excessive time expenditure. Training at home was reported to be beneficial, because it represents a known environment that makes patients feel more secure. However, the experts also stated that patients may not be capable of performing exercises or exergames independently and therefore need guidance throughout each training session (f=4) or at least partially (f=9); for example, when starting up the system or in case of technical problems:

> *The advantage of training at home is that "it's a known environment and they feel safer at home and also don't have to travel." However, "I would suggest that the help of a guiding therapist with experience will be necessary."* [E-09: exergaming researcher]

> *In a previous investigation [...], patients' feedback was that 70% could imagine doing the training from home. [...] For MCI-Patients specifically, relatives may be involved. But in general, the need for home-based exergame training is there, I would say.* [E-08: project manager therapy]

This is also reflected in the outcomes of the question of whether patients would be capable of performing home-based exergame training; the experts mainly reported that patients are certainly capable (f=4) or should be capable of considering some concerns (f=9) to perform such a training program independently at home. The concerns that need to be considered include the improvement of game instructions (f=2), accessibility of a handrail or similar for safety support (f=2), and avoidance of technical problems (f=2) or the integration of a guided familiarization period (f=1) or support of a care professional or partner (f=2):

> *I think if the system would really work properly then you could use it at home. However, if you just have some minor technical problems is already like a no-go to use it at home at all.* [E-01: exergaming researcher]

> *It would certainly be good if the patients could complete an accompanied training for a certain period of time in order to facilitate the transfer to training at home.* [E-04: exergaming researcher]

> *[...] some kind of adjustment of the instructions is needed [...], especially for this patient group and for independent training in the home-based setting. [...] The instructions have to be adapted in such a way that understanding can be achieved without someone having to stand next to the patients all the time.* [E-10: founder of an exergaming company]

Of those patients who responded to the question and had a clear preference regarding the training location, most (6/7, 86%) patients would clearly prefer to train individually at home, because it is less time consuming and more flexible. One patient did not have a clear preference; she simply wanted to perform the exercises where it was easiest for her and preferred group exercises:

> *For me, it is important that the training can be done independently at home. If I have to go to the doctor somewhere every time, it's simply too much work.* [P-01]

> *Preferably at home, if I can. Then I can also choose the time when I want to exercise. I have lived my whole life with a packed schedule. Now I want to be a little freer and more flexible.* [P-03]

Safety

The experts reported an increased risk for falls, as patients with mNCD (1) are easily distractable and (2) have difficulties in self-assessment and impaired planning abilities. Therefore, it was recommended to use the handrail in the beginning to minimize the risk of falls (f=3), which was also requested by 1 patient. In the case of a home-based exergaming system—which may not have a handrail—thorough and clear safety instructions are recommended (f=1):

> *Especially in the beginning, until the patients have understood what it is all about, it is very important to instruct using the handrail.* [E-04: exergaming researcher]

> *I definitely need a railing to prevent falls during training. I often fall down if I don't have anything to hold on to.* [P-02]

Instruction, Familiarization, and Guidance

As illustrated earlier, certain adaptations are required to enable a more independent use of the exergaming device. First, patients should be familiarized with the exergaming device and the corresponding games considering the following key elements: (1) start at an easy level (f=7), for example, by using the game "Simple" (f=4), (2) ensure that patients voluntarily try out the device (f=3), (3) ensure that you are not too confronting (f=2), (4) give patients enough time to familiarize with the new task (f=1), and (5) start with a reaction game, then progress to games for specific domains of neurocognitive function (f=1):

> *It is very important to start very slowly and at a low difficulty level until the patients can better assess their abilities on the "Senso". […] Since the game "Simple" waits for a reaction from the individual, it is very suitable to start with.* [E-04: exergaming researcher]

> *We always start with a reaction game so that the patients can learn the coupling of the cognitive-motor functions and learn to interact with the environment. Later on, we focus on specific cognitive functions.* [E-10: founder of an exergaming company]

Regarding the instructions, some adjustments are needed to improve comprehensibility. Currently, there is instructional text before starting each game. However, patients with mNCD have been reported to have limited comprehension of instructions. Therefore, adaptations are needed in the instructions of exergames in general and for a home-based exergaming system in particular. The experts mainly suggested to use step-by-step (f=3) instructions based on a combination of visual (ie, written instruction or video demonstration) and verbal instructions (f=4) guided by an experienced therapist (f=1). In case of more severely impaired patients or for home-based exergaming systems, it was suggested that practical demonstrations (f=2), video instructions (f=6) or even interactive "trial run" instructions (f=5) could improve comprehensibility of the games:

> *The transfer from the written instructions to the understanding of what is to be done in the game is sometimes difficult.* [E-06: physical and occupational therapist]

> *Personally, I would replace the written instructions with a short (few seconds) video sequence showing the most important functions of the games.* [E-08: project manager therapy]

> *I would recommend combining visual and verbal instructions. For example, through a visual presentation with additional step-by-step verbal instructions. Verbally we can "pick up" the patients very well and get a feeling whether the patients have understood the instructions.* [E-03: neuropsychologist]

> *[...], some kind of adjustment of the instructions is needed. [...] It is definitely important to pursue and use these adaptations, especially for this patient group and for independent training in the home-based setting", because "in the case of more severe impairments, it is often necessary to demonstrate the games step by step by yourself. [...] In other gaming systems there is a short test phase with explanations and trial runs [...]. However, this would have to be offered as an option, since most patients will no longer need it after a few sessions.* [E-10: founder of an exergaming company]

Finally, when guiding patients through their training sessions, social support and guidance by a care professional or partner might be beneficial (f=3). However, it was also mentioned that this might be critical because of personal conflicts or patients' psychological constraints (f=2):

> *Family members could play an important role in reminding and motivating patients to complete their training.* [E-06: physical and occupational therapist]

> *I don't think it's always a good idea to include family members as guidance, because the pressure to perform gets higher for the patients, since they try to hide their impairments from others. A health care professional like a nurse for example or physical therapists would be better than a husband or wife, I think. They already have a lot of fights in the households, because things are not working out as they should.* [E-09: exergaming researcher]

From a patient's perspective, all patients reported that they can imagine training alone, provided they had received thorough instructions and understood their tasks. One patient additionally requested regular support from a care professional or partner:

> *Yes, I think so. Once I learn that, I'm sure I can do it independently.* [P-03]

> *If I am supported by you or by my partner, then I can certainly train partly independently.* [P-07]

Exergame System and Content

Previous experiences of older adults with mNCD using the exergaming system "Senso" are illustrated earlier. Building on this, several game-specific adaptations were suggested by the experts (f=9):

> *More time should be provided between the balls so that the flood of information is reduced (it is often overwhelming when several balls are visible on the screen very quickly).* [E-07 (physical and occupational therapist): for the game "Targets"]

> *In the initial phase, until patients' have understood all the game tasks [...], the speed must definitely be reduced.* [E-06 (physical and occupational therapist): for the game "Habitats"]

> *There are already enough opportunities to increase the task difficulty. [...] However, it is very important to note that the game difficulty is adjusted downwards so that it is easier to start the training.* [E-08: project manager therapy]

In addition to these game-specific adaptations, multiple novel game designs and elements have been suggested and discussed by focus groups to address patients' needs optimally. In general, it has been recognized that there is a need for new games specifically targeting the neurocognitive functions of learning and memory (f=4) and executive functions (ie, working memory and cognitive inhibition; f=2). Specific game design suggestions were discussed for such a memory or working memory game. Additional suggestions for new game designs and elements include the use of music, addition of visual reminders to guide patients within the games, or adaptations in performance feedback:

> *With the "Senso", a certain spectrum of neurocognitive function domains is covered. However,*

> *games for working memory, inhibition or memory are completely missing. In the case of memory, there is currently only one game available specifically targeting the training of short-term memory span.* [E-05: neuropsychologist]

> *I think music would be very motivating for people with MCI or dementia also if is music from their youth or music they like. It's also been described in the literature that music has so many good effects on people when they have heard a song that they liked before and they are singing that song.* [E-09: exergaming researcher]

> *In addition, it would be good to include reminders, for example at the edge of the screen, which patients can use for orientation. [...] Additionally, [...] it would certainly be helpful here if the program not only displayed the performance curve, but also provided a reason or explanation.* [E-03: neuropsychologist]

As general requirements when designing new games, the experts recommended using simple graphics and ensuring good contrast (f=14), a comfortable relation, and good usability of the exergames (f=4) using easily comprehensible and clearly designed tasks (f=2) with a certain closeness to everyday life (f=7). Multimodal animations, including multisensory feedback (f=7), should additionally be integrated by focusing on positive reinforcement mechanisms (f=2) to motivate the patients during exergaming. In addition, it is important that the main task is in the center of the screen (f=1) and that only elements that are related to the game task are included (f=5). Moreover, too confronting performance feedback (f=1) and unexpected appearance or technical problems (f=2) should be avoided:

> *It is very important to create a good contrast. [...] It's generally important for the older population to keep the graphic representation as simple as possible, because for older people, the game is not characterized by great graphics, but by the game task as such. The main importance is that the right level of challenge is offered.* [E-08: project manager therapy]

> *It is much better to present a simple graphic and focus on the aspects that need to be trained. [...] unnecessary graphic gimmicks should be avoided!* [E-04: exergaming researcher]

> *It is important to have a main action that is in the center of the screen and to ensure that the player will have primary task in the center. If you put any secondary tasks into the games, it can be confusing for the patients.* [E-02: exergaming researcher]

> *Spontaneously, I would say that games close to everyday life are more popular. [...] These games were much better received than abstractly structured games ("visual exploration tasks").* [E-03: neuropsychologist]

> *My experience so far is that games that are designed to be more relevant to everyday life (and simpler) work better. Therefore, new game designs should be based on what patients know from their everyday lives.* [E-06: physical and occupational therapist]

Training Components

The recommended exercise frequency ranged from 2 (f=3) to 5 or more (f=4) training sessions per week, largely dependent on training location and motivation. The recommended session durations ranged from a maximum of 15 to 20 minutes (f=3) up to 30 minutes (f=2), with the aim of reaching a moderate exercise volume of approximately 150 minutes per week (f=1). Shorter sessions and a higher training frequency have been reported to be preferable to reach this training volume, mainly owing to attentional exhaustion:

> *The more the better! I would prefer shorter training sessions, especially because of attentional exhaustion. Here I would recommend a maximum of 30 minutes and at least 5 sessions a week. This is much better than training for 2 hours at a stretch!* [E-03: neuropsychologist]

> *I would recommend a training frequency of 2 – 3x/week. [...] The training duration is difficult to estimate. Some patients are already exhausted after 2 minutes, others can easily train for 20 minutes.* [E-10: founder of an exergaming company]

> *I think that a training frequency of 3x/week is already (too) much. 2x/week should be possible to arrange. 1x/week definitely works. This may be because three appointments, in combination with other activities, may already be too much for patients. If the training could be done at home, the training frequency could certainly be increased up to 4 - 5x/week. In this case, motivation could still be difficult.* [E-07: physical and occupational therapist]

> *I would aim for a training volume of 150 min/week. As far as I know, this is considered moderate for older patients. I would consider 100 min/week as the lower limit. A minimum of 3 x per week for 30 min would also be okay at best.* [E-08: project manager therapy]

Exercises requiring a coupling of physical and cognitive functions were described as preferable and should be prescribed domain-specific depending on the patient's abilities:

> *I think that the coupling of brain functions with physical functions is central. Whether this is ultimately an attention game, or a training of the executive functions is something I don't consider central at the beginning. Of course, it also plays a role here which cognitive functions are impaired. [...] If the frontal lobe is impaired, it is certainly important to train executive functions, attention and inhibition.* [E-10: founder of an exergaming company]

To maintain the training program in the long term (preferably >12 weeks), motivation is a key factor that can be facilitated by the playful character of the exergames and a variation in the choice of games. Nonetheless, patients seem to prefer a certain routine:

> *Of course, the training should be maintained over a certain amount of time at a stretch. So not just two*

> *weeks, but ideally longer (more than 12 weeks). Of course, motivation is also a very central point. If the training is varied and has a playful character, this should be feasible.* [E-03: neuropsychologist]

> *Patients are generally routine-oriented, which can also be observed in general. Therefore, it is also important to introduce a new game every now and then. The patients primarily prefer the familiar games and should therefore be challenged to a certain variety.* [E-10: founder of an exergaming company]

The physical exercise intensity should be maintained at a light to moderate level, while the focus should be on game complexity that should be challenging but feasible. Game complexity can be varied on multiple levels, for example, (1) stability support (use of handrail with both hands, 1 hand, or no support), (2) stepping direction, (3) game choice and tasks included, (4) game duration, or (5) game speed:

> *Adding new games. I always start with the game "Simple" and sometimes in the first session I also introduced "Birds" when I think it would be possible. If not, then I will do it the next session. If somebody is really performing well and understanding all the instructions, then I also progress to the game "Targets" and even "Birds".* [E-09: exergaming researcher]

> *I also often started with just stepping movements forward [...] and included the step direction to the right at a later timepoint.* [E-10: founder of an exergaming company]

> *We have a routine that we usually do the training sessions over 3 weeks and do the first 3 sessions with holding, just to get a feel for the games. After that, we gradually go back to holding on with one arm and without holding on.* [E-08: project manager therapy]

From the patients' viewpoint, a high training frequency (mean preferred training frequency 5.21 times per week; n=7), ranging from 2 times per week (n=1, 13%) to daily sessions (n=4, 50%)) with short session durations (mean preferred session duration 23.4, SD 10.3 minutes; n=8), ranging from 10 minutes (n=1, 13%) up to 30 minutes (n=3, 38%) was preferred. Five of 6 (83%) patients who responded to the questions about how long they would prefer to do the training stated that they would prefer to continue the training as long as they profit from it and are able to do it. All patients preferred a training that is individually adapted to apply moderate (4/5, 80% of patients) to high physical (1/5, 20% of patients) intensity and moderate (3/5, 60% of patients) to high (2/5, 40% of patients) cognitive challenges:

> *If the device was at home, I would do the training every day.* [P-01]

> *I don't want to make a guarantee now, but I could do a short training session every day for like 20 minutes or so. But I can't promise that I'll do 40 minutes every day, because I also want to do other things. Especially when the weather is nice, I like to go outside. And then I also must do the housework, which also takes time.* [P-03]

> *I think about 30 minutes is good. If it goes on too long or is too strict, then I get tired of it. I don't like that. That would be counterproductive.* [P-05]

> *If I have the device, I could do this training forever. As long as I still have the strength to do it.* [P-02]

> *I would need a bit of a start-up period first. If it's not effective, I'll stop again. Additionally, I don't know how my health will be in the future. But as long as I'm reasonably fit, I'll definitely want to do it.* [P-07]

Individualization

Individualization of the exergame intervention concept should mainly account for two aspects: (1) task type (ie, choice of exergames to individually focus on neurocognitive functioning; f=4) and (2) task demands (ie, adapting the game demands according to the individual capabilities to maintain a challenging but feasible cognitive load; f=5). In addition, it was recommended to change between games with different task demands to enable the maintenance of attention over the entire training duration (f=2) and to supervise training exertion (f=3):

> *It is important to have a system that will adapt the games according to the participant's performance.* [E-02: exergaming researcher]

> *The physical intensity is often not a problem, and it should primarily be the complexity of the training that is individually adapted so that it is doable and still has a certain physical demand.* [E-10: founder of an exergaming company]

> *[...] We also have to check whether somebody is very fatigued [...]. Sometimes you have to let someone take a rest because they will not always feel when they have to take a rest.* [E-09: exergaming researcher]

> *One should "[...]alternate between games that focus primarily on performance and less on cognitive aspects with more cognitively demanding games."* [E-08: project manager therapy]

Discussion

Principal Findings

The objective of this study was to determine the capabilities, treatment preferences, and motivators for training older adults with mNCD, as well as their perspectives on training goals, settings, and requirements for exergames and training components. This will—together and in line with a synthesis of the optimal evidence-based informed decisions—serve as basis for user modeling, determination of therapeutic needs, and definition of a set of requirements for the game design and development process of a novel exergame-based training concept. To the best of our knowledge, this is the first study to systematically and thoroughly investigate user requirements and preferences for an exergame-based training concept before it is designed and developed specifically for older adults with mNCD based on these findings.

The results of our qualitative study, which included focus groups with 10 experts or health care professionals and individual semistructured, in-depth interviews with 8 older adults with mNCD, yielded the following key findings: (1—capabilities) from a patients' viewpoint, the psychosocial consequences of their self-perceived cognitive deteriorations might be more burdensome than the cognitive changes themselves; (2—treatment preferences) more integrative forms of training (such as exergaming) including gamified tasks close to everyday life, multimodal animation, and acoustic feedback are preferred by patients. None of the interviewed patients reported any previous experience with exergaming, but all patients described the handling of different technologies as feasible despite some challenges and were willing to try out exergaming; (3—motivators for training) from the expert's viewpoint, the most frequently described motivators to train can be classified as intrinsically regulated motivators such as excitement, enjoyment, or fun in exercising that is maintained by the captivating character of exergames supported by specific game components (eg, game tasks or designs close to everyday life or with personal relations or memories including music or sound effects, animals or plants, landscapes, or colors); the feeling of being optimally challenged; and the variation of training. All patients reported that they could primarily be motivated by the effectiveness of the training, helping them to achieve success on an individual basis; (4—training goals and outcomes) the most important training goals of older adults with mNCD include improvements in ADLs and mobility (gait and balance) and memory, because these outcomes were described as central to improving their quality of life; (5—exergame and training components) the use of home-based exergames as a form of simultaneous-incorporated motor-cognitive training should be prescribed with a domain-specific training focus depending on a patient's cognitive abilities, a high training frequency (4-5 training sessions per week), short session durations (20-25 minutes), and individual adaption and progression of task type and demands to reach a light to moderate level of physical intensity and a challenging but feasible game complexity. To maintain the training program in the long term (preferably >12 weeks), motivation is a key factor and should be facilitated by the playful character of the exergames, variation in the choice of games, and ensuring that the patients are optimally challenged. To make home-based training interventions feasible, multiple factors that need to be considered were identified. Patient-friendly game instructions are needed, while the accessibility of a handrail or similar for safety support, avoidance of technical problems, and the integration of a guided familiarization period or support from a care person need to be ensured to make home-based exergame training feasible. As general requirements for exergame design, simple graphics with good contrast and easily comprehensible and clearly designed tasks with a certain closeness to everyday life should be used. Multimodal animations, including multisensory feedback that focuses on positive reinforcement mechanisms, should be integrated to motivate patients during exergaming. In addition, it is important that the main task be in the center of the screen and that only elements that are related to the game task are included. Moreover, confronting performance feedback and unexpected appearances or technical problems should be avoided.

Capabilities of Older Adults With mNCD

A variety of cognitive changes mainly affecting the neurocognitive domains of learning and memory, complex attention, and executive function were discussed by the focus groups and mentioned by the patients, whereas no serious restrictions on physical capabilities, mobility, and ADLs were reported. This is in line with DSM-5 [9]. According to the definition of mNCD, modest (ie, for mNCD, performance typically lies in the 1-2 SD range) deterioration in cognitive functioning can be observed, whereas the capacity for independence in everyday activities is preserved [9]. However, from the patient's perspective, the most prominent consequences of their disorder were described as affecting psychological factors, mainly by causing psychological distress, feelings of insecurity, and depression. It is well known that depression and anxiety are common in older adults with mNCD [72,73]. In addition, patients with depression have higher rates of conversion to dementia, indicating that depression is an important risk factor for cognitive decline and progression to dementia. This emphasizes the importance of assessing depressive symptoms in older adults with mNCD [72].

Treatment Experience and Preferences

Most of the interviewed patients had already gained experience with different treatment or training approaches to counteract cognitive decline and preserve physical capabilities, mobility, and ADLs. Although MTT, physiotherapy, and CCT were perceived as useful, the patients reported being insecure about the effectiveness of these approaches or that they would have to (be able to) do it more consistently to profit from it, which was described to be limited by the availability of therapists. More integrative forms of training, including gamified tasks close to everyday life, multimodal animation, and acoustic feedback, were reported to be preferred by patients.

This is in line with the literature, showing that "research involving older adults has found that CCT programs are associated with high satisfaction levels, and that they are also a feasible option for individuals with MCI, with equal or better adherence rates when compared with traditional cognitive training" [74-76]. This is also evident in the use of exergames. Exergame-based training interventions are widely accepted in individuals with mNCD, and exergames increase or enhance participants' motivation to engage in rehabilitation activities [40]. This is also reflected by the adherence rates to different types of exercises in patients with mild to major NCD. Recent systematic reviews and meta-analyses synthesized mean adherence rates of 70% [77] for physical exercise interventions, whereas the mean adherence rate was higher for exergame-based interventions at 84% [78]. To the best of our knowledge, there is no systematic review that has synthesized adherence rates to CCT. However, Turunen et al [79] investigated adherence to a long-lasting multidomain CCT among a sample of 631 older adults at risk of dementia. It was shown that only 20% of participants completed at least half of their CCT sessions, and only 12% of participants completed all (maximal number of training sessions=144) of their training sessions. In addition, 37% of the participants did not train at all, whereas "previous use of computers, better memory, being married/cohabiting, and positive study expectations were independently associated with the greater probability of starting the CCT. Previous computer use was the main determinant of the number of CCTs completed after the training was initiated" [79]. Therefore, when comparing these findings, it appears that exergame-based interventions have the highest adherence rates among different training programs. This is consistent with findings in HOAs, where adherence to technology-based training programs was higher than that to traditional training programs, independent of study site or level of supervision [80]. This finding may be largely explained by the high level of enjoyment in using technology-based physical exercise programs [80]. Technology-based training systems offer several advantages over traditional training programs that may contribute to a more enjoyable exercise experience. For example, exergames can provide real-time feedback and positive reinforcement while exercising and can monitor performance over time [80]. In addition, exergames enable individual real-time adaptivity of physical and cognitive task demands according to the participants' performance or physiological response (eg, heart rate and brain activity), which is considered a key advantage of serious video games (such as exergames) [81-83]. In fact, the findings of our study suggest that applying an optimal challenge is central to promote the use of exergames in patients with mNCD in the long term.

When considering the experts' previous experience in the use of exergames (ie, "Senso") with patients with mNCD, the interaction with the device, its overall usability, and the design of the exergames were described as good. Especially the simple and clear game design structures were reported to be highly appreciated by patients and to promote good task comprehensibility. Various minor usability issues were reported, including difficulties in the interaction with the exergame training system "Senso" (eg, unintendingly walk off the middle plate without noticing the feedback on the screen), but mainly, usability issues that related to capabilities of older adults with mNCD (eg, limited comprehensibility of the game instructions) were reported. These usability issues need to be considered and addressed when developing a training concept specifically for older adults with mNCD. Nevertheless, it is important to emphasize that these are only minor usability issues, and only minor refinements are required to optimize the exergame experience. This is also illustrated by recent studies showing that exergame-based training programs using the "Senso" are feasible; usable; and widely accepted in different populations including community-dwelling older adults [84], geriatric inpatients [51], and patients with major NCD [52], chronic stroke [85], or multiple sclerosis [86]. Therefore, when designing and developing an exergame-based training concept specifically for older adults with mNCD, these refinements should primarily target the adaptability and individualization of task demands and the optimization of the instruction of the exergames.

Motivators for Training

The motivating factors most frequently described by experts were classified as intrinsic motivators. These were described as being maintained by the captivating character of exergames and promoted by specific game components such as game tasks or designs close to everyday life or with a personal relation or memory, including music or sound effects, animals or plants, landscapes, or colors. In addition, patients were described to be intrinsically motivated by gamification and the feeling of being optimally challenged. From a patient's perspective, the effectiveness of the training, which helped them achieve their individual success, was clearly the most prominent motivator.

This is consistent with reports in the literature. More autonomous forms of motivation can be promoted by various factors, although these factors may vary depending on the population. For example, a small case-control study compared the motivational factors for using a balance exergame platform between healthy younger and older adults. It was shown that "older adults were more intrinsically motivated by the joy of playing and extrinsically motivated by the perceived health effects (physical and cognitive), with less regard for the in-game rewards" [87]. To provide effective interventions to promote physical activity [88] in patient with NCDs, a new theoretical model has recently been introduced. This theoretical model is based on the review of existing theories that explain behavior change in relation to physical activity in HOA, which were then adapted and integrated to a new theoretical model called the "PHYT in dementia" [88]. In this framework, several additional key elements for promoting behavioral changes in physical activity have been proposed. These consist of self-efficacy, including embarrassment (eg, supervision of activity had a negative impact on engagement in the intervention), personal concerns (eg, fear of falling), and routine (eg, flexible integration of physical activity intervention into daily life regarding place and time of performance), as well as appropriate challenges [88]. A detailed awareness of participant motivators is required, especially for the preference that the routine can be performed at home and at different times during the day [88], because self-determined motivation may be a central aspect of adherence to home-based training programs [89].

Training Goals and Outcomes

The interviewed experts recommended to mainly target cognitive functioning when developing a training concept for older adults with mNCD, while ADLs and mobility, physical capabilities, and psychosocial factors should also be accounted for. This is consistent with the patients' viewpoint that most frequently reported improving gait and memory as their primary training goals to increase their quality of life.

Similar results have been documented in the literature. According to a survey of patients who completed a multicomponent behavioral intervention for patients with MCI and their caregivers, quality of life was the most important outcome priority for patients with MCI, followed by self-efficacy, depression, basic ADLs, memory-based ADL, anxiety, and memory performance [90].

Exergame and Training Components

The use of exergames as a form of simultaneous-incorporated motor-cognitive training is recommended, which should be prescribed domain-specifically, depending on a patient's cognitive abilities. Previous studies applying exergame-based motor-cognitive training in older adults with mNCD or MCI have used commercially available exergame systems [76,91-96] or exergames that were specifically developed for patients with mNCD or MCI [97-100], which comprised sensor-based stepping platforms [94], video camera–based or wireless remote device systems [76,91,95,97,99], or exergames that were controlled using a cycle ergometer or similar [92,93,96,98,100]. The training programs can be classified as simultaneous-additional [92,93,96,98] or simultaneous-incorporated [76,91,94,95,97,99,100] motor-cognitive training that was applied targeting 1 [93,100] or multiple [76,91,92,94-99] neurocognitive domains, including complex attention [76,91,92,94-99], executive functions [76,91,92,94-100], learning and memory [91,93-95,97-99], or visuospatial skills [76,97,99]. Only one of these studies applied training that individually prescribed content on the basis of a patient's cognitive abilities [96]. However, it has not been performed or reported in a reproducible manner.

Therefore, so far and to the best of our knowledge, 11 studies have been published that investigated exergame-based motor-cognitive training in older adults with mNCD or MCI. Most of these studies designed or used exergames that could be classified as simultaneous-incorporated motor-cognitive training. Incorporating cognitive tasks into motor tasks may be more beneficial for consolidating neuroplasticity [42], because (1) it leads to greater (motor) cognitive improvements, (2) it is closer to daily life situations, (3) no prioritization effects occur, which can be observed in motor-cognitive training with additional cognitive tasks, and (4) multiple sensory systems are stimulated at the same time, which may provide an optimal basis for cognitive processes such as learning [42]. Meta-analytic evidence suggests that simultaneous motor-cognitive training is the most effective type of training for improving cognition in HOA [43,44] and in older adults with mNCD [44-46]. Nevertheless, it remains to be evaluated whether the incorporation of cognitive tasks into exercise or training interventions indeed results in more distinct effects on cognitive performance compared with simultaneous motor-cognitive training with a non–task-relevant secondary cognitive task [42]. Finally, there seems to be room for improvement regarding the domain-specific prescription of the training content, considering a patient's cognitive abilities and the adaptation and development of exergames specifically for patients with mNCD. This may be especially relevant when considering the large heterogeneity in the clinical symptoms of older adults with mNCD. Remarkably, most previous studies applying exergame-based motor-cognitive training in older adults with mNCD or MCI have used commercially available exergame systems [76,91-96], in which the training content does not specifically target patients with mNCD. This is consistent with the findings of HOA. In a systematic review, Valenzuela et al [80] emphasized that in HOA, most studies used commercially available exergame systems. It was argued that these systems may be difficult to use for those with little or no experience with technology, because these systems often lack clear instructions, present too much graphical information, and have not been designed and developed to provide optimal training components for the target population and aims of the studies in which they were used [80]. In fact, all previous studies applying exergame-based motor-cognitive training in older adults with mNCD or MCI have used exergames with complex 2D or 3D virtual environments [76,91-100]. This may not be optimal because the limitation that such systems may be difficult to use for those with little or no experience with technology could be even more pronounced in patients with mNCD, as these patients are easily distracted and quickly overwhelmed by the task demands. Indeed, according to the recommendations of the interviewed experts, it is beneficial to focus on the aspects that need to be worked on by implementing easily comprehensible and clearly designed exergame tasks and to only present elements that are directly related to the game tasks while avoiding unnecessary graphical information or distractors.

According to the recommendations of the interviewed experts, the training program should be maintained over the long term (preferably ≥12 weeks). A training frequency of 2 to 5 or more training sessions per week was recommended, largely depending on the training location and motivation. In addition, it is recommended to reach a moderate training volume of approximately 150 minutes per week. To reach this training volume, shorter training sessions and a higher training frequency should be applied, because longer training sessions might lead to attentional exhaustion in this group of patients. Therefore, the experts recommended session durations between 15 and 20 minutes up to a maximum of 30 minutes. Previous studies applying exergame-based motor-cognitive training in older adults with mNCD or MCI have prescribed training programs over durations of 5 weeks [97], 6 weeks [91,94,98,100], 12 weeks [96,99], 3 months [93,95], 24 weeks [76], or 6 months [92]. The prescribed training frequency was 1 time per week [76], 2 times per week [94,96,99], 2 to 3 times per week [95], 3 times per week [97,98], 3 to 5 times per week [92,93,100], or 5 times per week [91] with session durations of 15 minutes [99], 18 to 30 minutes [94], 20 to 80 minutes [97], 25 to 30 minutes [91], 20 to 40 minutes [93], 30 to 45 minutes [100], 40 to 45 minutes [98], 45 minutes [92], 60 minutes [96], 90 minutes [76], or not reported [95], resulting in a weekly training volume of 30 minutes [99], 36 to 60 minutes [94], 60 to 200 minutes [93], 90 minutes [76], 90 to 225 minutes [100], 100 to 145 minutes [97], 120 minutes [96], 120 to 135 minutes [98], 125 to 150 minutes [91], 135 to 225 minutes [92], or not reported [95]. Therefore, most of these studies prescribed a training volume that was in line with the recommendations of the experts in this study. However, the session durations often exceeded the experts' recommendations, whereas the training frequency was lower than recommended. To avoid attentional exhaustion of the patients during training, future training concepts might consider prescribing shorter session durations while increasing the training frequency to achieve a similar training volume per week. This might actually improve the effectiveness of the intervention because higher training frequencies have already been shown to promote the effectiveness of physical (ie, ≥4 times per week) [101] and cognitive training (ie, >3 times per week) [102], while shorter session durations (ie, ≤30 minutes) [101] of physical exercise have been shown to exert more pronounced training effects. These findings might also apply to simultaneous motor-cognitive training. A meta-analysis revealed that training frequency is a significant moderator of the effects of physical and motor-cognitive training interventions on cognitive functioning, favoring higher training frequencies (≥5 times per week) in a mixed population of HOA and patients with mNCD [103]. Finally, a high training frequency (approximately 5 times per week) with short session durations (approximately 20 minutes) would also match the preferences of the interviewed patients in this study.

The experts reported that the training should preferably be individually carried out at the patients' homes, not only because it represents a known environment that makes patients feel more secure and represents a less-confronting environment for them (because they do not have to hide their impairments from others when training alone), but also to allow higher training frequencies. Nonetheless, to ensure that training in patients' homes is feasible, multiple factors need to be considered. For example, improvements in game instructions are required, a handrail or similar needs to be made available to allow safety support during training, and technical problems must be avoided. In addition, a guided familiarization period and part-time supervision or support from a care professional or partner should be integrated to make the transfer to home-based exergaming easier. Previous studies applying exergame-based motor-cognitive training in older adults with mNCD or MCI have administered individual [91] or group-based [76,96,99] training sessions, and the training setting (ie, individual vs group sessions) has not been clearly reported [92-95,97,98,100]. The training sessions were conducted at the hospital [91], in a nursing home [94], at day-care centers or memory clinics [99], at a centrally located church [76], at patients' homes [93,100], or the training location was not clearly reported [92,95-98]. The training sessions were supervised by a therapist [91,94,96], or supervision was not reported [76,92,93,95,97-100]. Consistent with summarized previous studies applying exergame-based motor-cognitive training in older adults with mNCD or MCI, most cognitive training programs to date have also been conducted in group sessions [104]. However, most of our interviewed patients clearly stated that they would prefer to train individually at home or with the support of a care professional or partner. Therefore, it might be worthwhile to put more effort into designing and developing exergames that can be used individually at home. This would possibly also reduce the barriers of patients with mNCD to engage in exergame-based training programs in the long term.

Regarding training demands, the experts recommended focusing on game complexity to ensure a challenging but feasible cognitive demand. Physical exercise intensity should be maintained at a light to moderate level. To allow individualization of the cognitive demand in training, two main aspects should be considered: (1) task type (ie, choice of exergames to individually focus on neurocognitive functioning) and (2) task demands. To allow individualization of task demands, the following factors should be varied based on the experts' recommendations: (1) stability support (use of handrail with both hands, one hand, or no support), (2) stepping direction, (3) game choice and tasks included, (4) game duration, or (5) game speed. Previous studies applying exergame-based motor-cognitive training in older adults with mNCD or MCI have applied relatively effortful, high cognitive demands [92], low [97] to moderate [96-98] physical exercise intensities, or have not reported the physical [76,91-95,99,100] or cognitive [76,91,93-100] exercise load or training progression in a clearly reproducible way. This exemplifies the fact that the optimal cognitive load for motor-cognitive training remains unknown. To the best of our knowledge, there has only been 1 meta-analysis to date that compared the effects of training interventions on cognitive functioning in relation to different task complexities and found no difference between simple and complex cognitive games [105]. Therefore, further investigations are needed to identify the optimal cognitive training demands and optimize the monitoring and progression of training programs. For physical exercise intensity, the recommendations of the interviewed experts are in line with those of previous studies applying exergame-based motor-cognitive training in older adults with mNCD or MCI. This also matches the analysis of the moderating variables of the training parameters that influence the effectiveness of the interventions. Based on meta-analytic results from motor-cognitive training in older adults with mNCD, moderate physical training intensity [45] has been shown to be most effective in improving cognitive function. Finally, moderate physical exercise intensity would also match the preferences of the patients interviewed in this study.

Implications for Research

Our findings serve as a basis for user modeling, determination of therapeutic needs, and definition of a set of requirements for the game design and development of novel exergame-based training concepts. To increase the probability that the resulting training will be deemed feasible in future clinical practice, these considerations should be integrated to guide the decision process for the most suitable exergame design and intervention components when developing novel exergames and exergame-based training concepts.

Limitations

The outcomes of this qualitative study must be interpreted with some caution, considering the following limitations. First, none of the interviewed patients with mNCD belonged to the clinical subtypes of mild frontotemporal NCD or mNCD with Lewy bodies. Depending on the clinical subtypes and the associated clinical pictures of the patients, different findings may have emerged from patient interviews. However, a substantial fraction (ie, ≥60%) of mild or major NCD is attributable to Alzheimer disease, whereas mild vascular NCD is the second most common cause of NCD after Alzheimer disease; frontotemporal NCD only accounts for approximately 5% of cases [9]. Therefore, the included study population appeared to be representative of these clinical subtypes. Second, owing to difficulties in recruiting patients, those screened for MCI according to predefined criteria were recruited in addition to patients with a clinical diagnosis of mNCD, which increased the heterogeneity of the study population. By contrast, in our project, we aimed to develop an individualized exergame-based training concept not only to treat clinically diagnosed patients with mNCD but also to prevent progression to dementia in individuals at risk who might not have been diagnosed (yet). Third, owing to the COVID-19 pandemic, all focus group sessions were held as web-based meetings. Face-to-face focus group sessions might have promoted livelier exchanges and may have led to additional insights.

Conclusions

The psychosocial consequences of patients' self-perceived cognitive deterioration may be more burdensome than the cognitive changes themselves. Older adults with mNCD prefer integrative forms of training (such as exergaming) and are primarily motivated by enjoyment or fun in exercising and the effectiveness of the training. Putting the synthesized perspectives of training goals, settings, and requirements for exergames and training components into context, our considerations point to opportunities for improvement in research and rehabilitation, either by adapting existing exergames to patients with mNCD or by developing novel exergames and exergame-based training concepts specifically tailored to meet patient requirements and needs.

Acknowledgments

The authors would like to thank the Synapsis Foundation—Dementia Research Switzerland (grant 2019-PI06) for funding this project. The authors would like to thank all the participants in this study for their participation and valuable contributions to this project.

Data Availability

The data supporting the findings of this study are available from the corresponding author (PM) on reasonable request.

Authors' Contributions

PM was responsible for the conception and protocol development of this study under the supervision of EDdB. MAO contributed to the study conception. PM was responsible for the recruitment of participants, data collection, data analysis, and writing of the manuscript. Data coding and analysis was cross-checked by MAO. All authors have contributed to the revision of the manuscript. All authors have read and approved the submitted version.

Conflicts of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as potential conflicts of interest. Dividat AG was asked to suggest suitable participants for the expert focus group discussions by providing a contact list of experts and health care professionals, as the company is well connected with institutions for geriatric populations, physiotherapies, and rehabilitation clinics in Switzerland. Therefore, we were able to identify experts and health care professionals who experienced exergame training with older adults with mild neurocognitive disorder. Experience was preferred with the exergame training system "Senso (Flex)" or similar. In addition, the founder of Dividat AG was partaking in one of the focus group discussions as an industry representative in line with the Multidisciplinary Iterative Design of Exergames framework. Dividat AG had no other role in the study and did not play any role in the design and conduct of the study; they also did not play any role in the data analyses, interpretation, or decision to submit results.

Abstract

Background: Virtual reality (VR) has been suggested to be effective at enhancing physical exercises because of its immersive characteristics. However, few studies have quantitatively assessed the range of motion and brain activity during VR exercises.

Objective: We hypothesized that 3D immersive VR could stimulate body movement and brain activity more effectively than standard exercises and that the increased range of motions during 3D immersive VR exercises would be associated with orbitofrontal activation.

Methods: A randomized crossover trial was conducted to compare exercises with and without VR. A total of 24 healthy males performed the same motions when exercising with and without 3D immersive VR, and the recorded videos were used for motion analysis. Hemodynamic changes in the prefrontal cortex were assessed using functional near-infrared spectroscopy.

Results: There were significant differences in the total angle (z=−2.31; P=.02), length (z=−2.78; P=.005), calorie consumption (z=−3.04; P=.002), and change in accumulated oxygenated hemoglobin within the right orbitofrontal cortex ($F^{1,94}$=9.36; P=.003) between the VR and offline trials. Hemodynamic changes in the right orbitofrontal cortex were positively correlated with the total angle (r=0.45; P=.001) and length (r=0.38; P=.007) in the VR exercise; however, there was no significant correlation in the offline trial.

Conclusions: The results of this study suggest that 3D immersive VR exercise effectively increases the range of motion in healthy individuals in relation to orbitofrontal activation.

Introduction

Virtual reality (VR) is an artificially created sensory experience using digital technology, which provides users with a subjective sense of "being there" [1]. The format of VR, referring to the structure of the information displayed, can be either 2D or 3D multimedia. The main difference between the 2 formats is the level of interactivity, with 3D environments allowing changes in the user's point of view, navigation, and interaction with objects and people. The display devices, which are the technological equipment used to visualize the formats, are classified based on the level of immersion they provide: nonimmersive, semi-immersive, and immersive. Nonimmersive systems are simple devices that use a single screen, such as a desktop PC. Semi-immersive systems, such as the Cave automatic virtual environment and the Powerwall display, provide a stereo image of an environment using a projection linked to the observer's position. Immersive systems, such as a head-mounted display (HMD), isolate the user from external world stimuli [2]. An HMD gradually follows the users' movements, quantifies the position and direction of articles in reality, and creates a corresponding stereoscopic view. Users perceive themselves to be situated in a virtual environment and are temporarily unable to recognize behaviors and objects in the real environment [1].

VR is expected to have enormous potential in fields such as education, training, and entertainment [3]. In particular, the application of VR technology is promising in the field of sports, as it can overcome human limitations due to technical innovations, thus allowing for the development of effective training methods [4].

VR application in sports can increase motivation, enjoyment, and physical performance [5]. This may be due to the unique characteristics of VR, such as immersion, interaction, and infinite degrees of freedom in spatial and temporal situations [6,7]. Fox and Bailenson [8] showed that physical activity could be increased through a reinforcement mechanism using immersive VR technology. Jones et al [9] demonstrated that immersion in VR exercises was positively correlated with motivation, pleasure, and enjoyment after exercises. In addition, participants can interact with objects in a stereoscopic visual space without spatial limitations, which can be manipulated in various ways, depending on individual needs [10]. Athletes can use VR exercises to learn new sports strategies and compete with their virtual partners [10]. By using the unlimited spatial and temporal boundaries of VR, injury-prone skills can be safely trained [11]. For example, VR allows ski jumps and downhill skiing in a safe environment [11].

The shortcomings of physical exercise using an immersive VR have been attributed to the use of HMDs. Exercising while wearing an HMD can be uncomfortable due to sweating and head bumps [12]. In addition, HMDs can be impractical for movement accuracy and speed. They can also be potentially dangerous (eg, when the device blocks the vision of the moving treadmill while running [12]). Furthermore, interactive VR display systems linked to various eye-movement systems can cause motion sickness [13].

VR exercises are effectively used in the rehabilitation of patients who have lost motor skills [5,14]. They are also used to increase the physical fitness of patients with chronic medical conditions, such as hemodialysis or dementia, and developmental disorders, such as intellectual disability or autism [15,16]. Most previous studies on VR exercises have been conducted on patient groups [5,14-16]. However, VR exercises are increasingly used by athletes and other sports-related professionals, as they enable individualized training with real-time feedback without coaches [11,12]. Moreover, VR exercises have recently been widely used in the public sphere to promote physical fitness [5]. When applied to healthy individuals, VR exercise can increase exercise speed, heart rate, balance, motivation, enjoyment, adherence, executive function, and neuroplasticity [17-20]. Although many studies have suggested the qualitative effectiveness of VR exercise, few have quantitatively assessed its effectiveness [12].

Previous studies have suggested that the brain regions of interest in response to VR and physical exercises are the dorsolateral prefrontal cortex (DLPFC), ventrolateral prefrontal cortex (VLPFC), and orbitofrontal cortex (OFC) [9,21,22]. Of these 3 major prefrontal cortical regions, a functional near-infrared spectroscopy (fNIRS) study showed that VR stimuli activated the OFC [21]. The OFC has been associated with emotional and behavioral regulation, decision-making, maintenance of behavioral flexibility, and processing of anticipated rewards and punishments [23]. Inappropriate functioning of the OFC can lead to disinhibition, preservation, and impulse control problems [24]. Owing to the functions of rewards and decisions, the OFC can be associated with VR-induced immersion and flow [8,25].

This study aimed to investigate whether immersive VR technology can enhance physical exercise, in terms of the range of motion and brain activity, in healthy individuals. Kinematics and resting state fNIRS methodologies were adopted to demonstrate the quantitative effectiveness of 3D immersive VR exercise. Kinematics is useful for objectifying human movements and comparing different subjects or situations, such as before and after treatment or training in various fields (eg, sports science) [26]. For example, knee and hip angles at foot strikes during running have been quantified using 2D video recording and motion analysis software [27]. Vertical jump height, frequently used as an indirect measure of muscle power in the lower extremities, was also estimated using the video method [28]. In VR rehabilitation studies, the difference in ranges of motion before and after treatment was measured to assess improvement [29]. fNIRS is a noninvasive functional brain imaging tool that measures cortical hemodynamic activity [30]. Near-infrared light penetrates the brain, and oxygenation changes in regional cerebral blood flow are recorded [31]. fNIRS has the advantages of safety, low cost, portability, tolerance to motion artifacts, and good temporal and spatial resolution, overcoming the shortcomings of conventional brain imaging modalities, such as electroencephalography and functional magnetic resonance imaging (fMRI) [32,33]. fNIRS has been used in various fields, including sports medicine, neuroscience, behavioral science, clinical studies, and brain-computer interfaces [30].

We hypothesized that 3D immersive VR exercises would be more effective than offline physical exercises in increasing the range of motion and calorie consumption during exercise. In addition, we hypothesized that the effectiveness of 3D immersive VR exercises is associated with brain activation within the OFC before and after exercise.

Methods

Sample Size

The sample size was calculated using G*power software (Heinrich-Heine-Universität Düsseldorf) [34] based on a statistical test using repeated measures ANOVA. A type 1 error of .05 and a statistical power of 0.9 were used. The correlation among repeated measures was set conservatively at 0. Based on previous similar studies, an effect size of 0.25 was estimated. Based on these calculations, 22 participants were required. After estimating a 10% dropout rate, the required total sample size was set at 24 participants.

Participants

Through flyer advertisements, 24 healthy males were recruited for this study from Chung-Ang University. The inclusion criteria were as follows: (1) male sex, (2) age 20 to 29 years, and (3) no psychiatric or medical illness. The exclusion criteria were as follows: (1) history of head trauma; (2) history of substance abuse, including alcohol, tobacco, and drugs; and (3) IQ<80. The participants were instructed not to consume any food, caffeine, or alcohol 3 hours prior to participation in the study.

Ethics Approval

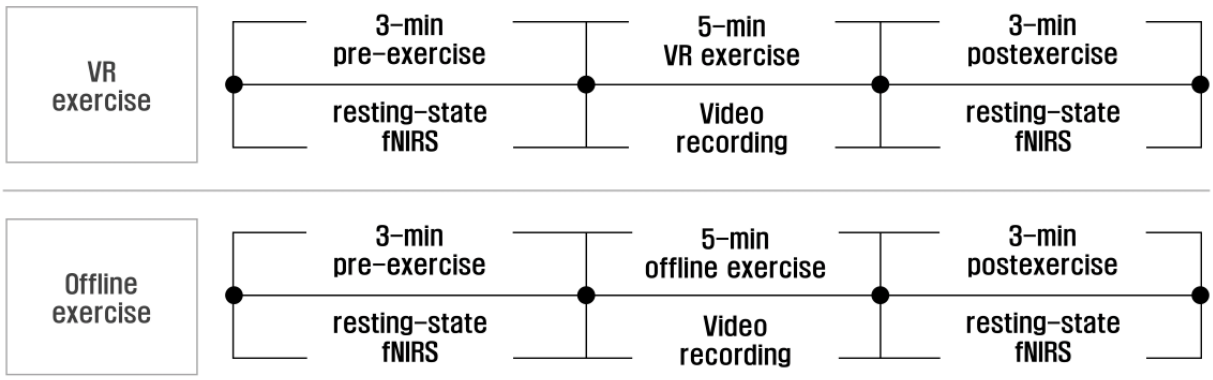
The institutional review board of Chung-Ang University approved this research protocol (1041078-201908-HRSB-231-01). Written informed consent was obtained from all participants.

Study Procedure

Overview

This study was a randomized crossover trial that compared responses to 3D immersive VR and offline exercises. The participants were blinded to the study hypotheses. Each participant underwent 1 3D immersive VR trial and 1 offline trial in a randomly assigned order at 10-minute intervals. Each session consisted of (1) a 2-minute practice to become familiarized with each exercise; (2) a 2-minute pre-exercise resting-state fNIRS measurement; (3) a 5-minute exercise, either 3D immersive VR or offline; and (4) a 3-minute postexercise resting-state fNIRS measurement (Figure 1). This trial was conducted in a curtained, dimly lit gym at a temperature of 23 °C with minimal ambient noise to control external noises as much as possible. The participants were instructed not to speak or move their heads during the fNIRS measurement to maintain good tissue-electrode contact. A 10-minute interval was given between sessions to return noncortical hemodynamic variables, such as skin blood flow and middle cerebral artery blood flow, to baseline levels.

Figure 1. Study design. fNIRS: functional near-infrared spectroscopy; VR: virtual reality.



Both VR and offline exercises consisted of 40 identical movements derived from Pilates. Pilates was chosen because it is a beneficial exercise method for healthy adults that enhances flexibility, muscular activity, and coordination [35]. In both exercises, the sequence was in the order of 8 types of simple behaviors involving just the body, arms, or legs; 16 types of 2 complex behaviors involving the body plus arms or legs; and 16 types of 3 complex behaviors involving 3 parts of the body, arms, and legs. The reason for exercising in this order was to gradually increase the number of muscle groups involved, starting from warming up. A resistance band (TheraBand) was applied to each participant in both sessions to maintain adequate exercise intensity and prevent less controlled behaviors. Pilates exercise with a resistance band was reported to increase muscle activity by more than 50%, whereas Pilates exercise without a resistance band increased muscle activity by only 20% [36].

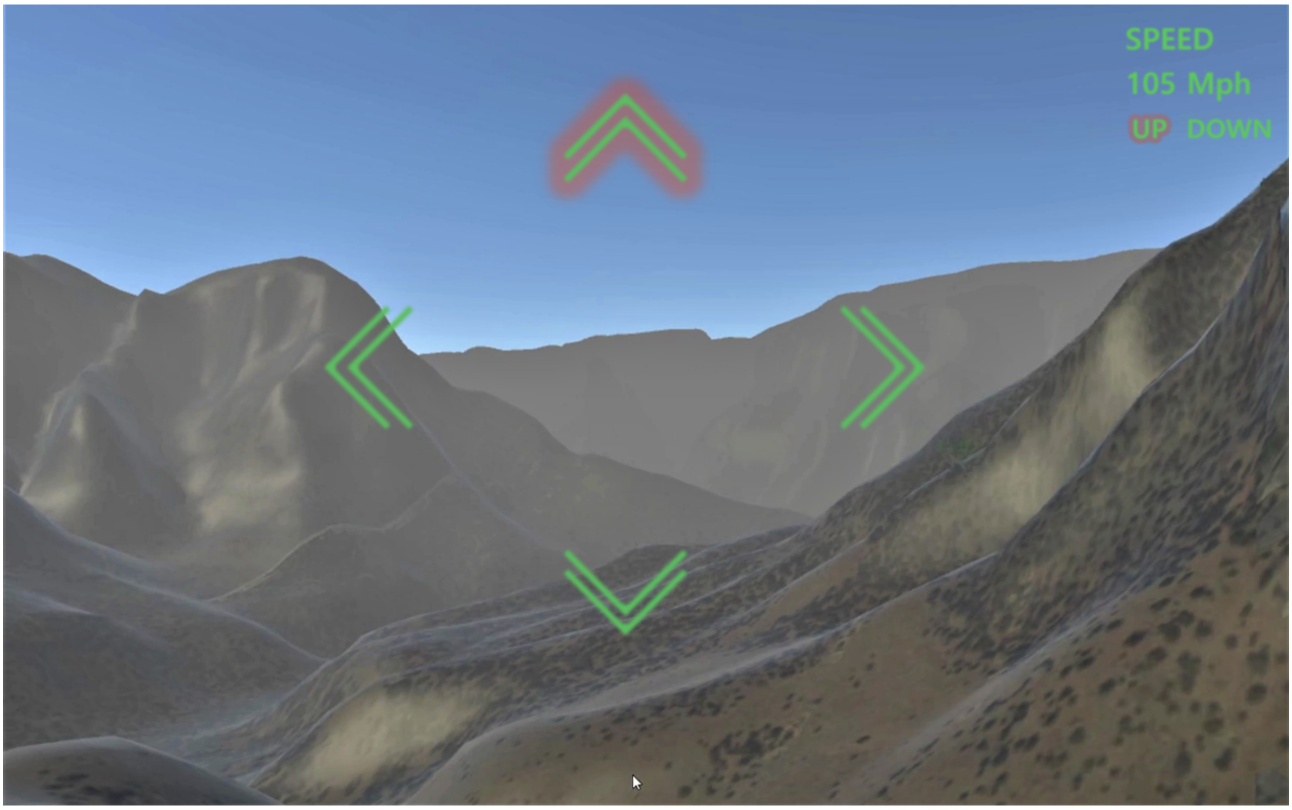
Before the VR exercise, the research staff provided brief instructions on the 3D immersive VR system and environment and asked the participants to report whether they experienced any discomfort while wearing the HMD, such as head bumps, sweating, or motion sickness. The research staff checked for any obstacles the participants might encounter during the VR exercise and monitored and provided immediate assistance to the participants during the exercise in case of danger. With the help of the research staff, the participants were positioned 2 m horizontally away from the VR device, wearing the HMD and holding resistance bands in both hands at shoulder level.

In this study, the Vive Cosmos Elite (High Tech Computer Corp) and Kinect V1 (Microsoft) were used as the HMD and motion sensors, respectively. A 3D map–based immersive VR software system that allows participants to interact with the VR environment was developed using Unity3D Engine (Unity Technologies). The Grand Canyon landscape was designed to enable participants to fly between canyons without crashing by performing the aforementioned movements in sequence. During the VR exercise, participants were asked to fly over the canyon without bumping into it, following visual and audio guidance. The direction in which to move, whether to accelerate or decelerate, and flight speed were displayed on the VR screen in real time, serving as visual instructions (Figure 2). When the participants tilted their upper body right, left, forward, or backward in the virtual space, they rotated right, left, upward, or downward, respectively. They could accelerate or decelerate by lifting or lowering their right arm.

In contrast, during the offline exercise, the participants performed movements in a standard manner following a demonstration by a professional instructor. In both sessions, audio guidance, such as “lean right and raise your left arm” were provided.

The research staff helped the participants accurately perform each movement in both sessions. They provided immediate feedback for incorrect movements and high-risk situations. The movements performed by the participants in the VR and offline conditions were considered identical since the audio guidance, use of the resistance band, and real-time feedback on behavior by the research staff were the same for all participants.

Figure 2. A representation of the virtual environment.

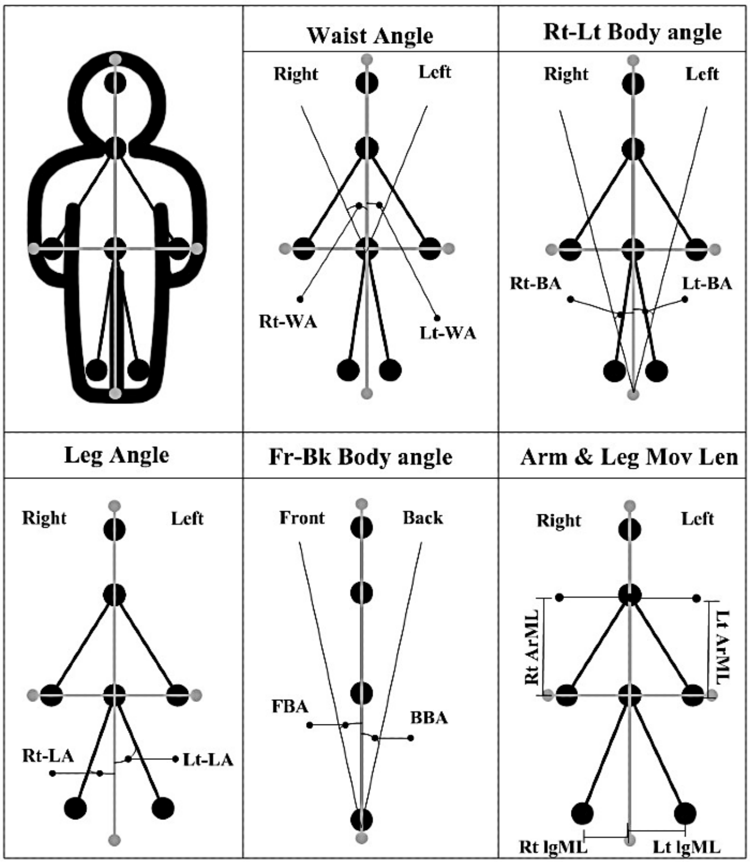


Motion Analysis to Measure Motion Angle, Length, and Retention Time

Participants’ movements during the VR and offline exercises were recorded using an iPhone 11 camera (Apple). The participants were asked to stand at the designated site 1.5 m away from the camera to maintain a constant camera angle. The recorded video was analyzed using the open-source video analysis software Kinovea (version 0.8.15; Kinovea Open-Source Project) [21]. Kinovea determines the distance between the camera and the recorded object by measuring the subject passing in front of the camera [21]. It has various analysis and measurement tools for adding annotations, drawing lines, and calculating distances and angles [37] and has been used in numerous sports and clinical studies [22-24]. Previous studies have shown the reliability and validity of the software at distances of up to 5 m with an angle of 90° to 45° [21].

In the motion analysis, eight types of motion angles were measured: (1) right waist angle, (2) left waist angle, (3) right body angle, (4) left body angle, (5) right leg angle, (6) left leg angle, (7) forward body angle, and (8) backward body angle. Additionally, four types of movement lengths were measured: (1) right arm movement length, (2) left arm movement length, (3) right leg movement length, and (4) left leg movement length (Figure 3). The total angle and movement length for simple behaviors, 2 complex behaviors, and 3 complex behaviors were calculated using each angle and movement length involved in each behavior. For example, for simple behaviors, 8 angles and 4 lengths were used to calculate the total angle and movement lengths. Two complex behaviors consisting of 16 movements, 24 angles, and 16 lengths were measured to calculate the total angle and movement length. Finally, 3 complex behaviors consisting of 16 movements, 24 angles, and 32 lengths were measured to calculate the total angle and movement length (Multimedia Appendix 1).

Figure 3. Movement angle and length. From top: Rt (Lt)-WA: right (left) waist angle; Rt (Lt)-BA: right (left) body angle; Rt (Lt)-LA: right (left) leg angle; FBA (BBA): forward (backward) body angle; Rt ArML: right arm movement length; Lt ArML: left arm movement length; Rt lgML: right leg movement length; Lt lgML: left leg movement length.



Comparison of Calories Using the Metabolic Equivalent of Task Formula and Motion Retention Time

Calorie consumption during each session was calculated using each participant's weights, motion retention time (from the start to the end of the movement), and the metabolic equivalent of task (MET) of the Pilates motion, according to the MET formula [38]. The MET formula has been adopted in various clinical studies, and its reliability has been demonstrated through meta-analyses [39,40]. MET is defined as the level of intensity of various physical activities, including daily activities and low-intensity to high-intensity exercises. The Pilates movements performed by the participants in this study were rated as 3.5 MET.

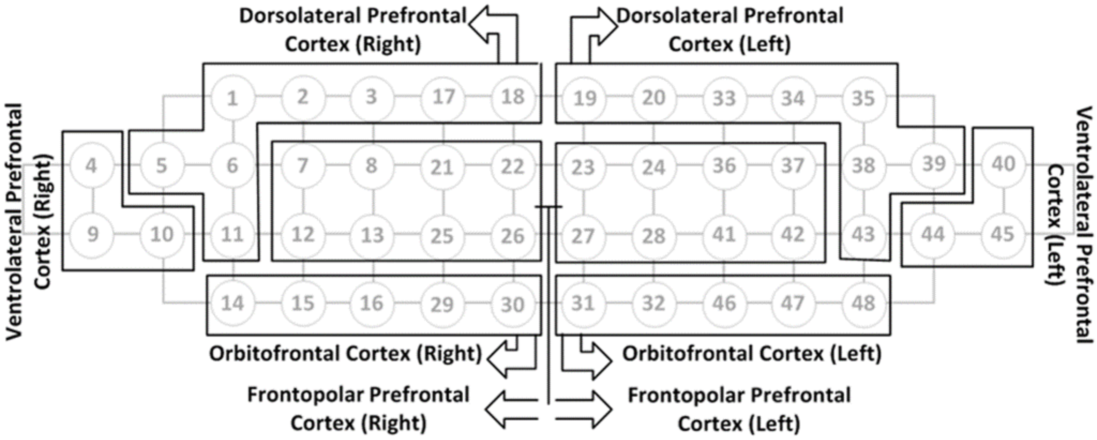
Hemodynamic Changes in the Frontal Cortex

Hemodynamic changes within the prefrontal cortex were assessed using a high-density fNIRS device (NIRSIT, OBELAB Inc). The curved panel of the NIRSIT has 24 laser diodes (sources) emitting 2 wavelengths (780 nm and 850 nm) of light and 32 photodetectors with a sampling rate of 8.138 Hz. The unit distance between the source and photodetectors was 15 mm. In this study, only the 30-mm channels were analyzed, since 30 mm is the most suitable sensor-detector separation distance for measuring cortical hemodynamic changes.

The fNIRS data were processed using the analysis toolbox provided by the fNIRS device manufacturer. The light signals in each wavelength within the 48 channels were filtered using a band-pass filter (between 0.0 Hz and 0.1 Hz) to reduce noise due to external light and body movements. Data derived from channels representing low-quality information (signal-to-noise ratio<30 dB) were not included in the hemodynamic analysis set to prevent misinterpretation. Relative hemodynamic changes during exercise were calculated using the modified Beer-Lambert law [41]. The accumulated oxygenated hemoglobin (accHbO2) values represent the activation of the prefrontal cortex during a resting state. Although both oxygenated and deoxygenated hemoglobin data could be obtained, previous studies have revealed that oxygenated hemoglobin has superior sensitivity and signal-to-noise ratio; therefore, only oxygenated hemoglobin data were used for this analysis [26,28].

The values (mean and SD) of accHbO2 were gathered from 8 regions of interest: the right and left DLPFC, right and left frontopolar cortex (FPC), right and left VLPFC, and right and left OFC. The right and left DLPFCs were composed of channels 1, 2, 3, 5, 6, 11, 17, and 18 and channels 19, 20, 33, 34, 35, 38, 39, and 43, respectively. The right and left FPC were composed of channels 7, 8, 12, 13, 21, 22, 25, and 26 and channels 23, 24, 27, 28, 36, 37, 41, and 42, respectively. The right and left VLPFCs were composed of channels 4, 9, and 10 and channels 40, 44, and 45, respectively. The right and left OFCs were composed of channels 14, 15, 16, 29, and 30, and channels 31, 32, 46, 47, and 48, respectively (Figure 4).

Figure 4. The channel configuration.



Statistical Analyses

For total behaviors, simple behavior, 2 complex behaviors, and 3 complex behaviors, the differences in total angles, total movement length, and consumed calories were compared using the Mann-Whitney *U* test. The statistical significance of the total angle and total movement length in the total behaviors was set at 0.02 (0.05/3, angle, length, and calories). In the post hoc test, the statistical significance of the total angle and total movement length in the simple behaviors, 2 complex behaviors, and 3 complex behaviors was set at *P*=.02 (.05/3, angle, length, and calories). Between the VR and offline situations, the difference in the change in accumulated oxygenated hemoglobin (ΔaccHbO2) from baseline and exercise was compared using repeated measures ANOVA. The statistical significance was set at *P*=.006 (.05/8, 8 brain regions). Correlations between the differences in accHbO2 within the right OFC, total angles, and total movement lengths were assessed using Pearson correlation coefficient. Statistical significance was set at *P*=.03 (.05/2, angle and length). Statistical analyses were performed using SPSS software (version 24.0; IBM Corp).

Results

Differences in Movement Including Angle and Length Between Offline and VR Trials During Exercise

During exercise, there were significant differences in the total angle (*z*=−2.31; *P*=.02) and length between the VR and offline trials (z=−2.78; *P*=.005). The VR group showed a 13.3% wider total angle range and an increase of 14.1% in the total movement length compared with the offline group. In the post hoc analysis, the VR group moved significantly more in simple and complex behaviors, except for the total angle in 2 complex behaviors, compared to the offline group (Table 1).

Table 1. Differences in angle and distance between the VR[a] and offline trials[b].

Types of behavior and parameters	VR trial, mean (SD)	Offline trial, mean (SD)	Statistics
Total behavior			
Angle total (°)	1359.39 (125.55)	1200.26 (195.68)	*z*=−2.31; *P*=.02
Length total (cm)	2568.20 (342.38)	2250.82 (382.20)	*z*=−2.78; *P*=.005
Calorie total (kcal)	9.36 (2.60)	5.79 (3.01)	*z*=−3.04; *P*=.002
Simple behavior (trunk leaning over)			
Angle total (°)	172.30 (19.2)	147.8 (27.64)	*z*=−2.74; *P*=.005
Length total (cm)	224.93 (34.3)	197.70 (31.9)	*z*=−2.53; *P*=.01
Calorie total (kcal)	2.46 (0.55)	1.18 (0.69)	*z*=−4.30; *P*<.001
2 complex behaviors (trunk leaning over + lifting arm or leg)			
Angle total (°)	449.26 (118.57)	415.87 (69.17)	*z*=−1.14; *P*=.27
Length total (cm)	966.09 (118.57)	860.06 (107.01)	*z*=−3.10; *P*=.001
Calorie total (kcal)	4.42 (1.35)	2.95 (1.58)	*z*=−2.55; *P*=.01
3 complex behaviors (trunk leaning over + lifting arm + lifting leg)			
Angle total (°)	737 .83 (63.61)	636.55 (112.77)	*z*=−2.72; *P*=.006
Length total (cm)	1377.18 (202.88)	1193.05 (125.55)	*z*=−2.69; *P*=.006
Calorie total (kcal)	2.47 (0.86)	1.65 (0.97)	*z*=−2.63; *P*=.009

[a]VR: virtual reality.

[b]*P*<.02 was considered to be significant.

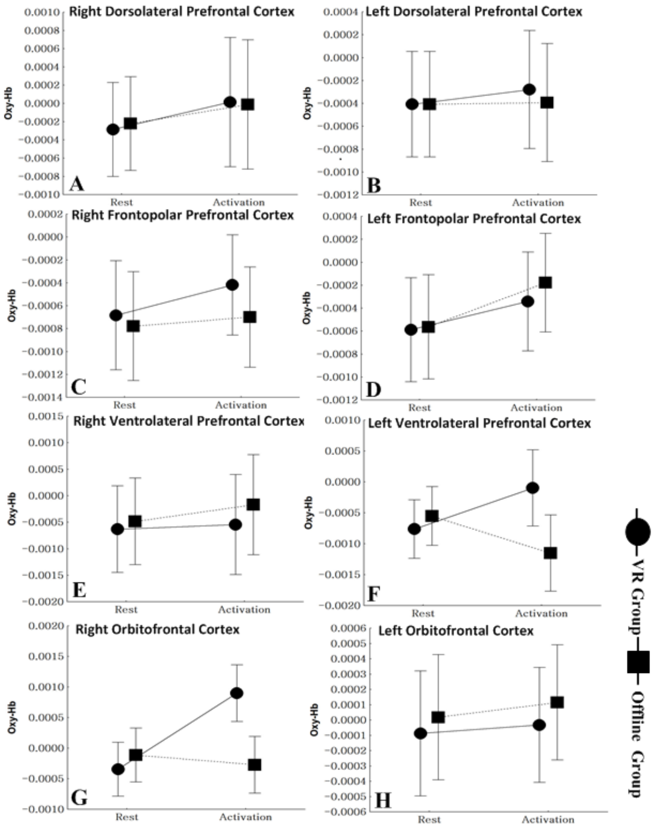
Differences in Consumption Between Offline and VR Trials During Exercise

During exercise, there were significant differences in the total calories between the VR and offline trials (*z*=−3.04; *P*=.002). During exercise, the VR group consumed 61.7% more calories than the offline group. In the post hoc analysis, the VR group showed significant calorie consumption with 2 complex and 3 complex behaviors compared to the offline group (Table 1).

Differences in ΔaccHbO2 Between Offline and VR Trials During Exercise

During exercise, significant differences were observed in ΔaccHbO2 between the offline and VR trials within the right OFC ($F^{1,94}$=9.36; *P*=.003) but not within the left VLPFC ($F^{1,94}$=5.69; *P*=.02), left DLPFC ($F^{1,94}$=0.06; *P*=.81), right DLPFC ($F^{1,94}$=0.02; *P*=.89), right VLPFC ($F^{1,94}$=0.06; *P*=.81), left OFC ($F^{1,94}$=0.01; *P*=.91), left frontopolar prefrontal cortex ($F^{1,94}$=0.05; *P*=.89), or right frontopolar prefrontal cortex ($F^{1,94}$=0.21; *P*=.65) (Figure 5).

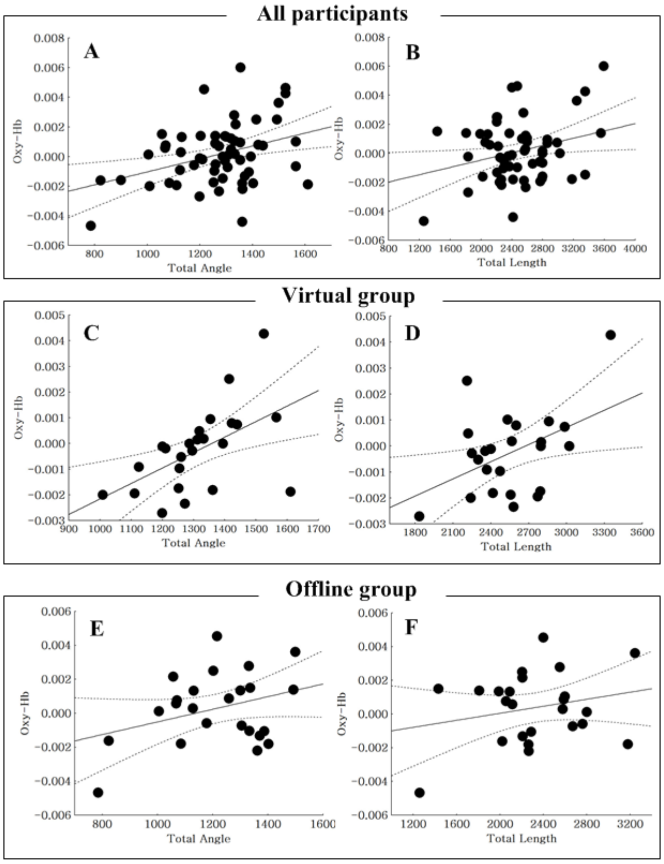
Figure 5. Difference in the accumulated oxygenated hemoglobin (ΔaccHbO2) between the offline and virtual reality trials during exercise. *P*<.006 was considered to be significant. Oxy-Hb: oxygenated hemoglobin; VR: virtual reality.



Correlation of ΔaccHbO2 With Total Angle and Movement Length

In all participants, the ΔaccHbO2 within the right OFC was positively correlated with the total angle (*r*=0.36; *P*=.005). However, it was not significantly associated with the total movement length (*r*=0.28; *P*=.03). In the VR group, the ΔaccHbO2 within the right OFC was positively correlated with total angle (*r*=0.45; *P*=.001) and total movement length (*r*=0.38; *P*=.007). In the offline group, the ΔaccHbO2 was not significantly correlated with total angle (*r*=0.28; *P*=.40) or total movement length (*r*=0.29; *P*=.37) (Figure 6).

Figure 6. Correlation between accumulated oxygenated hemoglobin in the orbitofrontal cortex (OFC) and movement change. *P*<.025 was considered to be significant. Oxy-Hb: oxygenated hemoglobin.



User Experience During VR Exercise

Of the 24 participants, 3 (12.5%) reported motion sickness, and 8 (33.3%) reported sweating after wearing the HMD device; however, none reported HMD slipping or severe discomfort.

Discussion

Principal Results

In this study, VR exercise increased the range of motion, calorie consumption, and brain activity within the OFC compared with offline exercise. In addition, increased brain activity within the right OFC was correlated with an increased range of motion.

Improvement of Movement Range and Calorie Consumption in Response to Immersive VR Stimuli

Our findings are consistent with previous studies on various patient groups. However, no studies have reported changes in the range of motion due to VR exercise in healthy individuals, as in this study [5]. VR exercises have been suggested to improve the range of motion in patients undergoing rehabilitation, both in the short term [42,43] and in the long term [14,44]. Immersive VR physical therapy significantly reduces pain and enhances the range of motion in patients with burn injuries (immediate effect) or chronic frozen shoulders (chronic effect) compared with standard therapies [14,42]. In addition, a 4-week VR exercise program in patients who underwent a stroke was more effective than a conventional program in improving the active range of motion and other scores, such as the Fugl-Meyer assessment score, Wolf motor function test score, and modified Barthel Index [44]. Children with cerebral palsy also reported a greater range of motion, better motion control, and greater interest as an acute effect after performing VR exercises than after conventional exercises [43]. In addition, the results of this study are in line with those of previous studies showing that participants who engaged in VR exercises had higher heart rates and burned more calories than those who performed standard exercises [45]. Therefore, VR has the potential to enhance physical exercises, and it may be a viable complement or alternative to traditional weight loss programs [46].

The larger range of motion and caloric consumption in the VR exercise may be associated with immersion. Immersion can be divided into 3 forms: sensory, imaginative, and challenge-based [47]. Sensory immersion is associated with audiovisual stimulation, and imaginative immersion is related to absorption in the narrative or identification with a character (eg, feelings of empathy and atmosphere). Challenge-based immersion is related to the balance between the activity's demands and an individual's motor and mental skills [48]. Challenge-based immersion is very close to the "flow" experience described by Csikszentmihalyi [49]. Immersion and flow share common features such as concentration, distortion of time perception, loss of self-awareness, and intrinsic motivation toward an activity [49]. The flow of physical exercise is related to peak performance [50]. The flow experienced during exercise is an autotelic experience with total concentration, merging of action and awareness, and the paradox of control [51]. In this respect, we cautiously suggest that VR exercise could be more immersive and helpful in achieving peak performance than exercise alone since sensory and imaginative components are added to the challenge-based immersion of physical exercise.

Increased Brain Activity Within OFC in Response to VR Stimuli

Another important finding of our study was that there were significant differences in brain activation within the right OFC between offline and exercise groups. To date, only a few studies have specifically investigated orbitofrontal activity in response to VR exercises. Most studies have focused on prefrontal activation caused by VR stimuli. Mao et al [52] suggested that VR training activates the prefrontal cortex and improves spatial orientation and motor function. However, recent studies have suggested that the OFC is one of the candidate brain regions that respond to VR [29]. Landowska et al [21] reported hemodynamic changes within the DLPFC and OFC in response to VR therapy for acrophobia. Dong et al [53] suggested that the activation of the OFC in response to VR tasks was greater than that observed in response to slide-based (control) tasks. Moro et al [54] reported that oxygenation in the OFC was increased when an incremental swing balance task in an immersive VR environment was performed. One possible explanation for this is that VR-induced immersion stimulates reward circuits involving the OFC. The OFC is responsible for sensory integration, regulation of visceral responses, learning, prediction, and decision-making for reward and affective values [55,56]. In addition, visual stimulation and immersion in VR are robustly involved in reward circuits [57].

The results of the correlation study between ΔaccHbO2 within the right OFC and the range of motion during VR and offline exercise showed that an increase in the range of motion and right OFC activation was correlated only in the VR group but not in the offline group. Thus, we suggest that immersion and visual stimulation of 3D immersive VR distracts the user from unpleasant interoceptive sensations caused by physical exercise. It is suggested that distraction caused by VR can reduce the perception of physical discomfort through an intercortical modulation of the anterior cingulate and OFC [9,58,59].

Additionally, the functional hemispheric differences shown in the results of this study are in line with a previous study that suggested that the more pronounced the shift in brain activity to the right hemisphere, the more flow experienced by elite tennis players [60]. Less synchronized brain activity in the left hemisphere and more coherent brain activity in the right hemisphere have been suggested to reflect less interference from irrelevant verbal-analytical processes with motor control mechanisms [60].

Strengths

To the best of our knowledge, this is one of the earliest studies to quantitatively evaluate the effects of 3D immersive VR exercise on brain hemodynamics in healthy individuals. Each participant's movement was measured using professional video analysis software, unlike other studies based on subjective performance improvement or satisfaction. Another strength of this study is that we directly compared performance in 3D immersive VR and real-world environments while performing the same activities. This comparison is important to reveal how 3D immersive VR influences exercise performance and brain activity. Finally, this study presents the potential for developing smart headsets by integrating wearable devices and connected technologies, such as VR, brain activity measurement, and motion tracking. Although these were performed with different devices in our study, using an integrated smart headset could enable effective exercise and immediate checking of the exercise amount and the consequent changes in brain activity. These wearable technologies and connected solutions with VR capabilities are already widely adopted in the workplace to promote occupational safety, productivity, and worker health. Examples include the Xsens MVN Animate and Xsens MTw Awinda for body movement tracking and the Muse 2 Melon's headband and IMEC's wireless electroencephalogram headset for brain wave sensing [61].

Limitations

This study had some limitations. First, due to the small number and gender disparity of the participants, the results cannot be generalized. In a follow-up study on VR exercise, scaling up the sample size by including virtual participants could be considered. However, this was not possible in this study due to the crossover design comparing VR and offline exercise. Second, there were limitations in the adequate pixel rate, capture rate, maximum aperture, depth of field capture, and frame capture rate of the iPhone 11, which was used as a video recording device. Third, since the fNIRS device used in this study can only measure brain activity within the prefrontal lobe, activity in other cortical regions and deep brain areas was not measured. Further studies using other functional imaging devices, such as fMRI, are required to determine the activity of the entire brain. Fourth, we did not employ additional physiological measures. The use of systemic physiologically augmented fNIRS in future studies may yield more meaningful results. Finally, a standardized questionnaire to check the inclusion and exclusion criteria and to assess motion sickness after VR exercise was not used in this study.

Conclusions

This study confirmed that 3D immersive VR exercise is more effective at increasing the range of motion and calorie consumption during exercise in healthy individuals via activation within the OFC.

Abstract

Background: The physical and cognitive loads borne during exergaming may differ from more conventional cognitive-motor dual-task trainings.

Objective: The aim of this pilot transversal study was to compare objectively measured and perceived exercise intensity during exergame, cognitive-motor dual-task, and single-task training sessions.

Methods: We recruited apparently healthy young adults who carried out one session of each type of training: exergaming, cognitive-motor dual-tasking, and single-tasking. We used a custom-made exergame as support. The sessions lasted 30 minutes, were spaced at least 24 hours apart, and took place in random order for each group of 4 participants. We used heart rates to assess exercise intensity and the modified Borg scale to assess perception of intensity. In all, 16 apparently healthy young participants carried out all sessions.

Results: There was no difference between the different types of training in mean heart rates (P=.27), peak heart rates (P=.50), or Borg scale scores (P=.40). Our custom-made exergame's objectively measured and perceived physical load did not differ between cognitive-motor dual-task and single-task training.

Conclusions: As a result, our exergame can be considered to be as challenging as more traditional physical training. Future studies should be conducted in older adults with or without cognitive impairments and incorporate an assessment of cognitive performance.

exergame; dual-task; exercise intensity; heart rate; cognitive load; active video game; physical activity

Introduction

Exergames (EGs), or "active video games," are video games played on a digital device, including a wide range of interfaces [1] that require physical activity when played [2]. EGs are a singular form of cognitive-motor dual-task (CMDT) training, which is known to be efficient in terms of both cognitive and physical functions [3,4]. In addition, EGs are considered fun and are enjoyed by most users, as they facilitate exercise in an attractive, motivating, and interactive environment [5]. However, EGs must be sufficiently demanding to induce effects, with regard to cognitive as well as physical loads [2,6], and their efficiency depends to some extent on their intensity.

As a singular form of CMDT training, EGs should not differ in terms of the physical level of solicitation. The tasks players are asked to perform are similar, one of them being cognitive and the other physical, with the difference residing in the support used. Previous studies have shown that most EGs induce moderate [7-10] to vigorous [8,9,11] exercise intensity in healthy young adults. However, there seem to be large variations in intensity between different EGs, depending on the hardware (primarily Kinect or Wii) or game used [11,12]. For example, EGs such as Wii Bowling induce low-intensity physical activity [8], whereas Kinect Boxing or "Your Shape Fitness Evolved 2012" indeed induce vigorous physical activity [9,11]. Variability in exercise intensity between tailor-made EGs is likely to be even greater.

Significant heterogeneity in exercise intensity during exergaming raises questions about the impact of the support used. Would exercise intensity be the same during similar physical training sessions presented in either single-task (ST) or CMDT conditions, whether using a tailor-made EG as a support or not? To our knowledge, no study has compared exercise intensity during exergaming and ST training, and only one study has compared exercise intensity during CMDT and ST training in healthy young adults [13], showing higher intensity under CMDT than ST conditions.

To date, we have been unable to conclusively determine the impact of the training support (ie, direct comparison between exergaming and CMDT training) or the impact of a concurrent cognitive task (ie, direct comparison to ST conditions, considered as the reference modality for physical training) on the level of physical solicitation in healthy young adults. The aim of this pilot transversal study was to compare objectively measured and perceived exercise intensity during EG, CMDT, and ST training sessions.

Methods

Participants

Apparently healthy students from the University of Limoges volunteered for this pilot transversal study. The inclusion criteria were young adults aged between 18 and 35 years and fluent in French. The exclusion criteria were having a contraindication to physical activity or having eaten or drunk during the previous 2 hours.

Ethical Considerations

In accordance with the Declaration of Helsinki as revised in 2013, the volunteers had received an information document detailing the protocol and gave their written consent to participate.

The study was carried out as part of student work in initiation to research during the year 2021. According to French regulations (Jardé law) [14], ethics review was not required.

Procedure

Participants were recruited during practical exercise courses. They carried out 3 types of training: EG, CMDT, and motor ST. The training sessions were designed identically: physical exercises (ST), with concurrent cognitive tasks (CMDT), using an EG as support (EG). The exercise sessions were organized in groups of 4 participants, and the order of training was randomized for each group. They lasted 30 minutes and were spaced at least 24 hours apart. They were divided into eight 3-minute-long exercise sequences (see Table 1), with 30 seconds of rest and instructions in between; therefore, effective physical activity lasted approximately 24 minutes. An instructor supervised, giving instructions and assisting the participants. Sessions were suspended in the event of an injury, significant pain, or heart rates above 90% of the theoretical maximums [15]. We have illustrated the differences between EG, CMDT, and ST training during stepping performance in Figure 1.

During EG training, sessions consisted of multiple dual tasks using a custom-designed EG as support (Figure 2). This EG was developed in the *Handicap, Activités Vieillissement, Autonomie, Environnement* laboratory, using the "Virtual Carpet," which is associated a video projector and HTC Vive cameras and trackers, as the play area [16-18]. The projected scene was a schematic city, and players were asked to move to different points of interest during exercises. Detection by the Vive trackers of a player's position at a point of interest triggered a change of scene and launched a mini-game, which was carried out by all the players. The motor tasks were mainly stepper, muscle strength, and balance activities. The cognitive tasks were verbal fluency, arithmetic, mental inhibition and flexibility, visuospatial memory, processing speed, and planning. Some exercises required gymnastic equipment (stepper, Swiss or medicine balls, chairs). The training sessions were designed to match with the American College of Sports Medicine [19] and the World Health Organization [20] guidelines and recommendations on physical activity, as well as the recommendations designed to prevent falls in older adults [21]. Details on the exercises are indicated in Table 1.

During the CMDT training, the participants used the same gymnastic equipment, and the sessions were made up of the same associations of cognitive and motor dual tasks as in the EG group but without using the EG (see exercise details in Table 1).

Finally, ST training required the same gymnastic equipment and the same motor tasks as those carried out during EG and CMDT training but without a concurrent cognitive task (see exercise details in Table 1).

Table 1. Details of the exercises proposed during the different types of training.

Training	Stepper (with and without a step)	Visuospatial memory and balance	Muscular strength and coordination
EG[a]	Arrows are displayed successively on the projected scene, and participants must reproduce them on a pad with 1 foot, 2 feet, doing a squat, a lunge, etc. The additional cognitive tasks are to not reproduce an arrow (go or no go), to invert them (mental flexibility), or to render them with a time lapse (working memory).	Eight elements displayed within the projected area will turn on and off at a fixed frequency, constituting a growing span. Participants must memorize this sequence and then recall it while moving around. At the same time, they perform motor exercises (knee raising, buttocks to heels, squats, lunges, and jumping jacks). The additional cognitive tasks are to not consider one of the icons or to recall the span from the end.	Participants must perform muscle-strengthening exercises (eg, squat and lunges). At the same time, they must (1) solve mental arithmetic exercises appearing on the projected scene; (2) alternate the exercises performed according to the images appearing on the projected scene; and (3) perform a "categories" game or build a word giving a letter, one at a time.
CMDT[b]	The instructor shows a sequence of movements that the participants must reproduce in mirror (step, squat, lunge, etc). The additional cognitive tasks are to not reproduce an arrow (go or no go), to invert them (mental flexibility), or to render them with a time lapse (working memory).	Participants must displace a total of 8 plots, one at a time. The plot-placing order constitutes the span. Participants must memorize this sequence and then recall it while moving around. At the same time, they perform motor exercises (knee raising, buttocks to heels, squats, lunges, and jumping jacks). The additional cognitive tasks are to not consider one of the icons or to recall the span from the end.	Participants must perform muscle-strengthening exercises (ie, squats and lunges). At the same time, they must (1) alternate the exercises performed according to the auditory or visual stimuli given by the instructor and (2) perform a "categories" game or build a word giving a letter, one at a time.
ST[c]	The instructor shows a sequence of movements that the participants must reproduce in mirror (step, squat, lunge, etc). There is no additional cognitive task.	The instructor demonstrates static and dynamic balance exercises to perform. The participants must perform movements of the limbs and trunk and pass a medicine ball while standing on a Swiss ball or standing on one leg. There is no additional cognitive task.	Participants perform a game mixing together muscle strengthening of the lower limbs and motor coordination by dribbling with a ball. There is no additional cognitive task.

[a]EG: exergame.

[b]CMDT: cognitive-motor dual-task.

[c]ST: single-task.

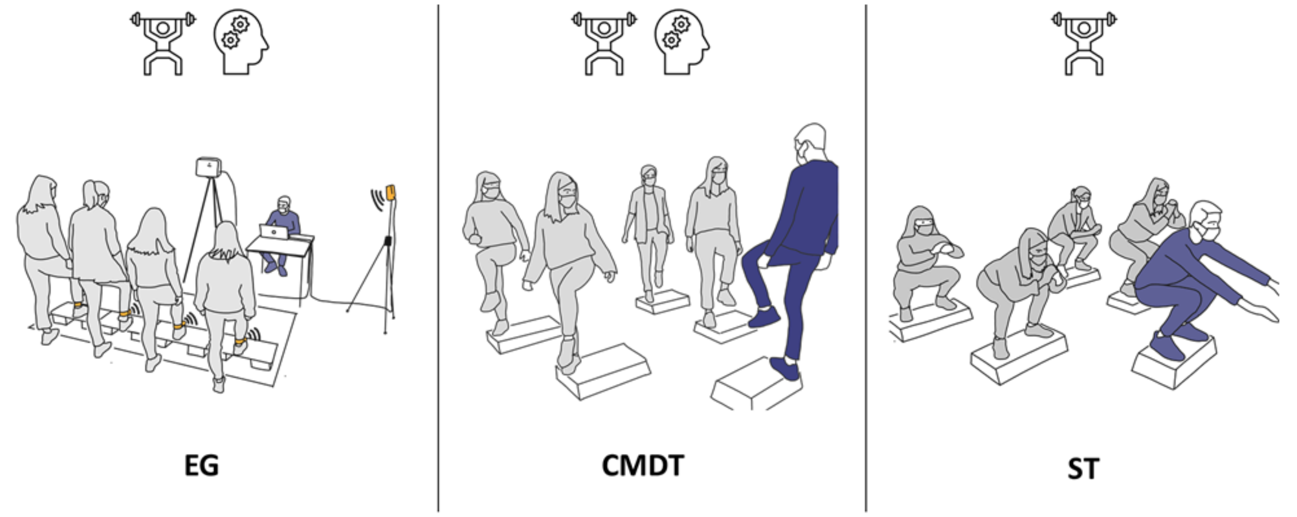

Figure 2. Illustration of the exergame. (1) Video projector, (2) HTC Vive infrared cameras, (3) computer, and (4) HTC Vive trackers. In this example, only 2 participants are performing a stepping exercise.

Outcomes

The primary outcome was the objectively measured exercise-intensity level assessed in terms of mean and peak heart rates (HRs) during training. We used HR because it is considered the most practical parameter to monitor, especially as regards reliability, safety, and cost [22]. We used validated chest HR Polar H10 monitors (Polar Electro Oy) [23], measuring the participants' HR_{mean} and HR_{peak} during the 3 types of training.

The secondary outcome was the rating of perceived exertion, using a validated modified Borg scale [24] completed by participants at the end of each training session.

Statistical Analysis

Quantitative variables were described according to mean and SD or median and IQR. The normality of data distribution was assessed using Shapiro-Wilk tests. Comparison between HR_{mean}, HR_{peak}, and Borg scale scores during the different trainings (EG, CMDT, and ST) was carried out using a 1-factor ANOVA or a Friedman test according to the normality of the variables concerned. Statistical analysis was performed using RStudio (Rstudio, Inc), and result significance was set at P<.05.

Results

In all, 16 apparently healthy young participants volunteered for the study (6 males, 10 females). Sociodemographic characteristics are presented in Table 2.

Although mean and peak HR variable distribution was normal during the 3 types of training, the Borg scale scores were not. There was no difference between the different types of training (EG, CMDT, and ST) for any of the variables studied: HR_{mean} ($F_{2,45}$=1.33; P=.27), HR_{peak} ($F_{2,45}$=0.7; P=.50), and Borg scale scores (χ^2_2=1.85, P=.40; see details in Table 3).

Table 2. Participant characteristics.

Characteristic	Value, mean (SD)
Age (years)	24.6 (3.1)
Height (m)	1.72 (0.11)
Weight (kg)	69.1 (15.1)
BMI	23.1 (3.2)
HR[a]$_{resting}$ (bpm[b])	66.9 (10.4)
HR_{max} (bpm)	187.2 (1.2)

[a]HR: heart rate.

[b]bpm: beats per minute.

Table 3. Results depending on type of training.

Result	EG[a]	CMDT[b]	ST[c]
Borg scale score (out of 10), mean (SD)	3.1 (1.4)	3.6 (1.3)	3.3 (1.0)
HR^{d}_{mean} (bpm[e]), mean (SD)	119.8 (12.2)	123.8 (16.1)	128.1 (14.7)
Percentage of theoretical HR_{max} (%)	64	66	68
HR_{peak} (bpm), mean (SD)	157.9 (10.1)	163.0 (12.8)	161.7 (14.5)

[a]EG: exergame.

[b]CMDT: cognitive-motor dual-task.

[c]ST: single-task.

[d]HR: heart rate.

[e]bpm: beats per minute

Discussion

This pilot transversal study was aimed at comparing objectively measured and perceived exercise intensity during EG, CMDT, and ST training sessions in healthy young adults. We observed no differences in mean or peak HR or perceived exertion between the 3 types of training.

Perceived and Measured Physical Activity Intensity

In our study, physical activity intensities during EG, CMDT, and ST training sessions did not statistically differ. This finding is discrepant with the results of a previous study, which showed higher HR_{mean} under CMDT than ST training [13]. Our results even seemed opposed, with a tendency toward higher HR_{mean} during ST training of nearly 10 beats per minute, close to 70% of theoretical HR_{max}, and moderate intensity [25]. This difference with our study may be due to the nature of the requested tasks. Exercise intensity varies considerably according to type of movement, the body part involved (upper or lower limb), the level of difficulty of a given game (frequency and speed), or the participants' previous experience as players [26-28]. In the study by Herold et al [13], subjects were asked to carry out squats under both conditions while additionally counting backward in CMDT training[13]. In our study, the physical and cognitive tasks were not only more varied but also and above all more complex (see Table 1). In addition, it is important to note the impact that different interfaces can have when comparing interventions. For instance, the quality of immersion and interaction highly impacts the user experience and the usability of immersive EGs [29]. We tried to reduce these effects of complexity and interface by proposing similar and transferable exercises between the different types of training. As a result, the exercises carried out in this study during training sessions were the same in EG, CMDT and ST conditions, with the differences consisting solely of the concurrent cognitive task and the use of a given game as support. In fact, instruction comprehension and error correction were time-consuming, decreasing effective exercise duration and HR over the course of the 30-minute sessions. Understanding more complex combined tasks during CMDT training along with adaptation to new game rules and to a new environment during EG may have been more time-consuming than during ST training.

Previous studies assessing the level of solicitation during exergaming in healthy young adults through HR have shown moderate [7-10] or vigorous [8,9,11] exercise intensity, with highly pronounced variability between studies according to the software or hardware used. Our custom-made EG seemed to induce moderate exercise intensity, equivalent to the physical exercises requested under CMDT or ST conditions. This is a relevant and interesting finding; since exercises under ST conditions are considered as the reference modality for physical training, their equivalence during exergaming and dual-task training enabled us to consider our EG as sufficiently soliciting to induce physical results, while adding a cognitive load in a playful environment.

Moreover, perceived physical intensity assessed through the Borg scale did not differ between the 3 types of training and was globally moderate. The perception of effort by participants in this study was correlated with the results obtained from the percentage of theoretical HR_{max} [25]. This is in line with previous studies showing that adults correctly estimate their less vigorous physical efforts [25,30].

Limitations

The first limitation of this study is the sample, for which no a priori sample size was carried out. However, our population was homogeneous and showed relative stability in physical intensity. This pilot study constitutes a proof of concept specific to our EG in a highly specific context and population. Consequently, the small extension of the knowledge provided by our study is specific, which complicates its extrapolation to other forms of EGs or populations.

A second limitation is due to the assessment exercise intensity modalities. In this study, given its reliability, safety, and cost, we used HR as a reflection of exercise intensity, whereas other studies have used more direct parameters such as oxygen consumption [8,31] or blood lactate responses [32] to assess exercise intensity during exergaming. Moreover, the software we used did not enable us to analyze HR in detail. It would be relevant to estimate the HR profile to determine whether it remains stable and close to the mean or varies with peaks and rest. Lastly, the assessment of effective HR_{max} rather than theoretical HR_{max} would have made it possible to evaluate reserve HR, thereby limiting impact of interpersonal variability.

Future Studies

Most of the EGs in which the intensity was assessed in previous studies were commercial video games [7-11]. This is broadly the case, especially insofar as commercial active video games are frequently used in rehabilitation [33]. The main consequence is a lack of control over qualitative and quantitative physical and cognitive exercises. Tailor-made software using mainstream hardware is designed to suit the specific needs of a given audience [34] while applying an easily available and relatively inexpensive solution. For example, the training of older adults presents specificities, in both form and in substance. Understanding is maximized through slow animations, large fronts, and simple rules [35]. With age, physical and cognitive capacities decline while cognitive-motor interference increases [36,37]. Fall prevention in older adults should focus on strength, postural control, stepping, and gait training [38-40], along with mental inhibition and flexibility, processing speed, and visuospatial memory [41-43]. In fact, a fall prevention training protocol with our EG seems possible and relevant, insofar as it facilitates the simultaneous training of cognitive and physical functions. By applying our pilot study's values and methodology, future studies may assess the extent to which and the efficacy with which our EG solicits in older adults. In addition to its pronounced beneficial effects, our EG may help promote physical activity [44], which is a point of major importance among older adults.

In this study, we investigated physical aspects, not cognition. However, cognitive efficiency and HR may be correlated; a meta-analysis found that participants with better cognitive task results often demonstrated greater cardiac parasympathetic control than those with poorer cognitive performance [45]. This question could be investigated using hybrid systems, coupling functional near infrared spectroscopy, and electroencephalogram headsets [46].

Conclusion

This pilot transversal study showed that a custom-made EG that could induce moderate perceived and objectively measured exercise intensity, equivalent to CMDT and ST training in healthy young adults. As a result, our EG can be considered as being as relevant as more traditional physical training with regard to exercise intensity. Future studies should investigate the cognitive and physical level of solicitation of our EG in older adults, who are likely to draw benefit from CMDT training.

Acknowledgments

The authors thank all the participants who volunteered, as well as the City of Limoges for their support. The authors also thank Dr Fanny Thomas for her contribution.

This research received a grant from the City of Limoges and the Nouvelle Aquitaine region. The funding source had no involvement in the conduct of the research.

Authors' Contributions

MG-G contributed to conceptualization, methodology, investigation, writing–original draft, and visualization. AP contributed to conceptualization, methodology, writing–original draft, and project administration. RM contributed to development and writing–review and editing. MB contributed to investigation. SM contributed to conceptualization, methodology, writing–original draft, project administration, and supervision.

Abstract

Background: Virtual reality (VR) technology has been widely used in rehabilitation training because of its immersive, interactive, and imaginative features. A comprehensive bibliometric review is required to help researchers focus on future directions based on the new definitions of VR technologies in rehabilitation, which reveal new situations and requirements.

Objective: Herein, we aimed to summarize effective research methods for and potential innovative approaches to VR rehabilitation by evaluating publications from various countries to encourage research on efficient strategies to improve VR rehabilitation.

Methods: The SCIE (Science Citation Index Expanded) database was searched on January 20, 2022, for publications related to the application of VR technology in rehabilitation research. We found 1617 papers, and we created a clustered network, using the 46,116 references cited in the papers. CiteSpace V (Drexel University) and VOSviewer (Leiden University) were used to identify countries, institutions, journals, keywords, cocited references, and research hot spots.

Results: A total of 63 countries and 1921 institutes have contributed publications. The United States of America has taken the leading position in this field; it has the highest number of publications; the highest h-index; and the largest collaborative network, which includes other countries. The reference clusters of SCIE papers were divided into the following nine categories: kinematics, neurorehabilitation, brain injury, exergames, aging, motor rehabilitation, mobility, cerebral palsy, and exercise intensity. The research frontiers were represented by the following keywords: *video games* (2017-2021), and *young adults* (2018-2021).

Conclusions: Our study comprehensively assesses the current research state of VR rehabilitation and analyzes the current research hot spots and future trends in the field, with the aims of providing resources for more intensive investigation and encouraging more researchers to further develop VR rehabilitation.

Introduction

In recent years, the number of people with rehabilitation needs has increased, particularly among groups of older patients, patients with disabilities, patients with chronic diseases, and patients with functional and cognitive impairments. The loss of movement, sensation, balance, and cognition, as well as other aspects, seriously affects patients' quality of life, work, study, and social life [1,2]. Such patients require long-term, consistent rehabilitation training and guidance [3]. However, traditional rehabilitation training has a number of problems, including fixed rehabilitation centers, a lack of rehabilitation resources, uninteresting training processes, high treatment costs, and a lack of automatic guidance and incentive mechanisms. These result in a lack of confidence in the rehabilitation process, which in turn affects the outcomes of rehabilitation treatments [4,5].

With the gradual popularization of virtual reality (VR) technology, rehabilitation training systems based on VR technology have been gradually applied in sports, exercise, and functional rehabilitation for various diseases and have achieved positive effect results [6,7]. The combination of VR technology and rehabilitation medicine can enable more patients to train regularly at home or in the community, as VR rehabilitation systems provide an immersive experience that stimulates patients' interest and improves their participation, thus overcoming the disadvantages of fixed centers and the lack of resources [8]. Furthermore, VR rehabilitation systems can sense and record a patient's movement and biological data via sensors to further improve existing rehabilitation programs [9]. This rehabilitation technology is a useful supplement to traditional rehabilitation and is a promising new research direction in the field of rehabilitation medicine.

A comprehensive bibliometric review is required to help researchers focus on future directions based on the new definitions of VR technologies in rehabilitation, which reveal new situations and requirements. Although bibliometric methods have yielded positive results in a variety of fields, we found that there is still a significant gap in the research on VR rehabilitation and its development trends by using bibliometric methods.

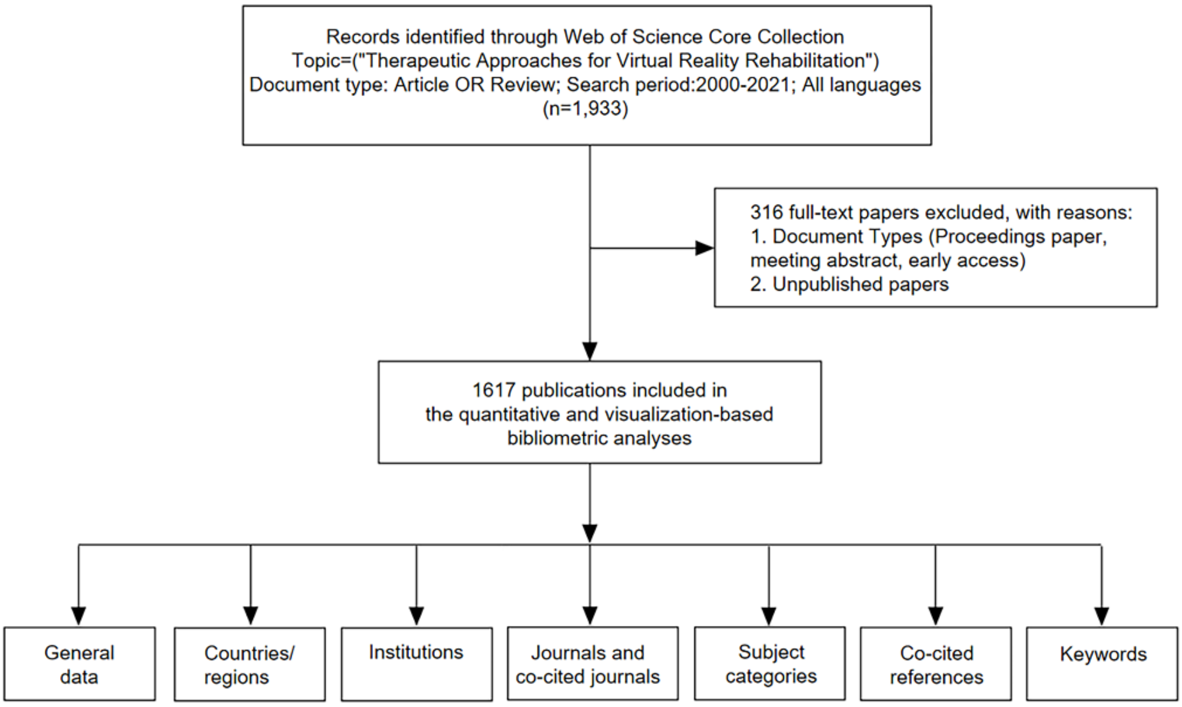
We used bibliometric methods to analyze SCIE (Science Citation Index Expanded) papers on studies related to VR rehabilitation research. Articles from different countries, regions, and research institutions were included. We identified papers in journals, gathered the top 10 citations, and enumerated how many times these citations were used. The VR rehabilitation knowledge base was analyzed by grouping authors' co-occurring keyword networks. Burst citations were used to identify research hot spots on this topic, which could provide a useful reference for future research [10,11]. These analyses will provide rehabilitation specialists with a macroscopic understanding of the knowledge domain as a whole, as well as a microscopic characterization. Compared to other reviews, our study is timely and visual and provides an impartial approach to developing and exploring particular knowledge domains. Our findings may encourage more researchers to conduct additional research in this field to further develop VR rehabilitation methods. The following basic information was gathered from studies: titles, abstracts, author information, institutions, countries, regions, keywords, and citations.

Methods

We created a clustered network, using the 46,116 references cited in 1617 published papers. The data came from the Web of Science Core Collection (WSCC), which was accessed on January 20, 2022. The search covered articles published from 2000 to 2021. The following search string, which included the search terms, was used: *Virtual Reality OR VR OR AR OR Augmented Reality*. Further, we limited our search to original articles and reviews, and the Web of Science category *Rehabilitation* was selected. To determine study inclusion, the aforementioned basic information was collected from articles in the WSCC. However, the following papers were excluded: (1) irrelevant proceedings and meetings papers, (2) chapters in books, (3) duplicated articles, and (4) unpublished papers with limited information. In total, 1617 papers were included, with duplicates excluded. The search and analysis procedures are outlined in Figure 1.

We defined most publication traits, including institute, country, journal, and keywords. We used Journal Citation Reports (2020 version; Clarivate) to identify impact factors, which reflect scientific research value [12]. All data were processed by using CiteSpace V (Drexel University) and VOSviewer (Leiden University). Both programs are used for collaboration network analysis to link publication traits [11,13]. From these analyses and measures, we obtained data on research hot spots, evolution paths, knowledge structures, and new trends in VR rehabilitation.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection. The diagram shows details on the selection criteria for virtual reality rehabilitation publications from the SCIE (Science Citation Index Expanded) database and the steps of bibliometric analysis.

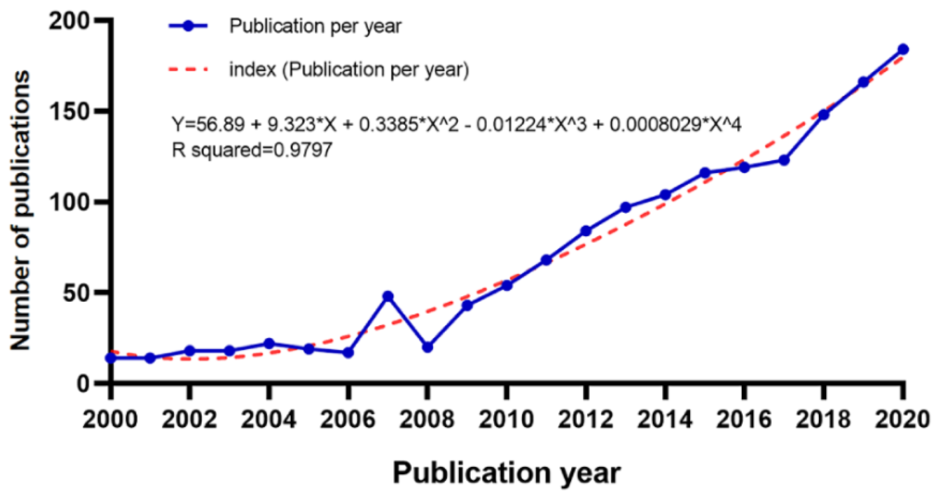


Results

Study Distribution by Publication Year

Between 2000 and 2021, a total of 1617 papers on VR rehabilitation were published. Emerging trends in VR rehabilitation research–related studies are outlined in Figure 2. From 2000 onward, VR rehabilitation research rapidly accelerated. In Figure 2, the blue line denotes the increasing trend in the annual number of studies from 2000 to 2021, whereas the red broken line represents the publication index, which also increased. In the initial 2000 to 2006 research period, publication numbers per year were relatively stable and were <25, suggesting an initial period of exploratory VR rehabilitation research. However, the rise in rehabilitation demands and the increased development of supporting technologies, which are due to the increased interest in applying VR to medicine and rehabilitation and the increasing, widespread use of VR technology, have resulted in a proliferation of publications since then. The number of publications in last decade accounted for more than 80% of the total publications found.

Figure 2. Trends in the number of publications on virtual reality rehabilitation.



Analysis of Countries and Institutes

The analyzed publications included contributions from a total of 63 countries and 1921 institutes. The top 10 countries and institutes are outlined in Tables 1 and 2, respectively, whereas collaborations between countries and between institutes are shown in Figure 3 and Figure 4, respectively. The United States published the most studies (n=663), followed by Canada (n=143). The United States also had the top h-index (59), followed by Canada (29) and Australia (21). Rutgers State

University New Brunswick had the most publications (n=52), followed by McGill University (n=45). Rutgers State University New Brunswick also had the highest h-index (27). On a global level, research institutes and associated research staff are collaborating and sharing experiences. However, although the United States has played a leading role, the international collaboration rates of the United States are low.

Table 1. The top 10 countries in terms of publications.

Rank	Countries	Publication count, n	h-index
1	United States of America	663	59
2	Canada	143	29
3	Australia	96	21
4	England	92	29
5	South Korea	83	26
6	Italy	81	26
7	Israel	71	27
8	Brazil	68	21
9	Netherlands	67	17
10	Spain	61	21

Table 2. Top 10 institutions in terms of publications.

Rank	Institutions	Publication count, n	h-index
1	Rutgers State University New Brunswick	52	27
2	McGill University	45	17
3	Pennsylvania Commonwealth System of Higher Education	38	13
4	Tel Aviv University	38	16
5	University of Wisconsin System	38	12
6	University of Haifa	37	19

Analysis of Journals

A total of 241 journals published articles related to VR rehabilitation; the top 10 are outlined in Table 3, and collaborations between cited journals are shown in Figure 5. *Archives of Physical Medicine and Rehabilitation* was the top journal (publications: n=847), followed by *Physical Therapy and Rehabilitation* (publications: n=608). Among these journals, *Cochrane Database of Systematic Reviews* had the highest impact factor (9.266), followed by *Stroke* (7.914).

Academic journals represent and reflect knowledge exchange in the research arena, where citing papers form a knowledge frontier and cited papers form a knowledge basis. A journal overlay dual map was assembled, as presented in Figure 6, wherein citing journals are shown on the left, cited journals are shown on the right, and citation relationships are represented by colored lines. These lines show that studies published in the molecular biology and genetics sector; the health, nursing, and medicine sector; the sports rehabilitation and sports sector; and the psychology, education, and social sector were usually cited in studies published in the medicine, medical, and clinical sector and the psychology, education, and health sector.

Table 3. The top 10 journals in terms of publications.

Rank	Cited journals	Publication count, n	h-index	Impact factor (2020)
1	*Archives of Physical Medicine and Rehabilitation*	847	197	3.966
2	*Physical Therapy and Rehabilitation*	608	150	3.021
3	*Disability and Rehabilitation*	550	111	3.033
4	*Journal of NeuroEngineering and Rehabilitation*	550	94	4.262
5	*Stroke*	484	319	7.914

Analyzing Citations

A citation is a vital bibliometric indicator, with frequently cited studies greatly influencing their research areas. We list the top 10 most highly cited publications in Table 4. *Effectiveness of Virtual Reality Using Wii Gaming Technology in Stroke Rehabilitation* by Saposnik et al [14], which was published on 2010 in *Stroke*, was the most highly cited article (cited 58 times); the article verified the effectiveness of rehabilitation for participants with stroke by using Wii (Nintendo Co, Ltd) gaming technology. Laver et al [15,16] published 2 articles with the same title—*Virtual reality for stroke rehabilitation*—on 2011 [15] and 2015 [16] in *Cochrane Database of Systematic Reviews*. These studies evaluated the rehabilitation impact of

VR technology for patients with stroke in accordance with the status quo in different periods.

In network research, betweenness centrality reflects node importance in a network; thus, a higher betweenness centrality signifies an important study [23]. The betweenness centralities of the top 10 studies are shown in Table 4.

A cocited document–centered clustering investigation was proposed to identify subnodes and connecting nodes in VR rehabilitation. To assess the scientific relevance of publications, we established a network of cocited references (Figure 7). The cluster settings were as follows: the number of years per slice was set to 1, and the top 0.5% of articles were selected for analysis; a pruning algorithm was used. The modularity Q score was 0.8029 (>0.5), which showed that the network was well separated into loosely coupled clusters. The weighted mean silhouette score was 0.941 (>0.5) and suggested acceptable cluster homogeneity. Study index items were used as cluster markers. The largest cluster—cluster 0—was labeled as *kinematics*, cluster 1 was labeled as *neurorehabilitation*, cluster 2 was labeled as *brain injury*, cluster 3 was labeled as *exergame*, cluster 4 was labeled as *aging*, cluster 5 was labeled as *motor rehabilitation*, cluster 6 was labeled as *mobility*, cluster 7 was labeled as *cerebral palsy*, and cluster 8 was labeled as *exercise intensity*.

Table 4. The top 10 cited articles on virtual reality (VR) in rehabilitation.

Rank	Authors and published year	Title of cited article	Citation count, n	Centrality	Interpretation of the findings
1	Saposnik et al [14], 2010	*Effectiveness of Virtual Reality Using Wii Gaming Technology in Stroke Rehabilitation*	58	0.04	This article verified the effectiveness of rehabilitation for participants with stroke by using Wii (Nintendo Co, Ltd) gaming technology.
2	Saposnik and Levin [17], 2011	*Virtual Reality in Stroke Rehabilitation: A Meta-Analysis and Implications for Clinicians*	51	0.10	This study performed a meta-analysis to determine the added benefit of VR technology in arm motor recovery after stroke.
3	Deutsch et al [18], 2008	*Use of a Low-Cost, Commercially Available Gaming Console (Wii) for Rehabilitation of an Adolescent With Cerebral Palsy*	37	0.04	This document is the first report on using low-cost, commercially available gaming technology for the rehabilitation of an adolescent with cerebral palsy.
4	Laver et al [15], 2011	*Virtual reality for stroke rehabilitation*	37	0.12	This study evaluated the effects of VR and interactive video gaming on upper limb, lower limb, and global motor function.
5	Lohse et al [6], 2014	*Virtual Reality Therapy for Adults Post-Stroke: A Systematic Review and Meta-Analysis Exploring Virtual Environments and Commercial Games in Therapy*	31	0.14	This analysis systematically reviewed the evidence for VR therapy in adults after stroke.
6	Levin et al [19], 2015	*Emergence of Virtual Reality as a Tool for Upper Limb Rehabilitation: Incorporation of Motor Control and Motor Learning Principles*	27	0.01	This article discussed how to exploit VR training environments and provided evidence concerning applications for upper limb motor recovery.
7	Laver et al [16], 2015	*Virtual reality for stroke rehabilitation*	27	0.02	This paper assessed the effectiveness of VR rehabilitation training.
8	Joo et al [20], 2010	*A feasibility study using interactive commercial off-the-shelf computer gaming in upper limb rehabilitation in patients after stroke*	26	0.02	The aim of this study was to assess the feasibility of using the Nintendo Wii as an adjunct to conventional rehabilitation for patients.
9	Adamovich et al [21], 2009	*Sensorimotor training in virtual reality: A review*	25	0.01	This paper discussed possible underlying mechanisms in the area of VR rehabilitation and provided some development direction.
10	Holden [22], 2005	*Virtual Environments for Motor Rehabilitation: Review*	25	0.05	In this paper, the state of VR applications in the field of motor rehabilitation was reviewed.

Analysis of Co-occurrence and Burst Keywords

Keywords in similar publications were identified and processed. The top 20 keywords, which had a high link strength, are outlined in Table 5. As well as identifying thematic areas in this research field, our keyword examination of all articles (N=1617) identified 50 keywords with at least 16 occurrences (Figure 8).

We investigated hot spot shifts from a temporal perspective, using the top 2 keywords with the strongest citation burst—*video games* (2017-2021) and *young adults* (2018-2021; Figure 9).

Table 5. Total link strength of the top 20 occurring keywords.

Rank	Keywords	Occurrences, n	Total link strength
1	*virtual reality*	543	1305
2	*rehabilitation*	318	924
3	*stroke*	242	671
4	*vocational rehabilitation*	85	115
5	*balance*	82	232
6	*cerebral palsy*	78	205
7	*gait*	54	160
8	*upper limb*	42	138
9	*upper extremity*	41	143
10	*video games*	41	138
11	*employment*	37	80
12	*technology*	37	75
13	*augmented reality*	37	69
14	*traumatic brain injury*	35	94
15	*exercise*	32	98
16	*postural balance*	31	96
17	*telerehabilitation*	29	84
18	*cognition*	29	82
19	*disability*	28	52
20	*motor learning*	27	96

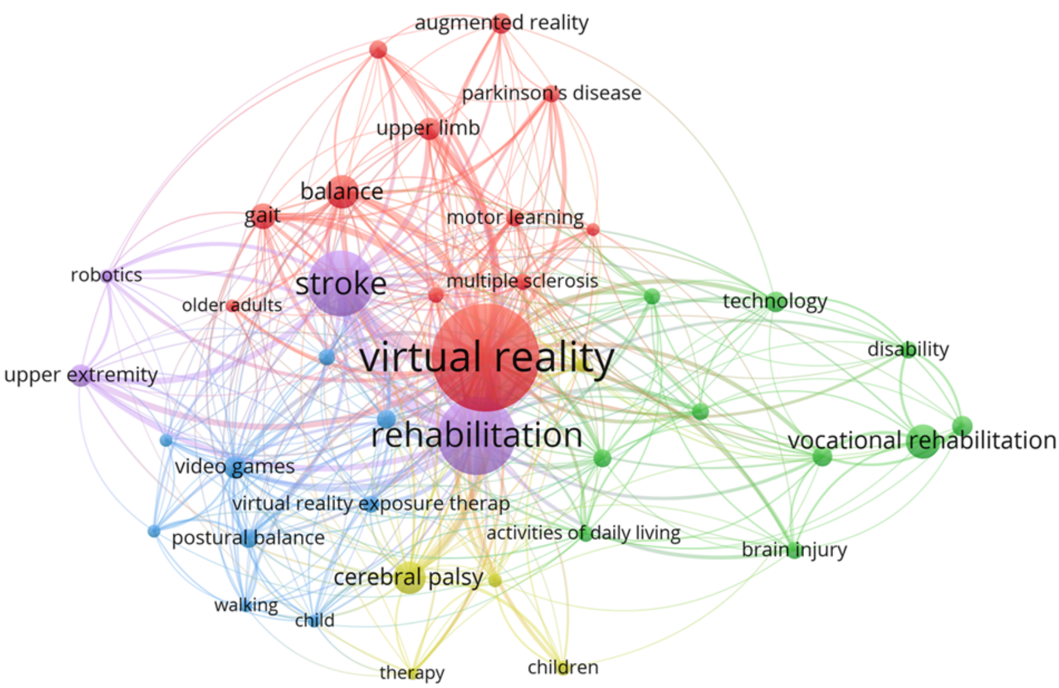

Figure 9. The top 25 keywords with the strongest citation bursts from publications on virtual reality rehabilitation.

Discussion

General Data

This study analyzed 1617 SCIE papers that were published between 2000 and 2021 and were related to the research of VR rehabilitation. The United States published the highest number of studies (663/1617, 41.01%), and Canada published the second highest number of studies (143/1617, 8.84%). Most of the core research institutions in this field are from the United States and Israel. The US Food and Drug Administration's encouragement of digital therapy innovation is the main reason that the largest number of publications is in North American countries, led by the United States. Israel encourages entrepreneurship in the high-tech industry; as such, 4 of the top 10 universities in this field are in Israel. The most widely read journal was *Journal of NeuroEngineering and Rehabilitation*. These findings showed that *Journal of NeuroEngineering and Rehabilitation* significantly contributed to research in this area. *Journal of NeuroEngineering and Rehabilitation* focuses on the publication of research results in the fields of neuroscience, biomedical engineering, and rehabilitation, which is very much in line with the publication of papers in this field and has attracted the attention of relevant researchers. We also examined the top 10 cited publications; the top article by Saposnik et al [14] appeared in *Stroke* and was cited 58 times.

The Knowledge Base and Current Research Characteristics

In previous studies, different VR-assisted rehabilitation systems were investigated in this field, with remarkable results. As indicated in Figure 7, after cocited reference clustering, key clustering nodes identified knowledge bases in this area, as follows: cluster 0 (*kinematics*), cluster 1 (*neurorehabilitation*), cluster 2 (*brain injury*), cluster 3 (*exergame*), cluster 4 (*aging*), cluster 5 (*motor rehabilitation*), cluster 6 (*mobility*), cluster 7 (*cerebral palsy*), and cluster 8 (*exercise intensity*). To this end, we described VR rehabilitation research knowledge bases by using different clusters, with time considerations.

For cluster 0, the *kinematics* cluster, scientists designed a VR rehabilitation system based on kinematics theory to measure, monitor, and predict outcomes; they achieved good results. For example, researchers developed various VR scenes for rehabilitation training for cervical vertebrae injuries; lower limb injuries of athletes; and arm, hand, and trunk movements in patients with stroke. They proposed kinematic evaluation and measurement methods based on the VR environment [24-26].

In cluster 1, the *neurorehabilitation* cluster, the research interest in VR technology for neurorehabilitation is increasing. Scientists have experimentally demonstrated the role of VR systems in neural rehabilitation and motor assistance from the perspectives of patients with impaired visuospatial perception after stroke, the augmented effect of intermittent theta burst stimulation on neurorehabilitation programs, and the use of motor imagination in brain-computer interfaces. Therefore, VR programs are considered safe and can be performed with standard neurorehabilitation protocols in patients with neurological conditions [27-29].

In cluster 2, the *brain injury* cluster, scientists demonstrated the experimental results of VR training systems for patients with brain injury, for those with acute onset central nervous system damage, and for vocational rehabilitation training from both the experimental perspective and the retrospective perspective. Importantly, most patients were responsive to VR training and showed improvements in gait function, balance control, vocational rehabilitation training, and other aspects [30-32].

In cluster 3, the *exergame* cluster, McMahon et al [33] investigated VR exergaming to augment physical activity in students (high school) with intellectual and developmental disabilities. Their findings indicated that when students used the VR exercise exergaming intervention, they increased the duration and intensity of their physical activity. Nambi et al [34], in their psychological and hormone analysis study, discovered that VR exergame training was effective for American soccer players with chronic low back pain when compared with conventional exercise training programs. In a multicenter controlled trial, Meyns et al [35] demonstrated that exergaming in children with spastic cerebral palsy improved balance after previous poor balance performances.

In cluster 4, the *aging* cluster, several investigations concentrated on upper limb rehabilitation intervention and overall skill improvement for older patients. Molina et al [36] analyzed the impacts of 13 VR sports games on physical function in older patients. Another group investigated the elbow and shoulder movements of older patients with chronic stroke, using the Predict Recovery Potential algorithm. The training improved motivation, but the benefits of physical function in aging were unknown [2,37].

In cluster 5, the *motor rehabilitation* cluster, scientists investigated various VR training devices. A team, for example, used VR-enhanced robot-assisted gait training to monitor the gait, motion, balance, fear of falling, and independence of 15 patients with chronic stroke. The researchers observed that cognitive performance and gait speed in tasks improved among study participants (P<.05) [38]. Maier at al [39], in their systematic investigation on randomized controlled trials, identified the benefits of specific VR systems for rehabilitating upper limb function and activity after stroke and reported that specific VR systems were highly beneficial for upper limb recovery when compared with conventional therapies.

In cluster 6, the *mobility* cluster, researchers designed remote VR and augmented reality rehabilitation training treadmills to record training data from patients with Parkinson disease or stroke. The experimental results showed that flexibility and balance improved and that VR rehabilitation methods could provide personalized rehabilitation strategies while also improving patient participation [40,41]. To identify the benefits of a VR-based interventional therapy, a previous scoping review reported that dynamic balance measures improved significantly following a therapeutic intervention; therefore, robust study designs that focus on intensity and dose responses from VR training could improve the efficacy of methods for treating mobility disorders [42].

In cluster 7, the *cerebral palsy* cluster, scientists studied gait, spatial perception exercises, functional mobility, exoskeletons, visuomotor construction, and other aspects of cerebral palsy in children by using data obtained through a VR rehabilitation training system. Bimanual performance and cognitive rehabilitation gains improved significantly during gait rehabilitation [43-45]. Furthermore, an augmented reality real-time feedback approach that incorporated infrared recognition technology was used to assess temporal and gait parameters during gait training in children with cerebral palsy. Importantly, cadence, velocity, functional ambulation, and bilateral step and stride length were augmented after the intervention [46].

For cluster 8, the *exercise intensity* cluster, scientists discovered that training factors (training intensity, prolonged activity, and rest were optimized) could potentially provide training optimization stimuli. de Vries et al [47] identified some elements of VR balance games that could potentially provide strength training stimulation. Baniña et al [48] investigated the relationship between upper limb motor recovery and exercise intensity in participants with subacute stroke. Importantly, they found that VR rehabilitation could be used to generate intensive exercise programs; however, clearer exercise progression guidelines should be published.

Scientific Frontiers and Future Research Trajectories

Keywords represent current research issues or topical concepts, while emerging trends and research frontiers are represented by burst keywords. We used the CiteSpace program to gather burst keywords and identified 2 scientific frontier areas with the strongest citation bursts—video games (2017-2021) and young adults (2018-2021).

Video Games

We found that VR video games are simple and appealing to patients and therefore encourage patient participation. Measurements and assessments that were taken after testing VR video games with 12 older patients and 13 children with intellectual disabilities showed clinical improvements in motor capabilities and a positive effect on quality of life [49,50]. Jung et al [51] investigated the impact of Xbox Kinect (Microsoft Corporation) training on lower extremity motor function in adolescents with spastic diplegia cerebral palsy. The outcome measurements, which were measured by using standard industry tools, showed that adolescents displayed significant improvements. A previous randomized controlled trial assessed the impact of a VR dance training program, which involved using an Xbox 360 Kinect game, on kyphosis angle and respiratory parameters in young women with postural hyperkyphosis and showed that dance games were an effective therapy [52]. Deutsch et al [53] asked 15 individuals with mild to moderate lower extremity deficits in the chronic poststroke phase to use the Kinect Light Race game and showed that video games provided comparable intensity, improved accuracy, greater enjoyment, and less exertion when compared with standard care activities. The application of VR-based video games in the field of rehabilitation is the current potential research direction.

Young Adults

VR rehabilitation training research has primarily focused on sport rehabilitation aspects, such as the spine, gait, or balance, with fewer studies on teenagers when compared to studies on adults. The burst keyword *young adult* appeared between 2018 and 2021, indicating that scholars have begun to pay attention to the positive physiological, social, and psychological impacts on teenagers. Fralish et al [54], in a case study of 6 VR sessions over a 3-week period, reported that specific VR programs were putatively physiologically and psychosocially helpful (mood improvement) for young adults with physical disabilities. Smith et al [55] proposed a VR job interview training system for participants with severe mental illness and transition-aged youth with autism spectrum disorders, which resulted in improved interview skills and employment access.

Conclusions

In this study, we used a bibliometric analysis to objectively, comprehensively, and systematically analyze the VR rehabilitation research literature. We identified the knowledge bases, current topical hot spots, and oncoming trends in this area. In this research field, the areas with acceptable knowledge bases included kinematics, neurorehabilitation, brain injury, exergaming, aging, motor rehabilitation, mobility, cerebral palsy, and exercise intensity. We theorize that future emerging trends and frontiers will focus on video games and young adults. We also identified contemporary research topics and future trends in VR rehabilitation research and provided guidance for future research in this exciting area.

Although papers that were published at different times were gathered for this study, some were not comprehensive in nature and may have introduced publication bias, thereby affecting study outcomes.

Limitations

Our study still has some limitations to be addressed. Although the WSCC database is reliable, other databases, such as non-English databases, should also be considered to ensure that all relevant papers are collected. Additionally, the rapid progress in the field of VR technology application limits the timeliness of this bibliometric study. Further, the VR-based rehabilitation activities we investigated included some gaming exercises, exergames, and video games that were not clearly defined. Finally, the results of the included studies only reflect current research trends in academia. In the future, VR technology is expected to be further integrated with clinical applications, which will enrich and improve the research in this subject field.

Acknowledgments

This study was supported by grants from the Association of Fundamental Computing Education in Chinese Universities, which were awarded to ZZ (grant 2019-AFCEC-199). Further, TF was awarded a grant for a research project titled “Research on the application of genetic big data analysis in the prevention and control of newborn birth defects” (grant 2900021013-CMU-013).

Conflicts of Interest

None declared.

Abstract

Background: Despite growing evidence showing the effects of exercise and cognitive trainings on enhancing attention, little is known about the combined effects of exergame on attention in children with attention deficit/hyperactivity disorder (ADHD). Exergame, a form of exercise using a video game, has both cognitive stimulation and physical activity components and has been shown to improve cognitive function in children.

Objective: The purpose of this study was to investigate the effect of exergaming on attention and to compare the effect induced by exergaming with the effect of aerobic exercise on attention in children with ADHD.

Methods: In all, 30 children with ADHD, aged 8-12 years, were randomly divided into an exergaming group (EXG; n=16) or a bicycle exercise group (BEG; n=14). Before and after the 4-week intervention, the *Frankfurter Aufmerksamkeits-Inventar* (FAIR; Frankfurt Attention Inventory) test was administrated, and event-related potentials during the Go/No-go task was measured to assess attention.

Results: After intervention, both the EXG and BEG had significantly increased selective attention and continuous attention (all *P*<.001), as well as self-control on the FAIR test (EXG: *P*=.02 and BEG: *P*=.005). Similarly, both the EXG and BEG had significantly reduced response time on the Go/No-go test (all *P*<.001). For the Go response, the N2 amplitude (frontocentral maximal negativity) was significantly increased in Fz (midfrontal line) in the EXG (*P*=.003) but was not changed in the BEG (*P*=.97). Importantly, the N2 amplitude in Fz was significantly greater in the EXG compared to the BEG (Go: *P*=.001 and No-go: *P*=.008).

Conclusions: Exergaming has the comparable effects to bicycle exercise to enhance attention in children with ADHD, suggesting that exergaming can be used as an alternative treatment for children with ADHD.

KEYWORDS

exergame; N2 amplitude; attention function; response time; attention deficit/hyperactivity disorder; ADHD

Introduction

Attention deficit/hyperactivity disorder (ADHD) is a neurodevelopmental disorder that is characterized by inattention, hyperactivity and impulsivity, or both [1]. Approximately 3% to 5% of the school-age population are living with ADHD [2,3]. Among symptoms of ADHD, hyperactivity tends to improve during adolescence, but carelessness and impulsiveness may persist into adulthood [4]. The impaired attention and executive function in children with ADHD lead to reduced inhibitory ability, working memory, and task shift due to an imbalance of neurotransmitters such as dopamine and norepinephrine [5-7]. The abnormal neuropsychological activities caused by these symptoms may disrupt the patients' learning ability, daily activities, professional activities, and social functions [8,9].

In children with ADHD (aged >8 years), dysfunctions in neuronal networks associated with attentional processes and cognitive control have been well documented using event-related potentials (ERPs) [10-13]. ERP studies used tasks (eg, Eriksen flanker and Go/No-go tasks) to assess both behavioral and neurophysiological perspectives of ADHD [14]. For example, behavioral performance (eg, response time [RT]) is commonly used to determine processing speed [15], and neurophysiological technology has been used to measure selective attention capacity and skills [16]. The No-go N2 components have been reported to be abnormally lower in children with ADHD than those in children with other neurodevelopmental disorders [17,18]. The N2 amplitude occurs for about 170-350 milliseconds and is related to attention and cognitive control, specifically an inhibitory control response [16,19,20]. Particularly, the amplitude of the N2 is an indication of the intensity of information processing required for the discrimination of stimuli, and the latent phase of the N2 reflects the time of the cognitive processing that distinguishes sensory stimuli [21].

Exercise has been known to enhance attention, executive function, impulsivity, and hyperactivity in children with ADHD by promoting the secretion of neurotransmitters (eg, dopamine and norepinephrine) in the brain, thereby inducing positive responses on the main symptoms of ADHD [22,23]. Although most of the evidence has focused on the acute effects of aerobic exercise on RT and P3 components of children with ADHD, N2 components have received comparatively little attention. Furthermore, there are mixed results in the study of exercise and N2 in normal young adults and preadolescent children [24-26]. For example, Ligeza et al [24] reported that acute moderate intensity exercise increased the conflict effect of N2 amplitude in young people, which suggested improvement in inhibition after a single session of moderate exercise compared to high-intensity interval exercise and seated rest condition. In another study, acute moderate-intensity exercise led to reduced N2 amplitude in preadolescent children and young adults, suggesting that acute exercise might have a general effect on the conflict detection process [25,26]. Therefore, further studies are needed to explore whether exercise can improve the N2 components of children with ADHD.

However, previous studies reported that cognitively engaging physical exercise leads to benefits for cognitive performance [27,28]. For example, a combination of physical activity and cognitive stimulation improved reaction times in inhibition and switching neural efficiency [27,28]. Exergaming is a video game that requires body movement and provides active gaming experience as a form of physical activity [29]. Due to motivational issues and a low level of positive reinforcement, traditional (cognitive) training programs are often uninteresting and fatiguing for children with ADHD [30]. Exergaming helps combine physical and cognitive training through an intriguing game. Recently, exergaming has attracted great attention because of their growing popularity among children, adolescents, and older adults [31-35] due to its effectiveness in motivating participants to engage in intervention [36].

Recent studies revealed that exergaming improves the executive function in healthy adolescents by increasing cognitive stimulation [31]. Exergaming has also been reported to enhance executive function in children with ADHD compared to the control group [37,38]. However, it is currently in question whether these effects are caused by games or exercise. Moreover, there is, to date, only one study that has measured the effects of exergaming on N2 amplitude. This study showed that exergaming led to greater aerobic capacity and larger N2 amplitude, an indication of improved selective attention in patients with metabolic syndrome [39]. Despite the evidence regarding the effects of exergaming on cognitive function, how the neural processing of N2 components is altered in children with ADHD after an exergaming intervention remains unclear. Moreover, it remains inconclusive if exergaming improves attention in children with ADHD and whether exergaming has additional benefits compared to traditional form of aerobic exercise. Therefore, the purpose of this study was to investigate the effect of exergaming on attention and to compare the effect induced by exergaming with the effect of aerobic exercise on attention in children with ADHD. Our first hypothesis was that exergaming will result in improved Go/No-go task performance and increased N2 amplitude in children with ADHD. Second, we hypothesized that the improvement in Go/No-go task performance and N2 amplitude will be greater in exergaming compared to bicycle exercise.

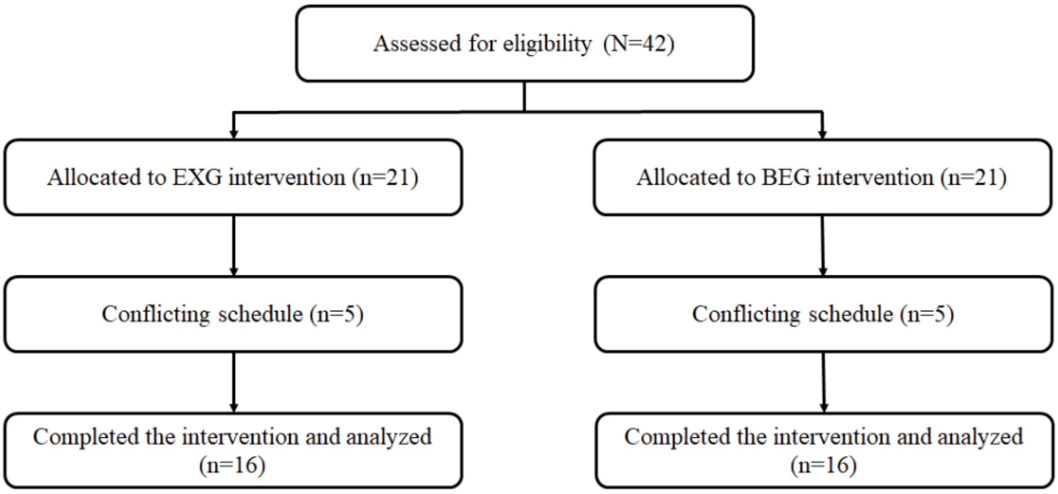
Methods

Study Design and Participants

We used a randomized controlled trial in which participants were randomly assigned to either the exergaming group (EXG) or the bicycle exercise group (BEG). Children with mild to moderate ADHD were recruited from the Children's Mental Health Medical Center in Busan, Republic of Korea. Participants who met the following criteria were included in the study: a Korean Attention-Deficit/Hyperactivity Disorder Diagnostic Scale score between 70-110, indicating a lack of attention; the absence of diseases other than ADHD; right-hand dominance; normal or corrected-to-normal vision; and the absence of physical impairment to perform exercise.

In all, 42 children (aged 8-12 years) with mild to moderate ADHD were recruited and then randomly assigned to either the EXG (n=21) or BEG (n=21). A total of 12 participants (5 for the EXG and 7 for the BEG) were withdrawn from the study, resulting in the final number of 30 participants in this study (16 in the EXG and 14 in the BEG; Figure 1). All participants maintained the same medication and dose during the exercise intervention.

Figure 1. Flowchart of participant eligibility, withdrawals, and the final sample included in the final analysis. BEG: bicycle exercise group; EXG: exergaming group.



Ethics Approval

Written informed consent was obtained from both the children and their parents or legal guardians. This study was approved by the Pusan National University Institutional Review Board in accordance with the Helsinki Declaration (PNU IRB/2018_30_HR).

Sample Size

The sample size was calculated using a sample size calculation software program (G*Power, version 3.1.9.2 for Windows), with an effect size of 0.58, statistical power of .80, and statistical level of significance of .05. The effect size was calculated from previous studies [40]. As a result, the sample size for each group was established at 15 patients, so we decided to recruit 42 patients for each group in consideration of a potential 30% dropout rate.

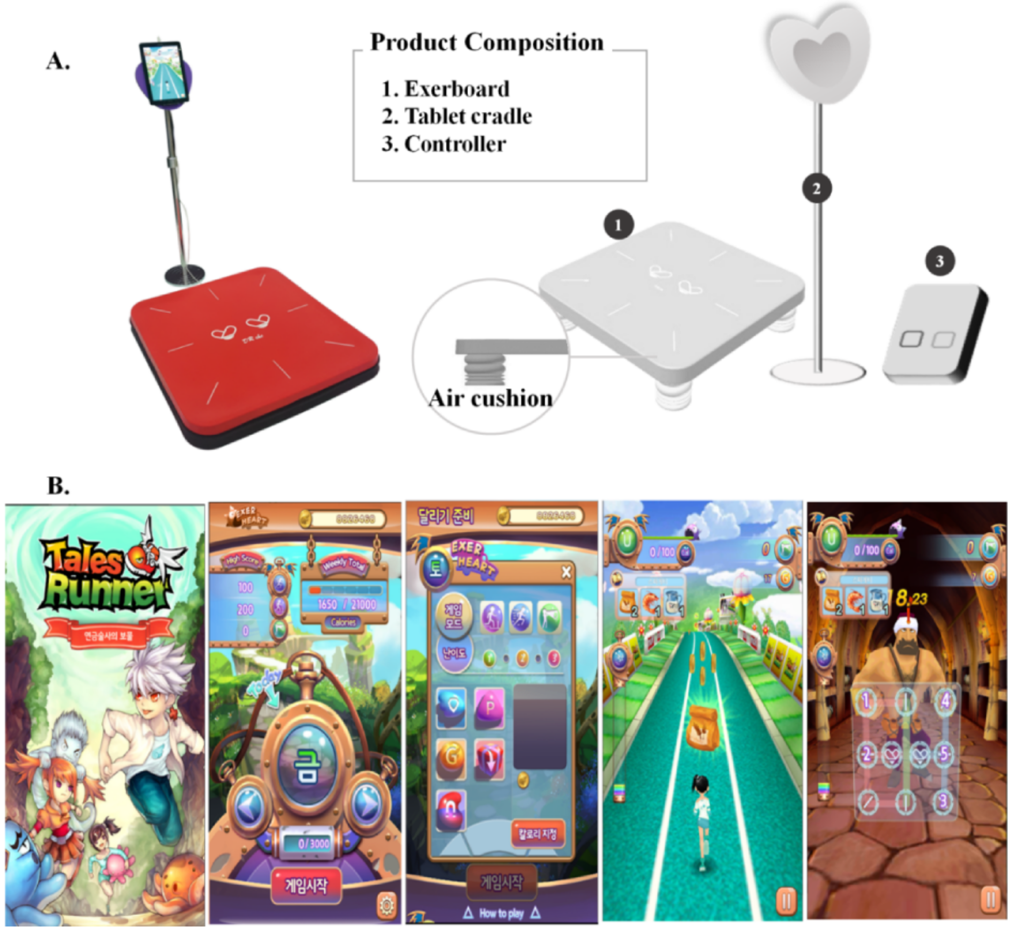
Exergaming and Bicycle Exercise Intervention

The EXG was administered using ExerHeart devices (D&J Humancare), which consisted of a running or jumping board (730-cm width × 730-cm depth × 130-cm height) and a screen connected to the board (Figure 2A). The exercise program called *Alchemist's Treasure* (D&J Humancare) was used for the EXG. In this game, participants run or jump in place with their avatars, using the front, back, left, and right sensors on the mat to avoid obstacles and acquire items (Figure 2B; Multimedia Appendix 1). The BEG performed stationary bike exercise using commercial Fit Elite-Whole body exerciser 1000, with resistance of 0.5~3 kiloponds.

Exercise session for both the EXG and BEG consisted of 3 days/week, 50 min/day, and 60% to 80% of heart rate (HR) reserve for 4 weeks. We monitored individual exercise intensity using an HR monitor (Polar RS400sd). Exercise intensity was determined by using the Karvonen target HR method: $[exercise\ intensity \times (HR_{max} - resting\ HR)] + resting\ HR$ [41]. Each exercise session consisted of 10 minutes of warm-up, 30 minutes of main exercise, and 10 minutes of cooldown. Exercise interventions were conducted at 2 separate child mental health care facilities so that the groups were not aware of the exercise program they were performing. Participants who did not complete more than 80% of the exercise sessions were excluded from the final analysis.

For both the EXG and BEG, all subjects' HRs during exercise were monitored using HR monitors (Polar RS400sd) to confirm that the values were within the target HR range.

Figure 2. (A) ExerHeart devices consisted of the Exerboard, a tablet cradle, and a controller. (B) Features of the video game Alchemist's Treasure.



Go/No-go Task

The Go/No-go task was used to measure the capacity to sustain attention and response control. We used the computerized Go/No-go task using a built-in software of the electroencephalography (EEG) analyzer (Telescan; LAXTHA). During the Go/No-go task, each participant was instructed to press a button for a frequent stimulus (ie, Go stimulus, 60% probability) or to withhold a response for an infrequent stimulus (ie, No-go stimulus, 40% probability). The stimulus was presented in the center of a 15-inch screen with a white background, and the size was 3 × 3 cm. In each trial, a signal consisting of an interstimulus interval was first presented for 1000 milliseconds to attract the participant's attention. This signal was followed by either the Go stimulus (ie, lion image), No-go stimulus (ie, tiger image), or Control stimulus (ie, leopard image) for 1500 milliseconds. Participants were instructed to press the left arrow keyboard for the Go stimulus and the right arrow keyboard for the No-go stimulus and not to respond to the Control stimulus. Participants underwent a familiarization session before starting the test. The number of practice trials was standardized (1 trial each) so that participants performed the same number of practice trials before each condition. The response time (milliseconds) and the accuracy rate (% correct) were recorded simultaneously from the start of the reaction. The entire task (including practice trials) lasted for 10 minutes.

EEG Measurements

EEG was measured from 31 Ag/Ag–CL electrodes, placed according to an augmented 10–20 International System. All EEG recordings were referenced to the average of the right and left mastoid, and the ground electrode was placed on the Fz electrode site. The electrooculogram activity was recorded from electrodes attached below and above the left eye and electrodes located at the outer canthi of both eyes. All electrodes were maintained at impedances <10 kΩ before data recording. After the completion of data collection, EEG signals were analyzed using software (Telescan; LAXTHA); the bandpass filter of the amplifier was 0.5-20 Hz, the sampling rate was 1000 Hz, and a notch filter was at 60 Hz.

The stimulus-locked epochs acquired for the Go/No-go test were extracted offline from 200 milliseconds before to 1500 milliseconds after the stimulus onset, and the period from –100 to 0 milliseconds before stimuli onset was used as the baseline. Peak amplitudes and latencies were measured automatically. The N2 peak amplitudes and latencies were measured in the difference waves of the attended condition. The N2 component was defined as the largest positive peak occurring between 170-320 milliseconds after stimuli. EEG data were collected before and after 8 weeks of the exercise intervention [42,43].

Frankfurter Aufmerksamkeits-Inventar

The *Frankfurter Aufmerksamkeits-Inventar* (FAIR; Frankfurt Attention Inventory) is a psychological test to assess attention and concentration [44]. The FAIR tests the ability to quickly distinguish correct signal among many other similar signals and to hide insignificant information (ie, external interference). Two different versions of the FAIR test were used for test reliability. A total of 640 test items were divided into tests 1 and 2. Each FAIR test paper was arranged in the shape of 20 horizontal and 16 vertical lines on a single sheet of paper, and there were a total of 320 test items. Participants were instructed to find 2 correct shapes, such as a "three-point circle" and "two-point square" among the 4 shapes and draw a line from left to right with a pencil on the test paper to mark them. The scoring was administered using the perspective of 3 attentional actions, and details are shown in Table 1. The ability index P is an index of the number of items related to attention during the test. The control index Q represents the proportional value of correct judgment as a result of attention among all responses. The persistence index C indicates how consistently the attention task was maintained.

Table 1. *Frankfurter Aufmerksamkeits-Inventar* inspection dimensions.

Test item	Related ability	Scoring method	Reliability
P[a]	Selective attention	$(T^b - EL^c) - 2(EO^d + EC^e)$	.944
Q[f]	Self-control	$P \div T$	.903
C[g]	Sustained attention	$P \times Q$	.941

[a]P: performance value.
[b]T: total number of items worked.
[c]EL: total number of line drawing errors.
[d]EO: total number of teeth not marked on a target item.
[e]EC: total number of teeth marked that are not a target item.
[f]Q: quality value.
[g]C: continuity value.

Statistical Analysis

The normality of Go/No-Go test performance was also tested using the Shapiro-Wilk test. Repeated measures ANOVA were used to compute the main effects of time (ie, before vs after intervention), group (ie, EXG vs BEG), and group × time interaction on the behavioral performance (ie, accuracy rate and reaction time), ERP (ie, N2 amplitude), and FAIR (ie, ability index P, control index Q, and persistence index C). If an interaction was identified, paired sample *t* test (2-tailed) was used to verify the direction of the interaction. Significance level was set at .05 for all analyses, effect sizes were assessed using partial eta squared (η^2_p), and all statistical analyses were performed using SPSS (version 24; IBM Corp).

Results

Participants

Of the 42 children who participated in this study, 5 in the EXG dropped out of the study due to conflicting schedule and 7 in the BEG dropped out of the study due to lost interest. Demographic and physical characteristics for all subjects are provided in Table 2.

Table 2. Summary of the participant demographic information.

	EXG[a] (n=16)	BEG[b] (n=14)
Age (years), mean (SD)	9.00 (1.46)	8.85 (1.63)
Male sex, n (%)	14 (88)	12 (86)
Height (cm), mean (SD)	129.38 (9.68)	134.69 (7.76)
Weight (kg), mean (SD)	31.66 (11.84)	35.31 (6.84)

Behavioral Indices

There was no significant group × time interaction on the changes in RT in response to Go and No-go stimulations before and after exercise intervention (*P*=.65 and *P*=.807, respectively). However, both groups significantly reduced RT for Go and No-go stimulations after exercise intervention (Figure 3). For Go stimulation, RT was significantly reduced in the EXG from 846.13 (SD 126.43) milliseconds to 764.56 (SD 107.05) milliseconds (P=.001; η^2_p=0.969) and in the BEG from 873.79 (SD 123.31) milliseconds to 780.79 (SD 96.41) milliseconds

(P=.001; η^2_p=1.267; Figure 3A). For No-go stimulation, RT was significantly reduced in the EXG from 872.25 (SD 96.53) milliseconds to 786.75 (SD 100.02) milliseconds (P=.001; η^2_p=1,211) and in the BEG from 903.71 (SD 130.78) milliseconds to 813.77 (SD 111.86) milliseconds (P=.001; η^2_p=1.114; Figure 3B).

N2 Amplitude

There was a significant group × time interaction on the Go and No-go N2 amplitudes in the Fz region before and after exercise intervention (P=.049 and P=.047, respectively; Table 3). The EXG had significantly increased Go N2 amplitude in Fz after intervention (P=.003), whereas the BEG showed no significant changes (P=.97). Neither group showed changes in No-go stimulus after intervention. In the between-group comparison, the EXG consistently demonstrated greater N2 amplitudes on both Go and No-go stimulations. The waveforms of Go and No-go N2 amplitudes in Fz for the EXG and BEG before and after exercise are shown in Figure 4.

Table 3. Results of changes in Go/No-go N2 amplitude in Fz.

Aufmerksamkeits-Inventar Data

There was no significant group × time interaction on the ability index P (selective attention) before and after exercise intervention (*P*=.79). However, both groups significantly increased ability index P after exercise intervention (both *P*<.001). Similarly, although there was no significant interaction between the EXG and BEG on the on the changes in ability index Q (self-control; *P*=.68), both the EXG and BEG significantly increased control index Q following intervention (EXG: *P*=.02 and BEG: *P*=.005). Lastly, there was also no significant interaction between the EXG and BEG on the on the changes in ability index C (persistent attention; *P*=.66), but both groups significantly increased index C in response to exercise intervention (both *P*<.001; Table 4).

Discussion

Principal Findings

The purpose of this study was to examine the effects of exergaming on attention in children with ADHD and whether these effects were driven by games or exercise by comparing the effects of exergaming and bicycle exercise. Through an examination of the behavioral performance and ERP during the Go/No-go task and FAIR test, our results may suggest that both exergaming and bicycle exercise elicited shorter RT during the Go/No-go task and improved selective attention, self-control, and persistent attention. Notably, larger N2 amplitudes were observed following exergaming compared to the bicycle exercise.

Our results are in agreement with prior findings that showed improved processing speed in children with ADHD after exercise. For example, acute aerobic exercise engendered significantly faster processing speed during the Stroop and flanker tasks compared to the control group [45]. In another study, an 8-week yoga program enhanced attention and processing speed in children with ADHD [46]. Research shows that exercise facilitates the upregulation of cerebral blood flow (CBF) [47] and that an exercise-induced increase in CBF promotes information processing speed [48]. Further, a possible neurophysiological mechanism underpinning the beneficial effects of exercise training on attention in children with ADHD was the exercise-induced secretion of catecholamine [49]. Therefore, in this study, it may be that both exergaming and bicycle exercise stimulate CBF increase and catecholamine secretion, thereby promoting the allocation of attention resources and improvement of processing speed in children with ADHD. However, since this study did not measure CBF and catecholamines levels, this interpretation should be viewed with caution, and the potential neurophysiological mechanism underpinning exergaming and attention should be further investigated in the future.

Novel to this investigation is that there was an interaction effect of exercise modes on changes in the N2 amplitude during the Go/No-go task after intervention, such that the improvements in the N2 amplitude were only manifested in exergaming while the intervention effects were not observed in the bicycle exercise. The N2 components provide important information through the amplitude and latent phase because it is an indication of attentional assignment of the anterior cingulate cortex (ACC) when performing cognitive tasks [50,51]. Baker and Holroyd [52] suggested that task demands involving high conflict and working memory loads should strongly activate the ACC, giving rise to increased N2 amplitudes. No-go stimulation activates the prefrontal cortex and can affect cognitive regulation and inhibition processes [53]. Previous studies have reported that the N2 amplitude reflects the neural changes associated with the task [54] and that the N2 amplitude increases with greater attention [51]. Drollette et al [25] reported that the N2 amplitude decreased after running on the treadmill for 20 minutes, but another study showed that the N2 amplitude remained unchanged after an acute exercise [55]. Additionally, Stroth et al [56] pointed out that greater physical fitness is associated with better task preparation as well as decreased amplitudes in N2 amplitude, indexing more efficient executive control processes. In our previous study, both exergaming and treadmill exercise improved selective attention (N2) in patients with metabolic syndrome [39]. The results indicated that exergaming facilitated visual perceptual stimulation in the virtual environment to enhance the selective attention activity within with the cerebral cortex, brain regions associated with executive function, which was not changed by normal aerobic exercise.

In light of our N2 amplitude findings, exergaming is likely to better regulate the activity of ACC in the ventral prefrontal cortex than traditional form of aerobic exercise and effectively increase attention. It is hypothesized that ACC activation may have been reduced due to less-engaging exercise environment, which engendered no beneficial effect on attention after bicycle exercise. This may also be associated with the fact that all participants who dropped out from the BEG (n=7) were due to lost interest, whereas all participants who dropped out from the EXG (n=5) were due to conflicting schedule. This obvious discrepancy between the groups in the dropout reasons occurred even though the interventions were administered in 2 separate child mental health care facilities, which was intended to avoid environmental factors that could influence the participants' motivation. Thus, the ACC is likely to be more actively stimulated during complex exercise that involves multiple aspects of environment (eg, exergaming) than monotonous exercise environment (eg, cycling). Performing exergaming requires a process of directional judgment (eg, front or back and left or right); thus, attention and cognitive control ability needs to be executed to successfully perform the task. However, further translational evidence is needed to clarify this hypothesis.

Interestingly, aerobic exercise has a faster judgment of response times when it comes to information processing, but cash realization during neuroelectrical activity has a different effect. It may be that in the applied exergaming, the inhibition and switching components are needed to a greater extent than updating for successful task performance [37]. The Alchemist's Treasure training program primarily includes strength training; coordination (and endurance); sensitivity training; as well as demands on cognitive functions such as inhibition, switching, updating, attention, and rapid action execution. Prior research has demonstrated that cognitively demanding physical activities (exergaming), such as coordination exercises, preferentially activate brain regions used to control higher-order cognitive processes, leading to improved performance [31,37]. In conclusion, exergaming has the characteristics of aerobic exercise, so it has the ability to judge reaction time quickly. Meanwhile, the brain area is stimulated by the corresponding stimulation more favorable to neuroelectrical activity than general aerobic exercise.

For the FAIR results, we found improved selective attention, self-control, and persistent attention following exergaming and bicycle exercise. The results of Medina et al [57] showed that physical activity increases the release of serotonin, dopamine, and norepinephrine, and it is assumed that the attention of the participants with ADHD is improved because of the release of these neurotransmitters. According to a previous investigation, tai chi training was conducted to investigate the attentional in children and adolescents with ADHD [58]. The results showed that continuous tai chi performance at a stable speed significantly enhanced the ability of selective attention and continuous attention. Studies in adolescents with ADHD have shown that exercise-based game intervention confers maximal benefits for selective attention, self-control, and persistent attention [59,60].

We surmise that 3 components of executive function (ie, selective attention, self-control, and persistent attention) have been facilitated during exergaming performance. First, selective attention is the process of stimulating specific consciousness. During exergaming, participants had to quickly avoid the obstacles that appear on the screen; thus, participants had to maintain their selective attention throughout the game. The second component is cognitive control, which is necessary to complete tasks within a certain period of time and is expected to be facilitated while pressing the displayed number on the screen quickly and accurately during exergaming. Lastly, sustained attention is the duration of concentration related to the duration of correct concentration. In this study, exergaming characters were controlled by the user's movement. To control the game character's movement accurately and quickly, participants had to maintain their attention throughout the game. Therefore, because exergaming contains general aerobic exercise elements as well as additional components to stimulate selective attention, self-control, and continuous attention, it may have had significant impacts on the attention and attention of children with ADHD.

Limitations

Our study is not without limitations. First, this study is subject to the limitation of lacking a nonexercise (or active) control group, warranting some caution in interpreting the results until they can be replicated in a larger randomized controlled trial. Second, this study is also limited by a relatively small sample size (n=30) and homogeneous characteristics of participants (ie, all Asian and 26/30, 87% male), so the results may not be generalizable to the entire population of children with ADHD. Third, only one type of game device was used in this study; thus, future studies also need to examine the effects of multiple exergaming devices and games on ADHD attention. Fourth, the relationship between game scores and attention was not considered in this study, which should be examined in future studies.

Conclusions

Our results showed that both exergaming and bicycle exercise training enhanced attention in children with ADHD, but the benefits induced by exergaming may be somewhat greater than those from bicycle exercise. These findings suggest that, through complex and stimulating environment during the training, exergaming may stimulate the frontal lobes of the brain and has a significant impact on attention, processing speed, and cognitive control function, thereby improving attention in children with ADHD symptoms. Therefore, this study may hold an important public health implication that exergaming could be used as a new exercise therapy for children with ADHD in the future.

Abstract

Background: Exergaming may be an important option to support an active lifestyle, especially during pandemics.

Objective: Our objectives were (1) to explore whether change in exergaming status (stopped, started or sustained exergaming, or never exergamed) from before to during the COVID-19 pandemic was related to changes in walking, moderate-to-vigorous physical activity (MVPA) or meeting MVPA guidelines and (2) to describe changes among past-year exergamers in minutes per week exergaming from before to during the pandemic.

Methods: A total of 681 participants (mean age 33.6; SD 0.5 years; n=280, 41% male) from the 22-year Nicotine Dependence in Teens (NDIT) study provided data on walking, MVPA, and exergaming before (2017 to 2020) and during (2021) the COVID-19 pandemic. Physical activity (PA) change scores were described by change in exergaming status.

Results: We found that 62.4% (n=425) of the 681 participants never exergamed, 8.2% (n=56) started exergaming during the pandemic, 19.7% (n=134) stopped exergaming, and 9.7% (n=66) sustained exergaming. Declines were observed in all 3 PA indicators in all 4 exergaming groups. The more salient findings were that (1) participants who started exergaming during COVID-19 reported the highest MVPA levels before and during the pandemic and declined the least (mean –35 minutes/week), (2) sustained exergamers reported the lowest MVPA levels during the pandemic (median 66 minutes/week) and declined the most in MVPA (mean change of –92 minutes/week) and in meeting MVPA guidelines (–23.6%). During the pandemic, starting exergamers reported 85 minutes of exergaming per week and sustained exergamers increased exergaming by a median 60 minutes per week.

Conclusions: Although starting and sustaining exergaming did not appear to help exergamers maintain prepandemic PA levels, exergaming can contribute a substantial proportion of total PA in young adults and may still represent a useful option to promote PA during pandemics.

Introduction

Many studies conducted early on during the COVID-19 pandemic suggest widespread decreases in physical activity (PA) related to public health lockdowns and restrictions [1-5]. Specifically, working from home was associated with declines in active transport, and the closure of gyms and recreational centers limited access to and opportunities for PA [1-5]. Conversely, some pandemic-related changes may have facilitated PA [6]. With less time needed for commuting to and from work, leisure time may have increased for some, thus affording more time to engage in PA [6].

A review on PA during COVID-19 suggested that "positive technology" (defined as a "scientific and applied approach to the use of technology for improving the quality of our personal experience") [7,8] represented a popular option to support or maintain an active lifestyle during the pandemic [9,10]. Use of technology has been suggested by the World Health Organization (WHO) as one alternative to stay physically active during confinements [11], and many appear to have turned to positive technology during the COVID-19 outbreak to maintain or increase PA [7,9].

Exergaming (or active video gaming), one form of positive technology that engages users in PA, can be played using gaming consoles, mobile devices, virtual reality, personal computers, and specific types of exercise equipment (eg, stationary bikes and treadmills with interactive screens) [7,10,12]. It offers a PA option that is both enjoyable and motivating because of self-monitoring options, gamification, and user interface technology [7,13]. Pokémon Go, for example, is a notably popular exergame that increased PA in both men and women of all ages and weights, even reaching low-activity populations [12]. Exergaming offers personalized, convenient activity options, as well as the possibility of playing with other users online, which, in addition to decreasing sedentary time, may decrease feelings of social isolation during pandemic-related restrictions [13-15]. Exergaming can help people cope with mental health issues such as anxiety [9,16,17], and it can support those with chronic disease, such as Parkinson diseases [17,18], poststroke sequelae [19], arthritis [20], and brain injuries [21], in maintaining PA levels in home-based rehabilitation situations during pandemics.

Before the COVID-19 pandemic, the prevalence of weekly exergaming among adolescents and young adults ranged from 18% to 43% in Canada [22-25]. However, it is not clear whether the prevalence changed during the COVID-19 pandemic. Further, no longitudinal studies have assessed whether exergaming was associated with changes in PA levels during the pandemic. Because future pandemics are possible, understanding exergaming behavior during the COVID-19 pandemic could shed light on potential benefits and challenges of using technology to encourage PA during lockdowns. Further, stressful times can encourage positive behavior change (eg, taking up exergaming) that may endure postpandemic [13,17,26]. Therefore, building the evidence base in this realm could inform public health decisions related to promoting PA during a pandemic.

The objectives of this study were to (1) explore whether a change in exergaming status (stopped, started or sustained exergaming, or never exergamed) from before to during the COVID-19 pandemic related to changes in walking, minutes of moderate-to-vigorous physical activity (MVPA), and meeting MVPA guidelines. We were particularly interested in ascertaining whether starting to exergame or sustaining exergaming were associated with maintaining pre–COVID-19 PA levels of walking, MVPA, or meeting MVPA guidelines. We also aimed to (2) describe changes in minutes of exergaming per week among past-year exergamers from before to during the COVID-19 pandemic.

Methods

Study Sample

Data were drawn from the Nicotine Dependence in Teens (NDIT) study [27], an ongoing 23-year longitudinal study that aims to describe the natural course of nicotine dependence in youth, but also collects data on a wide range of sociodemographic, substance use, psychosocial, lifestyle, and health-related variables. A detailed description of the NDIT study methods has been published previously [27]. Relevant to this study, data for 799 participants were collected in cycle 23 between January 2017 to March 2020 (n=551, 69% of participants completed the questionnaire in 2017; n=152, 19% in 2018; n=88, 11% in 2019; and n=8, 0.8% in 2020). Data were available for 722 participants in cycle 24, which was conducted online during the COVID-19 pandemic, from December 2020 to February 2021. Participants could use their mobile phone, tablet, or personal computer to complete the questionnaire. A total of 681 participants in cycle 23 (85%) also provided data in cycle 24 and were retained for this analysis. Participants received a CAD $50 (US $36.97) gift card or e-transfer in each cycle to cover any costs associated with their participation.

Ethical Approval

The study procedures were approved by the Montreal Department of Public Health Ethics Review Committee (2007–2384), the McGill University Faculty of Medicine Institutional Review Board (2017–6895), and the Ethics Research Committee of the Centre de Recherche du Centre Hospitalier de l'Université de Montréal (2021-9385, 20.278-YP). Parental consent was obtained at NDIT inception. Participants could legally provide consent in the post–high school data collections because they had all attained the age of 18 years.

Study Variables

PA Variables

Data on number of minutes per week walking, moderate physical activity, and vigorous physical activity were collected using the short form of the International Physical Activity Questionnaire (IPAQ-SF) [28,29]. The IPAQ-SF is used in cross-national monitoring of PA and demonstrates low to moderate reliability and validity against device-based PA measures [30]. Participants reported the number of days on which they had engaged in each type of PA over the past week and the average number of minutes per bout. The recommended truncation protocol [29] was used to exclude unrealistic values and reduce improbable

PA scores. Number of minutes walking per week was calculated as the number of days walking per week multiplied by the number of minutes per bout. Number of moderate PA minutes per week was computed as the number of days of moderate PA per week multiplied by the number of minutes per bout, and the number of vigorous PA minutes per week was computed as the number of days of vigorous PA per week multiplied by the number of minutes per bout.

Calculation of MVPA

Number of MVPA minutes per week was calculated by adding the number of moderate PA minutes per week and number of vigorous PA minutes per week.

Meeting MVPA Guidelines

Participants were categorized as meeting MVPA guidelines (yes or no) if they had engaged in MVPA for ≥150 minutes per week [31].

Exergaming Status

Using data from cycles 23 and 24, participants were categorized into 4 groups based on their exergaming behavior over time using the following item: "In the past 12 months, how often did you exergame using consoles, or using your cellphone and/or a mobile app?" Response choices included never, less than once a month, 1 to 3 times a month, 1 to 6 times per week, and every day. In both cycles 23 and 24, participants were categorized as exergamers if they chose any response option other than "never." The four groups included (1) never-exergamers (ie, participants who did not report exergaming in cycles 23 or 24); (2) stopping exergamers (ie, participants who reported exergaming in cycle 23 but not in cycle 24); (3) starting exergamers (ie, participants who reported exergaming in cycle 24 but not in cycle 23); and (4) sustaining exergamers (ie, participants who exergamed in both cycles 23 and 24).

Minutes Exergaming per Week

Items measuring the number of minutes exergaming per week were modeled on the IPAQ-SF [22,23,25]. Participants who reported past-year exergaming were asked: "Did you exergame using consoles such as Nintendo Wii, XBOX ONE Kinect, Sony Play Station Move, Sony Eye Toy: Kinetic, or using your cellphone and/or a mobile app in the past 30 days? (ex. ZOMBIES, RUN!, Nike+ Running App, Fit Freeway, Pokémon Go)?" Response options were yes or no. Participants who responded no were assigned a score of 0 for minutes exergaming per week. Those who responded yes were asked how many days per week they exergamed (the response option was from 1 to 7 days) and how many minutes they played on average during each bout in the past month (responses were open-ended). The total number of minutes exergaming per week was calculated as the number of days exergaming per week multiplied by the average number of minutes per bout.

Exergaming Intensity

Usual intensity of exergaming was measured by the following question: "What was your usual physical effort during play?" Response choices included light, moderate, and vigorous.

Sociodemographic Characteristics

Sociodemographic characteristics included age, sex, whether the participant was university educated (yes or no), whether their mother was university educated (yes or no), and whether they were French speaking (yes or no), were born in Canada (yes or no), had an annual household income <CAN $50,000 (US $36,966; yes or no), lived alone (yes or no), lived with children (yes or no), and were employed (yes or no).

Data Analyses

Descriptive statistics were used to compare sociodemographic and PA-related characteristics (ie, walking, MVPA, and exergaming) of participants retained in the analytic sample (ie, those who provided data in cycles 23 and 24) versus not retained (ie, those who provided data in cycle 23 but not cycle 24). Based on skewness and kurtosis, walking, MVPA, and exergaming minutes per week were not normally distributed. Therefore, the median (IQR) is reported for these variables. The proportion of participants that met MVPA guidelines is reported as a percentage.

Change scores were computed by subtracting number of minutes per week for each PA indicator (including exergaming) in cycle 23 from minutes per week in cycle 24. Because the distributions for the change scores were relatively normal in each of the 4 groups defined by exergaming status as well as in the sample overall, we report mean (SD) change scores. We report the median (IQR) for the change in minutes exergaming per week because the data were not normally distributed. Data were analyzed using SPSS (version 20.0; IBM Corp).

Results

Participants Retained Versus Not Retained

Table 1 compares the sociodemographic and PA-related characteristics of participants retained and not retained (ie, as measured in cycle 23). Lower proportions of those retained were male and French speaking. In addition, they reported fewer minutes per week walking and engaging in MVPA than participants who were not retained.

The mean age of the 681 participants retained for analysis was 33.6 (SD 0.5) years in cycle 24; 41% (n=280) were male, 95% (n=647) were born in Canada, 33% (n=225) were French speaking, 21% (n=143) had an annual household income of <CAN $50,000 (US $36,966), 15% (n=102) lived alone, 51% (n=347) lived with children, 83% (n=565) reported being employed, and 36% (n=245) met MVPA guidelines. The median (IQR) minutes per week during COVID-19 was 120 (45-240) for walking and 80 (0-240) for MVPA. Participants who exergamed during COVID-19 (n=122) reported a median (IQR) of 80 (9-240) minutes of exergaming per week.

Of 681 participants retained for analysis, 425 (62.4%) were never-exergamers, 56 (8.2%) started exergaming in cycle 24 (during the pandemic), 134 (19.7%) stopped exergaming in cycle 24, and 66 (9.7%) sustained exergaming. Among the 200 exergamers in cycle 23, 66 (33%) sustained exergaming in cycle 24, and 134 (67%) stopped exergaming.

Table 2 reports the median number of minutes walking per week, median number of minutes engaged in MVPA per week, and the percentage of participants who met MVPA guidelines before and during the COVID-19 pandemic. In addition to reporting values for the sample overall, data are provided for the 4 groups defined by exergaming behavior over time.

The data suggest declines over time in all 3 PA indicators in the sample overall (Table 2). Median minutes walking per week declined from 175 before COVID-19 to 120 during COVID-19, with a mean decline of 58 minutes per week. MVPA declined from a median 130 to 80 minutes per week among the participants overall, with a mean decline of 49 minutes per week. The proportion of participants that met MVPA guidelines declined from 48.3% (n=326) before the pandemic to 36% (n=245) during the pandemic, an absolute decline of 12.3%.

Table 1. Characteristics of participants retained and not retained for analysis from the Nicotine Dependence in Teens study (Montreal, Quebec, 2017-2021). Data were drawn from cycle 23[a].

Characteristics[b]	Total (n=799)	Retained in cycle 24 (n=681)	Not retained in cycle 24 (n=118)
Age (years), mean (SD)	30.6 (1.0)	30.5 (1.0)	31.0 (1.1)
Male, n (%)	351 (43.9)	280 (41.1)	71 (60.2)
Born in Canada, n (%)	799 (93.7)	642 (94.3)	107 (90.7)
Mother is university educated, n (%)	332 (46.2)	283 (45.6)	49 (50)
French speaking, n (%)	245 (30.7)	199 (29.2)	46 (39)
Walking (minutes/week), median (IQR)	175(60-350)	175 (60-350)	200 (70-420)
MVPA[c] (minutes/week), median (IQR)	135 (0-330)	135 (0-303)	180 (20-450)
Met MVPA guidelines, n (%)	387 (49.5)	326 (48.9)	61 (53)

[e]MVPA: moderate-to-vigorous physical activity.
[f]These values represent the absolute decline in percentage.

Change in Walking Across Exergaming Groups

Among the 4 groups defined by exergaming status, patterns of interest in walking from before to during COVID-19 (Table 2) show that those who started exergaming reported the highest level of walking during the pandemic (a median 195 minutes per week), and in addition, they declined the least (they had a mean decline of 38 minutes per week, compared to 58 minutes among all participants). Those who stopped exergaming had the highest level of walking before COVID-19 (median 178 minutes per week) and declined the most (their mean minutes walking per week declined by 97 minutes). Finally, sustained exergamers reported the lowest median levels of walking both before and during the pandemic; the mean decline in minutes walking per week in this group (–56 minutes per week) was similar to the mean decline among participants overall (–58 minutes per week).

Change in MVPA Across Exergaming Groups

Patterns of interest in MVPA in the 4 exergaming status groups (Table 2) show that never-exergamers reported the lowest MVPA levels before the COVID-19 pandemic (a median 120 minutes per week). Participants who started exergaming during the pandemic reported the highest MVPA levels both before and during the COVID-19 pandemic, and they declined the least (Table 2). Their mean MVPA change score was –35 minutes MVPA per week compared to –49 minutes among participants overall. Finally, sustained exergamers reported the lowest MVPA levels during the pandemic (a median 66 minutes per week) and they declined the most. Their mean MVPA change score was –92 minutes per week.

Change in Meeting MVPA Guidelines Across Exergaming Groups

Compared to the other 3 groups, a higher proportion of participants who started to exergame during the COVID-19 pandemic met MVPA guidelines both before and during the COVID-19 pandemic. Although the proportion of sustained exergamers that met MVPA guidelines was similar to the other 2 exergaming groups before COVID-19, this group reported the lowest proportion during COVID-19 and the largest decline over time (–23.6%). The proportion of participants that met MVPA guidelines was lowest among never-exergamers before COVID-19 (186/424, 44.8%), and this group had the lowest decline over time (–8.2%).

Change in Minutes Exergaming Among Exergamers

Table 3 reports change in exergaming minutes per week among sustained exergamers, participants who started exergaming, and participants who stopped exergaming. Participants who started exergaming reported a median of 85 minutes of exergaming per week during the COVID-19 pandemic. Sustained exergamers also increased exergaming by a mean 90.5 minutes per week (Table 3). Light intensity exergaming was reported by 65% (47/72) of exergamers in cycle 23 and 59% (55/94) of exergamers in cycle 24. Moderate or vigorous exergaming was reported by 35% (25/72) of exergamers in cycle 23 and 42% (39/94) in cycle 24.

Table 3. Number of minutes per week engaged in exergaming before and during the COVID-19 pandemic in groups defined by consistency in exergaming behavior over time (Nicotine Dependence in Teens study, Montreal, Quebec, 2017-2021).

	Exergaming (minutes/week), median (IQR)		
	Before COVID-19 (cycle 23[a])	During COVID-19 (cycle 24[b])	Change between cycles 23 and 24
Started exergaming (n=56)	0 (0 to 0)	85 (0 to 240)	85 (0 to 240)
Stopped exergaming (n=134)	0 (0 to 0)[c]	0 (0 to 0)	0 (0 to 0)
Sustained exergaming (n=66)	0 (0 to 63)[c]	68 (14 to 229)	60 (–4 to 188)

[a]Data were collected from January 2017 to March 2020 (mean age 30.6 years).

[b]Data were collected from December 2020 to June 2021 (mean age 33.6 years).

[c]Participants who reported past-year exergaming but 0 minutes exergaming in the past 30 days were assigned a score of 0 minutes exergaming per week.

Discussion

Overall Findings

Overall, the percentage of participants meeting MVPA guidelines, the number of minutes walked, and the number of minutes engaged in MVPA per week declined from before to during the pandemic regardless of exergaming status [6]. Our data suggest that sustained exergamers were not more active than never-exergamers during the COVID-19 pandemic and, in fact, appeared to be less active. In contrast, those who started exergaming reported the highest levels of walking and MVPA during COVID-19, although, as in all groups, the change scores suggest declines on average in both activities. Thus, it appears that even if exergaming encourages PA during periods of confinement, in and of itself exergaming may not be sufficient to help exergamers maintain prepandemic PA levels. It is possible, however, that without exergaming the declines observed among sustained exergamers could have been steeper.

Never-Exergamers

Never-exergamers reported declines of 48 minutes per week in walking and 41 minutes per week in MVPA from before to during the COVID-19 pandemic. Of the 4 exergaming groups studied, never-exergamers reported the lowest levels of MVPA and were least likely to meet MVPA guidelines before the pandemic. The relatively minor changes in PA in this group during COVID-19 may reflect a general disinterest in PA (so that closure of gyms and recreational centers during the pandemic made little difference to their PA levels). It is possible that level of motivation for PA remained low among these individuals during the pandemic, such that they did not benefit from any increases in time available for PA due to containment measures. It is also possible that this group had established (lower) PA levels and patterns that they were content with and that they felt little need to explore different ways of building PA into their routines, regardless of the pandemic context.

Stopped Exergaming

Among the 4 groups defined by exergaming status, those who stopped exergaming declined the most in walking (–97 minutes/week) from before to during the COVID-19 pandemic. Although stopping exergaming in this group was possibly related to COVID-19, the middle to early 30s is often a turbulent time during the life course marked by numerous important transitions as people complete their education, enter the workforce, and begin their own families [32]. Rather than being a consequence of the COVID-19 pandemic, exergaming may be a form of PA that is dropped during these life transitions to make way for engaging in new roles and activities. Alternatively, exergaming could be an intermittent activity [32] linked to the release of new games or consoles, and the lack of new releases during the pandemic could be among the reasons that participants stopped exergaming. Exergaming may also be a "transferable" PA, such that it is used to experiment with a new PA (eg, to begin jogging), which is then continued independently of the exergaming component. Finally, frustration with technical glitches, concerns with online privacy [33], reduction in enjoyment and game immersion (ie, how a videogame draws a player into the game) [33,34], and price have also been cited as reasons for stopping exergaming [33,34]. Qualitative studies may be helpful in identifying the reasons why exergamers in their 30s choose to stop exergaming during pandemics.

Sustained Exergaming

Of the 4 exergaming groups, sustained exergamers reported the lowest levels of walking both before and during the pandemic and the lowest levels of MVPA during the pandemic. Previous research suggests that although exergamers do not necessarily have higher PA levels than never-exergamers and may not be interested in traditional PA, they do understand the importance of movement and turn to exergaming for their PA [22,25,35]. Sustained exergamers may have continued to play games such as Pokémon Go during the COVID-19 pandemic. There is evidence that 2020 was the most profitable year ever for the Pokémon Go enterprise [36], suggesting that many exergamers continued to play this outdoor game during COVID-19. Zombies, Run! also had an increase of 2 million users during COVID-19 [37]. Further, Ellis et al [38] reported that among 2004 young adult gamers (aged 30.5 years on average), Pokémon Go and Harry Potter: Wizards Unite were played frequently during the pandemic to maintain exercise levels and for social connection. Many participants reported that Pokémon Go was "the one thing that keeps me going outdoors and moving each day" [34]. Ellis et al [38] also reported that those who exergamed during the COVID-19 pandemic did so to distract themselves, escape from reality for a short period of time, occupy themselves, and manage their mental health.

Sustained exergamers reported a median of 68 minutes per week of exergaming, an important contribution to overall PA. Exergaming is not usually dependent on fitness or recreational facilities outside the home; therefore, this group may not have been overly affected by pandemic-related lockdowns. While the change in walking levels among sustained exergamers was not as marked as among those who stopped exergaming, their decline in MVPA was substantial (–92 minutes per week). It is possible that sustained exergamers participated in other modes of PA before the pandemic that were not replaced during the pandemic. Minutes exergaming per week among sustained exergamers did increase (as also reported in the Ellis et al study), but this was not enough to replace MVPA lost in other PA modes.

Started Exergaming

Of the 4 exergaming groups, those who started exergaming during the pandemic reported the highest MVPA levels before the pandemic (210 minutes/week) and the smallest decrease in MVPA (–35 minutes/week) during the pandemic. This group may have started using exergaming to compensate for activities they could no longer participate in during COVID-19. In addition to compensating for the loss of PA during the pandemic, video games may have helped with the loss of social interactions, which might have been a particularly salient loss in this group [7,14,38,39]. Whatever the underpinning, starting exergaming during the pandemic likely reflects relatively high levels of "physical literacy," which represents the motivation and financial resources to search out new forms of accessible PA [40]. Alternatively, or in addition, this group may also have been particularly sensitive to public health messaging that recommended maintaining PA levels during the pandemic.

Future Research

More research is needed to examine fluctuations in exergaming behaviors over time, especially during such challenging times as COVID-19. Qualitative research may help identify reasons for stopping, starting, or continuing to exergame during pandemics. This study did not identify types of exergaming engaged in, who participants exergamed with, or the context (ie, indoors or outdoors) in which they exergamed. These areas could be important avenues to explore to better inform recommendations for starting exergaming or for maintaining previous levels of exergaming during pandemics, as well as in general.

Limitations

Limitations of this study include that self-report IPAQ-SF data are subject to overreporting, although Lee et al [28] suggest that because of its established reliability, the IPAQ-SF can be used with care in repeated-measures studies. There was loss to follow-up between cycle 23 and cycle 24, which may relate to competing interests in the busy lives of young people in emerging adulthood. Selection bias related to this loss to follow-up could have attenuated our estimates, although the small number of sociodemographic differences between those retained and not retained for analysis mitigates this concern somewhat. Use of a purposive sample of schools in the NDIT study may limit the generalizability of the findings. Finally, we were unable to categorize exergamers according to more refined categories of exergaming intensity and frequency, and this may have led to misclassification of some exergamers. Future studies should use more refined measures of exergaming to enable more accurate categorization of exergamers.

Conclusion

Although it may support PA at home during periods of confinement, starting or sustaining exergaming did not appear to be enough to maintain prepandemic PA levels in this population-based sample of young adults. However, the data suggest that exergaming can contribute a substantial proportion of total PA in young adults and may still represent a useful option to promote PA during pandemics.

Abstract

Background: This study explored the use of virtual reality (VR) technology to enhance the effectiveness and duration of low-intensity movements and postures in Pilates-derived exercises. We postulate that by leveraging the flow state in VR, individuals can engage in these exercises for longer periods while maintaining a high level of flow.

Objective: The purpose of this study was to compare differences in posture maintenance and flow between VR Pilates training and conventional Pilates training, and the correlation between the 2 factors.

Methods: The 18 participants in each group received either VR training or conventional training and were switched to the other training type after a 2-day wash-out period. Each group performed Pilates movements in a VR environment and a conventional environment, divided into 4 types. After training sessions, participants were evaluated for flow using a self-report questionnaire. In addition, a sports video analysis program was used to measure the duration of posture maintenance in 2 video-recorded sessions. Repeated-measures ANOVA and correlation analysis were performed on the measured duration of posture maintenance and flow scores. In all cases, the statistical significance level was set at $P<.05$.

Results: Results for the duration of posture maintenance verification by type showed that simple behavior ($F_{1,16}=17.631$; $P<.001$), upper body–arm coordination behavior ($F_{1,16}=6.083$; $P=.04$), upper body–leg coordination behavior ($F_{1,16}=8.359$; $P<.001$), and whole-body coordination behavior ($F_{1,16}=8.426$; $P<.001$) all showed an interaction effect at $P<.05$. Flow ($F_{1,16}=15.250$; $P<.001$) also showed an interaction effect. In addition, significant correlations were determined between duration of all types of posture maintenance and flow in the VR training group at $P<.05$.

Conclusions: Our results indicate that VR Pilates training may be more useful than conventional Pilates training in improving the duration of posture maintenance and that it promotes a significantly higher degree of flow when compared with conventional Pilates training.

Introduction

Virtual reality (VR) technology provides a virtual environment using virtually created graphics or images [1]. VR was previously seen as encompassing the implementation of virtual graphics—including 2D or 3D graphics—to simulate the real world, irrespective of the type of VR device used [2]. Currently, however, VR has come to be defined as a technology that induces users to enter a virtual world while wearing a head-mounted display (HMD) that completely blocks the wearer's visual senses [3]. This flow eventually digitizes the positions and directions of the real world (and those who live in it) while providing the wearer with 3D images, thereby affecting their movements [4].

Previous studies have emphasized the potential benefits of VR technology in certain specialty areas—such as education, training, and entertainment—with its usefulness further expanded to other disciplines [5]. The application of VR technology in sports is an innovative development for overcoming barriers through effective training methods [6,7]. This justifies the great academic interest in the applicability of VR technology to sports. Specifically, VR-based fitness effectively promotes muscle growth and aerobic capacity [8]. Moreover, VR technology is effective at improving physical activity in sports and military training [9]. A VR-based exercise rehabilitation program was effective in improving the physical strength of patients undergoing hemodialysis and in improving psychological outcomes—such as quality of life, depression, and anxiety—in those with cardiovascular diseases [10-12].

Previous studies have examined the effects of sports participation in VR environments on motivation and enjoyment. This was followed by studies showing that a high degree of flow is closely associated with VR sports games. Thus, these studies have demonstrated the effects of psychological factors [13,14]. Furthermore, mind-body physical activities—such as yoga or Pilates—conducted in a VR environment can simulate real situations [15].

Flow is defined as the degree to which individuals concentrate on an object in response to specific stimuli and can be expressed as a holistic sensation that individuals perceive while acting holistically. Moreover, flow is an inherently valuable concept closely associated with motivation, as it induces individuals to be fully engaged in an activity, experience it as intrinsically rewarding, and pursue it even without achieving an ultimate goal [16,17]. A recent study highlighted the impact of flow in the context of physical exercise; it showed that flow is closely associated with intention for sustainable use of Wii Fit or smartphone-based fitness apps [17].

Previous studies have shown that VR technology is effective in creating a state of flow because of its flow sensory and physical affordances [13,18,19]. Along the continuum of these previously published studies, we hypothesize that flow might be involved in the duration of posture maintenance in the context of VR Pilates. Therefore, we have conducted this study to assess the efficacy of VR Pilates in improving the duration of posture maintenance and its ability to promote a significantly higher degree of flow compared to traditional Pilates among typical healthy adults.

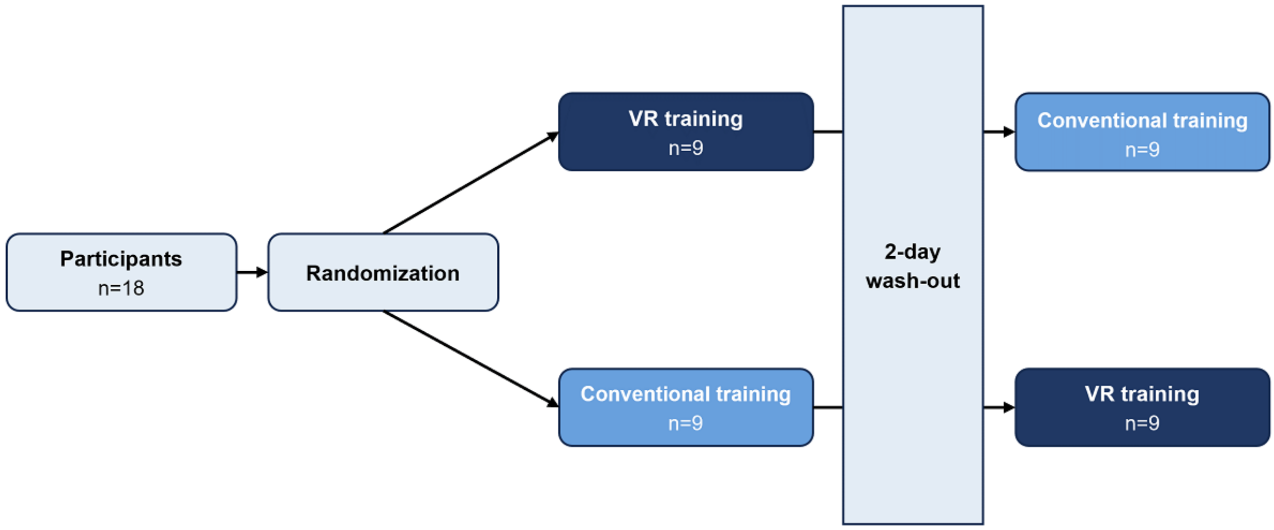
Methods

Study Design and Participants

Recruitment was conducted through an advertisement posted on the internet board of the College of Sport of Chung-Ang University. Participants were instructed to send a message of intent to participate to the researcher's messenger address posted in the advertisement. The recruitment period was from February 2021 to April 2021. Participants were included if they were male Korean nationals aged ≥20 years attending university with a major in physical education; participants' physical health, along with confirmation of an absence of mental illness, was confirmed by a health check-up program at a university-affiliated hospital. Participants were excluded if they had a history of head trauma; abused substances such as alcohol, tobacco, or drugs; were unable to understand the study and consent procedures; or had a confirmed diagnosis of a mental or psychiatric disorder [20]. For this study, we estimated the sample size using G* Power (Heinrich-Heine-Universität). To do this, we performed a repeated-measures ANOVA and used a type I error of .05, an effect size of 0.25, a statistical power of 0.9, and a drop-out rate of 10%; we also conservatively set the correlation between the repeated measures at 0. Therefore, we estimated the sample size to be a minimum of 18, and we enrolled 18 participants in this prospective, randomized, crossover trial. All 18 participants completed the trial; their age, height, and weight were measured as 24.17 (SD 2.81) years, 177.06 (SD 3.65) cm, and 75.21 (SD 9.49) kg, respectively. In this study, no participants presented with symptoms of motion sickness.

The participants were divided equally into 2 groups. Participants from each group received either 11 minutes of VR training or 11 minutes of conventional training and were switched to the other group after a 2-day wash-out period. Each session comprised a 3-minute warm-up, 5-minute main training session, and 3-minute cooldown session. The participants performed all the movements that were recorded on the video. Subsequently, the participants were evaluated for flow using a self-reported questionnaire. The study design is schematically illustrated in Figure 1.

Figure 1. Study design. VR: virtual reality.



Ethics Approval

This study was approved by the Institutional Bioethics Committee of Chung-Ang University (1041078-201908-HRSB-231-01), and the experiment and research were conducted with written consent from all participants.

Training Protocol

At baseline, the participants were evaluated for the possible onset of motion sickness or epilepsy after wearing an HMD (Vive Cosmos Elite; High Tech Computer Corp). The training protocol consisted of 40 types of Pilates movements. These included 8 types of simple behaviors, 12 types of 2 complex behaviors, and 16 types of 3 complex behaviors. The participants in each group were instructed to perform 40 Pilates movements using a voice-recorded file, supervised by a female expert instructor (Figure 2).

Figure 2. Virtual reality training and conventional training. Left: Participant receiving virtual reality training. Right: Participant receiving conventional training supervised by a female instructor.

Participants were allowed to interact with the VR environment using a Google Maps–based VR system (Vive Cosmos Elite). They were provided with views of tall mountains and the sky in a 3D video. They then felt as if they were flying through the valleys and sky while performing Pilates movements. Participants also performed Pilates movements under the guidance of a female expert instructor while listening to a voice recording.

Study Procedure

Throughout this trial, the participants' compliance and safety were meticulously monitored. At baseline, the participants were instructed to immediately quit Pilates movements as soon as they experienced nausea or dizziness while receiving VR-based training. They were instructed to wear the VR HMDs and a TheraBand (Hygenic Corp). However, in order to differentiate between the male participants and the female instructor, we used TheraBands with different colors. Subsequently, participants stood in a designated position. When participants sequentially performed all 40 Pilates movements in the VR environment, they received a response from the VR images.

Measurements

Measurement of the Duration of Posture Maintenance

The duration of posture maintenance for the 40 Pilates movements was measured using sports video analysis (Figure 3). To simplify video recording, participants were instructed to perform the movements in a location where footprints were marked before starting the session. During the session, all movements were video-recorded using an Apple iPhone 11. Then, the duration of posture maintenance was measured (in seconds) using a sports video analysis program, Dartfish (Dartfish SA).

Figure 3. Measurement of the duration of posture maintenance through video analysis.

Measurement of Flow

After completing both sessions, participants filled out a flow questionnaire to identify the challenges, behaviors, goals, feedback, concentration, and control that they experienced while performing the Pilates movements. Measurements of reliability and validity have confirmed the acceptability of the flow scale as a single factor, thus indicating that it is useful across diverse samples of physical activity [21]. The applicability of the single factor of 10 items to various environments, such as volleyball, swimming, golf, dynamic sports, and static sports, is well documented in the literature [22-25].

Data Analysis

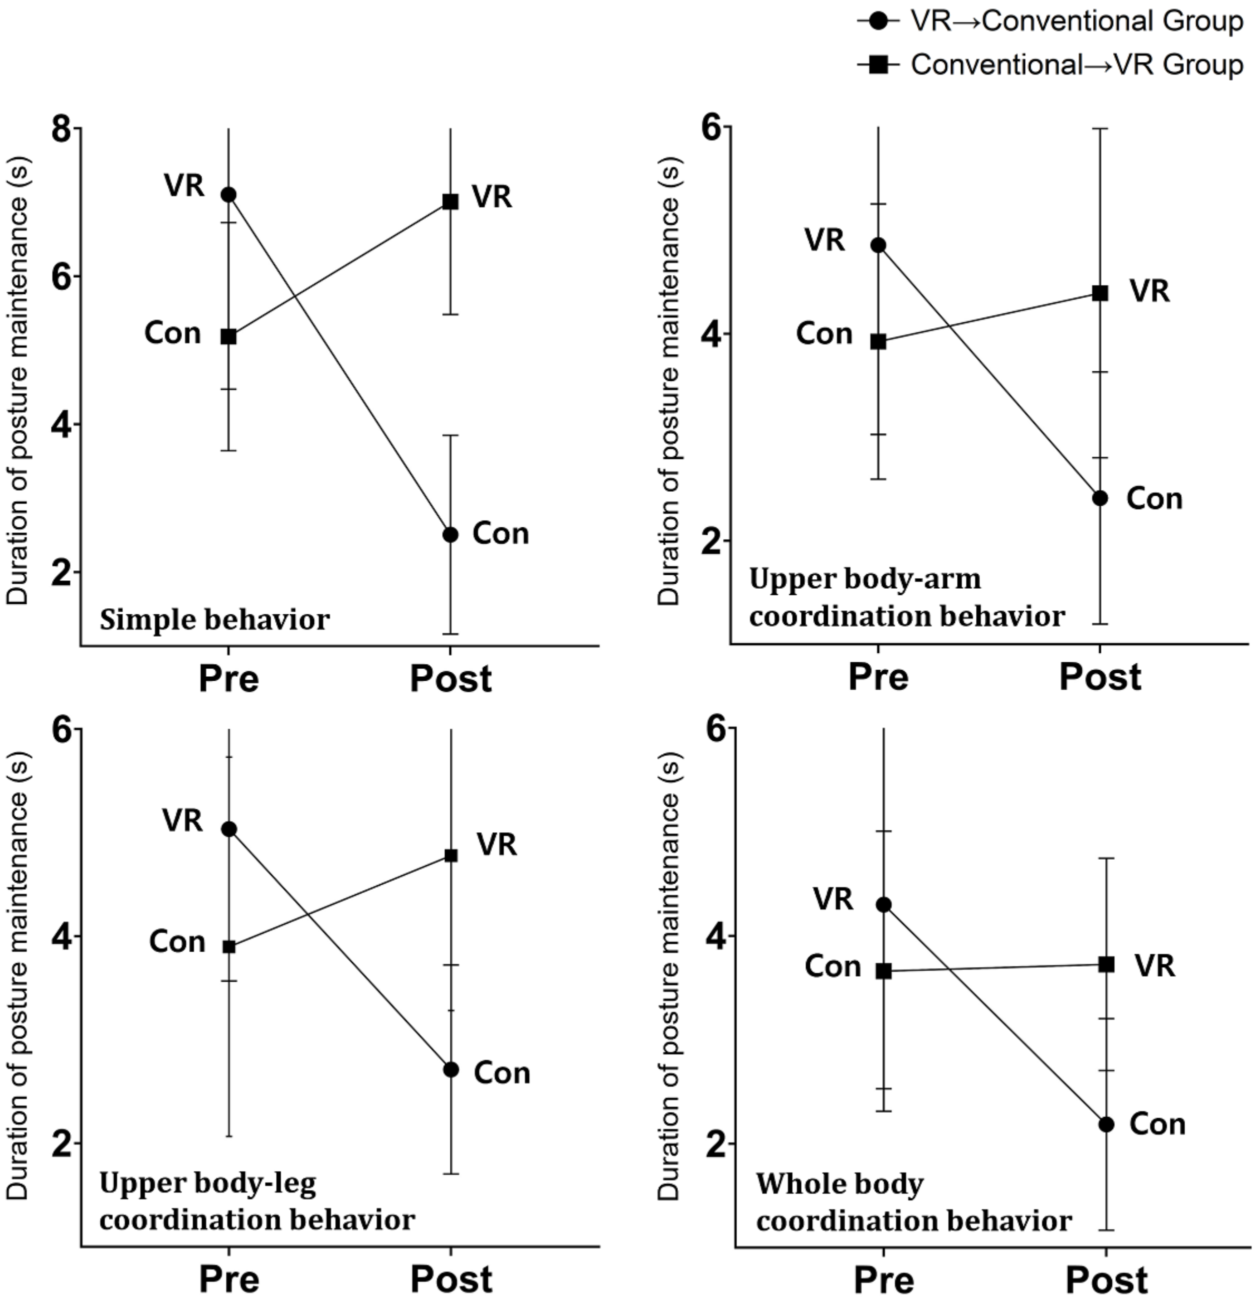
Data were analyzed using GraphPad Prism (version 9.0; GraphPad Software) and SPSS Statistics (version 25.0; IBM Corp). First, a repeated-measures ANOVA (period × group) was performed to compare the duration of posture maintenance between the VR training and conventional training sessions. Second, a Pearson correlation analysis was performed to confirm the relationship between flow and the duration of posture maintenance. In all cases, the statistical significance level was set at $P<.05$.

Results

Verification of Difference in Duration of Posture Maintenance by Type According to Group and Time

Results for the duration of posture maintenance by type showed that simple behavior ($F_{1,16}$=17.631; $P<.001$), upper body–arm coordination behavior ($F_{1,16}$=6.083; P=.04), upper body–leg coordination behavior ($F_{1,16}$=8.359; $P<.001$), and whole-body coordination behavior ($F_{1,16}$=8.426; $P<.001$) all had an interaction effect. All groups had high posture maintenance in the VR sessions both pre- and postintervention compared to the conventional session; the group where the VR session was performed first had reduced posture maintenance during the conventional session, and the group where the conventional session was performed first had increased posture maintenance during the VR session (Figure 4).

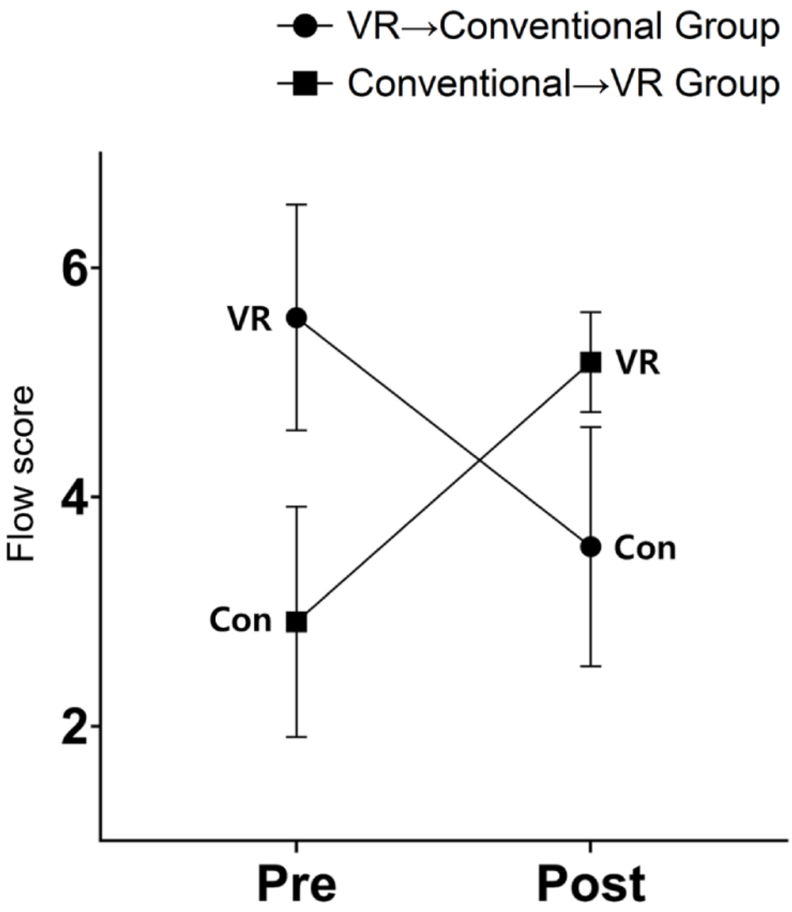
Figure 4. Interaction effects for all types of duration of posture maintenance among participants in a VR training session followed by a conventional session or vice versa. Con: conventional; VR: virtual reality.



Verification of Difference in Flow by Type According to Group and Time

Flow ($F_{1,16}$=15.250; P<.001) showed an interaction effect. All groups had a higher degree of flow in the VR sessions, both pre- and postintervention, compared with conventional sessions. The group in which the VR session was performed first had reduced flow during the conventional session, whereas the group in which the conventional session was performed first had increased flow during the VR session (Figure 5).

Figure 5. Interaction effects for flow among participants in a VR training session followed by a conventional session or vice versa. Con: conventional; VR: virtual reality.



Correlation Between the Duration of Posture Maintenance and Flow

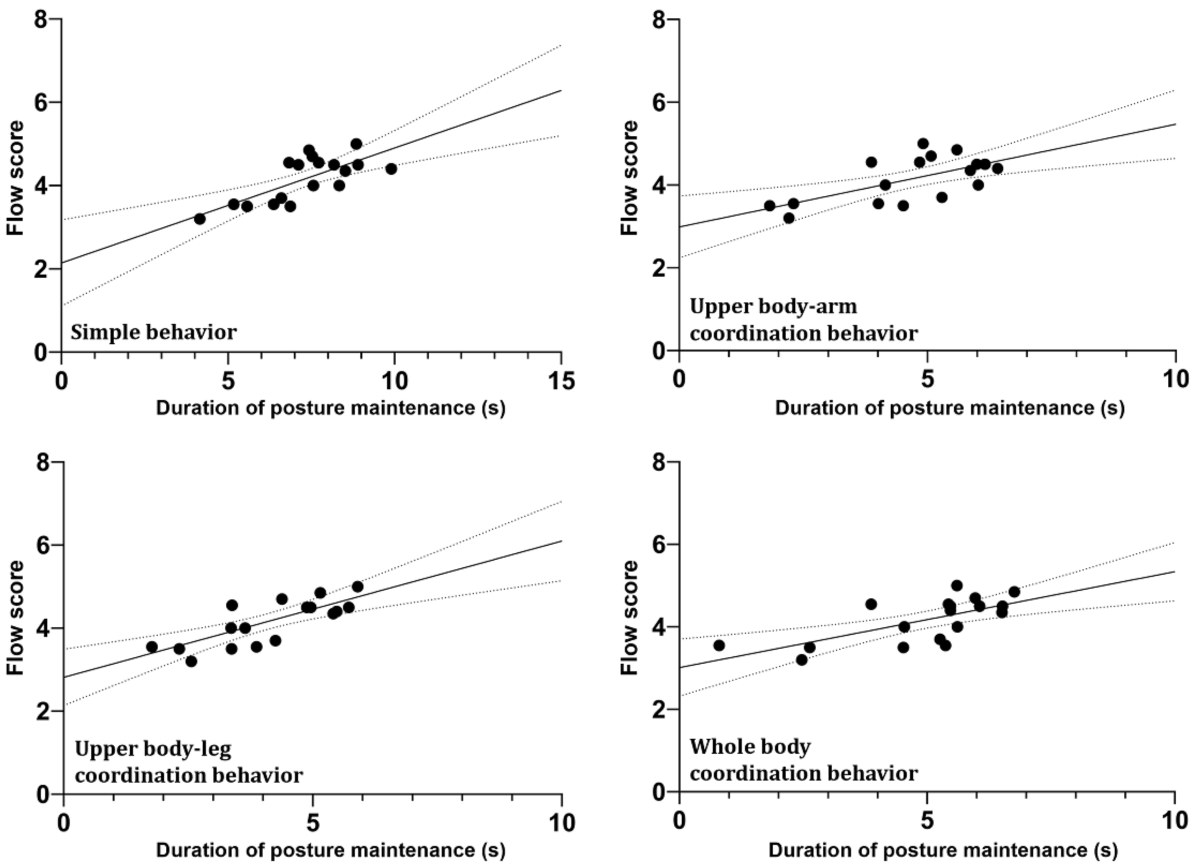
There were significant correlations between the duration of posture maintenance and flow in the VR training group. In detail, simple behavior was positively correlated with flow (r=0.49; *P*=.04), upper body–arm coordination behavior was positively correlated with flow (r=0.56; *P*<.001), upper body–leg coordination behavior was positively correlated with flow (r=0.70; *P*<.001), and whole-body coordination behavior was positively correlated with flow (r=0.60; *P*<.001). However, this was not observed in the conventional training group (Table 1 and Figure 6).

Table 1. Correlations between the duration of posture maintenance and flow (N=18).

Variable	*r*	*P* value
Simple behavior and flow		
VR[a] training	0.492	.04
Conventional training	0.153	.32
Upper body–arm coordination behavior and flow		
VR training	0.557	<.001
Conventional training	0.342	.10
Upper body–leg coordination behavior and flow		
VR training	0.702	<.001
Conventional training	0.372	.09
Whole-body coordination behavior and flow		
VR training	0.606	<.001
Conventional training	0.436	.05

[a]VR: virtual reality.

Figure 6. The results of Pearson correlation analysis for virtual reality training. There was a significant correlation between the duration of posture maintenance and flow in the virtual reality training group. Flow was positively correlated with simple behavior (r=0.49; *P*=.04), upper body–arm coordination behavior (r=0.56; *P*<.001), upper body–leg coordination behavior (r=0.70; *P*<.001), and whole-body coordination behavior (r=0.60; *P*<.001).



Discussion

Principal Findings

Participants in each group received either VR training or conventional training followed by a 2-day washout period before switching to the other type of training. Each group performed 4 different types of Pilates movements in a VR environment and a conventional environment. After the session, participants then evaluated the flow of the exercise using a self-report questionnaire. In all filmed sessions, duration of posture maintenance was measured using a sports video analysis program. Repeated measures were used to compare duration of posture maintenance and flow between VR and conventional sessions. Pearson correlation analysis was then performed to determine the relationship between flow and duration of posture maintenance. The results show that training in a VR environment improves balance and postural stability, which in turn increases the amount of time a person can hold a particular position steady. Participants also experienced higher levels of flow in VR training and found that the VR environment increased their focus on the exercise and induced a higher level of flow state. Third, we found a correlation between flow and exercise duration during VR training, suggesting that the higher flow that occurs in the VR environment induces improvements in postural stability and holding time.

Comparison to Prior Work

Movement duration was significantly different between the VR and conventional training sessions. A number of related studies have suggested 2 possible explanations for these results: improved posture and reduced resistance through VR. VR interventions have been shown to naturally promote exercise-specific behaviors through events presented in a virtual environment [26]. Furthermore, Lee and Kim [8] reported that sports VR training significantly influenced coordination related to balance and postural stability. In addition to this, various studies have found that VR simulation–based exercise increases body stability [27-29]. In other words, we can predict the mechanism by which VR increases action duration, as seen in this study: a sense of balance can enhance the stable continuation of a certain posture. On the other hand, Bryanton et al [30] reported that when children performed ankle flexion exercises in a VR environment for ankle joint rehabilitation, the duration of the dorsiflexion posture was enhanced compared to other environments, which may explain why the endurance required to fix and maintain a specific body pose for a long period of time is associated with training in the VR environment. Furthermore, previous studies showing that VR reduces the fatigue felt during isometric exercise may be related to the sustained effect of a similar mechanism in the static posture–holding movements performed in this study [31]. These findings suggest that VR environments may be useful in overcoming the negative sensations associated with exercise in a static position and modestly enhance performance potential. However, further studies that directly measure factors such as endurance and perceived resistance will be needed to prove this effect.

This study investigated whether VR environments provide an experience with high flow. After each session, participants reported that they felt more immersed in the VR training. Results from a randomized controlled trial evaluating a VR program for children with cerebral palsy highlighted maximizing engagement through flow in the VR environment as one of the strongest predictors of successful learning [32,33]. Vahle and Tomasik [34] reported that physical exercise in a VR environment led to a greater degree of flow as compared with a real-world environment, without respect to age. Moreover, according to Burt and Louw [35], VR technology was efficient in inducing a relatively higher level of flow. Virtual exercise environments can be characterized by a fundamental shift in focus from exercise to flow activity participation. While participants may perform physical movements of their own volition, the phenomenon of performing naturally guided behaviors in response to the interface provided by VR can also be explained. In this study, participants experienced flow states while performing the exercises, so it can be assumed that they adapted to the difficulty of the challenge and felt a sense of mastery. This is supported by research that suggests that flow is related to the balance between an individual's athletic and psychological abilities [36].

We conducted a correlation analysis to determine whether the participants adapted to the difficulty of the challenge and felt a sense of mastery over the duration of posture maintenance during training in the VR environment. The analysis confirmed a correlation between duration of posture maintenance and flow during VR training sessions. Virtual environments have been shown to induce psychological changes that engage participants in exercise [37] and enhance motor learning, including balance and posture [38]. These findings can be interpreted to suggest that performing physical activities while watching videos provided by VR devices increases motor focus. Specifically, participants experienced the possibilities and benefits of flow during physical activity combining Pilates and exergames in a virtual environment while performing naturally guided behaviors to respond to the videos provided in the game. VR exercise environments add virtual elements to real-world sensory elements and graphics to provide new challenges during real-world exercise [39,40]. Therefore, the findings of this study support the notion that VR training can provide seamless control over movement, as it allows for a gradual progression of the exercise protocol while maintaining the participant's attention. Furthermore, Mouatt et al [41] reported that VR-based flow engagement can have dramatic effects, especially for low-intensity exercise, by providing a virtual exercise environment for both able-bodied and disabled participants. In another study, an 8-week VR exergame training program designed to improve physical conditioning and increase performance yielded similar results to this study [42]. Virtual environments have also been proven to provide more intense visual stimulation than conventional physical activity, inducing changes in brain mechanisms responsible for high levels of concentration, thereby improving motor learning and body control, which are necessary for balance [43]. In another study, the authors interviewed users of a VR exercise program to gain insight into their experiences [44]. The participants expressed feelings of being in the environment as if they were floating in the air, able to observe the landscape in 360 degrees, and a sense of accomplishment after achieving what they wanted through postural control. The results of this study and various previous studies suggest that participants' flow responses are associated with increased playtime and improved performance in the long run. The psychological mechanisms of flow can be applied to dynamic and challenging exercises, physical activities, and even static, near-isometric movements in VR environments.

Strengths and Limitations

The VR environment's ability to improve an individual's stability in maintaining posture can be considered a major contribution to Pilates and physical activity. Traditionally, research avenues exploring physical activity and sports within VR realms have predominantly focused on the effects and efficiencies concerning dynamic performance parameters, such as strength enhancement and aerobic capacity. Nonetheless, this study ventured beyond the conventional boundaries by elucidating the efficacy of VR training methodologies specifically tailored for low-intensity, static movements and activities, wherein the core focus is balance retention and maintenance. Thus, this study not only corroborated the increasing importance of VR's flow environment but also exemplified its potential to enhance the quality of physical activities through improved postural stability and maintenance mechanisms.

There are several limitations to this study. First, it involved a small number of participants, which makes it difficult to generalize to the entire population. Therefore, a larger study that randomizes men and women in equal proportions and includes participants of different ages is necessary to generalize the findings. Second, this study focused on demonstrating the effect on duration of posture maintenance of a VR environment in relation to flow. Future research should expand the factors measured and types of physical activity to demonstrate the strengths of VR in improving postural stability and increasing duration from a variety of perspectives. Third, this study evaluated the effectiveness of VR training in the short term, so further research is needed to identify any adverse effects and obtain new insights that may have been difficult to detect in a short-term intervention when applied in the long term.

Conclusion

In conclusion, the findings of this study cautiously suggest that VR Pilates training might be more effective in improving duration of posture maintenance and inducing higher flow than conventional Pilates training. However, careful judgment is needed when asserting that physical activities in a VR environment are absolutely more beneficial than conventional training. Nonetheless, it suggests the possibility that a VR environment can enable effective performance even with different types of movement and when the difficulty of the applied movements increases in physical activity. In the future, there remains the challenging task of minimizing chronic stressors such as motion sickness and the weight of the device. Moreover, there is a need to develop distinct physical activities and exercise programs to overcome these challenges. We cautiously predict that if such efforts persist, useful VR environment training could be realized.

Acknowledgments

This study was supported by the Ministry of Education of the Republic of Korea and the National Research Foundation of Korea (NRF-2018S1A5B6070270).

Data Availability

The data sets generated and analyzed during this study are not publicly available for privacy and ethical reasons but are available from the corresponding author upon reasonable request.

Authors' Contributions

All authors conceptualized and designed the study. JWL conducted the data collection. SJP carried out the data management, analysis, and synthesis of data. All authors wrote the study. All authors critically reviewed, read, and approved the final version of the study.

Conflicts of Interest

None declared.

Abstract

Background: Balance impairments are common in people with multiple sclerosis (MS), with reduced ability to maintain position and delayed responses to postural adjustments. Pilates is a popular alternative method for balance training that may reduce the rapid worsening of symptoms and the increased risk of secondary conditions (eg, depression) that are frequently associated with physical inactivity.

Objective: In this paper, we aimed to describe the design, development, and usability testing of MS Fitness Intervention Training (MS-FIT), a Kinect-based tool implementing Pilates exercises customized for MS.

Methods: MS-FIT has been developed using a user-centered design approach (design, prototype, user feedback, and analysis) to gain the target user's perspective. A team composed of 1 physical therapist, 2 game programmers, and 1 game designer developed the first version of MS-FIT that integrated the knowledge and experience of the team with MS literature findings related to Pilates exercises and balance interventions based on exergames. MS-FIT, developed by using the Unity 3D (Unity Technologies) game engine software with Kinect Sensor V2 for Windows, implements exercises for breathing, posture, and balance. Feedback from an Italian panel of experts in MS rehabilitation (neurologists, physiatrists, physical therapists, 1 statistician, and 1 bioengineer) and people with MS was collected to customize the tool for use in MS. The context of MS-FIT is traveling around the world to visit some of the most important cities to learn the aspects of their culture through pictures and stories. At each stay of the travel, the avatar of a Pilates teacher shows the user the exercises to be performed. Overall, 9 people with MS (n=4, 44% women; mean age 42.89, SD 11.97 years; mean disease duration 10.19, SD 9.18 years; Expanded Disability Status Scale score 3.17, SD 0.75) were involved in 3 outpatient user test sessions of 30 minutes; MS-FIT's usability was assessed through an ad hoc questionnaire (maximum value=5; higher the score, higher the usability) evaluating easiness to use, playability, enjoyment, satisfaction, and acceptance.

Results: A user-centered design approach was used to develop an accessible and challenging tool for balance training. All people with MS (9/9, 100%) completed the user test sessions and answered the ad hoc questionnaire. The average score on each item ranged from 3.78 (SD 0.67) to 4.33 (SD 1.00), which indicated a high usability level. The feedback and suggestions provided by 64% (9/14) of people with MS and 36% (5/14) of therapists involved in the user test were implemented to refine the first prototype to release MS-FIT 2.0.

Conclusions: The participants reported that MS-FIT was a usable tool. It is a promising system for enhancing the motivation and engagement of people with MS in performing exercise with the aim of improving their physical status.

Introduction

Background

Balance control impairments are common in people with multiple sclerosis (MS) [1] and may affect approximately 75% of people with MS during the course of the disease [1,2]. Weakness, spasticity, and fatigue are just some of the factors that cause balance disorders; moreover, central sensorimotor integration of visual, proprioceptive, and vestibular inputs is a critical aspect of balance control that may underlie dysfunction in static and dynamic balance [3,4]. Imbalance is usually characterized by the reduced ability to maintain position and to move toward the limits of stability and delayed responses to postural adjustments [1,4]. These abnormalities, together with other impairments and disabilities, often prevent people with MS from correctly and easily performing daily living activities and are considered as a primary fall risk in MS [5] with many adverse physical and psychological consequences (eg, injuries, fear of falling, and loss of autonomy) [6,7].

Mainly for these reasons, MS is associated with physical inactivity [8,9] that may lead to rapid symptom worsening and increased risk of secondary conditions (eg, fractures, high rates of depression, and fatigue). In turn, these may seriously affect participation in societal interactions and ultimately translate into reduced quality of life (QoL) [10]. Thus, balance exercises have increasingly been recommended in MS to control symptoms, enhance participation in daily activities, and improve QoL [11]. Balance exercises can be considered as the cornerstone of MS interventions [4].

Pilates is a popular alternative method for the maintenance and improvement of balance [12]. It is a precisely controlled form of exercise that uses stabilizing muscles of the body. Specifically, Pilates uses a holistic approach: concentration, control, centering, flowing movement, precision, and breathing are 6 fundamental principles; if correctly followed, they can improve flexibility, strength, core stability, muscle control, breathing, and posture and increase body awareness with less ground impact and joint stress [12,13]. These aspects and the possibility to perform exercises at the most convenient intensity levels (ie, difficulty adjusted to own level of conditioning) make Pilates an ideal approach to treat physical symptoms of MS [14]. More specifically, although high-quality studies are needed owing to the methodological flaw of most of the current literature, a recent meta-analysis showed that Pilates exercises might be an optional effective method to treat balance in people with MS [15].

In this context, the advancement of technology makes new alternatives available to deliver rehabilitative interventions in the form of internet- and game-based exercises (exergames) [16]. Playing exergames is a form of whole-body physical exercise delivered via commercial nonimmersive virtual reality [17] that requires users to complete the assigned tasks aimed at improving fitness and promoting an active lifestyle [18]. Exergames stimulate users to be more active, allowing repetitive practice and real-time interaction with feedback and tracking of progress, which enhance motivation, treatment adherence, and training outcomes [19-21]. Games that are specifically designed to address a problem or teach a certain ability have had a lot of success [22]. Researchers have demonstrated that exergames are comparable with traditional therapies and can be more fun and acceptable [23].

In the field of neurological diseases, a recent meta-analysis [24] explored the extent to which exergaming was superior to physical therapy or other forms of rehabilitation in improving balance dysfunction. Results were consistent with those of previously published meta-analyses and systematic reviews supporting the efficacy of exergames in the neurological setting [25-28]. A beneficial effect of exergames was found in stroke; Parkinson disease; and to a lesser extent, in MS, whereas conclusions on other conditions, such as mild cognitive impairment or Alzheimer disease, traumatic brain injuries, and myelopathies, were not possible. Furthermore, the effect size of exergames on balance significantly depended on the weekly frequency of sessions, single session duration, and overall intervention duration, whereas it was independent of the setting (supervised or home-based) and strategy (exclusive or add-on) of the intervention. Finally, exergames were found to be safe, with only mild to moderate musculoskeletal adverse events found in a minority of patients, with no significantly increased risk of falls [29].

Among the internet- and game-based technologies used for exercise training, the Kinect motion sensor (Microsoft Corp) constitutes a high-potential approach; it provides a precise markerless, full-body 3D motion tracker with real-time feedback about user performance and enables users to virtually interact hands-free with a computer system without needing a remote controller [30-35]. Lozano-Quilis et al [36] demonstrated the effectiveness of RemoviEM, a Kinect-based system offering people with MS an intuitive and motivating way to perform weight transfer and upper limb coordination exercises. Results showed great improvement in balance outcomes in the group using RemoviEM compared with the control group receiving the same types of exercises in a standard rehabilitative intervention. More recently, Molhemi et al [37] assessed the efficacy of a rehabilitative protocol including standing, walking, and weight shifting exercises delivered through a Kinect-based versus conventional training on the improvement of balance and mobility in people with MS. Both interventions improved balance and mobility; however, training with exergames was more efficacious in enhancing cognitive-motor function and reducing falls, whereas conventional exercises led to better directional control.

In the next years, new exergames will become available to the therapists, and it is hoped that these will allow for the integration in MS outpatient and at-home settings to optimize patient clinical outcomes and to ensure the continuity of care [38]. On the basis of the usability challenges faced by people with MS, programmers should develop user-friendly interfaces customized for people with MS, which is the main assumption for high acceptance, adherence, and effectiveness.

Objective

The aim of this study was 2-fold: first, to design and develop a usable Kinect-based exergame implementing Pilates exercises appropriately adapted to MS requirements; second, to evaluate the usability in people with MS for future research and clinical use. An Italian network of experts in the field of MS rehabilitation was involved in the different phases of the study. The first steps were dedicated to literature revision and exercise identification, followed by prototyping based on co-design with MS health care professionals and people with MS. Usability testing was conducted on the final version of the tool.

Methods

Overview

This study consists of 2 parts: the design and development of an exergame implementing Pilates exercises and its customization for the needs of people with MS (part 1) and evaluation of its usability in terms of ease of use, playability, enjoyment, satisfaction, and acceptance (part 2).

The exergame was developed for asynchronous telerehabilitation purposes. The patient should be clinically supervised by a physical therapist for the evaluation of the progress of training and performances (Table 1). Moreover, for patients with neurological problems, no limitations in terms of session frequency and duration are considered; the more use, the higher the effect size of the exergame [24].

Table 1. Summary of the characteristics of Multiple Sclerosis Fitness Intervention Training.

Characteristic	Description
Basic characteristics	
Targeted population	• People with MS[a] (adaptation needed for other clinical populations)
Exergame idea	• The exergame is an internet game-based training system using Microsoft Kinect motion sensor technology • It comprises games implementing Pilates exercises for breathing, posture, and balance
Target player	• Individual
Behavior change	• An exergame to enhance the motivation and engagement of people with MS in performing regular exercise
Clinical supervision	• Physical therapist
Data shared with the user and clinician	• Data are saved and stored in the hard disk and, if the tool is connected to the internet, uploaded to cloud • Performances in terms of the level of correctness, gained internet-based coins, frequency and duration of exercise sessions, exercises performed or skipped, unlocked cities, and completed missions are given as feedback on the display screen during the execution of the game or through dedicated menus
Type of game	• Pilates exercises for breathing, posture, and balance
Software version	• Release 2.0
Game components	
Exergame goal	

Physical components	• Balance improvement
	  • Improve flexibility, strength, core stability, muscle control, and breathing
	  • Improve posture
	  • Increase body awareness
	  • Reduce ground impact and joint stress

Cognitive components	• Cognitive improvement (however, no specific exercises stimulated cognition)
	  • Improve verbal and visuospatial memory, verbal fluency, and information processing speed
	  • Decrease cognitive fatigue
	  • Improve cognitive-motor, dual-task performances

Rules	• Breathing: breathe in and breathe out in correspondence of the teacher's instruction • Posture: sitting or standing depending on the exercise requirements (a chair should be ready to use for the sitting exercises) • Prompts: follow trajectories or arrows displayed in correspondence of the user's avatar during the exercise execution
Game mechanics	• The user interacts with the exergame by repeating the gesture of the Pilates trainer's avatar • The exergame also provides audio and visual feedback to the users while they are playing the games
Web environment	• Travel to visit some of the most important cities around the world
Setting	• Outpatient and at-home room environment with at least 3-m distance between the sensor and user

Characteristic	Description
Hardware configuration	• Minicomputer, monitor with a HDMI[b] connector (minimum suggested size: 27 tTFT[c]), Microsoft Kinect Sensor version 2, and power lead controller
Sensors used	• Microsoft Kinect Sensor version 2 (or new compatible commercial sensors such as Microsoft AzureKinect or MentorAge)
Estimated play time	• 30 minutes per day

[a]MS: multiple sclerosis.

[b]HDMI: high-definition multimedia interface.

[c]TFT: thin film transistor.

Ethical Considerations

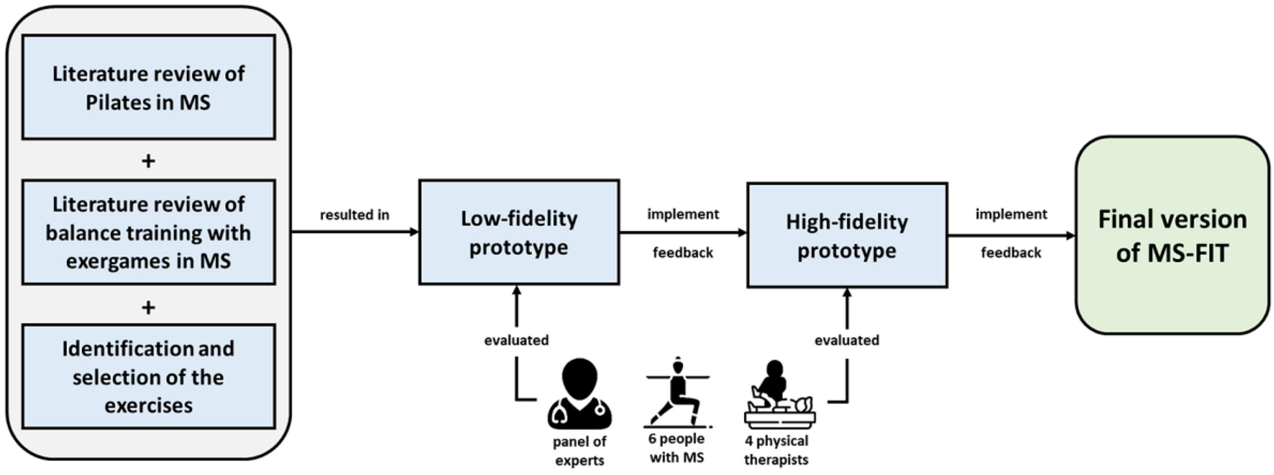
The study was approved by the regional ethics committee of the principal investigator (Azienda Ospedaliera San Martino Genoa; n° 134/2018). All participants gave written informed consent before entry into the study in accordance with the revised Declaration of Helsinki [39].

Part 1: Design and Development of a Pilates Exergame

Overview

Part 1 implements the user-centered design (UCD) approach [40-43], a user interface iterative design process that allows designers to gain the target user's perspective. Outcomes of the UCD process are products with a high degree of usability. The UCD approach is composed of 4 phases: design, prototype, users' feedback, and analysis [34]. All the study phases were performed between November 2018 and November 2019. The tool, customized for people with MS, was named MS Fitness Intervention Training (MS-FIT). Figure 1 presents the development process of MS-FIT.

Figure 1. The app development process involving a literature revision on Pilates and balance training with exergames in multiple sclerosis (MS) and the identification and selection of the exercises to be implemented in MS Fitness Intervention Training (MS-FIT). A low-fidelity prototype and a high-fidelity prototype have been developed after evaluation by people with MS, physical therapists, and a panel of experts. Feedback was implemented to obtain the final version of MS-FIT. The icons in the figure have been modified from free licensed images from Flaticon [44].



Phase 1: Analysis of Existing Findings and Tool Design

During the first phase, a development team of 4 members, composed of 1 physical therapist (25 years of experience in neurological disease, including MS, and certified Pilates instructor), 2 game programmers (5 years of experience in the Unity 3D game engine), and 1 game designer (10 years of experience in game design, game theory, innovative virtual reality, and computer vision techniques), provided the design of MS-FIT. It implements some decisive elements that could enhance usability and user experience such as accessibility, challenge, reward and feedback, skill development, and difficulty adjustment [45,46].

Potential core game ideas were generated by integrating the team knowledge and results from a literature review about Pilates in MS and balance interventions in MS with exergames [29,30,35-38,40-43,45-56]. The Pilates exercises were identified for feasible implementation and safe execution in a digital tool [46]. The exercises aimed to train *breathing* (exercises for abdominal, costal, and sternal breathing perception; sitting and kneeling Mermaid exercises; and sitting and standing arm circles exercises able to increase the respiratory capacity; improve mobilization of the rib cage; and align and stabilize the trunk, backbone, head, pelvis, and shoulder), *posture* (eg, arch-and-curl and spine stretch exercises for the correct alignment of the trunk, backbone, head, pelvis, and shoulder in neutral position and during flexion extension; spine twist exercises to correctly prepare the trunk and upper limbs to gait scheme; exercises for self-correction of posture; and elephant exercise to stretch the backbone and hamstring muscles), and *balance* (eg, side-to-side, hip circle, side leg kick, 1-leg circle, and single leg extension exercises for correct weight transfer and monopodalic support). To ensure that the exergame was appropriate for each potential user, exercises at different levels of accessibility were considered (eg, some exercises are executed while seated). The game-based training program underwent critical appraisal by the physical therapist.

Multimedia Appendix 1 includes the description of Pilates exercises considered to be clinically beneficial to improve physical (ie, balance, mobility, and fatigue) and cognitive performances and QoL and easily implementable in MS-FIT [49].

Besides the identification and selection of the exercises, the design model phase took into account other essential factors such as rules and gameplay, options, levels of challenge, game plot and story, and transfer into real life [46,57].

Phase 2: Prototyping

During the second phase, the Pilates exercises were implemented in a low-fidelity prototype. The characteristics of MS-FIT are presented in Table 1.

The developers used the Unity 3D game engine software with Kinect Sensor V2 for Windows, a markerless tool usually adopted in different research scenarios as a low-cost device alternative to time-of-flight sensors (eg, SR-4000 CW10 by Mesa technologies) and motion tracking systems (eg, Vicon and Optotrac). It was preferred to Kinect Sensor V1 because it provides great precision and more stable results [58]. Kinect Sensor V2 is a depth RGB (Red, Green, Blue) image sensor that provides information about the depth, color, and skeleton of a user who is standing in front of the sensor. Therefore, it can track and monitor full-body movements in 3D coordinates (ie, the x-axis, y-axis, and z-axis). It emits a grid of infrared light, and the distance of objects within the camera's recording range (0.5-4.5 m) is calculated using time-of-flight analysis of reflected light beams, which yields a depth model of the surrounding structures. On the basis of machine learning techniques, the software development kit of Kinect Sensor V2 allows the detection of human shapes and provides an artificial skeleton based on 25 anatomical landmarks ("Kinect joints") projected into these shapes based on depth data [59].

Kinect Sensor V2 acquired data at a rate of 30 frames per second, and all the tracked body joints were first filtered by using a third-order, low-pass Butterworth filter with a cutoff frequency of 5 Hz. The filter order and bandwidth were optimized to achieve the best results. The angle measures, velocity, and acceleration were computed for each joint type (eg, knee, shoulder, and neck) for each body frame. These measures were used to define the *gesture correctness*, calculated as the percentage of error (<5%) between the expected gestures shown by the avatar of a Pilates teacher and those executed by the user. The teacher's avatar gesture database was recorded, tagged, and compiled using a visual gesture builder app. On the basis of the gesture correctness, we also defined the reward and feedback system.

The hardware configuration of MS-FIT consists of other 3 devices: a minicomputer containing the exergame (eg, Intel Next Unit Computer), a monitor with a high-definition multimedia interface connector, and a power lead controller to access the exergame and move through the menus. Moreover, a chair without an armrest is needed for some exercises.

The Kinect sensor (in front) and the monitor (at the back) have to be set on a cabinet (or table) at a height of approximately 0.8 m. The user has to stay approximately 2 to 3 m from the Kinect sensor (Multimedia Appendix 2). At the first use of MS-FIT, the user has to calibrate the system, standing with the arms along the body for approximately 5 seconds in front of the sensor. The calibration will be valid for the next sessions also.

Phases 3 and 4: Co-Design With MS Health Professional Experts and People With MS

An Italian panel of experts in the field of MS rehabilitation composed of 12 neurologists, 3 physiatrists, 1 statistician, and 1 bioengineer (refer to Multimedia Appendix 3 for a list of participating centers) was invited to participate in the tool co-design [60]. Overall, 2 evaluation cycles were conducted during 2 separate meetings to refine the low-fidelity and high-fidelity prototypes. The evaluation was conducted by using a think-aloud method [61].

During the first cycle, the meeting started with a quick presentation of the aims of phases 1 and 2, followed by a demonstration of the low-fidelity prototype. Key questions regarding the advantages, disadvantages, and potential modifications were asked after each proposed feature. They suggested some preliminary customizations necessary for use with people with MS. Such modifications were mainly related to how the exercises should be implemented to take into account the different levels of physical disabilities of people with MS (eg, adaptation to safe positions).

Similarly, a first cycle of assessment was also conducted on the low-fidelity prototype with 60% (6/10) of people with MS and 40% (4/10) of physical therapists with experience in MS. They were required to specifically focus on user interface interaction, sound effects, and color contrast. Impaired movements and sensory loss (ie, somatosensory, auditory, and visual) such as those experienced by people with MS require specific user interface adaptations. People with MS proposed to use travel around the world as the game's context instead of a numbered track or an urban map; it was considered to be more motivating for themselves given that, often, MS limits the possibility to travel for both job and tourism.

Feedback from the first cycle was analyzed and used to modify the prototype before the second cycle. Experts, people with MS, and physical therapists agreed on the necessity of an introductory screen that reports safety information; moreover, they agreed on the necessity to wear comfortable clothes (eg, a tracksuit) while using the tool. No other relevant additional modifications were necessary.

Part 2: Usability Evaluation With Targeted Users

Part 2 was deputed to evaluate the usability of MS-FIT (release 1.0) with people with MS; an ad hoc questionnaire was used to analyze the ease of use, playability, enjoyment, satisfaction, and acceptance.

Participants

People with MS were enrolled at the Rehabilitation Service of the Italian Multiple Sclerosis Society in Genoa, IRCCS Institute of the Neurological Sciences of Bologna in Bologna, and Neurological Institute Carlo Besta IRCCS Foundation in Milan. The inclusion criteria were (1) age ≥18 years, (2) all MS courses (relapsing remitting, secondary progressive, and primary progressive), (3) disability level 2 to 4 as determined by the Expanded Disability Status Scale [62], (4) normal cognitive function (determined by a Mini-Mental State Examination score >24) [63], (5) no mood disorders as determined by a Hospital Anxiety and Depression Scale score <10 in the 2 subsets for anxiety and depression [64], (6) ability to maintain balance as determined by a Berg Balance Scale score >46 [65], and (7) at least 1 month without having been treated with rehabilitation. The exclusion criteria were (1) visual deficits that could compromise the use of MS-FIT and (2) relapses in the past 3 months.

Protocol

Each participant was involved in 3 outpatient usability test sessions. Before the first session, they received a comprehensive description of the MS-FIT concept and rules; furthermore, they learned to autonomously assemble and calibrate the MS-FIT tool. After the calibration, the participant could play the exergame.

Recent MS recommendations [66] encourage people with MS to practice ≥150 minutes per week of exercise or ≥150 minutes per week of lifestyle physical activity. For this reason, MS-FIT should be routinely used at home for 30 minutes per day for at least 5 days a week. Therefore, a minimum of 30 minutes per session was considered as proof of concept for the usability study.

Outcomes

Before the first session, participants were administered a questionnaire investigating their inclination to play traditional games (eg, game of checkers and cards; options: yes or no) and video games and exergames (options: nothing, consoles, tablets/smartphones, and PC), how long they play video games and exergames (options: 0, <4, 4-10, and >10 hours per month), and whether they agree (options: strongly agree, agree, do not know, disagree, and strongly disagree) that a digital assistant is an appealing way to present exercises.

After the last session, participants were asked to rate their experience through an ad hoc, 8-item questionnaire evaluating usability in terms of ease of use, playability, enjoyment, satisfaction, and acceptance, similarly to previous studies [67,68]. All items were rated on a 5-point scale ranging from 1 (strongly disagree) to 5 (strongly agree). Moreover, the usability was determined with a structured interview about the impressions of participants toward MS-FIT features in terms of rules, mechanics, interfaces, and scoring (Table 2).

In addition, the therapists involved in the user test were administered a structured interview about the interaction the participants had with MS-FIT. Specifically, we inquired them about whether the patients were autonomous at the end of the third session (options: yes/no) in using both hardware and software and how long the patients took to set up the system and start to play (options: <5, 5-10, 10-15, 15-20, and >20 minutes). Moreover, a free-text question was administered about their impressions and suggestions regarding the tool in terms of rules, mechanics, interfaces, and scoring.

Feedback from both interviews has been used by the research team to update MS-FIT to a new release for use in MS (MS-FIT 2.0 release).

Table 2. Questions of the ad hoc, 8-item questionnaire administered to the participants and the related scores.

Domain and question	Participants' score									Score, mean (SD)
	P[a]1	P2	P3	P4	P5	P6	P7	P8	P9	
Ease of use										
Are the instructions on the MS-FIT[b] hardware configuration clear to follow?	4	4	3	4	4	4	4	4	4	3.89 (0.33)
Is the hardware configuration easy in practice?	4	4	4	4	4	4	4	4	2	3.78 (0.67)
Are the instructions on the MS-FIT use clear and easy to follow?	4	4	4	4	5	4	4	4	4	4.11 (0.33)
Is the user interface pleasant?	4	4	4	4	4	3	4	4	3	3.78 (0.44)
Playability										
Is MS-FIT easy to be played?	5	4	4	4	4	4	4	4	2	3.89 (0.78)
Enjoyment										
Does a virtual trainer increase the enjoyment towards exercise?	4	4	4	4	5	3	4	4	5	4.11 (0.60)
Satisfaction										
Are you satisfied of the experience with MS-FIT?	3	4	3	4	5	4	4	4	4	3.89 (0.60)
Acceptance										
Are you motivated to use MS-FIT autonomously at home?	3	3	3	5	5	5	5	5	5	4.33 (1)

[a]P: participant.

[b]MS-FIT: Multiple Sclerosis Fitness Intervention Training.

Data Analysis

Descriptive statistics were used to describe both participants' characteristics and their scores on the ad hoc questionnaire. All data were analyzed using STATISTICA 7.1 (StatSoft).

Follow-Up

In total, 14 therapists with specific backgrounds in MS (one for each center; Supplementary Material 3) participated in a dedicated meeting in Milan to evaluate the MS-FIT 2.0 release and to suggest eventual further refinements.

Results

Part 1: Design and Development of a Pilates Exergame

MS-FIT is a tool for individual, internet-based, game-based training using Microsoft Kinect Sensor V2. The high number of implemented exercises (Multimedia Appendix 1) and the different levels of difficulty prevent boredom.

The MS-FIT context is *travel* around the world to visit some of the most important cities (Figure 2 and Multimedia Appendix 4) and to learn the aspects of their culture through pictures (eg, landscape) and stories (eg, curiosity; Textbox 1). At each stay of the travel, a teacher of Pilates, represented by an avatar, shows and explains to the user the exercise they will have to perform; a related caption is displayed. The teacher's avatar (a human model wearing web-based garments) is represented on the left of the screen, whereas the user's avatar (a human model in a density gradient visualization) is represented on the right and allows real-time feedback to the participant (Figure 3).

Accessibility was guaranteed through the implementation of exercises tailored for people with MS and owing to the use of auditory instructions provided by the teacher's avatar before starting the exercise while showing the related captions.

The challenge for the user is the execution of the exercises as correctly and accurately as possible at the same time as the teacher; green arrows (or circles for circular gestures), applied to the user's body joint and segment mainly involved in the exercise, are displayed to suggest the correct direction and to guide the execution (Figure 3). For each correct gesture, the user is rewarded with web-based coins visible while gaming; the reward represents the feedback about performances given to the participant while playing MS-FIT. The accumulated web-based coins can be used to unlock the next stay (ie, next city) and progress along the travel; this progress represents another feedback to the user. Besides this modality of game progress, MS-FIT also provides several missions; for example, twice-daily trainings for 5 consecutive days allow completing the mission, *Methodic* (Multimedia Appendix 5).

As the game progresses, the user develops more skills that motivate them to continue the training; according to the travel progress, the level of difficulty in the next city increases in terms of the number of consecutive repetitions of the same exercise or in terms of exercise complexity; however, the user can also repeat the exercises of previously unlocked cities without training at increasing levels of difficulty.

All these aspects of MS-FIT are expected to be crucial for the engagement of the users and the success of the product.

MS-FIT collects use data and exercise metrics about the frequency and duration of exercise sessions, types of exercises that are performed or skipped by the user, performance in each single exercise, and other statistics (eg, the ratio of unlocked cities to total cities and the ratio of completed missions to total missions). However, these in-game metrics are not shown to the user and were not investigated in this usability study. All data are anonymized and sent to a central server for storage.

Figure 2. (A) The main interface of Multiple Sclerosis Fitness Intervention Training. On the left, the different menus allow accessing the training, extra contents, user's profile, and unlocked missions and closing the program; a report of performances and metrics is also present. On the right, a representative picture of the current city and the preview of the last 4 unlocked cities are shown. (B) shows an example of the stays of the travel in Europe. In this case, Rome, Florence, Bologna, and Venice were already unlocked; the user has returned from Venice to Bologna to continue to Greece or Milan.

Textbox 1. Stories about a city—an example of stories related to Venice. In Multiple Sclerosis Fitness Intervention Training, each story is associated with the corresponding picture.

General

Venice is the capital of the Veneto region. It is built on a group of 118 islands separated by canals and linked by many bridges. During the Middle Ages and Renaissance the city played a central financial and maritime role in Europe. Today Venice is one of the most popular tourist destinations in Europe, so that most of its economy is based on tourism. One of the greatest challenges for Venice in the next future will be to face erosion and rising seas that threaten the delicate balance of this unique city in the world.

History

The popular class of Venice was divided into two factions: Castellani and Nicolotti. The former lived in the eastern part, i.e. the industrial area, of the city, while the latter prevalently resided on western area and were mainly engaged in fishing. Venice turned a blind eye to the skirmishes between the two factions, so much to permit them to clash during the so-called "Wars of the Fists." These battles took place on the bridges of Venice (one of these is still named "Ponte dei Pugni," i.e. "Bridge of Punches") and consisted of people fighting each other with bare hands. The fights could be one-on-one, multiple or as battle to take the bridge. During the clashes many contenders fell into the water, often injured, and more rarely someone dead. In 1705 Venice forbade these battles forever, replacing them with the custom of the "Forces of Hercules."

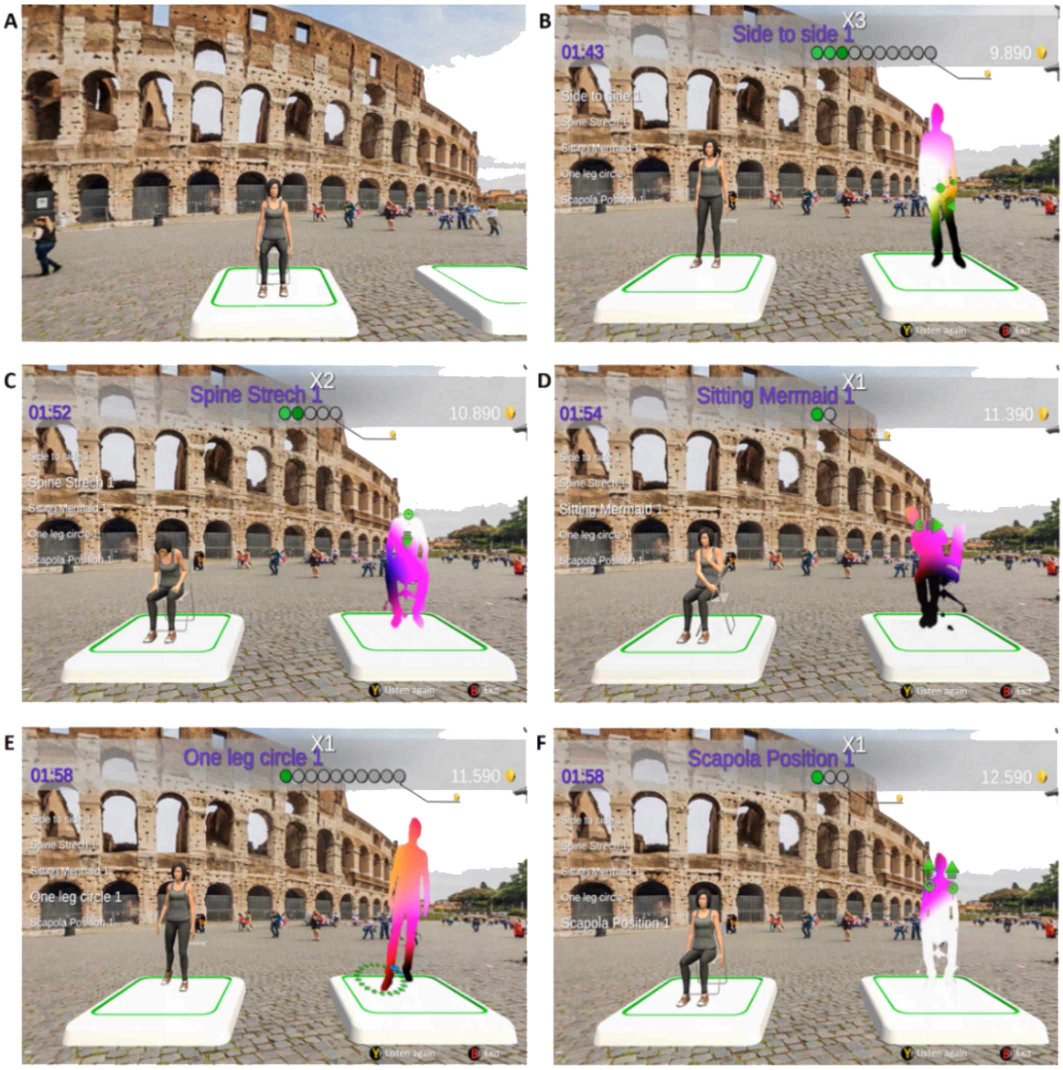
Monuments

The bell tower of of St Mark's Basilica initially had five bells used for different purposes. The "Maleficio" bell announced an imminent death sentence; the "Marangona" bell marked the beginning and the end of the Arsenale's workshift; the "Mezzana" bell rang at noon; the "Pregadi" bell announced the start of a meeting at the Doge's Palace; the "Trottera" bell, which takes its name from the trot of the horses, summoned the nobles to the Doge's Palace. Of these only the "Marangona" was saved from the collapse of the bell tower of St Mark's Basilica.

Curiosity

In the gardens of the Biennale of Venice there is a statue of Garibaldi on which a funny legend was born. The protagonist of this story is Giuseppe Zolli, a Venetian Garibaldian; it is said he swore to Garibaldi his protection for eternity. In 1921 some witnesses claimed to have seen the ghost of Zolli next to the statue of Garibaldi, intent on persecuting anyone who approached it. The inhabitants erected a statue of Zolli behind that of his protege, to allow him to always watch over him. The ghost has not been seen since.

Figure 3. The execution of some exercises implemented in the exergame. During the preview of the exercise (A), the teacher stays in the center of the view; she shows and explains the next exercise that the user will have to perform. Then, she moves to the left, and the user's avatar is displayed on the right. (B) to (F) represent instants of the execution of Side to side 1, Spide Stretch 1, Sitting Mermaid 1, One leg circle 1, and Scapola Position 1.



Part 2: Usability Evaluation With Targeted Users

Participants

A total of 9 people with MS (n=4, 44% women) participated in the usability phase. Their mean age was 42.89 (SD 11.97; range 22-61) years. Of the 9 participants, 8 (89%) were relapsing remitting, and 1 (11%) was secondary progressive; the mean Expanded Disability Status Scale score was 3.17 (SD 0.75; range 2-4), and the mean disease duration was 10.19 (SD 9.18) years.

Of the 9 participants, 6 (67%) did not have experience with video games, 1 (11%) played for <4 hours per month, and 2 (22%) played for 4 to 10 hours per month. Those who played video games used smartphones and tablets. Only 22% (2/9) of the participants reported to be traditional game players. In general, they agreed to consider a digital assistant (an avatar in MS-FIT) as a useful way to make exercise more appealing.

User Experience With MS-FIT

All people with MS (9/9, 100%) completed the 3 outpatient sessions of the user test and answered the ad hoc questionnaire. The average score on each item ranged from 3.78 and 4.11, which indicated a high usability level. The 8-item, ad hoc questionnaire scores are illustrated in Table 2.

As reported by the 5 therapists involved in the user test, of the 9 participants, all (n=9, 100%) were autonomous in using both hardware and software at the end of the third session, 6 (67%) needed <10 minutes to set up the system, and 3 (33%) needed 10 to 15 minutes.

At the end of the third session, on average, they visited 2 cities (range 1-3; Rome and Florence) and collected 1044 coins (range 945-1324).

Feedback and suggestions provided by the 9 people with MS and the 5 therapists are presented in Textbox 2 and were implemented in the MS-FIT 2.0 release.

A few final refinements were suggested by the 14 therapists participating in the follow-up meeting and have been implemented in the MS-FIT 2.0 release.

Thus, MS-FIT 2.0 was ready to be tested in a feasibility or a randomized controlled trial (RCT) study.

Textbox 2. Feedback and suggestions provided by people with multiple sclerosis (MS) and therapists.

Feedback and suggestions from people with MS

- Increment of the variety of exercises (especially for standing balance)
- Possibility of standby during the execution of an exercise (not only pause at the end of an exercise)
- Tailoring of treatment plan (eg, based on the disability level)
- Increment of the font size of writings (difficulty in reading for people with MS)
- Necessity of more colloquial terms for the instructions (very technical language is difficult to understand)
- Improvement of the reward system (need for visual feedback besides verbal feedback)

Feedback and suggestions from therapists

- Increment of the variety of exercises
- Possibility of detecting an aid (especially in the monopodalic exercises)
- Necessity of more colloquial terms for the instructions (very technical language is difficult to understand)
- Improvement of the reward system (although motivational feedback was implemented, more attention was required for negative performances)

Discussion

Principal Findings

In this study, we aimed to design, develop, and user test MS-FIT, an internet-based, game-based tool deputed to deliver Pilates exercises for people with MS. Study outcomes support the therapeutic use of Pilates in MS management because it is a safe, active treatment method (few adverse effects) with high adherence (low dropout rate) and can improve important parameters in the target population, such as balance, gait, physical functional capacities, and even cognitive functions [69].

MS-FIT was formulated by integrating the principal knowledge and existing evidence from MS literature and by subjecting the exergame to critical appraisal from patients and experts. We adopted a research-based and iterative development process that considered the knowledge gained from different disciplines (human movement science, rehabilitation, physical activity, game design, and research) and users' perspectives (people with MS and therapists) to holistically generate a potentially attractive and effective user-centered exergame for people with MS.

Although the participants had few experiences with exergames/video games and consoles, they became autonomous in using MS-FIT after only 3 sessions. All of them (9/9, 100%) completed the three 30-minute sessions and reported finding the tool easy to use, playable, enjoyable, and satisfactory. This result was corroborated by the quantity of coins gained and the number of cities unlocked, which could be considered as a surrogate index of the ease to use, playability, and acceptance. Feedback and suggestions provided by people with MS and therapists allowed for increasing the number of implemented exercises and, overall, improving the quality of the MS-FIT exergame.

Comparison With Previous Studies

In MS-FIT, we used Microsoft Kinect because it has been reported to be well accepted by users and for its effectiveness in several rehabilitative interventions for people with MS. For example, RemoviEM [36] is an intuitive and motivating way to train weight transfer and upper limb coordination of people with MS and to improve balance and mobility. Similarly, Molhemi et al [37] demonstrated the efficacy of a Kinect-based rehabilitative tool to train standing, walking, and weight shifting in MS. In addition, more consolidated experiences with a portable, low-cost tool such as the Nintendo Wii Balance Board could pave the way for an easy future adoption of Kinect-based exergames into clinical practice [24]. In this context, Brichetto et al [70] investigated the effectiveness of balance training based on the Nintendo Wii Balance Board versus a traditional rehabilitative training. Despite the excellent compliance with both interventions, a high clinically significant improvement in balance was shown in the group using the exergame. In addition, Prosperini et al [71] showed that training with the Nintendo Wii Balance Board induced microstructure modifications of the superior cerebellar peduncles, suggesting that high-intensity and task-oriented exercises such as those implemented in the Nintendo Wii Fit Plus package could favor brain reorganization in people with MS. Overall, internet-based, game-based training is an effective and efficient approach for empowering user engagement, which contributes to positive outcomes of an intervention [72,73].

To limit high dropout rates owing to potential low engagement with modern digital technology, the UCD approach, which incorporates game design principles (ie, goals, rules, feedback, points, time, reward structures, levels, and esthetics), was used in the process of designing and developing MS-FIT. Many studies demonstrated the benefits of using the UCD concept for developing exergames. For example, Lange et al [18] used the UCD approach to develop an internet-based, game-based program aimed at training the dynamic balance of individuals who had experienced a stroke. Hemingway et al [43] used the UCD process to develop a mobile game to influence the behavior of HIV service uptake among a key population. Howes et al [74] also used UCD to develop a bespoke exergame to deliver strength and balance exercise programs to older adults. Similarly, Kamnardsiri et al [34] developed and tested an internet-based, physical-cognitive, game-based training system using Kinect for older individuals. Therefore, the UCD approach is a core process that should be embedded in health game development to ensure usability and acceptability of and full benefit from exergame technology.

The findings from this study seem to be confirming these results. Consistent with previous studies, our game system provides feedback, including scores and performance outcomes, which enhances the motivation of the users [75,76]. However, it was not possible to evaluate the clinical benefit of MS-FIT because the number of user test sessions was very low; future planned studies will assess this aspect.

To the best of our knowledge, MS-FIT is the first exergame designed and developed to deliver Pilates exercises through an internet-based, game-based technology. Although MS-FIT was customized for people with MS, few adaptations would be necessary for use in the context of other clinical conditions [77-80].

Plans for Future Studies

The design, development, and usability testing of MS-FIT is the first step of a large research plan including an ongoing feasibility study followed by an RCT. The feasibility study has been planned to assess the satisfaction and acceptance toward the tool, adherence to the intervention, and dropout rate on a large sample size and for a long period of more intense use (ie, 5 sessions a week for 6 weeks). The use of validated questionnaires investigating usability [81-83] and the identification of potential bugs will be useful for further tool refinement. Moreover, the administration of clinical tests evaluating balance (eg, timed up-and-go test) will allow for estimating the effect of the intervention and its variance, which are necessary to calculate the appropriate sample size for the RCT. Finally, the feasibility study will allow the identification of groups of exercises with a level of difficulty that is suitable for the specific needs and capabilities of people with MS in different clinical stages.

An RCT (ClinicalTrials.gov; ID NCT04011579) will assess the effect of MS-FIT on physical and cognitive domains, mood, and QoL of people with MS. If RCT results are positive, MS-FIT could be proposed in combination with rehabilitation to potentiate the rehabilitative intervention effect or guarantee the continuity of care of people with MS.

Owing to the discontinuation of the Kinect Sensor V2, for the continued development of MS-FIT and successful translation into clinical practice, a new compatible commercial sensor must be identified and the app should be adapted. The Microsoft AzureKinect demonstrated sufficiently high interrater and intrarater reliability when compared with the Kinect Sensor V2. Moreover, a full-body skeletal tracking library in Python has recently become available. These aspects suggest that the Microsoft AzureKinect may be an adequate replacement within the MS-FIT system [84]. Another alternative solution to the Kinect Sensor V2 is MentorAge, a depth RGB (Red, Green, Blue) image sensor tracking system that operates on the Android system and uses infrared 3D capturing technology. It can detect a maximum of 4 people in a single room within a range of 0.6 to 5 m and has proven its capabilities and potentialities in real-life scenarios [80,85,86]. No additional equipment is thought to be used compared with the current version of MS-FIT.

Limitations

Some limitations of the study need to be acknowledged. First, the evaluation of the target user's experience involved a small number of participants. Furthermore, the usability results were obtained from a few training sessions. Thus, the findings should be considered as preliminary and interpreted with caution. Second, the minimum requested distance between the Kinect sensor and user could limit at-home use. New versions of the Kinect sensors could allow overcoming this limitation. Finally, this study investigated the usability by using an ad hoc questionnaire; however, in a future feasibility study, the use of validated questionnaires should be encouraged.

Conclusions

MS-FIT is an exergame using the Microsoft Kinect sensor for outpatient and at-home MS balance interventions. It digitally implements Pilates exercises for breathing, posture, and balance. MS-FIT is usable and well accepted by the target users, with positive feedback. Thus, the exergame is a promising tool for enhancing the motivation among people with MS to engage in exercise with the aim of improving their physical status.

Acknowledgments

The authors would like to thank the Italian Multiple Sclerosis Foundation and Roche Società per Azioni for supporting this study. The authors would like to thank Davide Cafiero and HELAGLOBE Società a Relazioni Limitate for the development of the Multiple Sclerosis Fitness Intervention Training exergame. Generative artificial intelligence was not used to generate text.

LL, MI, DC, EC, PG, DP, MR, GT, LP, FP, and PB were involved in conceptualization and reviewing and editing the paper. LS was involved in conceptualization, data curation, and reviewing and editing the paper FP was involved in conceptualization and reviewing and editing the paper. PB was involved in conceptualization and reviewing and editing the paper. EP was involved in reviewing and editing the paper. MAB was involved in funding acquisition and reviewing and editing the paper. GB was involved in conceptualization, data curation, funding acquisition, project administration, and reviewing and editing the paper.

Conflicts of Interest

AT, MP, PC, EC, MR, LS, GT, LP, FP, PB, EP, MAB, and GB have no conflicts of interest to disclose. LL has received honoraria for consultancy over the past 3 years from Almirall, Merck, Novartis, and Roche. MI received compensation for participation in advisory boards from Almirall, Biogen, BMS, Merck, Novartis, Janssen, Roche, and Sanofi. MI is coeditor for MS Journal. DC is an advisory board member or has given advice to Almiral, Bayer Schering, Biogen, GW Pharmaceuticals, Merck Serono, Novartis, Roche, Sanofi-Genzyme, and Teva; has received honoraria for speaking or consultation fees from Almiral, Bayer Schering, Biogen, GW Pharmaceuticals, Merck Serono, Novartis, Roche, Sanofi-Genzyme, and Teva; and is the principal investigator in clinical trials for Bayer Schering, Biogen, Merck Serono, Mitsubishi, Novartis, Roche, Sanofi-Genzyme, and Teva. His preclinical and clinical research was supported by grants from Bayer Schering, Biogen Idec, Celgene, Merck Serono, Novartis, Roche, Sanofi-Genzyme, and Teva. DP has received honoraria for consultancy and speaking from Biogen, Merck, Novartis, Sanofi, and Roche.

Abstract

Background: Replacing sedentary behaviors during leisure time with active video gaming has been shown to be an enjoyable option for increasing physical activity. However, most off-the-shelf active video gaming controllers are not accessible or usable for individuals with mobility impairments. To address this requirement, a universal video game controller (called the GAIMplank) was designed and developed.

Objective: This study aimed to assess the usability of the GAIMplank video game controller for playing PC video games among individuals with mobility impairments. Measures of enjoyment, perceived exertion, and qualitative data on the user experience were also examined.

Methods: Adults (aged 18-75 years) with a mobility impairment were recruited to participate in a single testing session in the laboratory. Before testing began, basic demographic information, along with minutes of weekday and weekend physical activity, minutes of weekday and weekend video game play, and video game play experience were collected. The GAIMplank was mapped to operate as a typical joystick controller. Depending on their comfort and functional ability, participants chose to play seated in a chair, standing, or in their own manual wheelchair. Leaning movements of the trunk created corresponding action in the game (ie, lean right to move right). The participants played a total of 5 preselected video games for approximately 5 minutes each. Data were collected to assess the usability of the GAIMplank, along with self-efficacy regarding execution of game play actions, rating of perceived exertion and enjoyment for each game, and overall qualitative feedback.

Results: A total of 21 adults (n=15, 71% men; n=6, 29% women) completed the usability testing, with a mean age of 48.8 (SD 13.8; range 21-73) years. Overall, 38% (8/21) of adults played while standing, 33% (7/21) of adults played while seated in a chair, and 29% (6/21) played in their own manual wheelchair. Scores from the System Usability Scale indicated above average (74.8, SD 14.5) usability, with scores best for those who played seated in a chair, followed by those standing, and then individuals who played seated in their own wheelchairs. Inconsistencies in the responsiveness of the controller and general feedback for minor improvements were documented. Rating of perceived exertion scores ranged from light to moderate intensity, with the highest scores for those who played seated in a chair. Participants rated their experience with playing each game from above average to very enjoyable.

Conclusions: The GAIMplank video game controller was found to be usable and accessible, providing an enjoyable option for light-to-moderate intensity exercise among adults with mobility impairments. Minor issues with inconsistencies in controller responsiveness were also recorded. Following further development and refinement, the next phase will include a pilot exercise intervention using the GAIMplank system.

Introduction

Background

Physical activity is an important component of a healthy lifestyle. A myriad of health benefits, both physical and psychological, can be achieved with daily physical activity [1]. Physical activity options, however, are limited for people with mobility impairments. Issues with accessibility and transportation are experienced by many individuals wanting to fulfill their daily physical activity needs. Fitness center parking, inaccessible entrances, limited staff knowledge on inclusive programming, and cost of membership and transportation are some of the limiting factors [2]. Equipment such as a stationary arm ergometer can provide a means to exercise at home but may be seen as boring and difficult to adhere to by many [3]. In an effort to combat the tedium of routine exercise, active video gaming (AVG) has become popular.

Replacing sedentary behaviors during leisure time with AVG has been shown to be an enjoyable option for increasing the amount of physical activity acquired each week [4-12]. The promise of AVGs is particularly appealing for people with disabilities, given the high rate of inaccessible features in the built environment and the difficulty in finding fun and engaging activities [5-8]. Because AVG systems are relatively affordable, they also hold promise as a scalable product for promoting improved health outcomes and higher levels of physical activity and fitness among people with disabilities [13]. Several AVG systems have been in the market for the last 2 decades; however, most are not adapted to suit the needs of individuals with mobility impairments. Using a mixed methods study, the usability of a somatosensory square dance system for older adults was examined [14]. The system was developed to support a popular fitness activity and to eliminate some of the common barriers (risk of injury, noise, and space) experienced by older adults. The system was well received by the participants, providing them with a fun fitness activity that could be safely performed indoors in a private space. The participants included a group of older adults (aged 55-68 years); however, specific adaptation for individuals with mobility impairments was not the focus and therefore was not considered. Another study examined the usability of an AVG platform for older adults with various physical and sensory impairments residing in long-term care homes, with 85% having a mobility impairment [15]. After several rounds of usability testing with residents, staff, and family, the feedback indicated that the system was an enjoyable way to engage in physical activity. Although efforts are being made, there continues to be a pressing need to make AVG controllers accessible to people who are unable to stand for long periods, cannot stand on a small platform because of poor balance or extreme obesity, or those who use a wheelchair for all daily activities.

Our engineering design and development team, with the Rehabilitation Engineering Research Center on Interactive Exercise Technologies and Exercise Physiology for People with Disabilities, previously built a proof-of-concept (PoC) wheelchair-accessible adapted gaming controller for the Wii system [16] and our research team tested its usability rating compared with the commercial off-the-shelf (OTS) balance board controller provided with the product [17]. Participants with mobility impairments found the wheelchair-accessible version to be more usable compared with the Wii OTS board ($P<.01$). The mean usability scores were 71.7 (SD 18.03) for the adapted controller and 32.1 (SD 36.72) for the Wii OTS board (higher scores reflect greater usability). In addition, a significant negative correlation (r=0.692; $P<.001$) was found between lower extremity function and system usability scores, indicating that for participants with poorer lower extremity function, the adapted board was perceived as more usable. Furthermore, participants reported activity using the adapted board to be enjoyable, achieving light-to-moderate intensity exercise [18].

As a next step, the aim was to transition from a PoC gaming controller to the performance of highly targeted proof-of-product (PoP) activities for the design of a new wheelchair-accessible AVG controller using the expertise and input of engineers, product designers, potential users, and other stakeholders from the community. The goal was to convert from a Wii-only interface to a universal controller for use with all games available to play on a PC.

Study Objectives

Following the design and development process, this study aimed to assess the usability of a wheelchair-accessible GAIMplank video game controller for individuals with mobility impairments. Measures of enjoyment, perceived exertion, and qualitative data on user experience were also collected.

Methods

PoP Development Process

To begin our PoP development effort, approximately 30 semistructured interviews were conducted with end users in various market segments to discover use cases that would be used to drive design features, functions, and capabilities. The physical therapy clinic market segment was found to be lacking in financial resources for investment into technology for nonreimbursable activities such as AVG. The market segment for inpatient rehabilitation and retirement facilities and communities was found to have the financial resources for recreational activities but lacked robust end user interest. The universal video game accessory market was found to be much more robust in terms of interest for nontraditional game controllers to facilitate intuitive player movement in virtual reality environments as well as to encourage AVG. Effective entry into this market requires the game controller to (1) be easily transportable and stowable, (2) have a purchase price comparable with other high-end game controllers (<US $300), and (3) be universally compatible with all major gaming platforms.

The design process began based on the PoC prototype developed previously (Figure 1), which used a custom-built aluminum frame, user interface, and load cell sensors combined with repurposed internal electronics from a deconstructed Wii Fit Board to allow for wireless connection to Wii game consoles. On the basis of the market study results, the preliminary PoP design effort targeted 3 areas for improvement, including reducing the weight of the balance board to <6.8 kg, integrating custom electronics for universal compatibility with all major gaming platforms, and optimizing design for low-cost manufacturing.

A redesign of the PoC balance board platform began with the determination of the critical dimensions for use by standing and seated users while also minimizing the footprint and structural support of the weightbearing structure. Early conceptual designs featured novel solutions to these design challenges through the integration of handrails, footrests, and ramps into the platform design (Figure 2). After evaluating a series of finite element models and simplified prototypes, a resin-infused sandwich composite was the material selected for use to reduce the weight of the balance board while maintaining the stiffness necessary to redistribute the user's weight to a minimum number of load cells.

The redesign of the PoC balance board electronics began with the selection of the embedded processor, load cell measurement integrated circuits, and wired and wireless communication modalities. The user interface components such as the sensitivity adjustments (overall, front and back, right and left) were upgraded from the PoC's buttons and knobs to an Android app that can easily provide access to any number of different controller settings and functions to optimize the user's game play experience. A Raspberry Pi Zero was implemented as the primary processor facilitating Bluetooth connection to an Android tablet as well as allowing remote access to data and programming via Wi-Fi. The USB Human Interface Device periphery connection to PCs and gaming console adapters was facilitated using an ARM Cortex-M4 microcontroller configured as a generic joystick device. Load cell measurements were performed using dedicated low-noise 24-bit analog-to-digital microchips.

The final design of the GAIMplank balance board platform (Figure 3) features rims on 3 sides of the board that serve as a physical barrier at the edge of the board. A downward tapered edge along the back of the board, and a slimline ramp, allowed for easy roll-on access (eg, if the user is in a wheelchair). The GAIMplank platform also features yellow high-visibility graphics that provide the user with a sense of their alignment on top of the board. The weight capacity of the GAIMplank platform is ≤270 kg, which is sufficient to support a wide range of users.

The final design of the GAIMplank Android App features real-time bidirectional information flow and access to a large range of customizable settings for real-time adjustments (Figure 4) to the measured load cells' bias, dead zones, and sensitivity, as well as to allow for on-demand calibration of the GAIMplank's output based on a player's measured weight and range of movement and game play mode (joystick vs directional pad).

The final design of GAIMplank electronics includes a custom printed circuit board (PCB) stack and an LED matrix display (Figure 5). The need for this display was discovered during the early developmental testing of prototypes with 3 volunteers recruited from local video gaming clubs, whereby they required instant feedback to build confidence that the board was indeed responding accurately and quickly to their movements during game play. This display is also used to guide the user through the required movements during calibration (step off, step on, move forward and backward, and move left and right). The PCB stack includes a Raspberry Pi as the central processor for the device, controlling wireless and wired communication, the LED matrix, and the measurement of the position of the user's center of balance at a rate of approximately 50 Hz. The stack also provides robust fixturing for the 22-pin D-Sub connector, which is used to connect to the load cells embedded in the platform via a flat flexible cable, as well as for the mini USB port for a wired connection to the gaming PC for the game console adapter.

To ensure safety during game play, height-adjustable handrails were located on 3 sides of the GAIMplank. In addition, a Microsoft adaptive controller was integrated into the system to facilitate the use of external buttons and triggers used during game play.

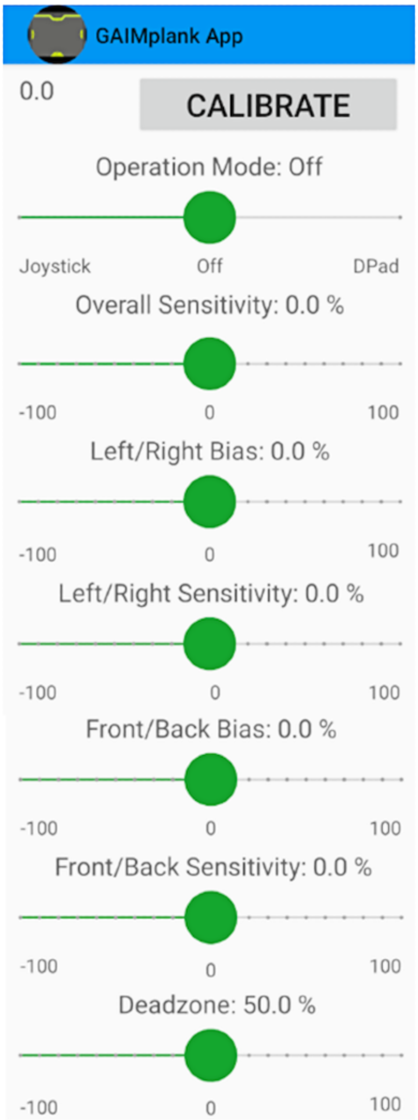

Figure 5. Proof-of-product design of the GAIMplank electronics stack.

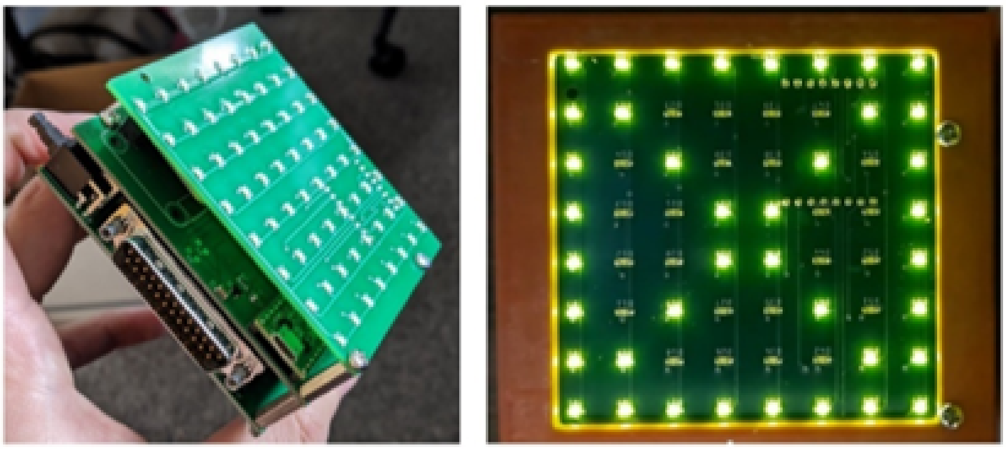

Usability Testing

Design and Setting

Data collection for usability testing was performed at the RERC RecTech Exercise Science and Technology Laboratory (University of Alabama at Birmingham). For the purposes of this study, participants came to the laboratory for a single visit, which lasted for approximately 60-90 minutes.

Ethics Approval

All study procedures were approved by the institutional review board at the University of Alabama at Birmingham (IRB-300003265).

Participant Recruitment

Participants were recruited via flyers and word of mouth at a local community health and fitness center for individuals with physical disabilities and chronic health conditions. To assess the usability of the GAIMplank for different play styles (sitting in a chair, personal wheelchair, and standing), recruitment was stratified. Sample size estimates were based on identifying common usability barriers and issues specific to the 3 game play styles. According to Cazañas et al [19], a sample of 17 individuals would reasonably identify 80% of common problems in the system, with groups of 4 to 9 sufficient to identify problems specific to the mode of play. Additional participants were recruited to account for modest attrition.

Inclusion criteria for potential participants were (1) age 18-75 years; (2) a self-reported lower extremity mobility disability (eg, spina bifida, cerebral palsy, muscular dystrophy, >1 year after spinal cord injury, multiple sclerosis, stroke, or limb loss) with partial or full use of the upper extremities; (3) mobility impairment (ie, gait deviation and balance issue) or use of an assistive device (manual wheelchair, walker, crutches, and canes) for balance or mobility purposes; (4) ability to use arms for exercise; and (5) body weight <180 kg. Exclusion criteria included (1) significant impairment in visual acuity that prevents seeing a 52” television screen to follow exercise, (2) cardiovascular disease event within the past 6 months, (3) severe pulmonary disease or renal failure, (4) current pregnancy, (5) ongoing exacerbation of a health condition, and (6) other conditions that would interfere with intervention or testing procedures. Following the distribution of a flyer, the project recruitment coordinator answered calls from or met interested individuals. If contacted, the recruitment coordinator reviewed the inclusion and exclusion criteria using a screening form to determine whether they were eligible to participate.

Testing Session

Upon arrival at the laboratory, all study procedures were reviewed with the participant. After being given an opportunity to ask questions, the participants provided informed consent. Before the testing began, basic demographic information, along with information regarding minutes of weekday and weekend physical activity, minutes of weekday and weekend video game play, and video game play experience were collected. All procedures for data collection and video game operation were reviewed with the participants before game play. The participants were then settled at the GAIMplank station. Before playing the first game, a calibration procedure was conducted by following a pattern of movements as indicated on the LED matrix.

The GAIMplank was mapped to operate as a typical joystick controller. Leaning movements of the trunk created corresponding actions in the game (ie, lean forward to move character forward and up, lean right to move character right; Figure 6). The participants played a total of 5 preselected video games. The game Feather, a slow-paced flying game, was played first by all participants to introduce them to the movements required for operating the GAIMplank. The order in which the remaining 4 games were played was randomized. To minimize offensive content, the games had an Entertainment Software Rating Board score of E (Everyone), E+10, or Teen. The description of each game played and movements required is provided in Table 1. Each game was played for approximately 5 minutes.

Figure 6. Participants standing (right), seated in a chair (upper left), or wheelchair (bottom left) engaging in active video gaming using the GAIMplank controller. Game play movement was controlled by shifting the body weight or leaning forward, back, right, left as needed. External buttons to activate actions such as jump or shoot could be configured in various formations on a flexible arm within the player's reach. A trigger button used for acceleration or shooting could be held in the hand or placed on the external button pad.

Table 1. Description of games played and movements required.

Game	Genre	Game description	Trunk leaning movements required	External buttons used
Feather	Flight; exploration	Relaxing flight to explore a scenic nature landscape	Left, right, forward (down), backward (up), diagonal	None
Let's Go Nuts	2D platformer; action	Jump, avoid danger, and collect nuts as you progress through the levels	Left, right	1 large button for jump
Horizon Chase Turbo	Racing; sports; arcade	Arcade racing games with various cars and tracks to select from	Left, right	Variable trigger for car acceleration
PAC-MAN Championship Edition DX+	Arcade; action	Move through the maze in this classic ghost chomping arcade game	Left, right, forward (up), backward (down)	1 large button to scare away the ghosts
Stardust Galaxy Warriors	Shooter; action	Soaring through space using various weapons to combat asteroids and enemy ships	Left, right, forward (up), backward (down), diagonal	Up to 4 buttons for weapon use

Measures

Quantitative Measures

The participants' responses to a series of survey measures were collected during the session. Descriptive information was collected regarding enjoyment and current level of physical activity and video gaming. Before beginning game play, participants were shown a short video demonstrating a player using the system under 3 different conditions: sitting in a 4-legged chair, sitting in a wheelchair, and standing.

Given that higher self-efficacy is correlated with higher exercise participation [20], positive physical activity behaviors [21], AVG enjoyment [22], exercise adherence [23], exercise duration [24], and AVG approval [25], participants were asked to rate their level of task self-efficacy after watching the video. This scale (Multimedia Appendix 1) was developed based on the recommendations of Bandura et al [26] and consisted of 6 items that best represent the dimensions of the task. These dimensions equally represent the steps to the Videogame Interaction Model proposed by Yuan et al [27], which include receiving stimuli, determining response, and providing input. Each item on the scale was scored on an 11-point Likert scale from no certainty (0) to absolute certainty (10) in performing the 6 dimensions related to game play (maintaining focus, seeing and hearing game information, reacting fast, determining movement strategies, coordinating movements, and moving well). The gradations of scoring for the scale were consistent with expert recommendations for measuring self-efficacy [26]. Participants rated their self-efficacy again at the end after playing all 5 games. An average score for the 6 items was calculated, with a higher score indicating greater self-efficacy in their ability to execute game play actions.

After playing each game, participants were asked to rate their level of perceived exertion (rating of perceived exertion [RPE]) and enjoyment. For RPE, the 0 (extremely easy) to 10 (extremely hard) point adult OMNI scale was used [28]. For enjoyment, participants were presented with a visual analog scale, with anchors from "Not at All Enjoyable" on the left to "Extremely Enjoyable" on the right, and were asked to mark a spot on the line to represent their enjoyment.

After finishing all game play, participants were asked to complete 2 usability surveys. The participants' perceived usability of the adapted video gaming controller was assessed using the System Usability Scale (SUS) and Health-IT Usability Evaluation Scale (HITUES). These 2 scales were selected to obtain general system usability data (SUS) in addition to usability data specific to AVG play using the GAIMplank (HITUES).

For the SUS, respondents answered 10 questions using a 5-point Likert scale ranging from strongly disagree (1) to strongly agree (5). The SUS is widely used as a reliable and valid measure of a system's usability [29-31]. Reliable results can be obtained with small samples [32], and the tool is applicable to a wide range of systems [29,33]. Using the recommended scoring guidelines, the SUS produces a score ranging from 0 to 100 [31,34]. An average SUS score of 68 corresponds to a percentile ranking of 50%, so a score >68 would be considered above average, and a score <68 is considered below average [30,33]. Adjective ratings, to help with interpretation, have been found to correlate well with the SUS scores [35].

The HITUES consisted of 20 items rated on a 5-point Likert scale ranging from strongly disagree (1) to strongly agree (5). The HITUES has 4 sections with questions to address impact, perceived usefulness, perceived ease of use, and user control. Furthermore, the HITUES allows questions to be tailored to the system under study. For the purposes of this study, each question was phrased to assess the use of the "adapted gaming board" for "active video gaming" (Multimedia Appendix 2). Studies have demonstrated the reliability and validity of the HITUES [36-38]. One recent study suggested a cutoff score of 4.32 to indicate acceptable usability, but further validation studies are required to confirm this [39].

Qualitative Measures

Completion of the usability surveys was then followed by collection of feedback data via surveys and semistructured interviews. The questions for both were written with input from members of our engineering team to obtain feedback regarding current usability and to identify issues that needed to be addressed in future iterations and to help in the next phase of the GAIMplank development. Initially, the participants provided written responses to a series of multiple choice, yes or no, and short answer questions to obtain feedback regarding the system (Multimedia Appendix 3). Participants completed these questions on their own. After the first 8 participants, the research staff began conducting semistructured interviews with participants to facilitate more in-depth responses. Using an interview guide (Multimedia Appendix 4), the feedback questions were asked by a member of the research team in a semistructured interview format, with simple prompts (eg, please tell me more) given when appropriate. The interviews were audio recorded and later transcribed.

Results

Overview

A total of 21 adults (n=15, 71% men and n=6, 29% women) completed the usability testing. The participant characteristics are provided in Table 2. The mean age of the participants was 48.8 (SD 13.8; range 21-73) years, with 57% (12/21) White, 38% (8/21) Black, and 5% (1/21) Asian. All participants had a mobility impairment resulting from a physical disability, including stroke (9/21, 43%), spinal cord injury (3/21, 14%), amputation (3/21, 14%), cerebral palsy (2/21, 9%), spina bifida (2/21, 9%), or other (2/21, 9%). The primary modes of mobility included walking without an assistive device (7/21, 33%), cane (6/21, 29%), prosthetic leg (1/21, 5%), rollator walker (1/21, 5%), and manual wheelchair (6/21, 29%). The participants played in 1 of the following 3 ways: standing (8/21, 38%), seated in a 4-legged chair (7/21, 33%), or seated in their own manual wheelchair (6/21, 29%).

Participants reported enjoyment of leisure time physical activity, were physically active, and varied in their level of video game play (Table 3). All but 2 participants were aware of AVG. The 2 most preferred devices for playing video games included video game consoles and cell phones.

The usability data for each individual participant are reported in Table 2, with the summary group scores in Table 4. Subscale scores (usability and learning) for the SUS usability tool are also reported. The overall SUS score for all participants was 74.8 (SD 14.5), suggesting above average usability for the GAIMplank. On the basis of the adjective ratings for the SUS scale as provided by Bangor et al [35], the participant scores suggested *good* usability. When broken down by play style group, the average SUS scores indicated that the usability was best for those who played while seated in a chair, followed by those who played standing, and lowest for individuals who played while seated in their own wheelchairs. A similar pattern of scores was seen with the HITUES scale, with an average score of 4.3 (SD 0.3) for all participants. The HITUES scores can range from 1 to 5, with a higher score indicating greater usability.

RPE and enjoyment scores are reported for each game by play style group in Table 5. RPE scores ranged from light to moderate intensity, with the highest scores for those who played while seated in a chair. Participants rated their experience with playing each game from above average to very enjoyable.

The task self-efficacy questions were used to gauge the participants' self-efficacy in performing certain video game play tasks using the GAIMplank system. Above average scores were reported by all 3 groups for each task (Table 6). It appears that one exposure to video game play with the GAIMplank did not diminish their task self-efficacy, and the participants felt confident in their ability to complete game video play tasks using the GAIMplank system.

Table 2. Participant characteristics and usability scores presented by play style grouping (wheelchair, seated, and standing).

ID	Age (years)	Sex	Condition	Primary, secondary assistive device	GAIMplank play style	Enjoy video game play (1-5)	Video game play (minutes per week)	SUS[a] total score	HITUES[b] score
4	38	Male	Spinal cord injury	Wheelchair	Wheelchair	5	320	52.5	4.35
12	52	Male	Spinal cord injury	Wheelchair	Wheelchair	4	480	70	4.3
13	52	Male	Double above-knee and double below-elbow amputation	Wheelchair	Wheelchair	4	210	87.5	4.18
14	39	Male	Spina bifida	Wheelchair	Wheelchair	5	120	40	4.15
20	48	Female	Spina bifida	Wheelchair	Wheelchair	3	0	87.5	4.1
21	58	Male	Spinal cord injury	Wheelchair	Wheelchair	5	2520	62.5	3.6

Participant Feedback

Overview

Feedback data were collected in a written response to multiple choice, yes or no, and open-ended survey questions (6/7, 86% seated and 1/7, 14% standing) or orally via a semistructured interview (5/11, 45% wheelchair; 1/11, 9% seated; and 5/11, 45% standing) conducted by the researchers. Data were missing for 1 survey participant and 2 interview participants.

From the survey feedback, when asked about the ease of mounting and dismounting the gaming board as "relatively simple," "needs improvement," or "difficult," all participants rated both actions as "relatively simple." When asked whether the gaming board was sturdy, 6 of the 7 participants reported "yes." All participants indicated that "yes" they were able to determine where best to position themselves on the gaming board and 86% (6/7) reported that "yes" visual cues should be included to locate the central position (on the gaming board). In addition, 86% (6/7) of participants indicated that "yes," moving their trunk (leaning) provided a responsive input for game control. Additional input functions that the participants would like to see incorporated into the gaming board included visual markers for foot placement, more games, and moving the side handrails closer. When asked to describe their overall experience on the gaming board, comments included "Positive, thank you!" "Very good," "Something new to keep alert and enjoy," "Entertaining," "A lot of fun," "It was cool to watch my character turn as I leaned left or right," and "It was great. It was challenging because I am not a gamer, but it was a good challenge."

Audio recordings of the interviews were transcribed verbatim. The transcripts were then reviewed independently by 2 members of the research team. From the independent reviews, themes were drawn, followed by discussion and review, with a final consensus reached on 5 main themes. These themes included accessibility of the GAIMplank for persons with mobility impairments, usability of the GAIMplank for persons with mobility impairments, overall experience using the GAIMplank, physical activity associated with game play, and suggestions for future iterations.

Accessibility of the GAIMplank

This category examined the perceptions of the participants regarding the accessibility of the GAIMplank controller for video game play. Three specific features were discussed, including mounting and dismounting of the GAIMplank, handrails, and accessories. Most participant comments indicated adequate accessibility for video game play. None of the participants reported difficulty in mounting or dismounting the GAIMplank. The handrails provided support when needed, an overall sense of safety, and facilitated greater movement during game play by reducing the fear of falling.

Overall, the use of an assistive device during the session (ie, manual wheelchair or prosthetic limb) did not inhibit gaming activities. For participants who played seated in their manual wheelchair, blocks were placed behind their back wheels to keep them stationary for a better response to their movements. However, both participants who wore a prosthetic leg (one above the knee and one below the knee amputee) reported that they had to adjust their stance on the GAIMplank to obtain a better response.

The positioning of the external buttons and variable trigger used for game play actions such as jumping, shooting, and car acceleration was acceptable for all participants. Participants reported that the ability to adjust the height of the buttons and position them relative to their arm reach and preferred side (right, left) facilitated game play. The participants felt that the size of the buttons was suitable and that they were easy to access. One participant, who had difficulty keeping his hand on the buttons because of partial paralysis, reported that the surface friction of the buttons could be improved.

Usability of the GAIMplank

This category describes the participants' perceptions regarding the use of the GAIMplank controller for playing video games. Specific aspects that were discussed included learning how to move for game control and responsiveness of the GAIMplank. Participants across the 3 groups acknowledged that it took some time to learn how to control and shift their weight to maneuver their character in the game. Sometimes it took time for them to feel secure to move.

Some participants reported inconsistency issues with the GAIMplank not calibrating correctly and not being responsive to their weight shifts. In some instances, recalibrating the system helped. Despite technical issues with the board during some sessions, the participants felt positive and eager to continue playing. Regardless of responsiveness issues with the GAIMplank, several participants indicated that this was the first time they were able to play such games because of accessibility issues with other AVG systems.

Overall Experience Using the GAIMplank for Video Game Play

Participants described their overall experience using the GAIMplank for video game play. Participants mainly shared positive feedback regarding their experiences with the device. As noted above, the most frequently reported barrier affecting the overall experience was the inconsistency in responsiveness of the GAIMplank system. Specific aspects highlighted by the participants regarding the GAIMplank were that the device is innovative, playing video games using the GAIMplank increases the physical activity demands of videogaming, and using the device is enjoyable. The participants expressed an interest in participating in future AVG research projects and having a device like the GAIMplank in their home setting.

"Active" Video Gaming

Several participants noted that playing video games using the GAIMplank system provided a level of physical activity. Participants described how they enjoyed the experience of moving their body to play the games instead of sitting on the couch and simply using a handheld controller or their phone. Although some frustration was experienced when the controller did not respond as expected to their movements, the participants acknowledged the value of this accessible controller in allowing them to engage in AVG play, which most of the participants were unable to do with current OTS products. Description of their game play experience included statements such as the following:

> *I like the board because I get to move with my body versus just sitting down. Gets me up instead of just using phone. This gaming board encourages body movement.* [AVGu011, walks without an assistive device, played standing]

> *It was fun. It was different. With me I'm reserved to buy some of the more active games, not knowing if I can do them. To come to a controlled environment and be able to do the movements, able to sense the movements with a prosthetic.* [AVGu017, walks with a prosthetic leg, played standing]

> *Use the whole body. It would be great to know how many calories burned.* [AVGu013, uses a manual wheelchair for mobility, played in a wheelchair]

> *But at the same time its accomplishing different goals, its being more core strength and stuff than with a (hand) controller and so...(shoulder shrug).* [AVGu014, uses a manual wheelchair for mobility, played in a wheelchair]

Future Iterations

The participants were asked to provide suggestions for improving the GAIMplank and any additional features they would like to see incorporated. The input from standing players included visual markers for foot placement, inward adjustment of handrails, handrail hook–like grip to accommodate persons without dexterity, and elevated placement of the LED matrix for better visibility. For individuals who were seated in their wheelchair, a suggestion was made to eliminate the use of the blocks behind the back wheels by adding some sort of ridge or divot to keep them from rolling.

Researcher Observations

During data collection for several participants (approximately 50%), technical difficulties with the GAIMplank controller occurred. The most frequent were calibration issues. During these sessions, the calibration procedure did not work as intended resulting in an inability of the device to find center, and causing difficulty for players to produce the necessary actions for game play. Recalibration and adjustments to the sensitivity and bias were attempted, but the problem was not corrected. Adjustments to the participant's positioning on the board were also attempted, but these were not successful. Sometimes it was just one particular game during a session that would not respond to the participant's movement. A pattern to these difficulties was not detected, and usually during the next testing session the controller worked appropriately. Specific issues based on play style (wheelchair, seated in a 4-legged chair, or standing) were not evident, except for participants who played standing and were not able to distribute their weight evenly. It appeared that the calibration procedure may not have accounted for this shift in body weight. Owing to time constraints, sufficient time was not always available to spend on troubleshooting during participant visits. Although enjoyment and RPE scores were likely affected by technical issues, participants still reported having fun and felt confident in their ability to use the system. Participants also recognized the system as providing an opportunity, typically not available to them, to engage in AVG.

Discussion

Principal Findings

Physical activity options are limited for people with mobility impairments. AVG, also known as exergaming, has the potential to provide a fun and engaging way to increase daily physical activity or reduce sedentary time. This project aimed to develop an AVG controller that was accessible and usable by individuals with mobility impairments. A sample of 21 adults with various mobility impairments was able to successfully access and play a series of standard PC video games using trunk and body movements to produce game play action. Participant usability scores (SUS and HITUES) and qualitative feedback indicated above average usability for the GAIMplank system. A previous study adapted the Wii Fit balance board controller and demonstrated successful use among people with mobility impairments with an average SUS score of 71.7 (SD 18.03) [17]. Physiological testing during game play on the adapted board indicated light-to-moderate intensity exercise for some participants [18]. This previously adapted gaming board controller was limited to use with only Wii Fit games, whereas the new GAIMplank system includes several new options for playing AVGs among people with mobility impairments and allows use with all PC games. The GAIMplank system provides a means for making games that are typically sedentary, using only the hands and fingers, more active by incorporating larger body movements. Furthermore, participants reported game play enjoyment and for some their first opportunity to engage in AVG owing to accessibility issues with OTS systems.

Looking at the average SUS scores for each participant, the lowest score was 40, well below what is considered acceptable usability. Similarly, the participant's HITUES score (4.18) suggested below acceptable usability. The participant was a regular video game player (120 minutes per week), played seated in his wheelchair, reported moderate level enjoyment across games, game play was rated as a light-intensity exercise, and a large drop in self-efficacy was reported at the end of the session for the questions that pertained to reacting fast enough to choose the next action and moving well enough to maintain successful play. His postplay feedback highlighted issues with responsiveness, which he found frustrating. The next lowest SUS score (52.5) was also reported by a wheelchair user, which can be attributed to the GAIMplank malfunctioning, making the calibration off and the games moving slow. Regardless, this participant who was physically active (960 minutes per week) and a frequent video game player (320 minutes per week) reported above average enjoyment scores, game play as light-intensity exercise, with an improvement in overall self-efficacy after using the GAIMplank system. Of the 4 other participants who reported less than optimal usability (62.5-65), 3 (75%) were standing players who were all physically active, with varying levels of weekly video game play. Two players also had low HITUES scores (4.15) and reported moderate enjoyment, light-intensity exercise, and above average self-efficacy. In both cases, technical issues were encountered with the GAIMplank system during the testing session, resulting in poor responsiveness and making the games very difficult to play. The other standing player typically used a rollator to assist with mobility but was able to play without it. His average enjoyment score was high (86) with light-intensity RPE ratings and maximum self-efficacy scores. Although his SUS score was low (62.5), his HITUES score (4.8) was the highest among all participants. These scores may suggest that although the participant perceived general usability (SUS) issues with the system, he recognized the usability of the GAIMplank as an adapted controller to provide an option for active video game play for individuals with mobility impairments.

At the other end of the spectrum, 7 players reported "excellent" usability (SUS ≥85) for the GAIMplank system. Of those, 2 played in their wheelchair, 2 played standing, and 3 played while seated in the chair. For the standing and seated players, the HITUES scores reflected acceptable usability. All 3 seated players (poststroke) spent little to no time playing video games each week but were physically active, with 2 reporting >400 minutes per week of physical activity. The average enjoyment scores were high, the RPE scores varied, and all were reported to have certainty in their ability to conduct various video game play tasks using the GAIMplank system. Both standing participants were physically active (120 minutes per week); one spent a lot of time playing video games each week (630 minutes), whereas the other played very little, if any. Average enjoyment scores were higher for the person who typically spent a lot of time playing video games each week, whereas RPE was higher for the other participant. Both participants reported high self-efficacy in using the GAIMplank system for video game play. Both participants who played seated in their wheelchairs with high SUS scores were physically active (120 minutes per week); one spent a lot of time playing video games each week (210 minutes), whereas the other one played none. The HITUES scores were lower than those of other participants who reported high SUS scores. Both players enjoyed the games, with RPE scores indicating light-to-moderate intensity exercise. The self-efficacy scores were high for both players at the end of the session.

The results demonstrate the usability of a newly developed adapted gaming board for AVG play, but attention is needed to improve the stability of responsiveness and to address issues experienced by different subgroups of individuals with mobility impairments. Considerations for the engineering team during the next phase of development include different weight distribution patterns during game play by individuals wearing a prosthetic leg, varying movements associated with spasticity among certain players, foot placement outside the board (ie, on stool in front) for some seated players, and overall improvement to better accommodate wheelchair play. Overall, the ability of the adapted controller to provide a fun and accessible option for AVG play was clearly recognized by the players, suggesting the need for additional development and research in this area.

Study Limitations

The heterogeneous nature of the sample makes it difficult to determine whether different aspects of the GAIMplank better suited one group over another. The number of participants within each play style group was small and consisted of individuals with various mobility impairments. In addition, participants were recruited from a community-based health and fitness center, so all had experience with physical activity and were currently active with reported weekly physical activity minutes ranging from 60 to 960 (mean 375, SD 257) minutes. Therefore, the results cannot be generalized to more sedentary populations. Previous gaming experience was captured, but its influence on system usability or their game play experience could not be teased out. With regard to the specific games used for the sessions, game selection was limited and may not have appealed to some participants. In addition, sufficient time to learn how best to move for each game was not provided. Initially, qualitative feedback data were not collected from participants. As the need for more in-depth user input was recognized, semistructured interviews were conducted to collect richer feedback data. This change occurred after most of the seated players had completed testing; therefore, limited qualitative data were available from this group.

Future Considerations

Continued testing and refinement of the GAIMplank system are underway. The usability testing results were discussed with the engineering and design teams, and a new wave of refinements is planned with a focus on improving the stability of the platform. Specifically, elimination of the Raspberry Pi and addition of a custom-fabricated PCB board are being considered. Following further refinement of the system, the plan is to conduct a feasibility study to examine the use of the GAIMplank for an AVG exercise intervention. The outcomes of interest will include various physiological and psychosocial measures. Other factors to be considered include game play selection and preferences, previous gaming experience, participants' physical activity level, and single versus multiplayer options. In addition, consideration of factors that affect game play-by-play style (eg, seated and standing) needs to be examined. The potential of integrating other gaming controllers is also of interest.

Conclusions

The GAIMplank, an adapted gaming controller, allowed people with various mobility impairments to engage in AVG. Using the GAIMplank system, standard PC video games can be played while sitting, standing, and in a manual wheelchair. Participants reported above average usability for the GAIMplank and found game play to be enjoyable and provide light-to-moderate intensity exercise. Further design and development work to refine the device is recommended.

Acknowledgments

Abstract

Background: Successful cause-related marketing (CRM) campaigns can help companies stand out from their competitors; however, CRM may not have pleasant outcomes, even if it receives substantial investment.

Objective: This research aimed to investigate how gamified CRM projects influence consumers' favorability.

Methods: We introduced 3 different CRM projects in 3 different studies. Every project had 2 versions according to the level of gamification, and participants were randomly assigned into these 2 groups. Additionally, we used a 2 (gamification: lower, higher) 2 (rules presentation: without visual cues, with visual cues) between-subjects design to test the moderation role of rules presentation in gamified CRM projects.

Results: In Study 1, we identified that the highly gamified CRM program induces more enjoyment ($F_{1,139}$=21.11, P<.001) and higher favorability ($F_{1,139}$=14.57, P<.001). Moreover, we found that enjoyment played a mediation role between gamification and favorability (P<.001) in Study 2. In addition, the results of Study 3 indicated rules presentation in a gamified CRM program can moderate the indirect effect of gamification on favorability via enjoyment (index of the moderated mediation: 95% CI –1.12 to –0.10; for rules presentation with visual cues: 95% CI 0.69 to 1.40; for rules presentation without visual cues: 95% CI 0.08 to 0.83).

Conclusions: Overall, this research contributes to the CRM literature and suggests gamification is an effective way of managing CRM campaigns.

Introduction

Background

Corporate social responsibility practices are currently popular for firms to enable themselves to stand out from their competitors and achieve sustainable performance [1]. Generally, companies undertake cause-related marketing (CRM) as one solution to show their commitment to corporate social responsibility [2]. Successful CRM campaigns can help companies elicit positive attitudes [3] and emotional bonds between them and their customers [4]. However, CRM may not have pleasant outcomes, even if it receives substantial investment [5,6]. It is therefore critical to understand the related predictors so that practitioners can develop CRM activities that will have desirable outcomes.

Gamification is a new and effective way to generate CRM success. Recently, some companies have applied gamification to their CRM practices. For example, Alipay, one of the famous e-payment applications in China, launched a gamified CRM scheme called “Ant Forest” in 2016. Users grow virtual trees in Ant Forest by collecting game points. As users complete the game tasks, they earn points for taking buses, walking daily steps, or using online payment in a low-carbon lifestyle. After obtaining enough points, users can turn their virtual trees into real ones and thus contribute to environmental protection. The hedonic benefit provided by a gamified system motivates users to take action. However, to our best knowledge, few studies discuss gamified CRM and its impact on people's attitudes or behaviors [7]. In this article, we advanced previous research and performed empirical studies to answer related questions.

Enjoyment and Favorability

Consumers are not totally rational. As they make purchase decisions, they involve their fantasies, emotions, or other experiential perspectives rather than just processing the information [8].

Gamification is thus the popular choice for practitioners to satisfy consumers with utilitarian values, hedonic values, and social values [9]. On one hand, the concept of gamification originates from “game.” Gamification indicates the use of game design elements, game mechanisms, or games in nongame contexts [10]. It aims to provide consumers with positive emotional and involved experiences (ie, gameful experiences) [11]. On the other hand, some research (eg, Jung et al [12], Kim and Ahn [13], and Sailer et al [14]) has proved that game design elements (eg, points, badges, and leaderboards) can not only evoke users' intrinsic motivations and yield performance gains but also internalize extrinsic motivations (eg, external rewards).

Therefore, we believed that, compared with traditional CRM activities, consumers enjoy more hedonic values and feel as if they are more involved in gamified activities, leading to the following hypothesis: (H1) Gamification has a positive influence on enjoyment.

Consumers do not adopt CRM activities casually [6]. Consumers’ personal evaluation of or beliefs around the cause can influence the success of CRM [15]. Thus, in this study, we defined favorability as consumers' positive attitudes toward CRM activities [16,17], to measure the success of CRM programs.

Generally, CRM campaigns work when consumers benefit from feeling pleasure during participation [18]. We posited that consumers are more willing to accept gamified CRM activities, since they can offer more opportunities for consumers to interact with the cause and the perceived enjoyment from gamified CRM campaigns positively influence consumers’ favorability.

Extant research suggests that positive emotions can arouse individuals' positive attitudes [19]. Especially in the context of CRM, hedonic products that are associated with positive emotional processing are more likely to provoke emotional contagion; individuals thus have more favorable attitudes toward the CRM programs [20].

Although studies examining the relationship between enjoyment and favorability in the context of gamified CRM are lacking, various studies (eg, Yang et al [21], Catalán et al [22], and Hwang and Choi [23]) validated the positive influence of perceived enjoyment from gamification on positive attitudes, such as consumers’ brand attitudes [24], continuous use intention [25], and brand loyalty [26].

Therefore, we hypothesized that (H2) enjoyment has a positive influence on favorability and mediates the relationship between gamification and favorability.

Rules Presentation

Gamification embraces the nature of games. Importantly, rules are the core factors of games [27]. Containing various game mechanics [28], rules stipulate how to achieve the goal of a game and the outcome of each trial [29].

In this article, we defined rules presentation as the way of presenting the rules of a CRM project, with or without visual cues. We believe that the way rules are presented can influence people's enjoyment. Rules with visual cues tend to help people to process information fluently and thus induce enjoyment at a higher level. According to processing fluency theory, the ways of processing information vary from the degrees of effort and speed [30]. With a fluent process, it is faster and easier to make judgments; however, a process that is not fluent has the opposite effect.

Generally, individuals prefer a stimulus that is easier to perceive and tend to favor it [31-33]. Thus, fluency always results in positive outcomes [34]. Past research has shed light on that fact that fluency of information processing (eg, rules processing) leads to consumers' positive affective responses (eg, Janiszewski [35] and Gamblin et al [36]) or leads to purchase intentions (eg, Zhang et al [37], Jaud and Melnyk [38], and Wang et al [39]).

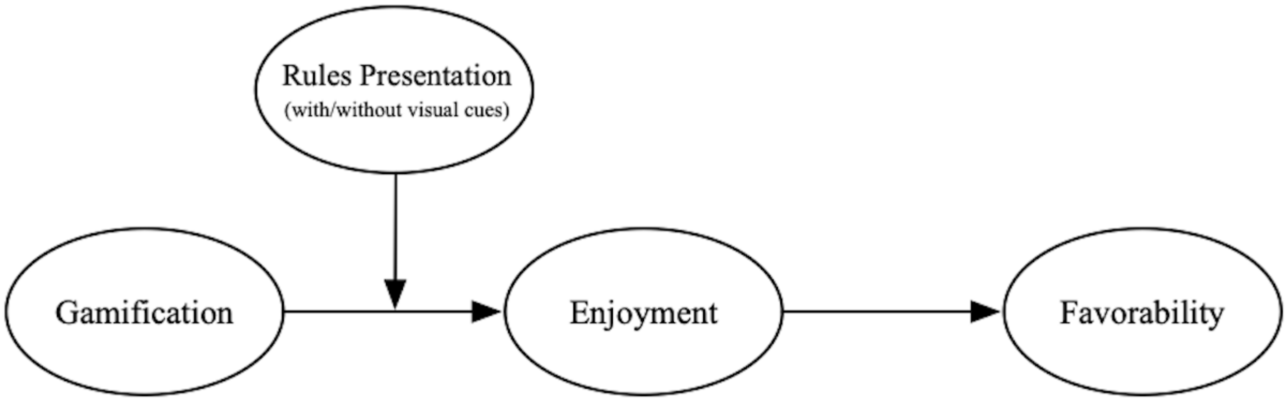
Meanwhile, fluent processes are always involved in visual categorization [40,41]. When faced with experiential-attribute (ie, affective or sensory) targets, consumers are more likely to receive stimuli and respond immediately, without elaborating or reasoning [42].

Therefore, we hypothesized that, if the rules of gamified projects are performed with visual cues (eg, in figurative or other sensory ways), consumers tend to perceive higher enjoyment. On the contrary, however, when the rules are presented in plain and monotonous literal words, consumers perceive less or even no enjoyment from gamified CRM programs. We thus predicted that (H3) visual cues in rules presentation moderate the relationship between gamification and enjoyment. People tend to have a higher level of enjoyment under the condition with visual cues (vs the condition without visual cues).

The conceptual model is illustrated in Figure 1.

Overall, this research aimed to test if consumers have a higher level of favorability to respond in the context of gamification and try to explain why gamification strategy can work. Specifically, we hypothesized that gamification has a positive influence on enjoyment and consumers' favorability toward gamified CRM programs and that enjoyment mediates the relationship between gamification and favorability. Moreover, we also hypothesized that visual cues in rules presentation can moderate the relationship between gamification and enjoyment. People tend to have a higher level of enjoyment under the condition with visual cues (vs the condition without visual cues). We described 3 studies in detail to test our hypotheses. Finally, we addressed the theoretical and managerial implications of this research and put forward some future research directions as suggestions.

Figure 1. Conceptual model.



Methods

Study Design in Study 1

We created 2 videos to introduce the Ant Forest of Alipay. The higher gamification version illustrated the real-life version of Ant Forest. For example, users can gain points by finishing certain assignments or games or stealing from friends. After accumulating enough points, they can turn their virtual plants into real ones. However, the lower gamification version presented a fictitious Ant Forest interface. We deleted all the add-in games. Specifically, users could only accumulate points from conducting eco-friendly behaviors (eg, using public transit) but could not accumulate points from other highly gamified methods (eg, finishing games or interactions with friends). Since the basic rules were retained, we regarded the fictitious version as a lower gamified program. To minimize noise, we kept 2 versions of the same visual designs (eg, images) and presentation length (ie, 30 seconds).

A pretest was first conducted to show that the 2 versions of Ant Forest were not significantly different in relevant factors except for the level of gamification. In the pretest, we told the participants to evaluate the given Ant Forest programs. Participants were randomly assigned to 1 of 2 conditions. We performed a confounding check of brand trust, brand attitude, and brand familiarity (7-point scales; see Multimedia Appendix 1 for details [43-45]). We then asked participants to rate the perceived gamification level. The measurement was adapted from that of Hwang and Choi [23]: "This Ant Forest program entails a game component." (1=Strongly Disagree; 7=Strongly Agree).

After the pretest, we collected a new data sample to conduct our main study. In the main study, we first provided 2 versions of the Ant Forest introduction videos and asked participants to rate their willingness to favor the programs. The measurement was adapted from that of Speed and Thompson [46]: "This form of Ant Forest makes me feel more favorable toward the program." "This form of Ant Forest would improve my perception of the program." "This form of Ant Forest would make me like the program more." (1=Strongly Disagree; 7=Strongly Agree; =.78). Second, to measure enjoyment, we used the scale from Höllig et al [47]: "I would find the program presented in the video game enjoyable." "I would find the program presented in the video game enjoyable and pleasant." "I would find the program presented in the video game enjoyable and exciting." "I would find the program presented in the video game enjoyable and interesting" (1=Strongly Disagree; 7=Strongly Agree; =.81). Third, we asked the participants to rate the perceived gamification level for our manipulation check. Finally, we also performed a confounding check.

Study Design in Study 2

In Study 2, we focused on the relationships among gamification, enjoyment, and favorability and tested if enjoyment plays the role of mediator (H2). We proposed that individuals are more likely to perceive higher enjoyment from a gamified CRM program and in turn have higher favorability toward the program (H2). In Study 2, we created a new stimulus to test the hypothesis. Moreover, to provide generalizability for our results related to H1, we also tested them in this study.

Similar to Study 1, we created 2 videos to introduce a CRM program sponsored by Douyin. Douyin (also known as "TikTok" in western countries) is a popular video-sharing social network service in China. The program is named “Dream Fairy” and aims to donate books to children. The higher gamification version was the real-life version of Dream Fairy in which users can gain points by watching or publishing instant videos, participating in question-and-answer games, or interacting with friends. When they have accumulated enough points, they can make their donations in reality. On the contrary, the lower gamification version presented a fictitious Dream Fairy interface. We deleted all the games. Specifically, users could only accumulate points from watching instant videos or lives and from publishing instant videos. They could not accumulate points from other highly gamified methods (eg, playing games or social interactions). We also kept 2 versions of the same image designs and presentation duration (ie, 30 seconds) to minimize noise in the data. In Study 2, we also performed a pretest and a main study to verify the internal validity.

Study Design in Study 3

In Study 3, we conducted the mediation analysis again as a robustness check and explored the moderation role of visual cues between gamification and favorability.

We proposed that rules presentation moderates the effect of gamification on enjoyment and finally influences individuals’ favorability toward CRM (H3). In Study 3, we provided the rules to participate in a CRM either with or without visual cues. Presumably, people tend to process rules with visual cues more fluently and thus perceive more enjoyment. Therefore, we anticipated that, when rules are presented with visual cues, a higher (vs lower) gamified CRM facilitates higher favorability.

In Study 3, we chose a CRM program called “Protect Pandas” as the stimuli material. This CRM program aims to protect pandas and is sponsored by Weibo, a quite trendy mobile application in China.

Similar to previous studies, we created 2 videos to introduce the CRM program. The higher gamification version was the true version in reality. For example, users can gain points by logging into the app; publishing, reading, sharing, or liking posts; commenting; or interacting with friends. After accumulating enough points, Weibo helps users to plant actual bamboo to feed pandas. On the contrary, the lower gamification version presented a fictitious interface. The higher game elements were all deleted. Users could not accumulate points from social interactions with friends but only from daily routine behaviors in the app (eg, publishing or reading posts). We kept 2 versions in the same image designs and presentation duration (ie, 30 seconds) to avoid noise in the data. A pretest and a main study were also conducted in Study 3.

Ethical Approval

The university institutional review board at Zhejiang Shuren University approved all data collection procedures and scales we used (20221225).

Data Source

All the data in this research were collected in Credamo, which is an online survey platform. The questionnaires were randomly distributed to a registered consumer panel by the platform system, and researchers can collect data in exchange for monetary compensation. All the studies performed in this research were in accordance with the Checklist for Reporting Results of Internet E-Surveys (CHERRIES). All participants provided written consent to participate in the research and were informed that they had the ability to opt out.

Results

Results of Study 1

Pretest

We recruited 50 participants from Credamo. The results revealed that there were no significant differences between the 2 conditions for brand trust (lower gamification mean 6.19; higher gamification mean 6.42; P=.17), brand attitude (lower gamification mean 6.04; higher gamification mean 6.22; P=.38), or brand familiarity (lower gamification mean 6.12; higher gamification mean 6.35; P=.41). As expected, levels of perceived gamification were significantly different between the 2 conditions (lower gamification mean 3.87; higher gamification mean 5.91; $F_{1,48}$=31.63, P<.001).

Main Study

We recruited 141 participants from Credamo; 78 (55.3%) were female, and 129 (91.5%) were aged from 21 years to 40 years. All the confounding variables (eg, brand trust, brand attitude, and brand familiarity) showed no significant differences (P=.09, P=.07, P=.19, respectively). Since all the participants were randomly separated into groups, we did not discuss any covariates (eg, age) further. We also performed the manipulation check on the variable of perceived gamification. The result revealed that the levels of perceived gamification were different between the 2 groups (lower gamification mean 4.89; higher gamification mean 5.83; $F_{1,139}$=32.63, P<.001).

We then took enjoyment as a dependent variable and conducted a similar analysis. The result showed that gamification has a positive influence on enjoyment (lower gamification mean 5.44; higher gamification mean 6.04; $F_{1,139}$=21.11, P<.001; partial ^{2}=0.13), which means the higher gamified program leads to higher enjoyment than the lower gamified program.

We finally took favorability as the dependent variable and conducted a similar analysis. The result showed that gamification has a positive influence on favorability (lower gamification mean 5.63; higher gamification mean 6.13; $F_{1,139}$=14.57, P<.001; partial ^{2}=0.09), which means the higher gamified program leads to higher favorability than the lower gamified program.

The results of Study 1 supported H1. The highly gamified CRM program induces more enjoyment and higher favorability.

Results of Study 2

Pretest

A pretest was conducted with 42 participants recruited from Credamo. Participants were randomly assigned to 1 of 2 conditions and were instructed to evaluate the given programs. We also performed a confounding check of brand trust, brand attitude, and brand familiarity. The results revealed that there were no significant differences between the 2 conditions for brand trust (lower gamification mean 5.66; higher gamification mean 5.66; P=.98), brand attitude (lower gamification mean 6.11; higher gamification mean 5.91; P=.40), or brand familiarity (lower gamification mean 6.05; higher gamification mean 6.13; P=.79). However, perceived gamification differed between the 2 conditions (lower gamification mean 4.21; higher gamification mean 5.83; $F_{1,40}$=10.81, P=.002).

Main Study

We recruited 114 participants from Credamo; 55 (48.2%) were female, and all the participants were aged from 21 years to 40 years. We randomly assigned them to view 1 of the 2 videos. After viewing, we first asked the participants to rate the perceived gamification and then asked them to rate the perceived enjoyment (α=.76) and favorability (α=.87) toward the Douyin CRM program. Confounding variables (ie, brand trust, brand attitude, and brand familiarity), as in Study 1, were also checked, and they showed no significant differences between the 2 groups (P=.08, P=.14, P=.12, respectively). All the measures were the same as those in Study 1.

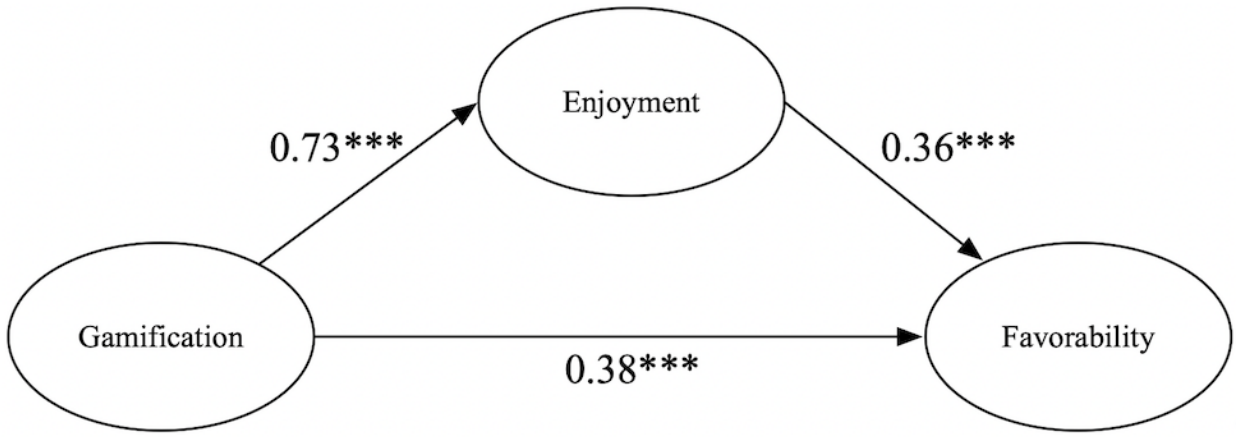
We performed the manipulation check on the variable of perceived gamification in Study 2, replicating the results of the pretest. The 2 videos were significantly different in levels (lower gamification mean 4.36; higher gamification mean 5.77; $F_{1,112}$=33.87, P<.001).

As in Study 1, we conducted a series of analyses of variance (ANOVAs) on the dependent variables. The results showed that gamification positively influenced enjoyment (lower gamification mean 5.21; higher gamification mean 5.94; $F_{1,112}$=19.57, P<.001; partial ^{2}=0.15), with higher gamification leading to more enjoyment. The results also revealed that gamification had a positive impact on favorability (lower gamification mean 5.67; higher gamification mean 6.05; $F_{1,112}$=11.18, P=.001; partial ^{2}=0.09), with higher gamification leading to higher favorability.

To test H2, we conducted a mediation analysis using the bootstrap method (5000 bootstrap samples) in the mediation package of R. The results indicated that the effect of gamification on favorability was fully mediated by enjoyment. As Figure 2 illustrates, the total effect of gamification on favorability was significant (β=.38, P<.001). Controlling for gamification, enjoyment also had a significant effect on favorability (β=.36, P<.001). However, controlling for enjoyment, gamification no longer had a significant influence on favorability (β=.12, P=.17. The indirect effect of gamification on favorability through enjoyment was 0.730.36=0.26 (P<.001), with the 95% CI ranging from 0.16 to 0.63, excluding 0. Thus, H2 was supported.

Study 2 not only reinforced H1 but also gave support to our hypothesis on the mediation role of enjoyment (H2) between gamification and favorability.

Figure 2. Path coefficients of the mediation model. ***P<.001.



Results of Study 3

Pretest

We performed a pretest with 30 participants recruited from Credamo. Participants were randomly assigned to 1 of 2 conditions, and there were no significant differences between the 2 groups in brand trust (lower gamification mean 5.66; higher gamification mean 5.48; P=.58), brand attitude (lower gamification mean 5.55, higher gamification mean 5.73; P=.66), or brand familiarity (lower gamification mean 6.14; higher gamification mean 6.06; P=.84). However, perceived gamification differed between the 2 conditions (lower gamification mean 5.21; higher gamification mean 6.12; $F_{1,28}$=8.62, P=.007).

Main Study

Study 3 used a 2 (gamification: lower, higher) 2 (rules presentation: without visual cues, with visual cues) between-subjects design. We recruited a new sample of 250 participants from Credamo; 128 (51.2%) were female, and all the participants were aged from 21 years to 40 years. In the videos, we first presented the rules (with or without visual cues) for “Protect Pandas” and then showed the interfaces of the program. After viewing, the participants were asked to rate the perceived gamification, enjoyment, and favorability toward the CRM program as in the previous studies. A confounding check was conducted and revealed no significant differences (P=.30, P=.78, P=.70, respectively).

Similar to the results of the pretest, the results of the manipulation check on the variable of perceived gamification showed that the 2 videos were significantly different in levels (lower gamification mean 5.16; higher gamification mean 5.72; $F_{1,248}$=19.48, P<.001).

We first conducted an ANOVA with enjoyment as the dependent variable and gamification and rules presentation as the independent variables. The results confirmed the main effect of gamification on enjoyment (lower gamification mean 4.71; higher gamification mean 5.56; $F_{1,246}$=30.06, P<.001; partial ^{2}=0.10) and the main effect of rules presentation (without visual cues mean 4.86; with visual cues mean 5.43; $F_{1,246}$=13.91, P<.001; partial ^{2}=0.05). These simple effects were also qualified by a significant gamification rules presentation interaction effect on enjoyment ($F_{1,246}$=4.98, P=.03; partial ^{2}=0.02). The planned contrast revealed that, when rules were presented with visual cues, higher gamification led to more enjoyment than did lower gamification (lower gamification mean 4.81; higher gamification mean 6.02; $F_{1,246}$=30.92, P<.001). Meanwhile, when rules were presented without visual cues, there was also a significant difference between the 2 groups (lower gamification mean 4.60; higher gamification mean 5.11; $F_{1,246}$=5.43, P=.02). See Figure 3.

We next performed an ANOVA with favorability as the dependent variable and gamification and rules presentation as the independent variables. The results confirmed the main effect of gamification on favorability (lower gamification mean 5.03; higher gamification mean 5.86; $F_{1,246}$=29.93, P<.001; partial ^{2}=0.10) and the main effect of rules presentation (without visual cues mean 5.21; with visual cues mean 5.72; $F_{1,246}$=11.83, P<.001; partial ^{2}=0.04). These simple effects were also qualified by a significant gamification rules presentation interaction effect on favorability ($F_{1,246}$=5.08, P=.03; partial ^{2}=0.02). The planned contrast revealed that, when rules were presented with visual cues, higher gamification led to more favorable attitudes toward the CRM program than did lower gamification (lower gamification mean 5.11; higher gamification mean 6.29; $F_{1,246}$=30.92, P<.001). Meanwhile, when rules were presented without visual cues, there was also a significant difference between the 2 groups (lower gamification mean 4.95; higher gamification mean 5.44; $F_{1,246}$=5.29, P=.02). See Figure 4.

Figure 3. Mean (SD) enjoyment in the higher gamification group compared with the lower gamification group.

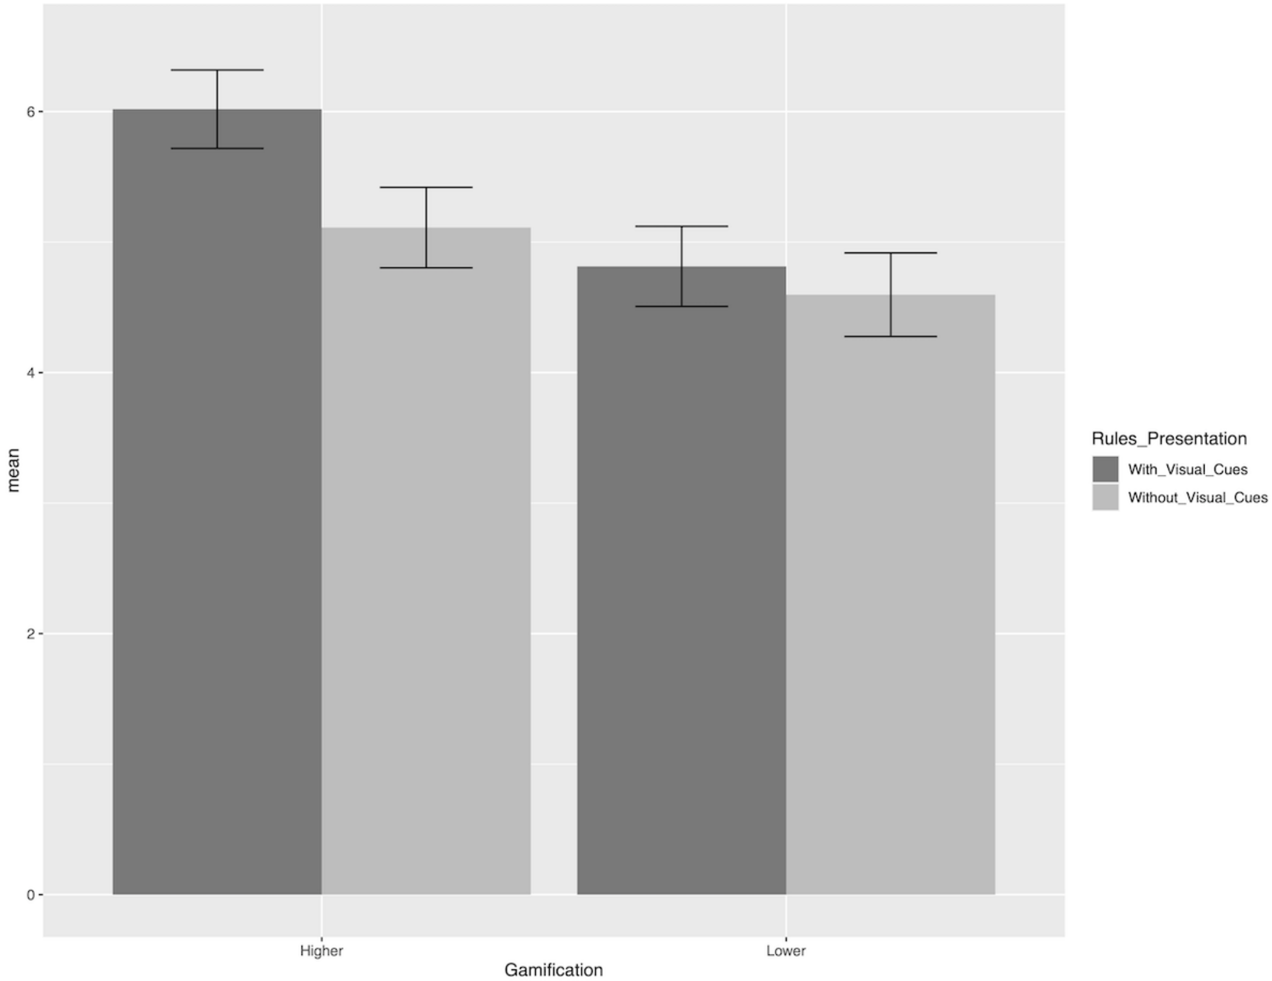


Figure 4. Mean (SD) favorability in the higher gamification group compared with the lower gamification group.

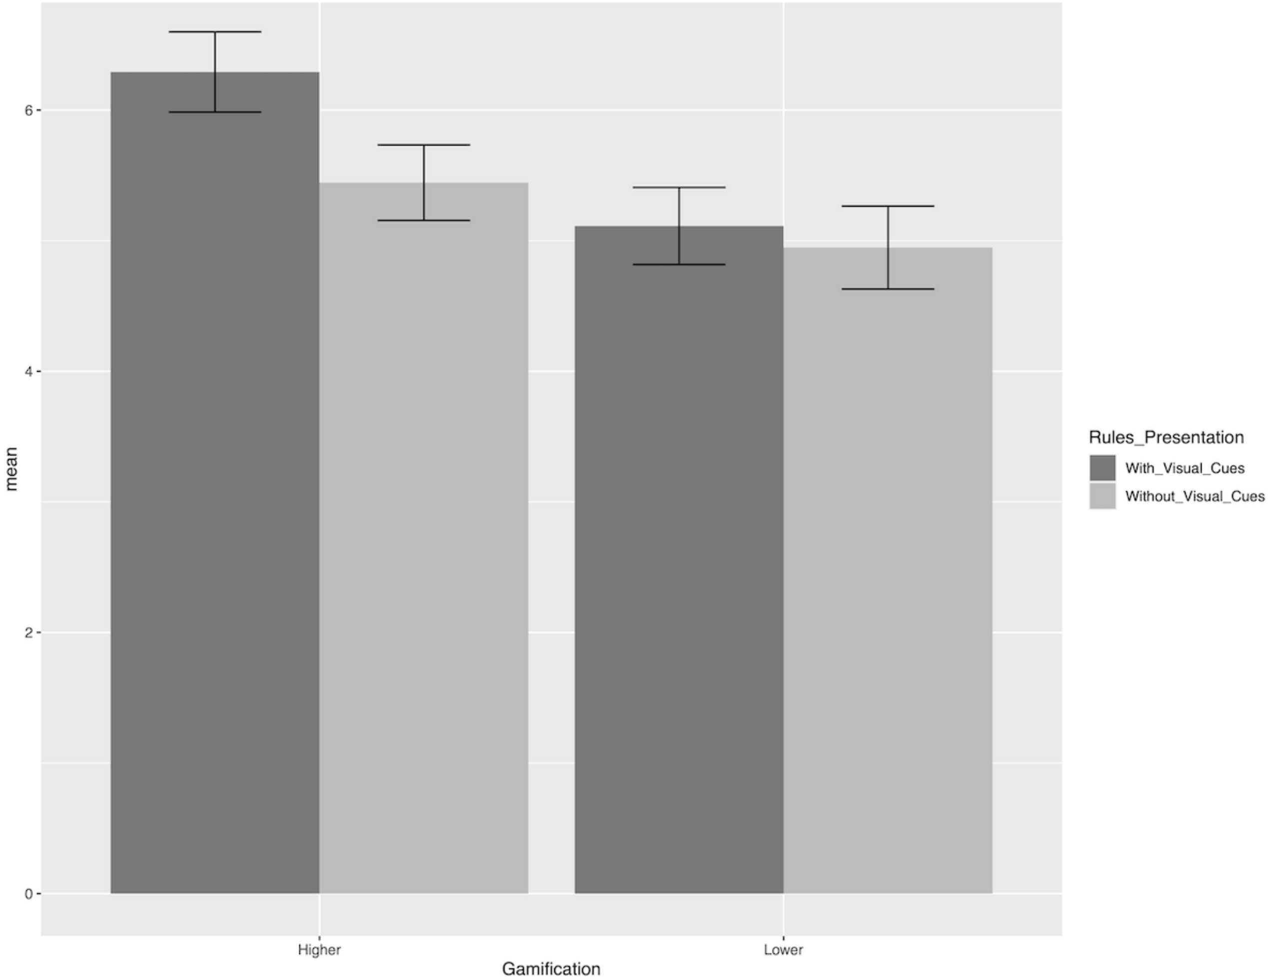

Finally, we estimated our moderated mediation model (in the mediation package of R; 5000 bootstrap samples) to test whether the visual cues in rules representation moderate the underlying process via enjoyment. The model used gamification as the independent variable, enjoyment as the mediator, and visual cues as the moderator. Similar to Study 1 and Study 2, gamification positively influenced enjoyment (β=.51, t_{246}=2.33, *P*=.02). Moreover, the interaction between gamification and visual cues was significant for enjoyment (β=.69, t_{246}=2.23, *P*<.03). Enjoyment, in turn, facilitated favorability (β=.87, t_{245}=30.80, *P*<.001). Visual cues significantly moderated the indirect effect of gamification on favorability via enjoyment (index of moderated mediation: 95% CI –1.12 to –0.10; for rules presentation with visual cues: 95% CI=0.69 to 1.40; for rules presentation without visual cues: 95% CI 0.08 to 0.83). However, the direct path from gamification to favorability was not significant (*P*=.61) nor was its moderation by visual cues (95% CI –0.39 to 0.20).

In summary, the findings from Study 3 supported our hypotheses (H1 to H3). Gamified CRM projects can induce more enjoyment and higher favorability. Importantly, when rules were presented with visual cues, the impact of gamification on enjoyment was more positive than when without visual cues. The results highlight the notion that consumers perceive enjoyment from not only game design elements of the CRM program but also the rules presentation.

Discussion

Across 3 studies, we showed that gamified CRM programs can increase consumers' perceptions of enjoyment and, in turn, enhance their favorability toward the program (Studies 1 and 2). We also showed that the relationship between gamification and enjoyment is moderated by the visual cues of rule presentation (Study 3). Our findings have several implications for marketing research and practice.

Theoretically, our research contributes to the CRM literature by highlighting the impact of gamification. It is not always easy to get consumers' responses to or willingness to participate in a CRM program (eg, Chuah et al [6] and Jun et al [48]). However, in this article, we showed that gamification is an effective alternative for CRM projects to gain more favorability by improving consumers' enjoyment. Moreover, our work adds to the literature exploring the impact of visual design on consumers' psychological mechanisms. The results of our study indicate that, when rules are presented with visual cues, consumers are more likely to perceive higher enjoyment and, in turn, feel greater favorability.

Additionally, the current research yields some implementable managerial implications. On one hand, managers can gamify their CRM programs to enhance consumers' enjoyment and favorability. For example, practitioners embed not only game design elements but also games into their projects. On the other hand, some gamified CRM programs merely present rules in monotonous words (eg, Dream Fairy in Study 2); however, according to our research, practitioners are better to present their rules with visual cues (even in a dynamic way) to induce more enjoyment.

We provide a range of evidence for our model, but there are still some limitations for future research. First, we only discussed the psychological mechanism of enjoyment between gamified CRM programs and favorability. However, there may exist multiple mediators. For example, engagement is another mediator to investigate. Since gamified CRM programs are possibly more interesting than ordinary CRM programs and provide various game design elements with which to interact, consumers may be more easily engaged [49,50]. When highly engaged, consumers are more inclined to believe the cause is connected with their lives [51] and thus are more willing to favor it [52]. Furthermore, engagement may increase the perception of one's personal role in contributing to the cause [18], which evokes an intention to participate. Second, in this article, we performed studies online and merely introduced CRM programs via videos. However, for more strict control and data collection, future studies can choose the context of a laboratory and provide opportunities for participants to conduct operations on certain programs. Finally, as the experience with gamification has not been defined clearly, the current manipulation check is limited. Future studies can develop scales for the gamification experience.

Abstract

Background: Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) are neuromuscular diseases. DMD is the most prevalent in children. It affects dystrophin production, reducing the patient's mobility and quality of life. New technologies have become a part of physical therapy in DMD and BMD. During the COVID-19 pandemic, conducting telerehabilitation through virtual reality–based games could help these children maintain their physical abilities.

Objective: This study examined if the use of a virtual platform in a multimodal intervention program changes the results of the 6-minute walk test (6MWT) in children with DMD and BMD. The main objective was to test whether children with DMD and BMD obtain different results on the 6MWT after completing 10 telerehabilitation treatment sessions. The secondary objective was to measure whether other specific motor scales also produce different results after the 10 defined sessions.

Methods: This was a descriptive, open, and quasi-experimental study with a prospective A-B (control-intervention) design. A sample of 12 participants who fulfilled the inclusion criteria followed the program for 5 weeks with 10 telerehabilitation sessions. During the sessions, the participants used virtual reality glasses to train for the treatment goals. All participants were assessed in person before and after the intervention. Analysis was performed using R software according to the different functional assessments performed for each test.

Results: The participants showed a 19.55-meter increase in the 6MWT. Motor function also remained stable according to other scales used to assess it. The North Start Ambulatory Assessment scores were stable in both treatment conditions (P=.20). Furthermore, the timed up and go test results were 0.1 seconds faster in the telerehabilitation condition, and the Motor Function Measure in all of the 3 dimensions showed no significant differences (P=.08). Finally, the Effort Perception Infant scale showed that during the training, fatigue increased in the middle and decreased by the end of the sessions, but the perception throughout the sessions was lower even as the exercise intensity increased.

Conclusions: There were no differences between conventional and telerehabilitation treatments, so the telerehabilitation tool could be used without harming children with DMD and BMD, facilitating their access to therapies and stimulating learning to maintain their functional capacity. Therefore, telerehabilitation in general may be helpful in maintaining motor function in children with DMD and BMD. The learning effect helped reduce the feeling of fatigue in the children during the program.

Introduction

Background

Duchenne muscular dystrophy (DMD) and Becker muscular dystrophy (BMD) are rare neuromuscular diseases caused by a mutation in the gene that produces dystrophin, which is responsible for maintaining muscle properties [1]. The lack of dystrophin leads to the progressive degeneration of muscle fibers, which become connective tissue and fat [2]. The worldwide prevalence is approximately 0.5 per 10,000 male individuals for DMD and 1 per 3500 male individuals for BMD [3]. The loss of ambulation occurs at a median age of 12 years, and ventilation starts at about the age of 20 years, making it a disabling disease with severe motor sequelae and respiratory and cardiac problems, with a high cost to health [4].

Maintaining function as long as possible is the primary goal of physical therapy for these conditions. To start intervention from the beginning of the diagnosis or to document the evidence of a motor delay, physical therapy is carried out using techniques such as contracture and posture management, as well as aerobic, proprioceptive, coordination, balance, and respiratory work [5]. Children with DMD and BMD have associated disorders such as autism, speech limitations, and behavioral problems in most cases, so the proposed treatment was aimed at treating these associated disorders [3].

The global situation due to COVID-19 has led health professionals to carry out interventions through video calls to support families. The impact of the pandemic, confinement duration, and health care changes could affect the mental health of young people with intellectual disabilities and their environment. Their behavior could be aggravated, and mental disorders could appear [6]. Furthermore, the characteristics of children at advanced stages of DMD and BMD, such as muscle weakness, impaired cough reflex, mucus in the airways, cardiac deterioration, and the very early intake of corticosteroids, may predispose them to severe COVID-19 [5]. A major difference between DMD and BMD is that BMD progresses slower and has a later onset than DMD [5].

The World Confederation for Physical Therapy, in its report on the regulation of clinical practice through digital platforms, summarizes the following benefits: this practice facilitates connection, reduces barriers and waiting times, increases safety, reduces mobility problems, improves user independence, improves flexibility, and lowers costs of care [7]. During this time, the effectiveness of active video games, a game system where the player's movements through the game space are displayed on a television screen, and virtual reality (VR) games, which provide an artificial 3D environment using VR technology, has been demonstrated in the physical rehabilitation of children with disabilities at home [8].

As part of telehealth, telerehabilitation uses telecommunications technologies to control or monitor remote rehabilitation. Its objective is to increase accessibility and continuity of care for vulnerable, geographically remote populations with disabilities, thus saving time and resources for health care providers [9]. In addition, telerehabilitation implementation is feasible, it can be offered to diverse groups of patients, and therapists accept it as an effective model of care for children [10].

The use of VR in physical therapy programs for children can provide a personalized and flexible treatment by allowing us to integrate the child's preferences into the intervention program, improve attention and motivation, and increase sensory feedback [11]. Despite the effectiveness of the programs in general, there are few studies about children with DMD and BMD.

Previous studies have used accelerometers to measure functional tasks and the effectiveness of dynamic arm support at home in young patients with DMD [12,13]. Web-based platforms have also been used to demonstrate respiratory exercises to relatives and provide a satisfaction survey to measure the participation and acceptance of the program [14].

Objectives

The main objective of this study was to test whether children with DMD and BM obtain different results on the 6-minute walk test (6MWT) [15] after completing a multimodal telerehabilitation program of 10 sessions over 5 weeks with VR glasses as a part of the treatment. As a secondary objective, other specific motor scales were used to measure changes after receiving the 10 defined sessions. These scales were the North Star Ambulatory Assessment (NSAA) [16], timed up and go test (TUG) [17], Motor Function Measure (MFM) [18], and Effort Perception Infant (EPInfant) [19], which will be described in the *Methods* section.

The purpose of this study was to examine if the use of a virtual platform in a multimodal intervention program changes the results of the 6MWT in children with DMD and BMD.

Methods

Study Design

This was a descriptive, open, and quasi-experimental study using an A-B design with a prospective control condition and an intervention condition. It was carried out nationally, according to a multicentric scheme.

The principal investigator conducted the sessions with all participants. In all, 3 researchers from the Canary Islands, Madrid, and Almería conducted the pre- and poststudy assessments of the variables. The interviews were conducted by the associate researcher in each department.

All caregivers were notified by email and WhatsApp 1 day before the session was held, to ensure the continuity of the study and its frequency of 2 weekly sessions for 5 weeks.

A control condition and an intervention condition were defined for the entire sample. Both results were compared, and each child was only compared to their own results. Upon the completion of the multimodal physical therapy program, the main researcher performed an outcome assessment and functional assessment of the intervention face to face.

The following sections describes the training carried out with the study participants. Over 5 weeks, the participants passed a pretraining assessment (control condition) and then attended ten 30-minute physiotherapy sessions (intervention condition).

Control Condition

The participants first underwent the control condition, where they performed the functional tests by following a conventional physical therapy program without the use of VR glasses.

Intervention Condition

The participants then underwent the intervention condition of ten 30-minute sessions, which included self-stretching, yoga, aerobic work, breathing and relaxation, mindfulness, and training with VR glasses (Table 1). We used sources on the internet such as videos on YouTube [20] to carry out the guided exercises, as well as music on Spotify. Visual and musical support during the sessions was one of the key factors for the child to want to participate and maintain their attention during the treatment. Cardboard VR glasses sent to each of the participants were also used as support.

Table . Exercises performed during the telerehabilitation sessions.

Type of exercise	Material resources	Time	Example
Aerobic	• Video game • Dancing • Walking • Therapist	Gradual increase in exercise duration from 3 min to 6 min	While watching a video of a walk, the child keeps walking in place.
Respiratory	• Video story • Therapist	10 min	The reading of a visual story with music is used as an opportunity for breathing exercises, prolonged expirations, strengthening of the muscles involved in breathing, deep diaphragmatic inspirations, etc.
Self-stretching	• Music • Therapist • Yoga • Videos	4-5 min	A guided self-stretching session is performed with the therapist following the rhythm of the music.
Relaxation	• Mindfulness • Videos	3 min	Using mindfulness as a tool, we integrate a child's ability to stop, relax, breathe, and disconnect through listening.
VR[a]	• VR glasses • VR videos	6-8 min	Through the VR glasses, the child is required to perform various activities such as swimming, crouching, walking on the spot, or breathing by viewing a VR video.

[a]VR: virtual reality.

The participants used the Zoom (Zoom Video Communications) video call platform to carry out a program of web-based gamification activities. The multimodal physiotherapy treatment, adapted to a virtual platform, was aimed at global work of the child at different levels (respiratory, aerobic, and mental levels), postural re-education, and self-stretching; in addition, gamification, dance, yoga, and meditation were used as tools within the physiotherapy framework [21]. The child performed the intervention alone or with their caregivers. A physiotherapist guided all sessions. Neither the participants nor the caregivers received training or have knowledge of how they were going to perform the exercises.

Recruitment

The recruitment of participants started in March 2021 and was completed in October 2022. Recruitment took place at each child's referring physiotherapy center. To be included in the study, the principal investigator was contacted directly. This investigator's contact information was provided in the study information sheet. Participants who met the inclusion requirements of the study were contacted by a phone call as the first contact and for the clarification of doubts.

The technique used to select the participants was of an intentional, nonprobabilistic nature. The selection was made according to the inclusion and exclusion criteria, and all who met them were included.

Due to the low recruitment capacity (scarce eligible population), convenience sampling was carried out. The allocation process was not randomized. A random sample of 12 individuals was considered significant enough to estimate, with a 95% confidence and an accuracy of within 80 meters, the population mean values with an expected SD of around 134.35 meters. The SD of the control treatment and telerehabilitation was 95 meters. The predicted withdrawal rate was 5% or below. The estimate was made using the GRANMO calculator (Institut Municipal d'Investigació Mèdica) [22].

Inclusion and Exclusion Criteria

Participants were children between the ages of 5 and 15 years with muscular dystrophy (DMD or BMD) who could walk and follow the web-based intervention program; were diagnosed according to the International Classification of Diseases, 10th Revision (code G71-01); and had an NSAA score greater than

20 [23-25]. The characteristics of the participants are shown in Multimedia Appendix 1.

Participants who did not walk were excluded, as well as those with associated heart disease, any fracture or sprain, heart rate >120 beats per minute, or oxygen saturation <89% [15,26,27] and those who did not have internet literacy.

Primary and Secondary Outcome Measures

The primary outcome measure was the change in the 6MWT (time frame: from baseline up to 5 wk) [15]. The 6MWT is a well-established outcome measure in various diseases. It is accurate, reproducible, easy to administer, and well tolerated. The 6MWT is a robust assessment tool for clinical trials, given its ability to assess ambulation quantitatively in a controlled setting.

The following secondary outcome measures were also considered:

- The EPInfant is a perceived child effort measurement scale (time frame: to study completion, 5 wk on average) [19]. It shows 11 numerical descriptors (from 0 to 10), a total of 5 verbal descriptors placed at every 2 intensity levels, and a set of illustrations depicting a boy running at increasing intensities along a bar scale of increasing height following an exponential-type slope from left to right. Higher values correspond to worse results.
- The NSAA is functional scale for children with DMD (time frame: from baseline up to 5 wk) [16]. It is expressed in points and shows the acquisition or loss of functions. Although children with DMD can generally show recognizable adaptations to activities due to the underlying progressive muscle weakness, they may modify their activities to achieve functional goals in slightly different ways. In general, activities receive the following scores: 2 ("Normal")=no obvious modifications to the activity; 1=modified method that achieves the goal independently of physical assistance from others; and 0=unable to achieve the goal independently. The best score is 34 points.
- The MFM measures motor performance (time frame: from baseline to 5 wk) [18]. It has 3 dimensions: D1, standing and transfers (13 items); D2, axial and proximal motor function (12 items); and D3, distal motor function (7 items; 6 of which evaluate the upper extremities).
- The TUG is expressed in seconds (time frame: from baseline to 5 wk) [17]. It shows the time it takes children to stand up, walk 3 meters, return to the seat, and sit down.
- The Vignos Scale ranges from 1 to 10 and assesses lower-extremity function. A score of 1 refers to being able to walk without assistance and 10 refers to being confined to a bed. It is embedded within the MFM data collection [18].

The CONSORT (Consolidated Standards of Reporting Trials) flow diagram of participants' recruitment and progress through the phases of the trial is shown in Multimedia Appendix 2.

Data Analysis

The analysis was organized according to the different functional assessments performed for each test. Analysis was performed using R (R Foundation for Statistical Computing) software. Scores were calculated using the corresponding guidelines. Each variable was analyzed to measure the motor function used: 6MWT, NSAA, TUG, and MFM. In addition, we analyzed the perceived fatigue with EPInfant, including the variation during the course of the sessions and the relationship with the rest of the variables.

The correlation between fatigue and motor function was assessed using the Pearson correlation coefficient. Paired tests were used to account for the inherent dependence and correlation among the variables. The 2-tailed paired t test was used for variables conforming to a normal distribution, whereas the Wilcoxon signed-rank test was used for variables that did not adhere to normal distribution assumptions. The Anderson-Darling and Fligner-Killeen tests were used to evaluate normality and homoscedasticity assumptions, respectively. The Friedman test was used when the evaluation spanned beyond 2 distinct time points. In cases where statistically significant relationships were detected ($P<.05$), we applied the Bonferroni correction method to rigorously examine post hoc relationships. Additionally, 2 linear mixed-effects models (random intercepts) were fitted to evaluate child stress. The first model, M1, does not incorporate an interaction between time and sessions and can be represented as:

The second model, M2, incorporates an interaction and is expressed as:

The above equations apply for patient $j=1...j$.

Ethical Considerations

The project's development followed the World Medical Association Declaration of Helsinki in 1964 and the ratifications of the subsequent assemblies on ethical principles of medical research involving human participants. The researchers in this study agreed that all clinical data collected from study participants would be separated from personally identifiable data to ensure patient anonymity. The researchers collected the patients' clinical data in the study-specific data collection notebook. Each data collection notebook was coded and pseudonymized, thus protecting the patient's identity.

It was guaranteed that the treatment, communication, and transfer of personal data of all participants complied with the provisions of Organic Law 3/2018, of December 5, on protecting personal data and guaranteeing digital rights. The participants were informed about their rights to access, cancel, or oppose the use of their data by emailing the researchers. There was no compensation for participation.

This trial has the approval of the Andalucía Ethics Committee with Portal de Ética de la Investigación Biomédica de Andalucía code 0107-N-20.

All participants were informed, and all signed a paper-based informed consent form in person.

Results

Primary and Secondary Outcome Measures

Overview

Table 2 describes the results for each variable.

Table . Summarized means and SDs of the variables (N=12).

Variable	Conventional treatment, mean (SD)	Telerehabilitation, mean (SD)	Difference, mean (SD)
6MWT[a]	408.24 (115.61)	427.79 (134.40)	19.55 (43.83)
NSAA[b]	0.76 (0.18)	0.71 (0.21)	–0.05 (0.11)
Vignos Scale	2.08 (0.79)	2.25 (1.06)	0.17 (0.39)
TUG[c]	7.70 (3.49)	7.60 (3.75)	–0.10 (0.90)
Total MFM[d]	0.89 (0.10)	0.85 (0.14)	–0.04 (0.13)

[a]6MWT: 6-minute walk test.
[b]NSAA: North Star Ambulatory Assessment.
[c]TUG: timed up and go test.
[d]MFM: Motor Function Measure.

6MWT Outcomes

After completing the conventional treatment and then changing to telerehabilitation, the patients walked an average of 19.55 (95% CI –8.30 to 47.40) meters more. This increase was not significant against the distance walked after the conventional treatment (*P*=.15; Table 3).

Table . Results of the 6-minute walk test (6MWT)[a] (N=12).

6MWT (m)	Conventional treatment	Telerehabilitation	Difference
Value, mean (SD)	408.24 (115.61)	427.79 (134.40)	19.55 (43.83)
Value, median (IQR)	364.50 (323.62 to 459.38)	375.50 (346.88 to 428.75)	15.00 (–5.25 to 37.50)
Value, range	294.00 to 630.00	324.00 to 750.00	–51.50 to 120.00
Value, 95% CI	334.79 to 481.70	342.40 to 513.19	–8.30 to 47.40

[a]Paired *t* test: t_{11}=–1.545, *P*=.15 (not significant).

NSAA Outcomes

The NSAA scores were kept stable at around 73%. Although the score for telerehabilitation decreased (5%, 95% CI –13% to 2%), this decrease was not statistically significant with respect to the conventional approach (*P*=.20; Table 4).

Table . Results of the North Star Ambulatory Assessment (NSAA)[a] (N=12).

NSAA score	Conventional treatment	Telerehabilitation	Difference
Value, mean (SD)	0.76 (0.18)	0.71 (0.21)	–0.05 (0.11)
Value, median (IQR)	0.85 (0.63 to 0.88)	0.68 (0.62 to 0.89)	–0.03 (–0.09 to 0.01)
Value, range	0.44 to 1.00	0.32 to 0.97	–0.26 to 0.09
Value, 95% CI	0.65 to 0.87	0.57 to 0.84	–0.13 to 0.02

[a]Paired Wilcoxon test: *V*=40.000; *P*=.20 (not significant).

TUG Outcomes

The time used in the TUG during the telerehabilitation period was 0.1 (95% CI –0.67 to 0.49) seconds shorter than that during the conventional period. This decrease was not statistically significant (*P*=.72; Table 5).

Table . Results of the timed up and go test (TUG) (N=12).

TUG (s)	Conventional treatment	Telerehabilitation	Difference
Value, mean (SD)	7.70 (3.49)	7.60 (3.75)	–0.10 (0.90)
Value, median (IQR)	6.54 (5.40-9.51)	6.26 (5.27-9.48)	0.22 (0.59-0.21)
Value, range	2.79 to 14.51	2.25 to 14.07	–1.56 to 1.61
Value, 95% CI	5.48 to 9.92	5.22 to 9.99	–0.67 to 0.47

[a]Paired *t* test: t_{11}=–0.370, *P*=.72 (not significant).

MFM Outcomes

Total MFM

Both the total scores and scores for each of the 3 dimensions in the MFM were analyzed. No significant differences were found in the total MFM score between the conventional and telerehabilitation approaches (*P*=.08). Telerehabilitation had an average decrease of 4% (95% CI −12% to 4%; Table 6).

Table . Results of the Motor Function Measure (MFM)[a] (N=12).

Total MFM score	Conventional treatment	Telerehabilitation	Difference
Value, mean (SD)	0.89 (0.10)	0.85 (0.14)	–0.04 (0.13)
Value, median (IQR)	0.95 (0.84 to 0.97)	0.90 (0.77 to 0.96)	0.00 (–0.02 to 0.00)
Value, range	0.74 to 1.00	0.54 to 0.99	–0.44 to 0.02
Value, 95% CI	0.83 to 0.96	0.76 to 0.94	–0.12 to 0.04

[a]Paired Wilcoxon test: *V*=18.500; *P*=.08 (not significant).

D1: Standing and Transfer

No significant differences were found between the conventional and telerehabilitation approaches (*P*=.08). Telerehabilitation had an average decrease of 8% (95% CI −21% to 4%; Multimedia Appendix 3).

D2: Axial and Proximal Motor Function

No significant differences were found between the conventional and telerehabilitation approaches (*P*=.75). The scores remained stable at around 98% (95% CI −3% to 3%; Multimedia Appendix 4).

D3: Distal Motor Function

No significant differences were found between the conventional and telerehabilitation approaches (*P*=.89). Telerehabilitation had an average decrease of 4% (95% CI −15% to 7%; Multimedia Appendix 5).

EPInfant Outcomes

Fatigue was measured for each session (before, in the middle of, and at the end of each session) during the telerehabilitation process. Both fatigue and fatigue evolution were estimated during each session. A clear evolution can be seen in the perception of fatigue throughout the 10 sessions.

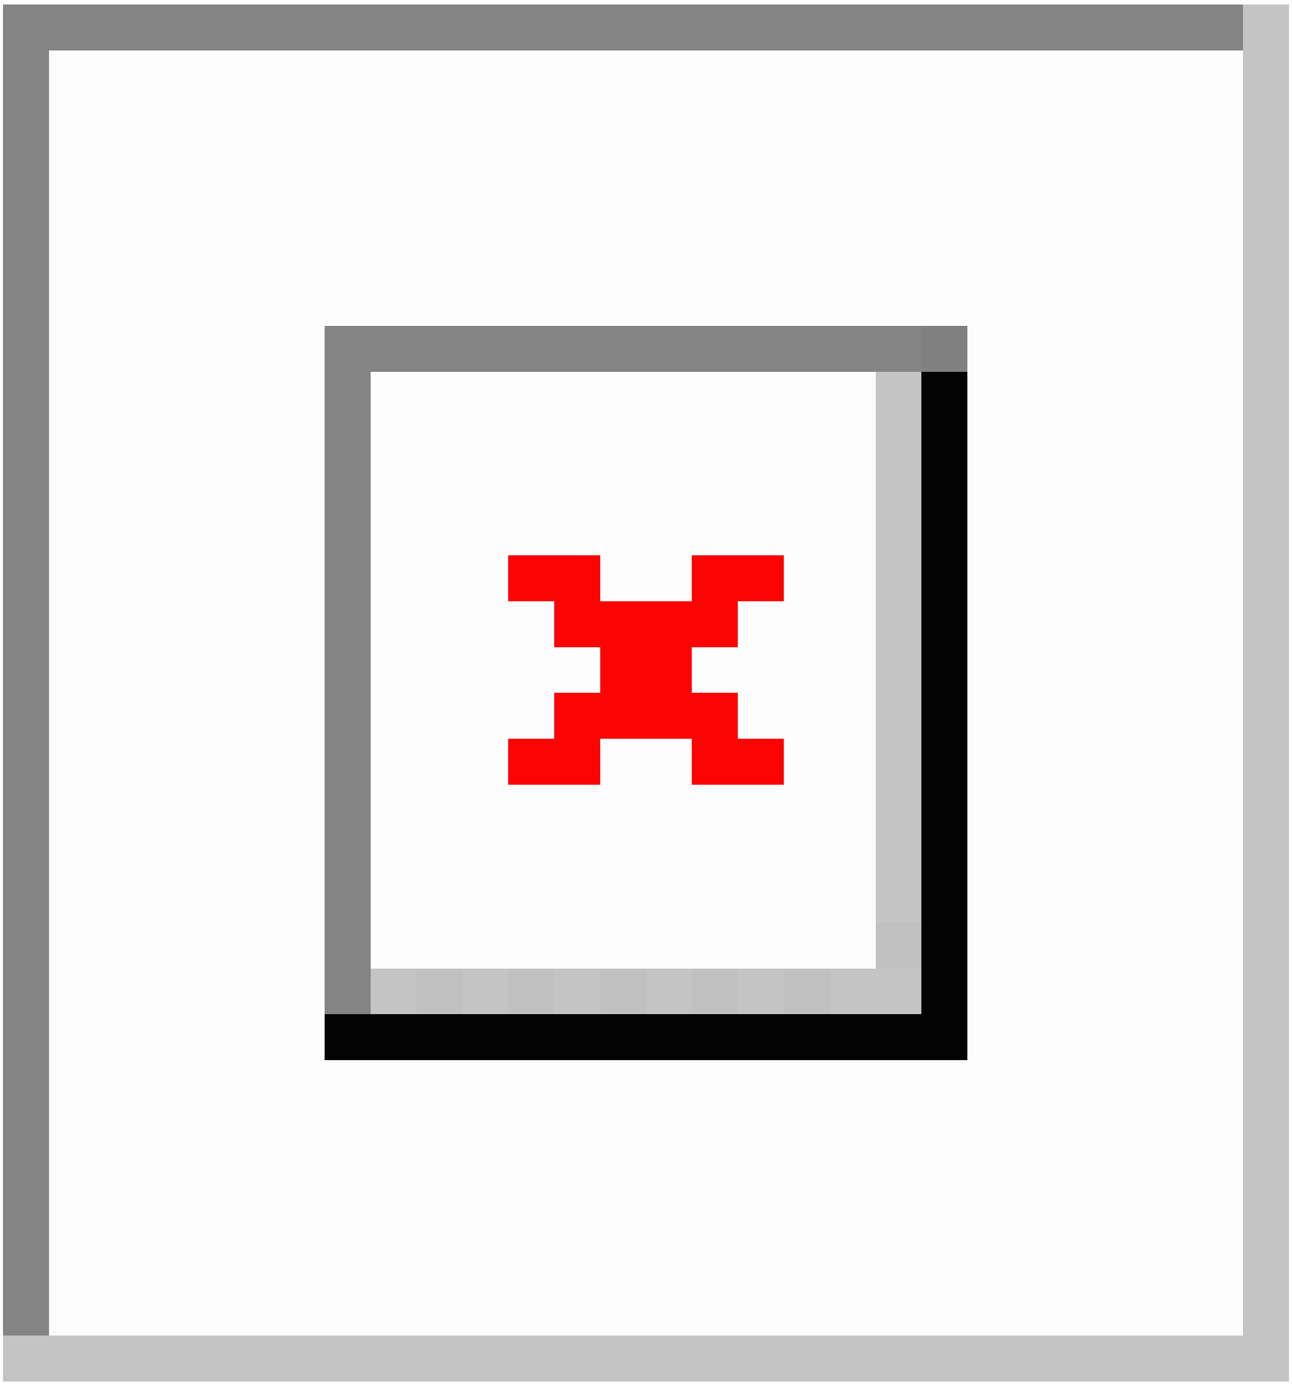
EPInfant Within Sessions

Infant effort significantly changed during the training sessions (*P*<.001; Table 7 and Figure 1). Fatigue peaked during the sessions but decreased by the end.

Table . Effort Perception Infant (EPInfant) score variability within the sessions.

Time point	Data points, n	EPInfant score			
		Range	Median (IQR)	Mean (SD; SE)	95% CI
Before the session	120	0-5	1 (0-3)	1.558 (1.549; 0.141)	1.278-1.838
In the middle of the session	120	0-7	4 (0-4)	3.633 (2.215; 0.202)	3.233-4.033
At the end of the session	120	0-9	2 (0-6)	3.117 (2.554; 0.233)	2.655-3.579

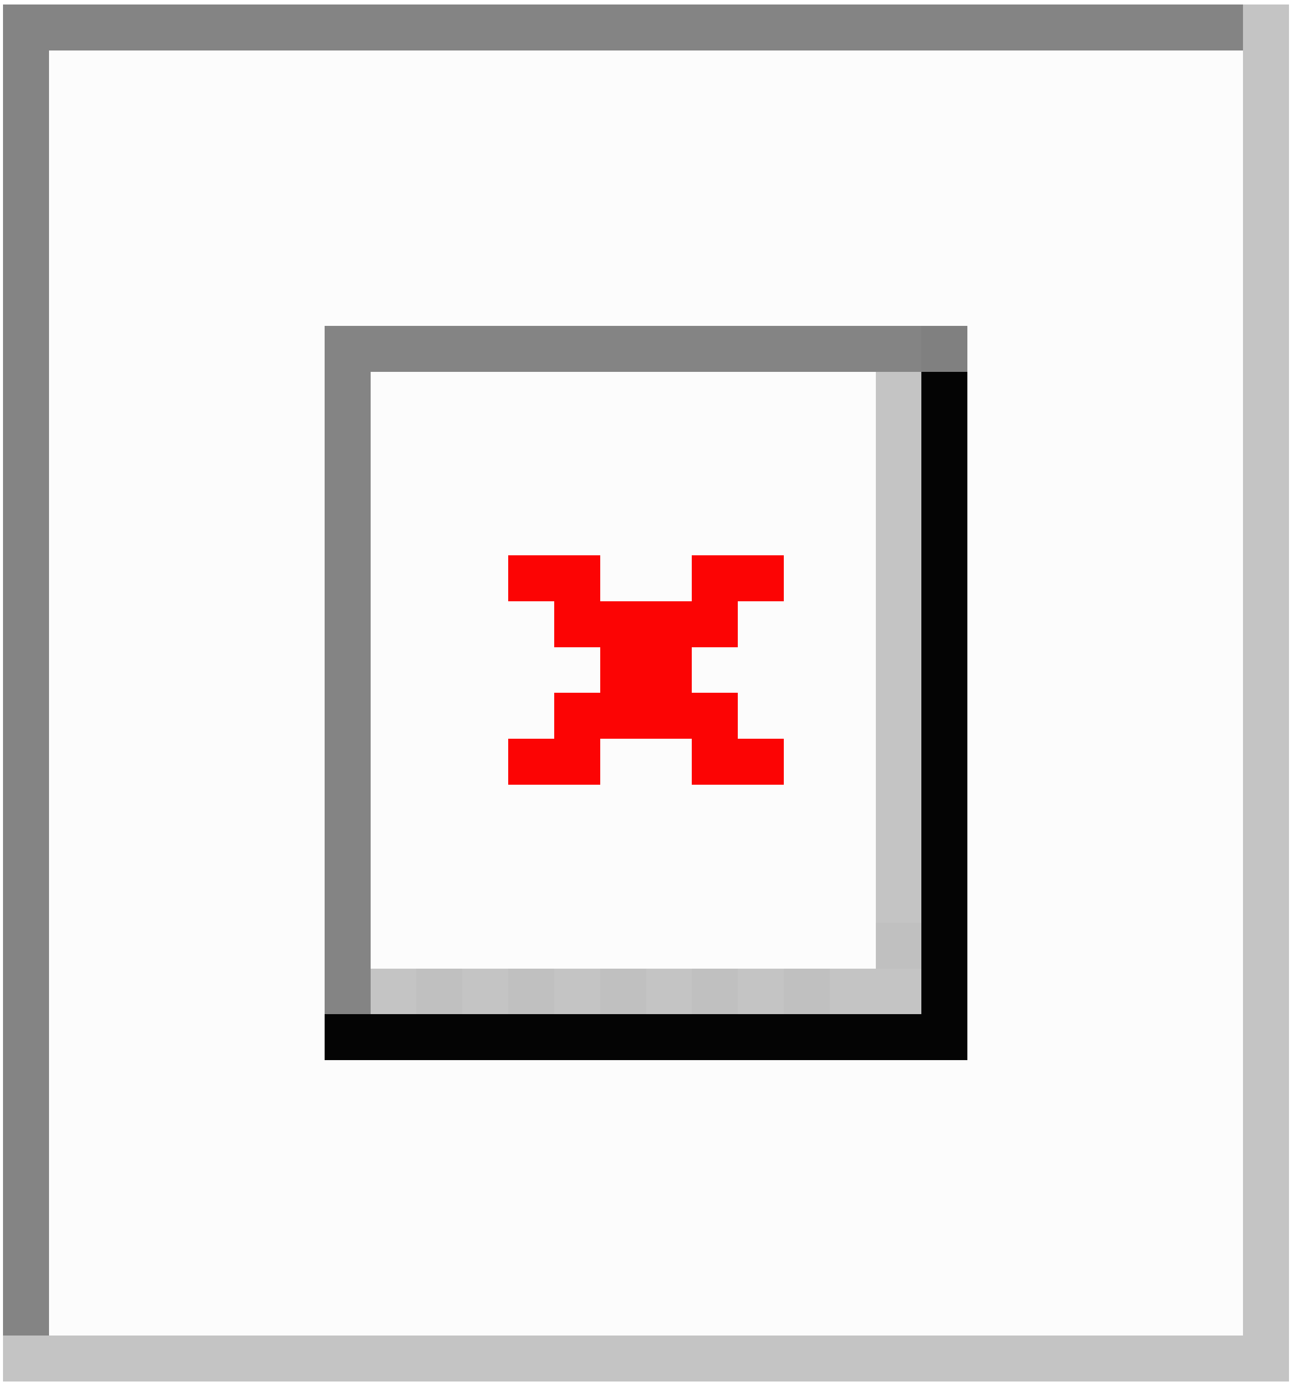
Figure 1. Effort Perception Infant (EPInfant) score variability within the sessions. Friedman test: χ^2_2=104.57, *P*<.001, n=120. Pairwise comparison by Wilcoxon test, with *P* values adjusted by Bonferroni correction. **P*<.05 and *****P*<.0001.



Evolution Throughout the Sessions

Infant effort significantly changed throughout the training sessions (*P*=.02; Figure 2). The highest fatigue peaks occurred during the first session, and fatigue perception was lower starting in the third session, even though the exercise intensity actually increased.

Figure 2. Fatigue perception evolution during the 10 sessions. Friedman test: χ^2_9=19.41, *P*=.02, n=36. Pairwise comparison by Wilcoxon test, with *P* values adjusted by Bonferroni correction.



The *P* value of the comparison between sessions 1 and 10 was statistically significant (*P*=.005), but the Bonferroni-adjusted *P* value was not (*P*=.24). Therefore, there was no significant comparison between the groups after the post hoc analysis.

Linear Mixed-Effects Model

There were significant differences between the different times and sessions (*P*<.05; Figures 3 and 4). The perception of fatigue decreased as the number of sessions increased; the perception of fatigue at the middle and end time points within the sessions was higher than at the beginning.

Figure 3. Linear mixed-effects models for the perception of fatigue. M1: model 1; M2: model 2. *P<.05 and ***P<.001.

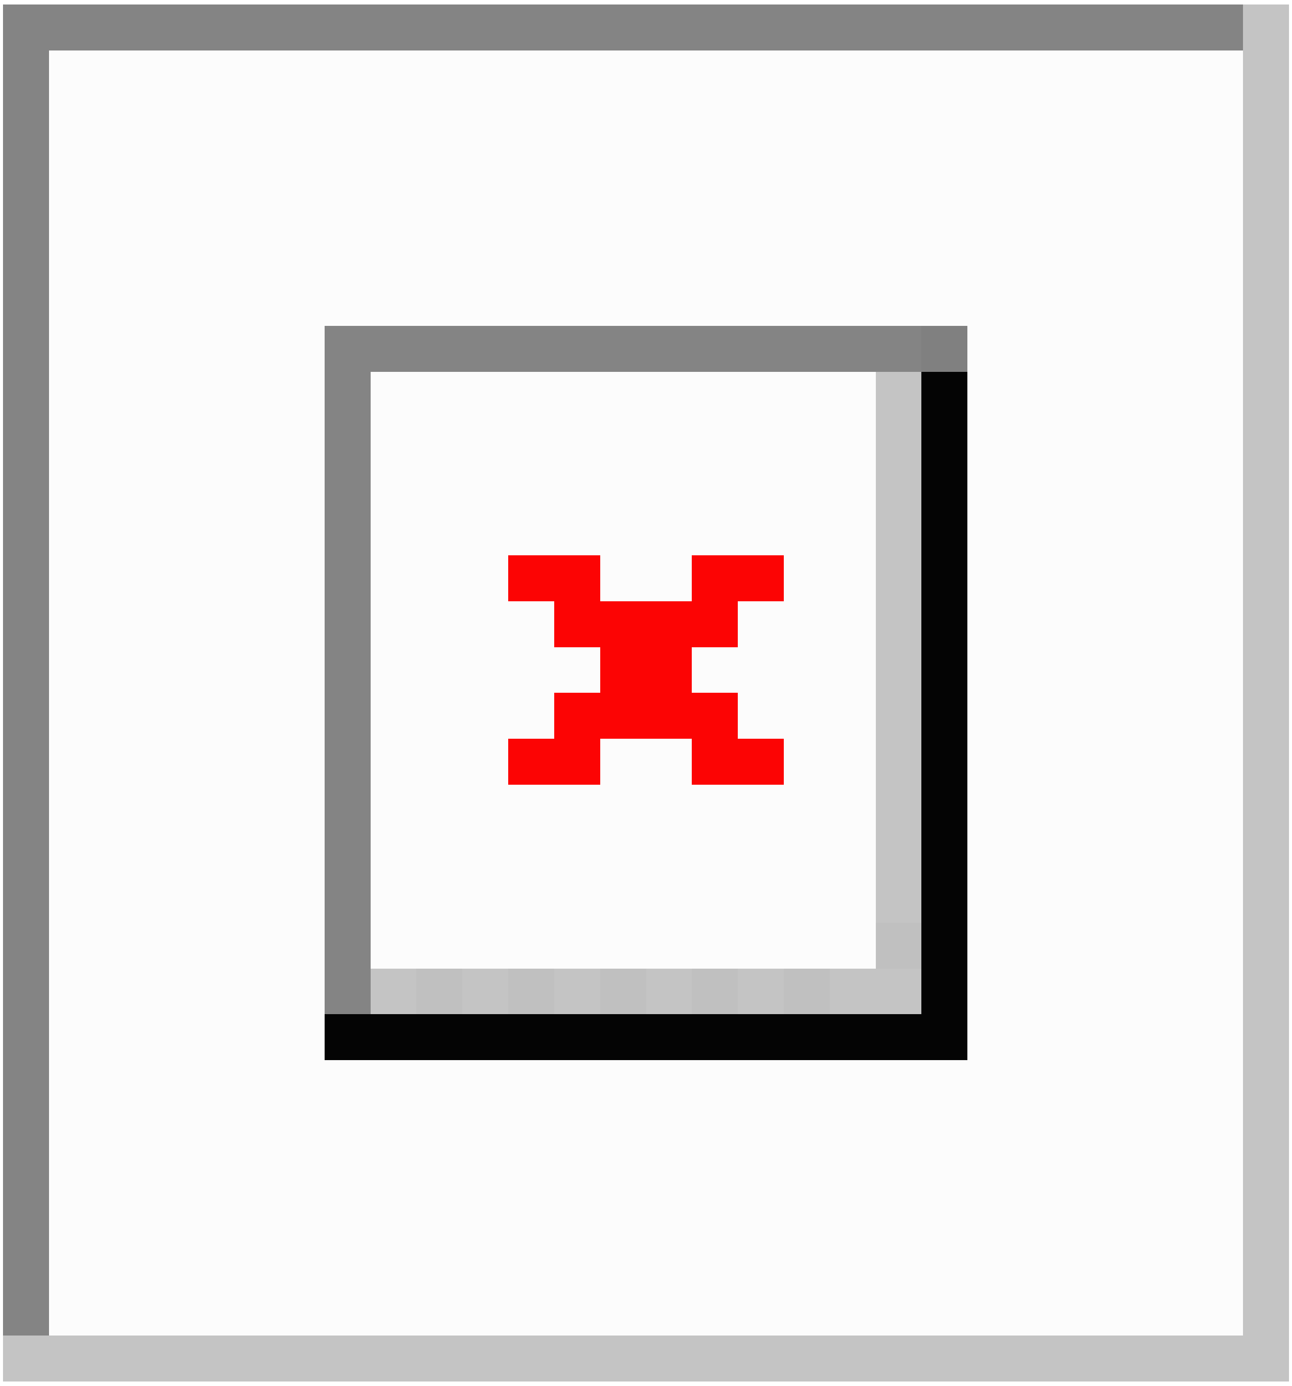


Figure 4. Comparison of 2-to-2 beats (comparing the start of the session to the middle, the middle of the session to the end, and the start of the session to the end. M1: model 1; M2: model 2.

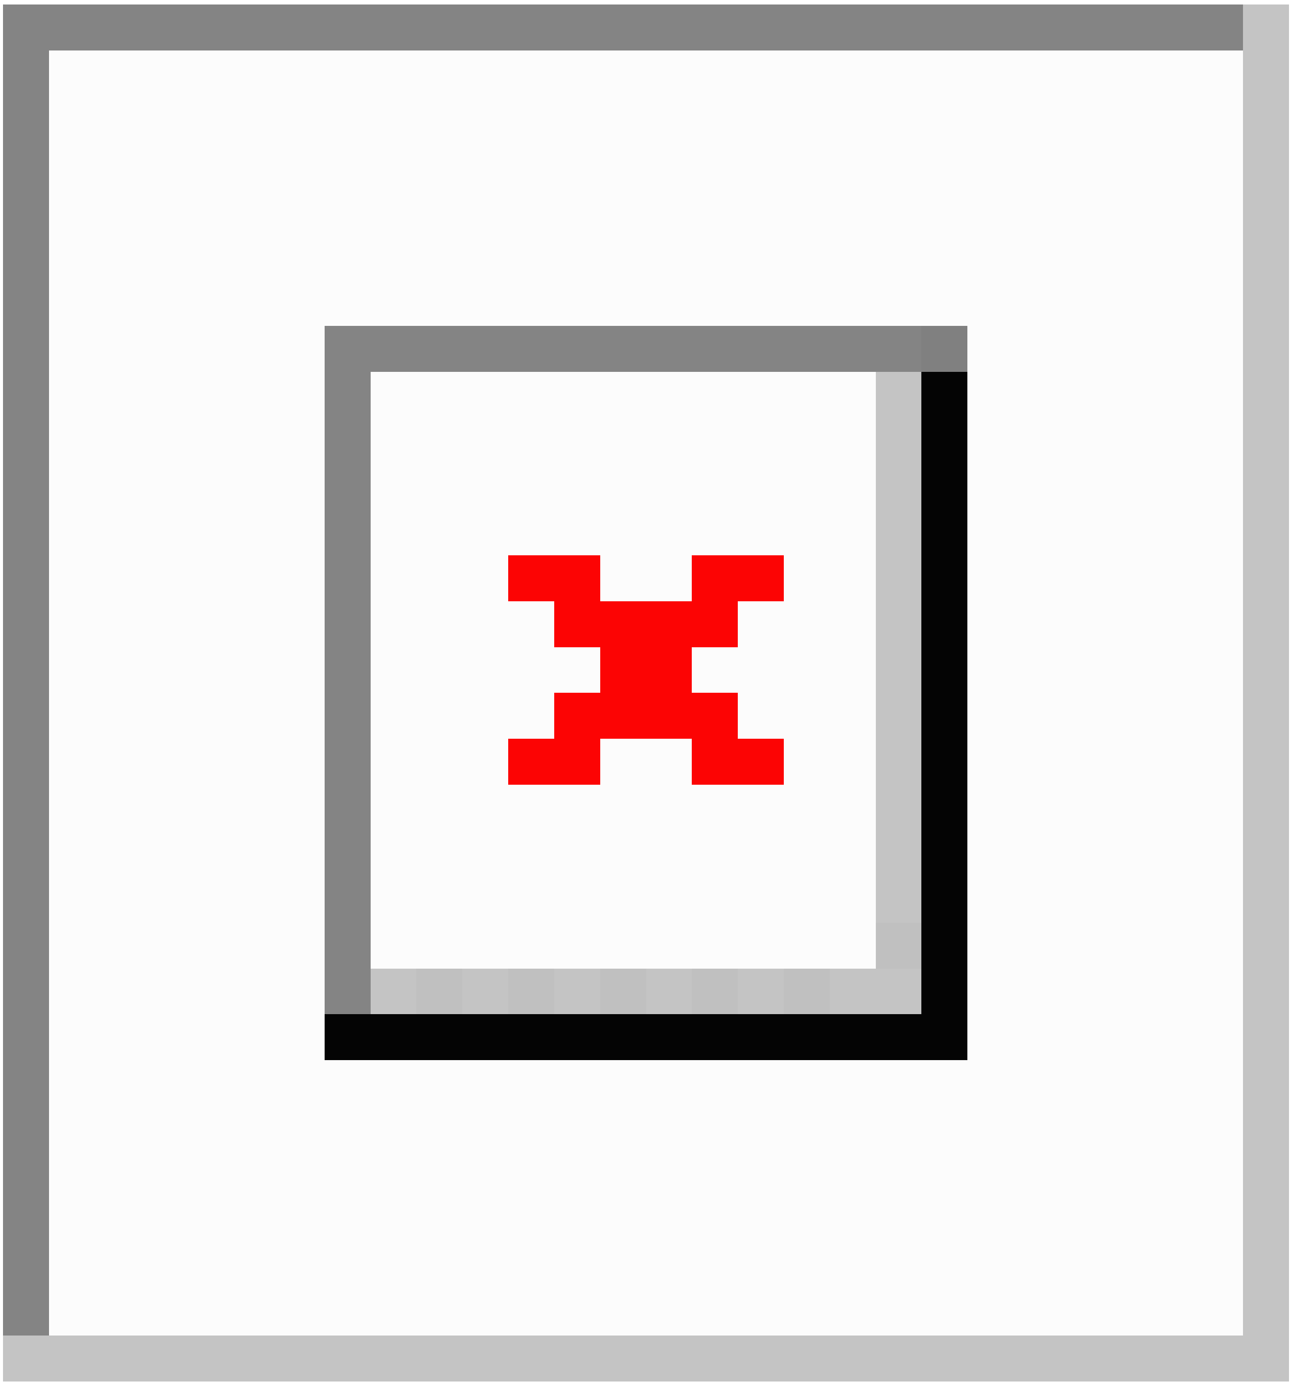

Fatigue Versus Motor Function Correlation

The Pearson correlation coefficient estimates the linear relationship between 2 continuous quantitative variables. The correlation is interpreted as follows: a positive correlation indicates a direct linear relationship between the 2 variables, whereas a negative correlation indicates an inverse linear relationship. The absolute value of the correlation indicates the strength of this association: 0-0.25=no correlation or very low correlation; 0.25-0.50=the association is weak; 0.50-0.75=the association is moderate to strong; and 0.75-1=the association is strong to perfect.

In Figures 5 and 6, the correlation values are shown in the lower-left triangle, and in the upper-right triangle, these values are depicted graphically. Blue color represents a positive relationship, whereas red color represents a negative relationship; furthermore, a larger circle represents a higher correlation.

Figure 5. Correlation matrix between fatigue data (session 1) and motor function (conventional treatment). 6MWT: 6-minute walk test; MFM: Motor Function Measure; NSAA: North Star Ambulatory Assessment; TUG: timed up and go test.

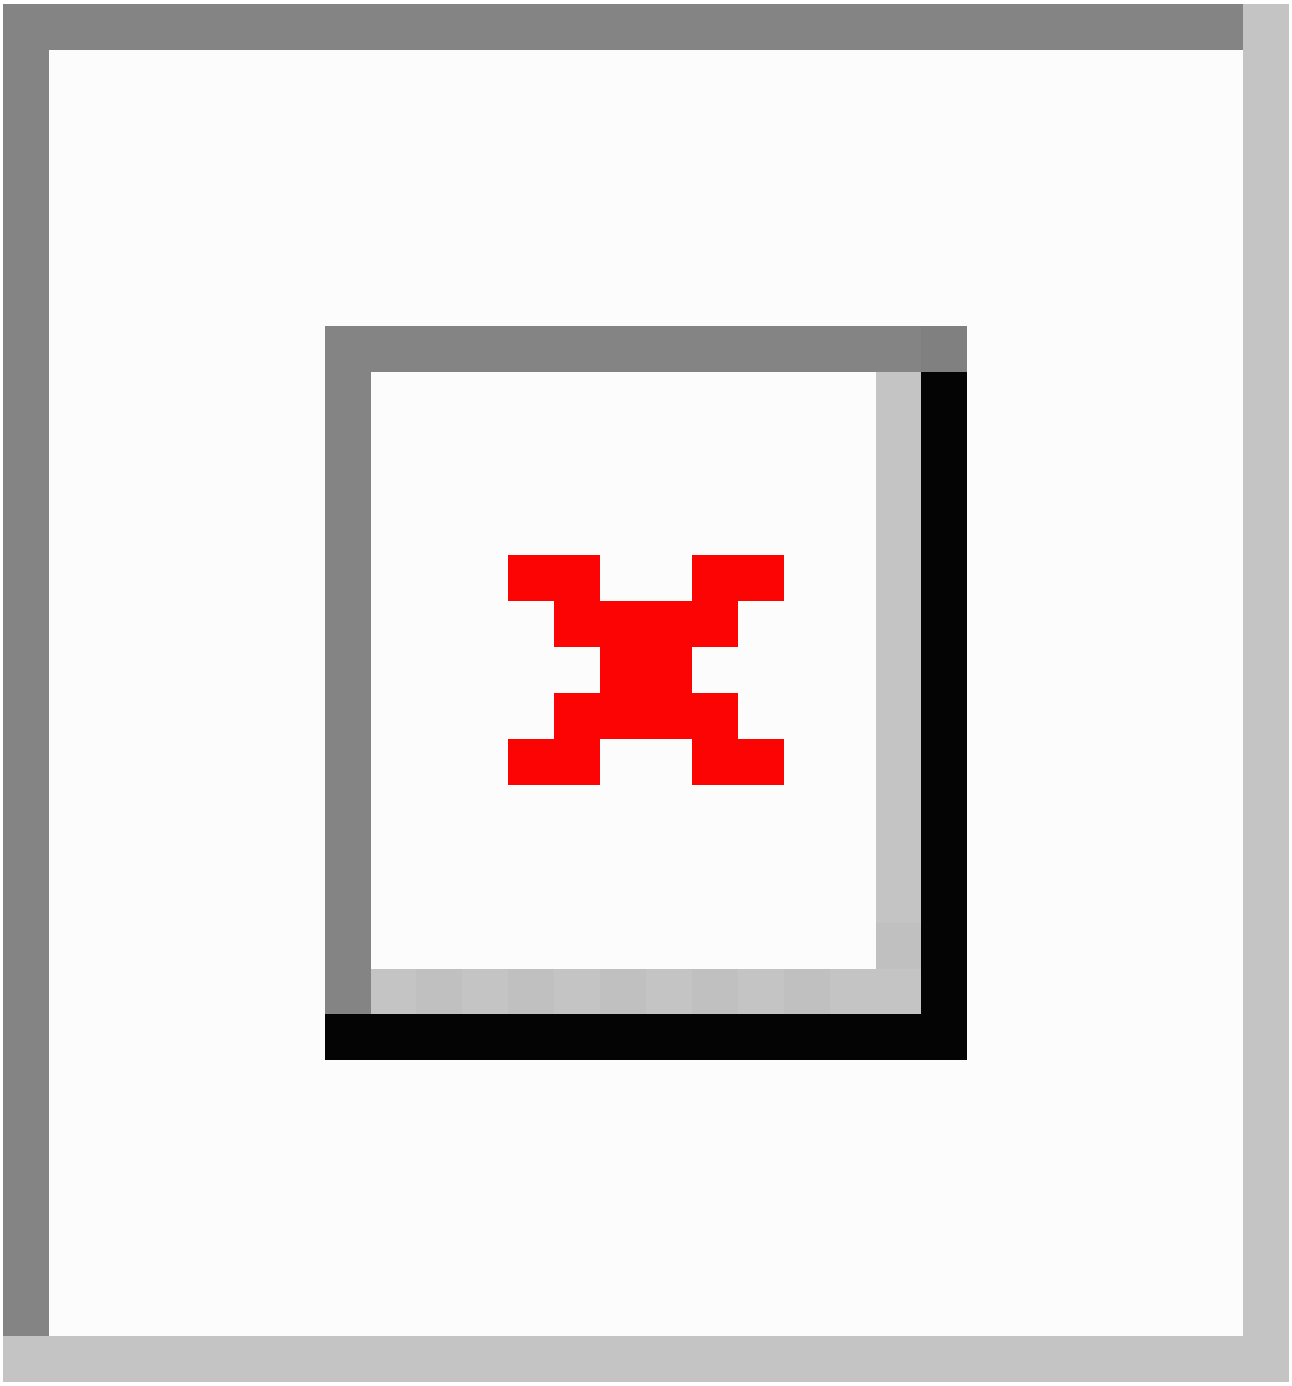

Figure 6. Correlation matrix between fatigue data (session 10) and motor function (telerehabilitation). 6MWT: 6-minute walk test; MFM: Motor Function Measure; NSAA: North Star Ambulatory Assessment; TUG: timed up and go test.

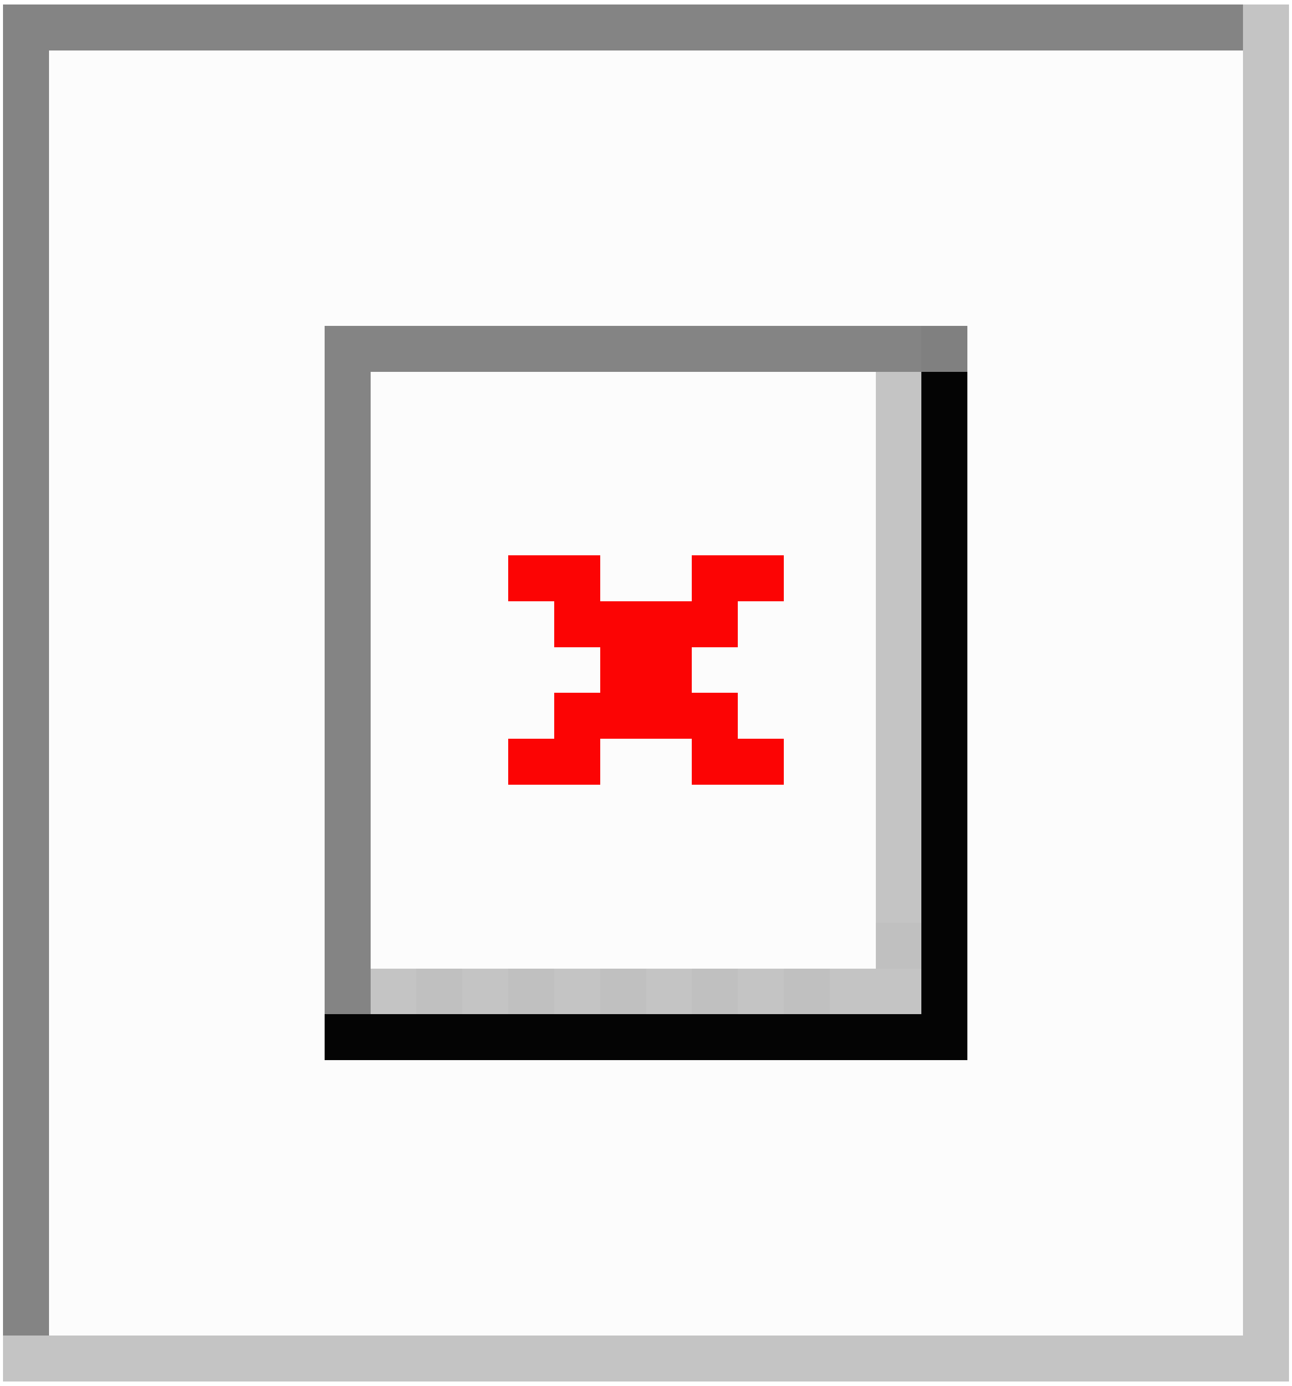

Discussion

Principal Findings

Considering telerehabilitation as a tool for physical therapy in children with DMD and BMD, the results of the functional tests did not show a significant change after 5 weeks of intervention. Although the 6MWT showed a 19.55-meter increase in the distance walked, this finding is not enough to confirm that one treatment is better than the other. However, it does help us understand that by conducting targeted training with children to carry out the test, its results are improved by decreasing the feeling of fatigue throughout the sessions.

The scores for the rest of the functional tests were the same before and after the program. Since the study was about progressive diseases, we can say that it is safe to carry out this type of program for short periods and that the motor skills of the children in the study did not get worse, as shown by the maintenance of the average score on the Vignos Scale.

Comparison to Prior Work

The study of the efficacy of physiotherapy techniques within the framework of neuromuscular diseases is very broad. In a recent systematic review [28], an analysis was carried out on the quality of the studies applied in DMD and the field of study, obtaining some enlightening results on the disease. There are studies on the quality of life and studies that show data on the costs of the disease and mortality [28]. Furthermore, there are studies of the progression and prevalence of the disease and treatment guidelines [4,21,24].

The COVID-19 pandemic physically affected children with DMD and BMD. The study conducted by Tunç et al [29] on the parents of 272 children confirms the significant effects on both the medical care and the patients' physical health. The reason the children did not attend physical therapy centers at the time was concern for contracting COVID-19. Most children did not follow physical therapy throughout the pandemic, and only 6% of the interviewed families had access to a telerehabilitation program at home.

It is well known that an established, continuous physical activity program is needed to maintain functioning in these types of dystrophy. Although the sample of our study was minimal and not limited to the Spanish territory, some of the children lived in towns far from resources and only received therapy once a month. In contrast, other children received weekly physical therapy and other therapies such as hydrotherapy.

Being able to bring physical therapy closer to these children is an achievement within the framework of telemedicine, which should be applied on a more regular basis. In fact, no patients abandoned the therapy during this study. In addition, we observed that the participants learned while performing the exercises, leading to decreased fatigue during the 10 sessions.

The main variable considered in this study was the 6MWT, since research for this disease considers it as a criterion for inclusion in pharmaceutical studies [30]. The NSAA also helped us predict the risk of the loss of ambulation of the participants [31].

Scientific literature supports the use of new technologies as a treatment for children with DMD. Thus, in 2019, de Freitas et al [32] compared performance in a virtual task using interfaces with and without physical contact to identify the use of different devices according to the functionality of the population with DMD. They found that leap motion provided better performance for people with DMD. Similarly, in 2020, Capelini et al [33] conducted a study with 50 individuals with DMD and a control group of 50 healthy individuals using a motor and visual task on a mobile phone. Performance improvement was obtained in a motor learning protocol using a mobile phone. The authors concluded that the use of technology could improve function in people with DMD.

In this study, since there was no control group, the 2 conditions were compared: when the children with DMD and BMD who could walk received the conventional treatment and when they received telerehabilitation. This differs from the study by Kenis-Coskun et al [34], which compared 2 groups with a sample of 19 children, where 1 group followed a telerehabilitation program and the other group performed exercises led through videos. Regarding the duration of the study, we conducted 2 sessions per week for 5 weeks, whereas Kenis-Coskun et al [34] conducted 8 sessions per week for 8 weeks. That study concludes that the telerehabilitation approach led to improvements compared to the group that performed exercises autonomously through the video program. Their conclusion reinforces our opinion that even in telerehabilitation, the presence of the physical therapist during the sessions to adjust the exercises helps to maintain functioning in children with DMD and BMD. The stretching-based program did not lead to clear results that could be implemented in future studies. However, we added aerobic exercises and the child's own work at submaximal levels of physical effort, and the results showed that the functional capacities of these children did not decrease, even though the 19.55-meter increase in the 6MWT was not significant enough to conclude whether the program duration was long enough. In future studies, the programs should be extended for several months to show clearer results.

This program included respiratory exercises that are meant to be fun and designed for autonomous practice. However, some of them needed some family support, mainly to maintain the attention needed to do them. All the children who participated completed the exercises independently and found them to be fun. Sobierajska-Rek et al [5] conducted a study in 2021 where 45 children were instructed to do some exercises at home and then answer a survey. The caregivers explained that the exercises could be carried out at home, although most of the children needed help to be able to do them.

Strengths and Limitations

A positive aspect that we found after carrying out the web-based program is its acceptance by children and their families. All the participants completed the 10 sessions at the indicated time.

The main limitation of this study was the small sample size. Since DMD and BMD are rare diseases, the eligible population was scarce. Furthermore, as the aim was to enroll children who could walk to perform the exercises while guided by the physical therapist as autonomously as possible, many children could not participate due to related cognitive and attention problems.

The second limitation was that we were unable to obtain significant differences between the variables measured. Future studies should assess maintaining the program for a longer time to see if there are significant differences.

The third limitation was regarding the economic aspect. Carrying out the study with glasses that could measure other parameters, such as heart rate, would have made it easier to measure fatigue during the exercises instead of relying on the child's own perception. However, such glasses would be more expensive to send 1 to each participant, limiting participation to those who have a specific type of glasses.

Future Directions

Telerehabilitation should be considered as an additional tool that has come to stay and should be implemented as routine therapy [35]. Since muscular dystrophy is a progressive disease, other types of interventions that manage the maintenance of motor functions instead of their improvement should be considered for future long-term studies. This type of program could be carried out in web-based groups, facilitating fun during physiotherapy training and not just passively stretching the muscles. It would initiate more conscious and active work at home by the child and their caregivers.

Conclusions

Telerehabilitation is a useful tool to bring physical therapy to children who cannot go to a specific place to follow it. Although motor function as measured through the applied scales generally remained the same in the study, we can conclude that there were no significant differences between a conventional physical therapy treatment and a telerehabilitation program applied for 5 weeks. Therefore, this tool could be used without harming children with DMD and BMD, facilitating their access to therapies and stimulating learning to maintain their functional capacity. The learning effect helped reduce the feeling of fatigue in the children during the program.

Future studies should be carried out with a larger sample size and for a more extended period, to show whether a telerehabilitation program sustained over time helps maintain functioning in children with DMD and BMD and perhaps compare the results obtained between children with DMD and children with BMD.

Acknowledgments

MRB-B would like to thank her director, RM-V, and her thesis tutor, MTLM, as well as the Physiotherapy Department of the University of Málaga. The authors are also very grateful to Lidia Parra, the funder of Arenas de Monsul, Almería, and Beatriz de Andrés, the director of Ríe, Madrid. We would also like to thank the BIOSTATECH company for helping us with the statistical analysis. The funding source for this study is the Illustrious Professional College of Physiotherapists of Andalusia (COD. AI-05/2021).

Data Availability

The 11 videos used to carry out this project can be found on the web [20]. Some cannot be added to the list because they contain children's content.

Abstract

Background: Children with chronic ankle instability (CAI) frequently experience ankle unsteadiness, causing trips, falls, and ankle sprain injuries resulting in poor quality of life. A specific exercise program focused on physical and psychological purposes in children with CAI is needed.

Objective: The purpose of this study was to investigate the feasibility of a 4-week home-based exercise training program using active video games (AVGs) for balance, motor proficiency, foot and ankle ability, and intrinsic motivation in children with CAI.

Methods: Sixty children with CAI (mean age 10, SD 2 years) were randomly assigned to an experimental group (AVG group; n=30) or a control group (CG; n=30). The AVG group played 2 selected video games, Catching Fish and Russian Block, while the CG received the traditional exercise program for CAI. Both programs were scheduled for 30 minutes per day, 3 times per week, for 4 weeks at home. The single-leg stance test was used to assess static balance. The walking forward on a line and standing long jump tests were used to assess motor proficiency. The Foot and Ankle Ability Measure (FAAM) and the Intrinsic Motivation Inventory questionnaire were used to assess foot and ankle ability and intrinsic motivation, respectively. Assessments were conducted at baseline and after 4 weeks.

Results: In the AVG group, the single-leg stand test (eyes open; on floor and on foam conditions), the FAAM (activities of daily living subscale), and intrinsic motivation (interest/enjoyment, pressure/tension, and value/usefulness dimensions) were improved compared with the CG (all *P*<.05). Motor proficiency did not differ between the 2 groups at the end of the 4-week program (*P*=.31 for the walking forward on a line, *P*=.34 for the standing long jump test).

Conclusions: A 4-week home-based exercise training program using AVGs can be beneficial and may be an effective approach for improving balance, foot and ankle ability, and enhancing positive motivation by increasing the interest/enjoyment and value/usefulness dimensions and lowering the pressure/tension dimension in children with CAI that require long-term rehabilitation sessions.

Introduction

Chronic ankle instability (CAI) is a condition characterized by a recurring giving way of the lateral side of the ankle and usually develops after repeated ankle sprains [1]. The indicators of CAI include mechanical instability, perceived instability, and recurrent sprain, which can occur independently or in combination [1]. In children, CAI has been reported in those with a history of ankle sprains or a high BMI and in youth athletes (eg, soccer players and dancers) [2-4]. Children with CAI frequently experience ankle unsteadiness, causing trips, falls, and ankle sprain injuries [4]. To prevent the long-term detrimental impact of CAI on quality of life and activities of daily living, the feasibility of therapeutic exercise programs for children with CAI would appear warranted.

The mainstay of research to date has focused on specific exercise programs in the adult population with CAI [5-11]. For example, Seyedi et al [11] investigated the efficacy of a 4-week progressive home-based balance training program using single-leg stance, crossed-leg sway, single-leg squat, heel raise, and lunge/jump exercises in college students with functional ankle instability. The results demonstrated notable improvements in daily activity following training. Interestingly, scant research attention has focused on developing specific exercise programs in children with CAI [12,13]. To the best of the authors' knowledge, only one study in children with foot and ankle weakness demonstrated that a 24-week high-intensity progressive resistance foot and ankle exercise program could strengthen the affected muscles and enhance the quality of life of children [14].

It is important to note that children commonly show nonadherence and lack of motivation during long-duration in-home physiotherapy training. It has been suggested that this might, in part, be due to the repetitive nature of therapeutic practices [15,16]. Therefore, much attention has recently been paid to the use of active video games (AVGs) or "exergaming" as an alternative method for therapeutic exercise in children with conditions [17,18] such as attention-deficit/hyperactivity disorder [19], type 2 diabetes [20], cerebral palsy [21], cancer [22], and developmental coordination disorder [23]. AVGs are technology-based games that track body movement or reaction to the game with instantaneous visual or audio feedback. It is proposed that this could promote physical and psychological benefits by offering the opportunity to enjoy training [18]. Furthermore, the interactive and engaging nature of the training program could result in promoting adherence and motivation through the player's desire to complete the challenges of the game [7,24].

In children, previous studies have reported the effectiveness of AVG training on physical activity [22], gross motor skills [25,26], balance [26], daily living ability [26], voluntary motor control [27], and dynamic postural stability [28]. However, the effectiveness of AVG training in children with CAI has yet to be investigated. In a previous study at our laboratory, Chuadthong and Lekskulchai [29] compared movement patterns in children with CAI while playing 4 AVGs, including Catching Fish and Russian Block, as well as dancing and running games. The findings suggested that Catching Fish and Russian Block elicited greater specific movement patterns, such as single-leg stance, double-leg stance, and reaching direction, suggesting that these might be effective game-based rehabilitation programs for children with CAI.

Therefore, this study selected these 2 video games (ie, Catching Fish and Russian Block) from Stepmania Coilmix [30] to be used in the AVG training program due to the movement strategies of the games. We hypothesized that an AVG training program would have positive physiological and psychological outcomes in this population. More specifically, this study aimed to investigate the effectiveness of a 4-week home-based AVG exercise training program for improving balance ability, muscle strength of the foot and ankle, and intrinsic motivation in children with CAI.

Methods

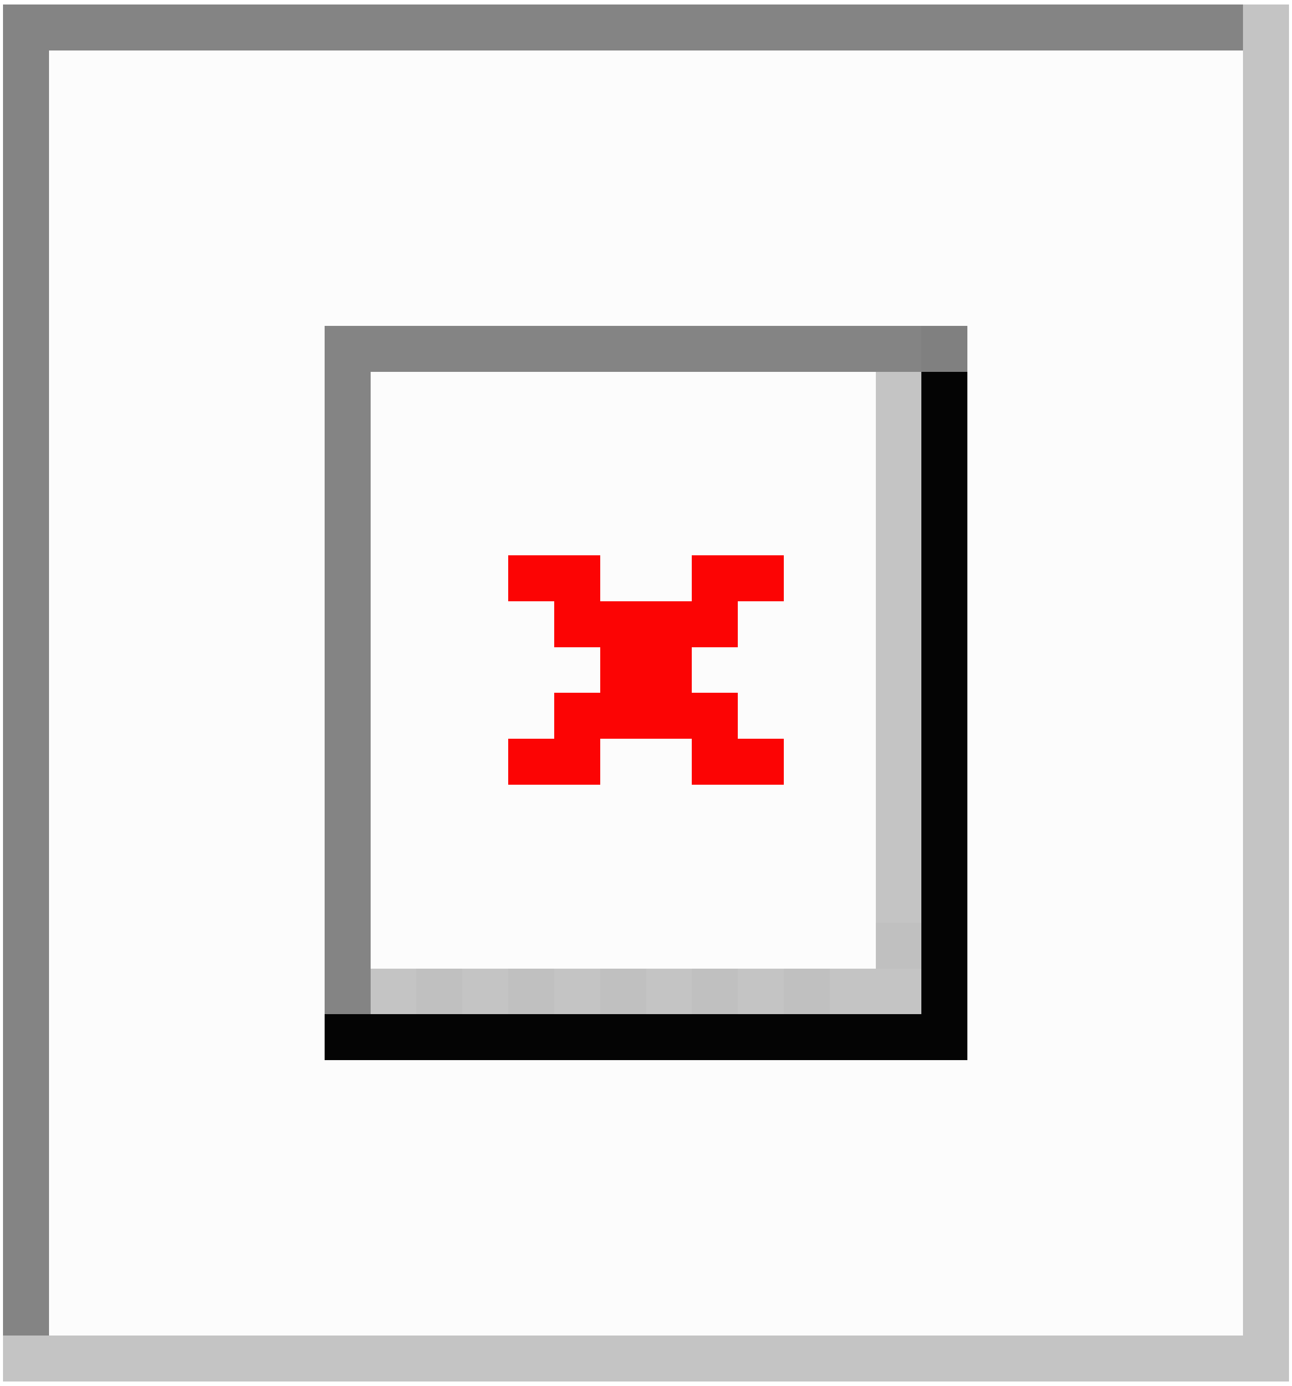
Sample Size

This study calculated sample size estimates from a previous study [3] using G*Power (version 3.1.9.2; Universität Düsseldorf) with a Cohen *f* effect size of 0.7, an α of .05, and a power of 0.8. The calculated sample size was 54 plus 6 for 10% dropout, so a final sample size of 60 participants (30 participants for each group) was needed.

Study Design and Participants

This study was a single-center, assessor-blinded, randomized controlled trial. The participants were matched by age and gender and randomly assigned to either the AVG group (n=30) or the therapeutic exercise program for the control group (CG, n=30) using a computer-generated program. The CONSORT (Consolidated Standards of Reporting Trials) flow diagram of this study is shown in Figure 1. Sixty nonathletic, typically developing children with CAI aged between 7 and 12 years and with BMI between the 5th and 85th percentiles on the US Centers for Disease Control and Prevention growth chart [31] volunteered for the study. Inclusion criteria were (1) a score equal to or less than 25 on the Cumberland Ankle Instability Tool–Youth (CAITY), Thai version [32], (2) recurrent ankle sprain more than 3 months before enrollment, (3) a feeling of giving way at least twice a year, and (4) unilateral ankle sprain at least 1 year before enrollment. Participants were excluded if they had a history of either (1) ankle fracture, ankle surgery, or neurological disorder; (2) health problems such as uncontrolled seizure, asthma, severe heart disease, hearing problems, or visual problems that could not be corrected by using a lens; and (3) current participation in another rehabilitation program for the ankle joint.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of the study participants.



Ethical Considerations

The study conformed to the Declaration of Helsinki and was approved by the local Institutional Review Board Ethics Committee (MU-CIRB 2020/387.2311). After an explanation of the exercise protocol, testing procedures, and benefits and possible risks of the study, the informed consent form was signed by the parents or guardians and the assent form was signed by the participants.

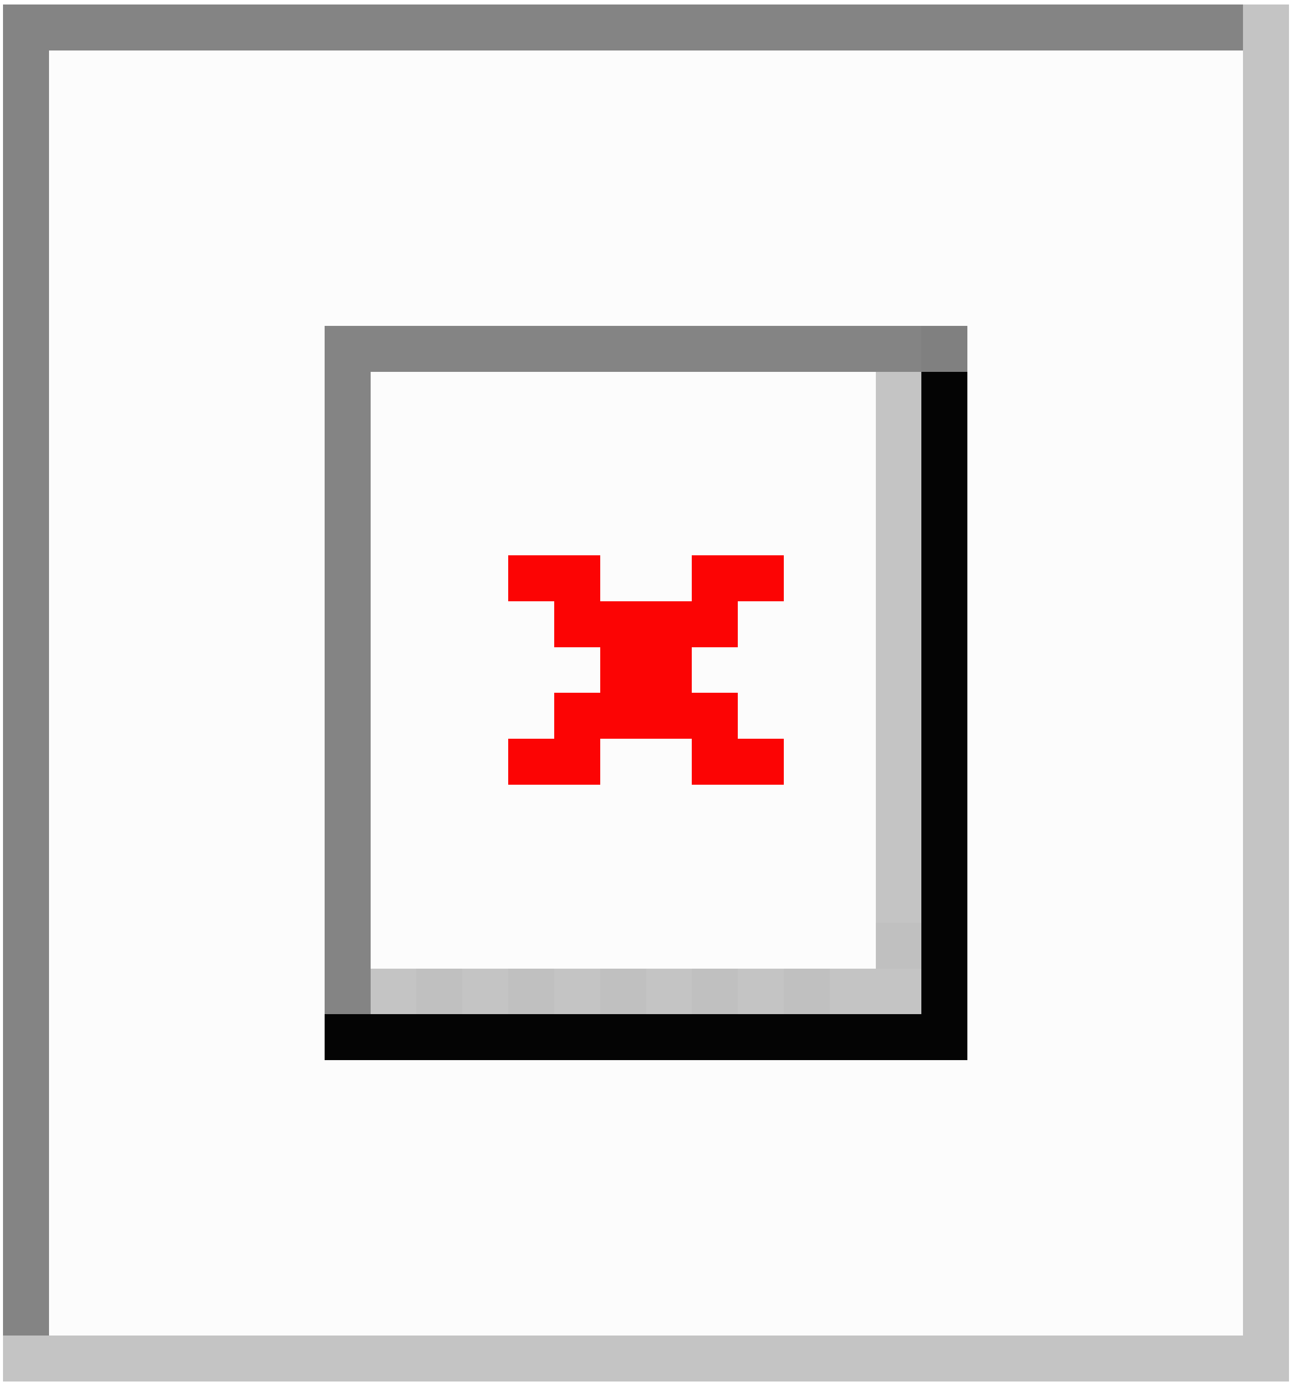
Experimental Procedure

The experimental group performed the AVG exercise program, whereas the CG performed the therapeutic exercise for the CAI program [33]. Both programs were scheduled for 3 sessions per week and 30 minutes per session for 4 weeks at home (a total of 12 exercise sessions). The 30-minute CG and AVG exercise programs consisted of a 5-minute active warm-up, a 20-minute main exercise, and a 5-minute cooldown. To assess compliance with the study protocol, the researchers followed up with participants once a week with a phone call. Balance ability tests and ankle instability questionnaires were evaluated at week 0 and week 4. The Intrinsic Motivation Level (IML) questionnaire was assessed each week over the course of the 4-week program [34].

Therapeutic Exercise Program for CAI (CG)

The design of the exercise program used in this study was adapted from the Star Excursion Balance Test (SEBT) [28]. Briefly, participants were asked to stand on one leg and then slowly reach with the other leg in different directions. This involved reaching in the anterior posteromedial and posterolateral directions as far as possible, touching down along the guideline, and then returning to the starting position (Figure 2). Each direction was completed as a separate trial. Participants were asked to perform 10 trials in each direction for 2 rounds with a 5-minute rest between rounds (for a total main exercise duration of around 20 minutes). Participants used their affected limbs first and then changed to the other limb. The program was designed to gradually increase the reaching distance of the leg (in centimeters) every week (by 50%, 60%, 70%, and 80% of the baseline value in weeks 1, 2, 3, and 4, respectively).

Figure 2. Outline of the therapeutic exercise for chronic ankle instability.

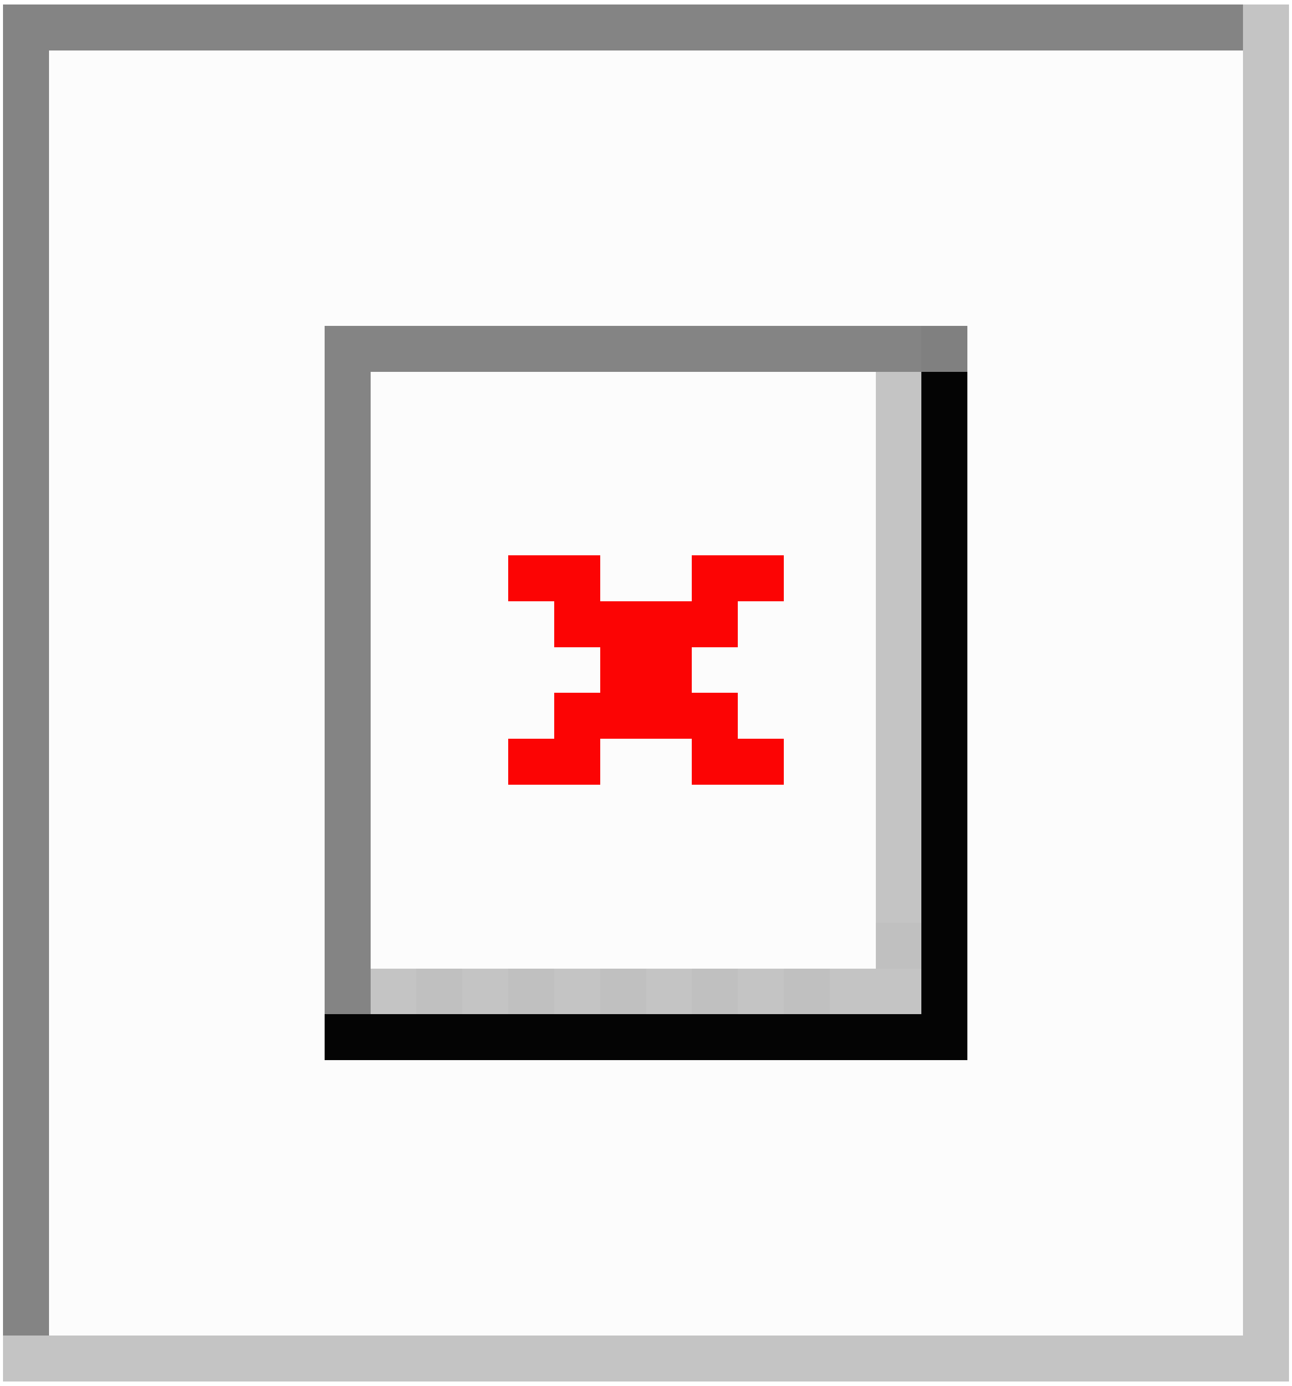


AVG Exercise

The AVG program (Figure 3) comprised 2 selected video games (ie, Catching Fish and Russian Block) from Stepmania Coilmix, a cross-platform rhythm video game and engine with a wireless dance mat [30]. In Catching Fish, participants stood in the center of the mat before starting the game, then moved their feet either in the left or right direction in response to the game (ie, they pressed the corresponding arrows to catch the yellow or red fish). Participants had to continue playing the game as long as possible, with 4 chances to obtain a higher score. Similarly, for the Russian Block game, participants stood in the center of the mat before starting, then moved their feet in the left or right direction to change and manipulate the shape of the falling Tetromino piece shown on screen. To challenge the players, the piece will be moved faster, and it will become more difficult to correct the position. By the end of the game, the total score is shown.

The total exercise duration for the 2 games was approximately 20 minutes. If one of the games ended before 10 minutes, participants were required to start playing again from the beginning. For convenience and to promote adherence, the AVG devices were set up in the participants' homes. The researchers provided instructions and demonstrations until the parents and children could operate the device correctly with no assistance.

Figure 3. Outline of the active video games. (A) Catching Fish; (B) Russian Block.



Outcome Measurements

Static Balance Tests

A single-leg stance test (SLST) was used to assess static balance. Participants were asked to stand on their affected limb and flex the hip and knee joints of the unaffected limb to 90 degrees for up to 30 seconds [35]. The tests were assessed in 4 conditions, including standing with eyes open (EO) or eyes closed (EC) on a stable surface (EO-floor and EC-floor) or a foam surface (EO-foam and EC-foam). The start time was when the foot was lifted off the floor. The test was stopped when any of the following occurred: (1) 30 seconds expired, (2) there were changes in the position of the weight-bearing foot, (3) any body part except the weight-bearing foot touched the floor, and (4) the participants opened their eyes during the EC trials. The test was measured 3 times. The test-retest reliability of the test was assessed and ensured using the intraclass correlation coefficient

(ICC). We used the ICC (3,1) type and found that ICC was 0.793.

The Bruininks-Oseretsky Test of Motor Proficiency

The balance subtests (ie, walking forward on a line test and standing long jump test) of the Bruininks-Oseretsky Test of Motor Proficiency, second edition (BOT-2) [36,37] were used to assess functional balance and muscle strength. The ICC of the BOT-2 was 0.789.

For the walking forward on a line test, participants stood with feet together and hands on hips, with the preferred foot on and parallel to the line. This test was conducted one time but allowed for a second time if a participant did not achieve the maximum score of 6 correct steps. The primary investigator recorded the number of correct steps, up to 6. An incorrect step was recorded when the participant either stepped off the line, failed to keep hands on hips, or stumbled or fell.

For the standing long jump test, participants were asked to stand behind the start line, then jump forward as far as possible and try to land on their feet. This test was conducted one time; however, if the participant stumbled or fell, a second attempt was conducted. The researcher recorded the distance (in cm) from the start line to the heel.

Ankle Instability Questionnaire

The Foot and Ankle Ability Measure (FAAM) questionnaire is a commonly deployed diagnostic tool to assess foot and ankle ability for participation level [38,39]. It contains 2 subscales, one including 21 items on activities of daily life (FAAM-ADL) and the other 8 items for sports (FAAM-Sport). All participants rated their current level of difficulty when performing various tasks (eg, standing, walking up and down hills, and going up and down stairs for FAAM-ADL and running, jumping, and cutting or lateral movements for FAAM-Sport) with one response that most closely described their condition within the past week. If an activity was limited by something other than their foot or ankle, the question was marked not applicable (4=no difficulty, 3=slight difficulty, 2=moderate difficulty, 1=extreme difficulty, 0=unable to do, and N/A=not applicable). Percentage scores were obtained by converting item score totals ranging from 0 to 84 for the ADL subscale and from 0 to 32 for the sports subscale. A score below 90% on both subscales signifies functional ankle instability in participants. Higher scores indicate better self-reported function.

Intrinsic Motivation Inventory Questionnaire

The Intrinsic Motivation Inventory (IMI) is a multidimensional questionnaire used to assess the participant's subjective perception of a target activity [34,40]. It uses a 7-point Likert scale (ranging from 1=strongly agree to 7=strongly disagree) [41]. This questionnaire assesses 5 dimensions: interest/enjoyment; perceived competence; effort/importance; pressure/tension; and value/usefulness. The mean IMI scores were calculated for each dimension. According to a previous study conducted at our laboratory, the IMI is feasible and understandable for children aged 7 years without any indications, since the questions consist of simple words and are easy to understand [29]. However, to ensure correct use, parents and children practiced under the supervision of an investigator before going home. For the first use, the investigator visited each child's home to supervise them. Later, any problems with the use of the questionnaire were noted by the parents in the child's logbook. Furthermore, the investigator called once a week to assess their compliance with the study protocol.

In the child's logbook, feasibility was recorded as the rate of recruitment, retention, and adherence to the training intervention; safety was also recorded as the number of adverse events during testing or training.

Statistical Analysis

Shapiro-Wilk tests were carried out to examine the normality of the data, and all data were found to be suitable for parametric testing. In addition, the sphericity of data was considered using the Mauchly test of sphericity; where the sphericity assumption was violated, Greenhouse-Geisser corrections were applied. Independent 2-tailed *t* tests were performed to compare the means and differences of each dependent variable at the baseline assessment. A 2-factor mixed model ANOVA was used to evaluate the effect of treatment group and time for the SLST, functional balance and strength test, and FAAM questionnaire. A repeated measure ANOVA was used for the IMI questionnaire. Any interactions between group and time were revealed using post hoc 2-tailed paired *t* tests with a Bonferroni correction to determine any differences within each group between the time points. The observed effect size was expressed as partial η squared (ηp^2), with values of 0.1-0.29, 0.3-0.49, and >0.50 representing a small, medium, and large effect size, respectively [42]. The change score was calculated from the difference between data from week 4 minus data from week 0 using independent 2-tailed *t* tests. A $P<.05$ was considered statistically significant.

Results

Demographic characteristics and screening tests of participants are displayed in Table 1. Independent 2-tailed *t* tests showed no significant differences between the AVG and the CG at week 0 at the $P>.05$ level.

Table . Baseline characteristics of the active video game (AVG) group and the control group (CG), which received therapeutic exercise for chronic ankle instability (n=30 for each group). Data were analyzed with an independent 2-tailed *t* test. The significance level was set at *P*<.05.

Characteristics		AVG group	CG	*P* value
Gender, n				.43
	Boy	14	11	
	Girl	16	19	
Age (years), mean (SD)		10 (2)	10 (2)	.51
Weight (kilograms), mean (SD)		32.8 (9.6)	34.0 (11.1)	.68
Height (centimeters), mean (SD)		135.2 (11.7)	136.7 (11.9)	.62
Side of chronic ankle instability, n				.43
	Right	20	17	
	Left	10	13	

For the SLST, the mixed model ANOVA tests revealed significant interactions between groups for EO-floor ($F_{1,58}$=7.11; *P*=.004; ηp^2=0.02) and EO-foam ($F_{1,58}$=7.80; *P*=.002; ηp^2=0.03). Further post hoc analysis revealed that the AVG group had higher values than the CG for EO-floor (*P*=.03) and EO-foam (*P*=.01) at week 4. In addition, the differences in change score between groups indicated that the AVGs elicited a change in EO-floor (95% CI=−8.01 to 0.71; *P*=.04) and EO-foam (95% CI=−7.47 to 0.05; *P*=.03) over the CG at week 4. However, there were no changes in EC-floor between time and groups for either group (*P*=.44) (Table 2).

Table . Observations from the single-leg stance test (SLST) with eyes open (EO) and eyes closed (EC) on floor and foam; the balance and strength subtests of the Bruininks-Oseretsky Test (BOT-2), including the walking forward on a line test and standing long jump test; and the Foot and Ankle Ability Measure (FAAM) for activities of daily life (ADLs) and sports at baseline (week 0) and week 4 in the active video game (AVG) exercise group and control group (CG), which received therapeutic exercise for chronic ankle instability (n=30 for each group). The significance level was *P*<.05.

Variables		AVG group			CG		
		Week 0	Week 4	Change score	Week 0	Week 4	Change score
SLST (seconds), mean (SE)							
	EO-floor	24.6 (1.2)	25.3 (1.1)	0.7 (1.3)	22.2 (1.4)	19.3 (1.6)[a]	−2.9 (1.7)[b]
	EC-floor	8.8 (0.9)	9.9 (1.1)	1.1 (1.0)	8.7 (1.0)	8.2 (1.1)	−0.5 (1.0)
	EO-foam	15.9 (1.4)	18.0 (1.4)	2.1 (1.3)	13.1 (1.4)	11.5 (1.3)[a]	−1.7 (1.4)[b]
	EC-foam	3.1 (0.2)	3.6 (0.3)	0.5 (0.3)	3.1 (0.2)	3.3 (0.2)	0.2 (0.2)
BOT-2							
	Walking forward on a line (steps), mean (SE)	5 (0)	6 (0)	0.7 (1.7)	5 (0)	6 (0)	0.4 (1.4)
	Standing long jump (centimeters), mean (SE)	107.9 (4.9)	108.5 (4.8)	0.6 (3.2)	103.6 (4.4)	106.8 (2.9)	3.2 (3.1)
FAAM (%), mean (SE)							
	FAAM-ADL	87.2 (1.3)	91.3 (1.1)[c]	4.3 (0.9)	82.2 (2.1)	84.1 (2.1)[a]	2.0 (1.1)[b]
	FAAM-Sports	89.6 (1.9)	91.5 (1.4)	1.9 (2.1)	83.7 (3.0)	87.1 (2.4)	3.3 (2.8)

[a]Significant difference between the AVG group and the CG at week 4 using mixed model ANOVA.

[b]Significant difference between the AVG group and the CG for change score using independent 2-tailed *t* test.

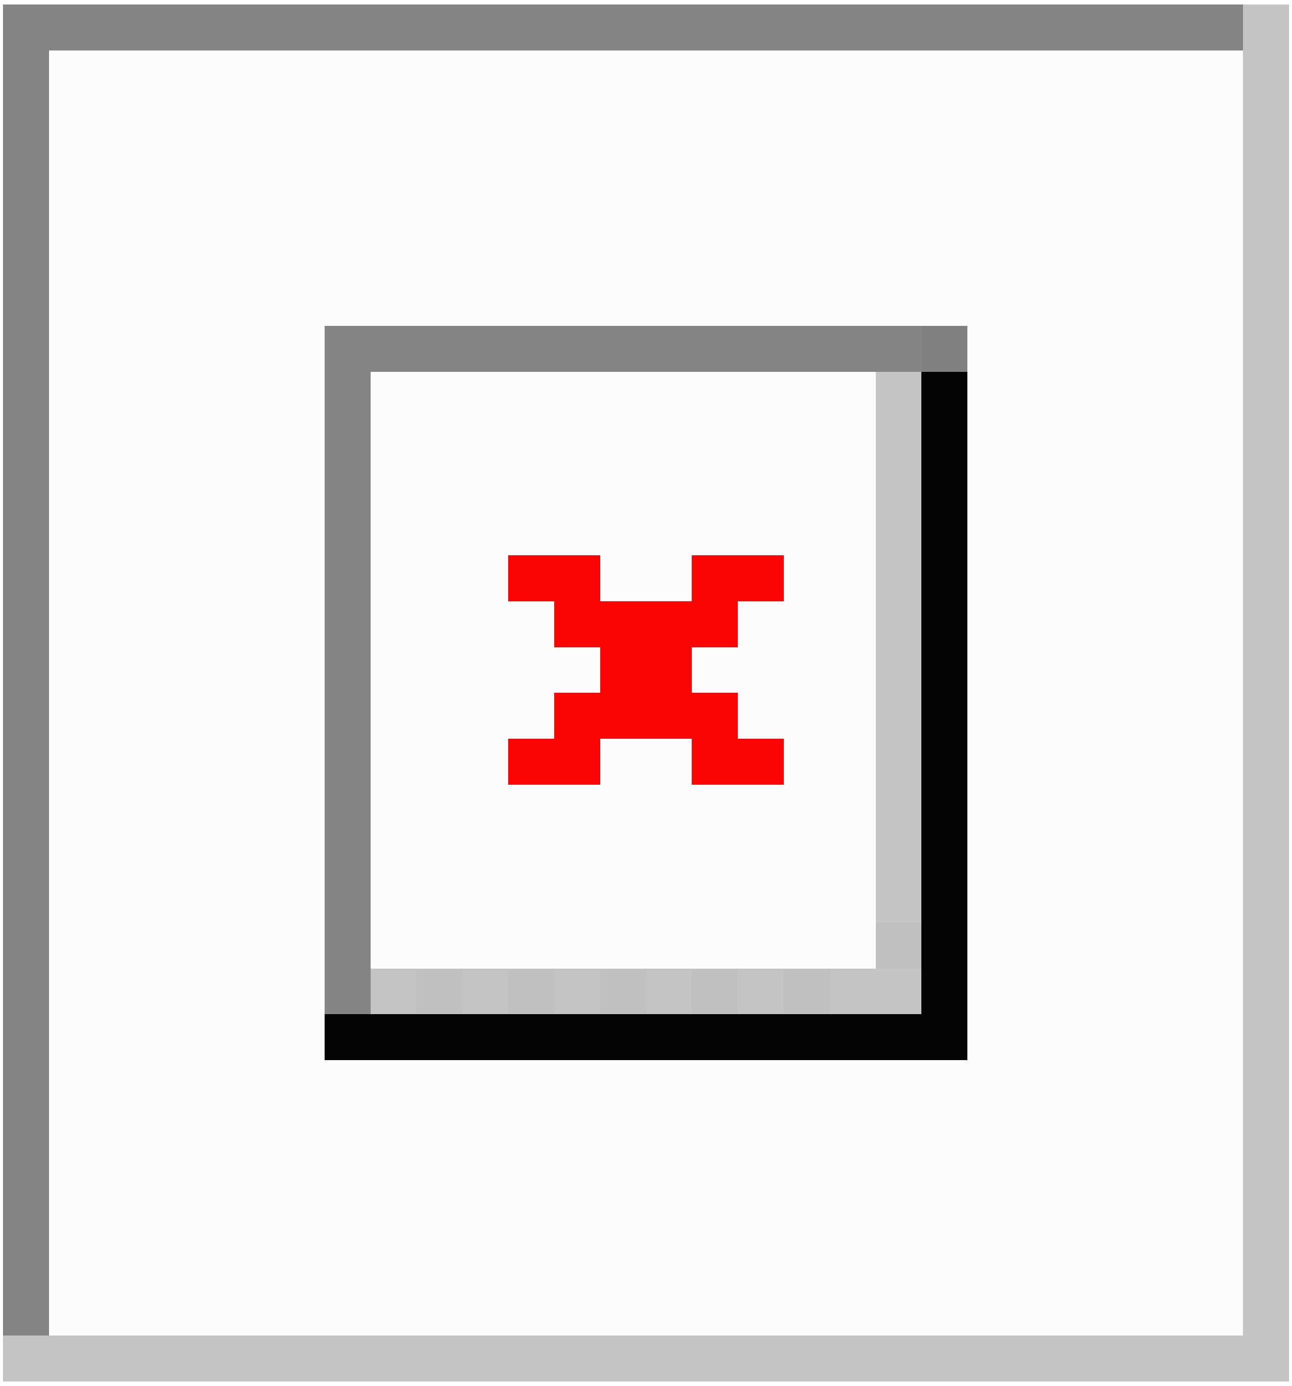
[c]Significant difference between week 0 and week 4 using mixed model ANOVA.

Regarding the BOT-2, including the functional balance and strength test, there were no significant interactions between time and group on the walking forward on a line (*P*=.31) and the standing long jump test (*P*=.34) in both groups (Table 2).

For the FAAM-ADL, the mixed model ANOVA tests revealed significant interactions between groups ($F_{1,58}$=6.77; *P=.01*; ηp^2=0.56) where the FAAM-ADL values for the AVG group were greater than those for the CG at week 4 (*P*=0.01). Also, significant interactions between times were found ($F_{1,58}$=19.03; *P*<.0001; ηp^2=0.25) in the AVG group, but not in the CG. The AVG group increased mean percentage on the FAAM-ADL from week 0 to week 4 (*P*<.001). Moreover, the differences in change score between groups indicated that the AVG group showed a change in percentage on the FAAM-ADL (95% CI−5.16 to 0.445; *P*=.04) over the CG at week 4. However, there were no changes in FAAM-Sports between time and group for either group (*P*=.69) (Table 2).

For the IMI, A 2-way repeated-measures ANOVA determined an effect of group for the interest/enjoyment ($F_{4,116}$=2.59; *P*=.04; ηp^2=0.08), value/usefulness ($F_{4,116}$=2.71 *P*=.03; ηp^2=0.09), and pressure/tension ($F_{4,116}$=2.50, *P*=.04, ηp^2=0.08) dimensions. Post hoc pairwise comparisons using Bonferroni correction showed a significantly greater score for interest/enjoyment and value/usefulness on the IMI in the AVG group compared to the CG (AVG group vs CG: 7, SD 0 vs 6, SD 0 for interest/enjoyment, *P*<.001 and 6, SD 0 vs 5, SD 0 for value/usefulness, *P*=.005) at week 2. Additionally, at week 4, the AVG group had a lower score for pressure/tension on the IMI than the CG (AVG group vs CG: 1, SD 0 vs 2, SD 0; *P*<.001). Significant interactions for time were found in the CG ($F_{4,116}$=4.39; *P*=.002; ηp^2=0.17) but not in the AVG group. The CG had increased perceived competence scores from baseline to week 4 (baseline vs week 4: 5, SD 0 vs 6, SD 0; *P*=.005) and week 1 to week 4 (week 1 vs week 4: 5, SD 0 vs 6, SD 0; *P*<.001). There were no significant differences observed between the group and time on any other dimension of the IMI (*P*>.05) (Figure 4).

Figure 4. Observations from the intrinsic motivation inventory questionnaire at baseline, week 1, week 2, week 3, and week 4 in the active video game (AVG; n=30) exercise group and the control group (CG; n=30), who received therapeutic exercise. The data are shown as the mean (SEM). **P*<.05; repeated measures ANOVA.



Exercise adherence was measured using the child's logbook. All participants performed 100% of the exercise as per each week's exercise protocol. Furthermore, there were no reports of harm or injury occurring during training in either the AVG group or the CG.

Discussion

Principal Findings

The major finding of this study provides evidence that a 4-week AVG home-based exercise training program can have a positive and significant therapeutic effect on children with CAI as determined by improving static balance, foot and ankle ability, and key measures of intrinsic motivation (ie, interest/enjoyment, pressure/tension, and value/usefulness).

For balance control, after 4 weeks of the training program, the AVG group could perform the SLST with EO on a stable surface as well as on a foam surface better than those who performed the traditional CAI program. When playing video games, children learn how to act and respond to the game scenario promptly, which is considered to enhance sensorimotor learning after training [43]. Moreover, the improvement of balance following the AVG training could be related to the movement strategies inherent in the games. The games provide visual feedback via a variety of visual-perceptual processing challenges and prompt lower-extremity muscle responses to control posture and balance. The results of this study support previous findings that have demonstrated the effectiveness of using visual feedback tools as a therapeutic training modality [28,44-46]. For example, Kim and Heo [44] reported the benefits of 4 weeks of balance exercise using the Wii Fit Plus program (30 minutes, 3 times a week) for improving static balance in people with functional ankle instability. Moreover, Fitzgerald et al [28] found that a therapeutic exergaming system showed an improvement in postural stability when compared to a group doing similar balance training without the game system. Therefore, this study offers further support for using an AVG visual feedback training program as an effective modality for improving the balance of children with CAI.

The results of this study showed no significant difference in the subtest of the BOT-2 for functional balance, measured by walking forward on a line, and for leg muscle strength, measured by a standing long jump, in the AVG group and the CG after 4 weeks of training. This might be caused by either the movement patterns of the AVGs (moving feet to the left or right) and the traditional CAI program not being potent enough or the period of the exercise program (4 weeks) being too short to improve functional balance and lower-extremity strength.

This study revealed that foot and ankle ability measured by the FAAM-ADL in the AVG group improved after the 4-week training, and interestingly, it was greater than the CG. This result is congruent with the results of Punt et al [47], who found an improvement in foot and ankle ability during a 6-week follow-up of users of the Wii Fit game (twice per week, for 30 minutes per session) in lateral ankle sprain patients. Perceived instability of the foot and ankle has been reported to be associated with decreased health-related quality of life in individuals with CAI [43]. Thus, the exercise program with AVG could be used as exercise therapy to increase foot and ankle ability and might provide a better quality of life in children with CAI.

The participants' subjective perception of the program was assessed every week. Notably, in week 2, the perception of interest/enjoyment was increased in the AVG group, whereas the perception of value/usefulness was decreased in the CG. Interestingly, the perception of pressure/tension was increased in the CG and greater than the AVG group at week 4. These results are consistent with previous findings [28,45,48] that reported that a video game–based rehabilitation approach could provide a greater intrinsic motivation level to engage in the activity for a longer period of time when compared to a group doing similar balance training. These results might explain that increased interest and enjoyment may have occurred due to the achievable challenges provided by the games (ie, Catching Fish and Russian Block) and the subsequent feelings of achievement when each game level was completed. By contrast, in the traditional CAI program, there was no feedback mechanism during the exercises. The participants simply had to count the number of repetitions and sets performed, and this might have contributed to the reduction in value/usefulness levels, as well as the pressure/tension level increasing during the program. It is noteworthy that the results of this study illustrated that effort/importance slightly declined after 2 weeks and was still declining in week 4. It may be possible that the children became accustomed to the exercise program, as they had to repeat the same exercise again and again to achieve the aim of the intervention. This result is consistent with the findings of previous research that reported nonadherence and lack of motivation in long-duration training in home-based therapeutic practices [15,16].

Furthermore, the protocol and training intervention using the AVG program has been shown to be feasible, as indicated by the retention and adherence of participants. The safety of the program is evidenced by the lack of adverse events reported. This suggests that the design and progression of the training had an appropriate intensity and the interactive video game did not present any harm. Therefore, the above results suggest that AVG programs provide an engaging and interactive environment that results in less fatigue, more relaxation, and enhanced adherence throughout the rehabilitation period.

Limitations

There are some limitations to this study. First, observations were not obtained in a controlled laboratory environment. However, the researchers gave instructions, set up the exercise environment at the participants' homes, and made telephone calls to give reminders to the participants. Second, the relatively small sample size may not be representative of the characteristics of the broader population of children with CAI. Third, follow-up measurements are required so that the longitudinal effects of the AVG program can be better understood. Lastly, a 4-week program is a relatively short intervention period. Thus, further studies would appear warranted to determine the effects of a longer-duration AVG training program.

Conclusions

This study found that children with CAI showed significant improvements in single-leg standing, foot, and ankle ability measured by the FAAM-ADL and intrinsic motivation in the interest/enjoyment, pressure/tension, and value/usefulness dimensions after following a home-based exercise program with AVGs. Furthermore, it was discovered that playing video games while exercising comprised a visuomotor feedback task that was lacking in the therapeutic exercise program. Thus, visual feedback while exercising with AVGs may be an effective way to improve balance ability, especially in the EO condition. This highlights that AVGs focused on balance exercises can be beneficial and may be an effective approach for improving balance and enhancing positive motivation in children with CAI who require long-term rehabilitation sessions.

Acknowledgments

All children and their parents are gratefully acknowledged. The authors would like to thank Dr Andrew James Mills, College of Sports Science and Technology, Mahidol University, Thailand, for his editorial assistance on this manuscript. This study was supported by the Scholarship of the 60th Year Supreme Reign of His Majesty King Bhumibol Adulyadej, Mahidol University, Thailand.

Authors' Contributions

JC conceptualized and designed the study, performed data collection, analyzed the data, interpreted the results, and wrote the first draft of the manuscript; RL and AA contributed to the conception and design of the study, performed the statistical analysis, interpreted the results, and drafted the manuscript; CH contributed to the conception and design of the study and supervised the study. All authors have read and approved the final version of the manuscript and agree with the order of presentation of the authors.

Conflicts of Interest

None declared.

Abstract

Background: We developed the Blexer system consisting of a database and a web interface for therapists that can host different types of adaptive and personally configurable virtual reality exergames based on Kinect (Microsoft Corp) motion capture to provide entertaining exercises for children with motor disabilities. It allows for parameter adjustment and the monitoring of results remotely, thereby providing a useful tool to complement traditional physical therapy sessions with home exercises.

Objective: The aim of this study was to observe the motor benefits achieved through the use of a video exergame and the importance and implications of correctly setting the game's difficulty parameters.

Methods: This was an observational case study of 6 children with different physical disabilities receiving physical therapy at school combined with the use of a fully configurable exergame under research that forms a part of the Blexer environment. The game integrates 4 repeatedly appearing upper limb exercises with individually adjustable difficulties (intermittent arm rising, arm forward and backward movement, rising and holding of one arm, and trunk control in all directions). The outcomes were 3 assessments of 2 efficacy measures: Box and Block Test and Jebsen Taylor Hand Function Test.

Results: A total of 5 children with cerebral palsy (mean 8.4, SD 2.7 years; Gross Motor Function Classification II—2/5, 40%; III—2/5, 40%; and IV—1/5, 20%) and 1 child with obstetric brachial plexus palsy (aged 8 years; Mallet Classification III) received between 8 and 11 sessions of training (10-20 minutes per session), depending on age, motivation, and fatigue. Significant associations were observed between game parameter settings and improvements in motor function, on the one hand, and between the type of improvement and disability severity, on the other: with adjusted game parameters *goal* and *time* in the range of 70% to 100%, only less affected children improved in the Box and Block Test (+11 blocks vs −1 block), and more affected children improved more in the Jebsen Taylor Hand Function Test (+90 seconds vs +27 seconds).

Conclusions: When defining the difficulty parameters for an exergame, we suggest a classification in levels ranging from *very easy* to *very hard*. For practical use, we suggest setting the difficulty for the player to an *easy* or *medium* level rather than high-commitment goals, as this leads to a longer playtime with more fun and, therefore, seems to improve the results of the game and, consequently, mobility.

Introduction

Background

Cerebral palsy (CP) and obstetric brachial plexus palsy (OBPP) are 2 of the pathologies that most frequently cause problems in the upper limbs in children and adolescents. According to the International Classification of Functioning, Disability, and Health (ICF), these problems affect corporal structure and function, limiting, in many cases, activities of daily living [1]. CP is considered a global disorder because of a permanent and nonprogressive lesion in the brain, before its development is complete, producing alterations in tone, posture, and movement, resulting in functional limitations and other associated alterations [2,3]. OBPP is generally caused by an elongation of the brachial plexus during childbirth, although it can also have an intrauterine, genetic, or postural origin. Alterations range from nerve conduction impairment to total rupture of anatomical structures [4,5]. Common problems of both pathologies are muscular atrophy and weakness, imbalance, alteration of the coordination of different muscle groups, secondary joint pathology, and decreased general use of the arms and hands in daily activities [6,7].

Regarding the different conservative treatments for both pathologies, we found that different systematic reviews proposed repetitive, challenging, high-intensity, and motivational interventions [5,6,8,9].

When analyzing the interventions that are considered effective in CP, we found that training with video games or virtual reality (VR) is among the interventions for which there is promising evidence suggesting possible effectiveness [8]. In OBPP, VR associated with other therapeutic strategies is also considered significantly more effective than conventional physical therapy programs [4,10]. Therefore, serious games and VR are considered promising interventions in both conditions.

Systematic reviews that analyzed the effectiveness and clinical utility of VR interventions indicated that motion capture devices have beneficial effects in the rehabilitation of patients with neurological disorders, achieving high levels of compliance, motivation, and commitment that can help improve one or more levels of ICF. The greatest benefits were found in domain 1 of the ICF, being effective in improving upper extremity function, hand coordination, balance function, gait, and postural control. In addition, benefits are associated with aspects such as participation in the community and improvements in psychological and cognitive functions [5,9,11-13].

The benefit of video games is that they offer immediate feedback and rewards that stimulate the brain so that the user wants to play more. Providing challenging and fun environments that keep the player motivated increases the number of repetitions of certain movements compared with conventional therapy. Thus, neuroplastic changes and cortical reorganization, which could produce improvements in performance, are elicited [14,15]. The use of these types of games encourages participants to direct their attention to an external focus, which helps them to learn faster and more accurately than requests from an internal focus [16].

As for motion-controlled video games, most studies use Kinect devices (Microsoft Corp) along with commercial video games, which provide accessibility and portability and are low cost. However, these video games do not address the specific needs of patients who sometimes cannot perform the required movements quickly or efficiently enough to succeed during play. Therefore, different reviews point to the advantages of specifically designed games that provide appropriate challenges and adapt to the player's speed and quality of movement, thus avoiding boredom and frustration. However, the negative aspect is that commercially available mainstream video games cannot be personalized and that there are still very few offers for therapeutic video games, which are quite expensive [11-13,17-20].

Some commercial solutions we found are the MIRA software platform (MIRA Rehab Limited), [21], VirtualRehab (Evolv) [22], and REHABILITY (Imaginary SL) [23], all of which seem quite complete, but it is not clear from the information provided on the web pages how and to what extent the different exercises involved in the games are configurable for each user.

The common opinion of researchers is that games should complement therapy with both options, accompanied by a professional or used at home [9,12,24]. In any case, it is recommended that computer-based training be followed by the practice of activities in the physical environment to ensure adequate perceptual adjustment and the transfer of the benefits of training to activities of daily living performed in a real environment [24].

Objectives

The purpose of this study was to observe how much influence the adjustment of the games' objectives has on the child's performance in upper limb movements. We suppose that there is a small range of adjustments that ensures that the challenge for the child is neither too low (leading to boredom) nor too high (leading to frustration). Therefore, we wanted to prove the hypothesis that the optimal settings (of the goal and the time parameters) are those that ensure that the goal can be reached within the given time limit. Furthermore, the aim was to derive some practical adjustment rules from our results that could be useful for our and other similar configurable games.

Methods

Therapeutic Video Game Environment

The Blexer system has been described in detail in various previous publications [25,26]. It consists of a database and a web platform that integrates different video games and is accessible only to clinicians. On the user side, a PC with a motion capture camera (Kinect X360, Microsoft Corp) is required. The PC hosts one or more games and a middleware [27] that acts as a communicator among the camera, the database, and the games. It provides the games with motion data, downloads the game settings established by the clinician, and uploads the users' results after each play to the database.

The game used in this study, Phiby's Adventures (version 1), is a semi-3D third-person video game extensively described in the study by Eckert et al [26]. The main character, Phiby, is a small amphibian that must be helped to get out of a valley, which is represented by a modular 2D map with 16 × 8 cells. The cells are connected through different obstacles such as rivers, trees, lakes, or trunks that Phiby must pass while finding its way out of the valley. Each obstacle is an independent exercise scene (refer to the description provided in Table 1) that needs arm and trunk movements of different intensities to pass through. The logs obtained from chopping the trunks can be used to build bridges or huts. A hut allows the player to rest and to save the game state for resuming from that point in the next session. With the aim of increasing the player's interactivity and decision-making, they are given an option to freely choose the path to follow and, therefore, take the obstacles they like. By passing through the cells, the areas of the map are gradually discovered and can be visualized through an arm movement. The 4 exercise scenes have adjustable difficulty parameters (objective and time limit), as explained in Table 1. An initial calibration measures the players' range of movement for adapting the game to their capacities.

Table 1. Overview of the 4 exercises inherent in the video game.

Exercise	Description	Abilities to train	Pictures
Chop the wood	Exercise using the affected limb: this exercise provides a specific activity for the use of the affected side in which maximum shoulder flexion is requested based on the initial calibration. The child works on support and shoulder girdle stability to keep the axe elevated until it is loaded as well as on arm speed to lower the axe and split the wood. The amount of wood to split (=number of arm lifts) and the time limit to achieve all can be modified.	• Proximal arm movement (shoulder flexion) • Movement speed • Initiation of use of assisting hand • Reaches • Endurance • Stabilization of the shoulder and shoulder girdle	Dive and eat	Trunk control exercise: in this exercise, the objective is to catch some of the pieces of plankton floating in the water. The player controls the direction of the fish with their trunk movements. It favors trunk control and can be performed in a sitting or standing position. The number of planktons to catch and the time limit can be modified.	• Trunk control and stability	Row the boat	Symmetrical movement exercise of upper extremities: in this exercise, the symmetrical use of both upper limbs is proposed, and the objective is to row a boat until reaching the opposite bank of the river. The speed of the boat depends on the speed of the user's movements. The distance to travel (=number of arm movements) and the time limit can be adjusted.	• Proximal movement of the arm (shoulder flexion-extension) and elbow • Movement speed • Initiation of use • Hand and arm coordination • Execution flow of bimanual activities	Climb the tree	Alternated movement exercise in upper limb abduction: this exercise involves alternating movements of the arms in abduction, and the objective is to reach the top of a tree to see the valley. The parameters to be modified are the height of the tree (=number of arm movements) and the time limit.	• Proximal arm movement (shoulder abduction and flexion) • Movement speed • Initiation of use • Reaches • Hand and arm coordination • Execution flow of bimanual activities	
Study Design and Participants

This case study was jointly driven by the Research Center for Software Technologies and Multimedia Systems for Sustainability of the Universidad Politécnica de Madrid (UPM) and the Public School CEIP (Centro de Educación Infantil y Primaria) Pinar de San José in Madrid. UPM developed the Phiby's Adventures video game and the Blexer-med web platform used in this study. The game is connected to the platform, which allows for the adjustment of the difficulty of the game parameters and the supervision of the results for each participant.

CEIP Pinar de San José is an integrative primary school (5-12 years) with 28 pupils (out of 950) having motor disabilities (13 CP, 2 OBPP). Informed consent was obtained from the parents and children involved in this study.

Inclusion criteria for the study were the following: being a scholar receiving physiotherapy care at the Pinar de San José school, being aged between 5 and 12 years, having a major functional impairment of an upper limb because of CP or OBPP, and being able to understand and follow the game. Exclusion criterion was poor trunk control that prevents activity from being performed in a freely seated position. The children were classified based on their functional level according to the *Gross Motor Function Classification (GMFCS)* [28], *Manual Ability Classification System (MACS)* [28,29], and *Mallet Classification* [30,31].

Intervention

Initially, several instructional sessions were conducted for 8 weeks to familiarize the children with the dynamics of the game. Then, the intervention took place for 6 weeks, using the game as a part of the usual 45-minute physiotherapy sessions (2 or 3 times a week), for approximately 10 to 20 minutes, according to age, motivation, and fatigue. In the remaining time, they received the usual physiotherapy treatment. They also continued with activities and therapies outside school.

During the instructional sessions conducted before the intervention, all the children played with the same default difficulty adjustments, which were 60 seconds time limit per exercise with the following goals: chopping 60 trunks, climbing up 100 meters, catching 10 planktons diving, and rowing 100 meters. After these sessions, the objectives of each game were adjusted individually for each child according to our subjective observations during training and with the intention to provide affordable challenges.

During the intervention, physiotherapists constantly supervised the children and verbally motivated them. They were allowed to vary their pose (sitting or standing) depending on their abilities and how they felt that day; however, all participants selected their favorite posture once and then always played in the same way and without any physical help from the therapists. Depending on the results observed, that is, considering whether the objectives were achieved and how quickly or whether the children were bored or stressed, the difficulty of each exercise was readjusted after each session to maintain the challenge. In the case of being tired or unmotivated, the goals were lowered, whereas they were raised when improvement or low challenge was observed. The time limit was kept constant at 60 seconds in all exercises. These decisions were based on subjective observations (of movements and mood) as the objective results (time needed for an exercise and score) were not graphically presented on the web at that moment. They could be revised in form of tables, but this was not useful for making instantaneous objective decisions. All the children were able to complete the activity.

Data Analysis of the Exercise Results and Jebsen Taylor Hand Function Test and Box and Block Test Assessments

The web platform receives the following for each exercise: its difficulty parameters (objective and time limit), the time stamps of entering and leaving, and the score reached. We analyzed the *relative* scores for each type of exercise, that is, the percentage of movements in relation to the objective established by the therapist, and correlated these data with the outcomes of 3 evaluations: previous evaluation (*Vp*) 8 weeks before, initial evaluation (*Vi*) immediately before, and final evaluation (*Vf*) immediately after the intervention. Between Vp and Vi, conventional therapy was performed, and after Vi, the game was used as a part of the therapy sessions for 6 weeks.

The assessments were made using the Box and Block Test (BBT) [32] (counting the number of blocks put from one part of the box to another; the more blocks, the better the result) and the Jebsen Taylor Hand Function Test (JTHFT) [33] (measuring the time required to perform 7 activities; the quicker, the better the result). Both tests have demonstrated reliability, especially for measuring changes that focus on improving hand dexterity and function in children with CP after intensive intervention. The reliability and responsiveness of these tests are better for short evaluation periods [18,19].

Statistical calculations were performed using SPSS software (version 26; IBM Corp). Descriptive statistics were used to summarize baseline characteristics and feasibility data. We used the Levene test to assess the normality of data distribution. Differences of means were calculated and proved by 2-tailed significance tests, and the differences were considered statistically significant at $P<.05$.

Ethics Approval

This study was approved by the Universidad Politécnica de Madrid (UPM) ethics committee and also complied with the Declaration of Helsinki.

Results

Study Design and Participants

For the study, 54% (15/28) of the children aged 5 to 12 years were screened for eligibility among the ones receiving physical therapy support at the Public School CEIP Pinar de San José in Madrid. Out of these, 47% (7/15) met all inclusion criteria and 7% (1/15) had to be excluded because of poor trunk control and inability to maintain stability during play without external aids; so finally, the analysis group was reduced to 6 children (Table 2). The mean age of the participants was 8.3 (SD 2.4) years; 5 (83%) children with CP were aged 8.4 (SD 2.7) years, and 1 (17%) child with OBPP was aged 8 years. We used the following code to identify the participants: *CP/OBPP+age+hand+group.*

The participants were divided into 3 groups based on the results of the functional classifications of GMFCS, MACS, and Mallet (Table 2):

1. Group 1: CP (GMFCS ≥III, MACS ≥III; 3/6, 50% participants)
2. Group 2: CP (GMFCS<III, MACS <III; 2/6, 33% participants)
3. Group 3: OBPP (Mallet III; 1/6, 17% participants)

The participants in group 1 had a lower functional level, with an average age of 7 (SD 2.6) years. The participants in groups 2 and 3 presented a similar profile with higher functional levels in both gross and fine motor skills; therefore, these 2 groups were merged into group 2+3 (average age: 9.7, SD 1.5 years). Thus, 2 homogeneous groups of 3 children each were formed, considering similar functionality and age.

Table 2. Details of the participants' age, sex, diagnosis, affected hand, playing position, motor function ratings, and assigned group.

ID	Age[a] (years)	Sex	Diagnosis	More affected hand	Play position	Classification			Group
						GMFCS[b]	MACS[c]	Mallet	
CP5L1	5	Female	CP[d]	Left	Seated	IV	III	N/A[e]	1
CP6R1	6	Male	CP	Right	Seated	III	III	N/A	1
CP10R1	10	Male	CP	Right	Standing	III	III	N/A	1

CP11R2	11	Female	CP	Right	Standing	II	I	N/A	2
OBPP8R3	8	Female	OBPP[f]	Right	Standing	N/A	N/A	Mallet III	3

[a]Age, mean (SD): all=8.3 (2.4) years; CP=8.4 (2.7) years; group 1=7.0 (2.6) years; group 2+3=9.7 (1.5) years.

[b]GMFCS: Gross Motor Function Classification.

[c]MACS: Manual Ability Classification System.

[d]CP: cerebral palsy.

[e]N/A: not applicable.

[f]OBPP: obstetric brachial plexus palsy.

Intervention

On average, 9.8 (range 8-11) sessions were conducted per participant, adjusting the duration of each session according to age, motivation, and fatigue. Given the fact that each player needed individual adjustments of the time limit and the objective of an exercise, comparisons could be made only through relative values; therefore, we defined 2 variables that represent the results as percentages of what was achieved in relation to what was configured: pct_{goal} (percentage of goals, equation 1) is the number of movements performed in relation to the objective established by the therapist and pct_{time} (percentage of time, equation 2) is the time needed to finish the exercise in relation to the time limit set.

Table 3 presents the individual results that the participants obtained for each exercise during the intervention sessions.

For analyzing how well the target values of the exercises were adjusted in each session according to the child's abilities, pct_{goal} and pct_{time} were plotted over time. The aim was to avoid excessive exertion and under exertion and to achieve the highest possible level of motivation. Figure 1 shows 4 examples of the performance of different players in different exercises, comparing the time and score achieved during the intervention.

Participant CP5L1 achieved a 100% score on the rowing exercise (Figure 1, top left) in less than half the time, and our observation was that the child quickly became bored. The plot on the right side of the top row in Figure 1 shows the opposite situation for the same child during the dive exercise: 100% of the time limit was almost always used but to no avail, and we also observed difficulties and frustration. However, in this case, it was not possible to set an easier target because it was already set at the minimum value. The third case (CP6R1 in the climbing exercise) shows a good balance between the score obtained and time taken, with both percentages being similar and mostly close to 100%. The child also played with fun and seemed challenged. The fourth case, CP10L2 in the chopping exercise (Figure 1, below right), shows a readjustment situation: the first 16 exercises were completed with a high goal and a short time limit so that the goal was almost never reached in the given time. We observed stress and reduced the goal (keeping the time limit the same), resulting in a setting that allowed reaching the goal 100% and in a short time.

The graphical representation of all individual results from Table 3 is shown in Table 4 and in the graph in Figure 2. It shows a group of settings in the top right where both the score and the time spent are high (between 70% and 100%). Very few cases had settings that resulted in very low scores or high scores obtained in a short amount of time (blue and yellow outliers). Accordingly, and also considering our observations of the children during play, we classified the setting ranges from *very easy* to *very hard*. To do this, we divided each axis into thirds.

Table 3. Individual playing results, relative to the adjustments.

Participants	Chop		Row		Dive		Climb	
	pct_{goal} [a] (%)	pct_{time} [b] (%)	pct_{goal} (%)	pct_{time} (%)	pct_{goal} (%)	pct_{time} (%)	pct_{goal} (%)	pct_{time} (%)
Group 1, value

All participants, mean (SD)	82 (13)	80 (18)	90 (8)	67 (14)	46 (26)	88 (6)	64 (15)	92 (6)

[a] pct_{goal}: percentage of points obtained with respect to those established.

[b] pct_{time}: required time percentage of set time limit.

Figure 1. Four examples of different player experiences. Top left: easy play (100% goal achieved in a very short time). Top right: difficult play (100% time consumed but nearly no hits). Bottom left: challenged play (high percentage of goals, high time consumption). Bottom right: initially difficult play, finally easy play. The following code was used to identify the participants: CP/OBPP+age+hand+group.

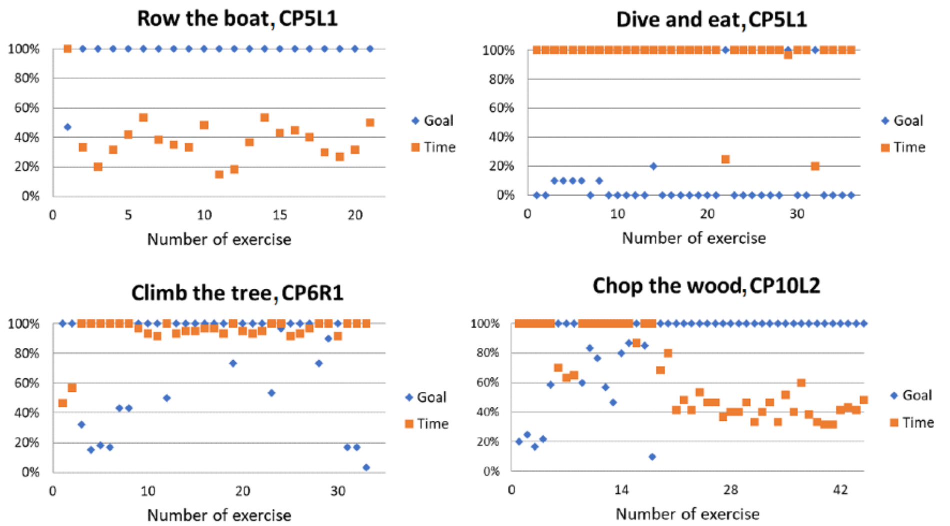

Table 4. Relation between playing time, score, and adjusted game difficulty level.

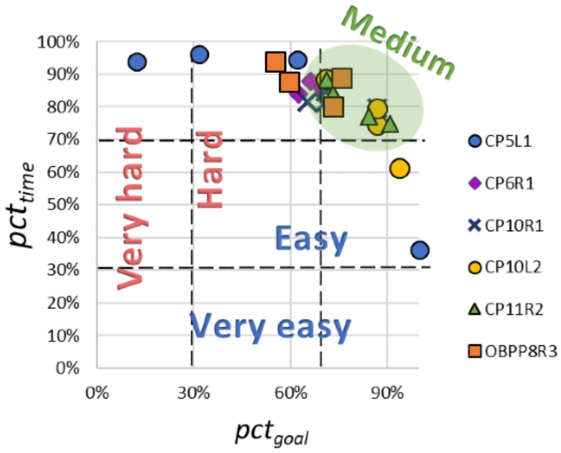
pct_{time} [a]	pct_{goal} [b]	Game difficulty level
≤30%	>pct_{time}	Very easy
>30% and ≤70%	>pct_{time}	Easy
>70% and ≤100%	>70% and ≤100%	Medium
>pct_{goal}	>30% and ≤70%	Hard
>pct_{goal}	≤30%	Very hard

[a] pct_{goal}: percentage of points obtained with respect to those established.

[b] pct_{time}: required time percentage of set time limit.

Figure 2. Graphical representation of all individual results for all exercises. Adjustment of time and objective. The following code was used to identify the participants: CP/OBPP+age+hand+group.



Data Analysis of the Exercise Results and JTHFT and BBT Assessments

Table 5 presents the data of the individual results of the 3 evaluations, and Figure 3 is a visualization of these values showing the improvement in both tests.

In addition, the graph in Figure 4 has been created to perform a visual analysis of the relation of the JTHFT ratings with the BBT scores for each participant. We added a hull around the 3 evaluations to show at first glance how much a child improved between assessments: the larger the shape, the more the results differed between the JTHFT and BBT. A very horizontal slant indicates better performance in the BBT, and a vertical slant indicates more improvement in the JTHFT. Round shapes indicate few differences between both assessments, and a slant toward 45° indicates that the improvements were similar.

Table 5. Individual results of 3 evaluations with the Jebsen Taylor Hand Function Test (JTHFT) and Box and Block Test (BBT).

Participants	JTHFT (seconds)					BBT (number of blocks)				
	V_p[a]	V_i[b]	V_f[c]	$V_i - V_p$	$V_f - V_i$	V_p	V_i	V_f	$V_i - V_p$	$V_f - V_i$

[a]V_p: previous evaluation.

[b]V_i: initial evaluation.

[c]V_f: final evaluation.

In addition, we assembled the evaluation data with exponential trend lines to demonstrate the correlation between them. The resulting curves from the 2 initial assessments did not differ, indicating that the children's mean scores were very similar.

However, the curve of the third assessment stood out significantly, showing a more vertical slope, indicating that there were greater differences between JTHFT and BBT in this final assessment, pointing to an improvement in skills owing to the games.

Figure 3. Visual comparison between the 3 evaluations with the Jebsen Taylor Hand Function Test (JTHFT) and Box and Block Test (BBT). Vf: final evaluation; Vi: initial evaluation; Vp: previous evaluation.

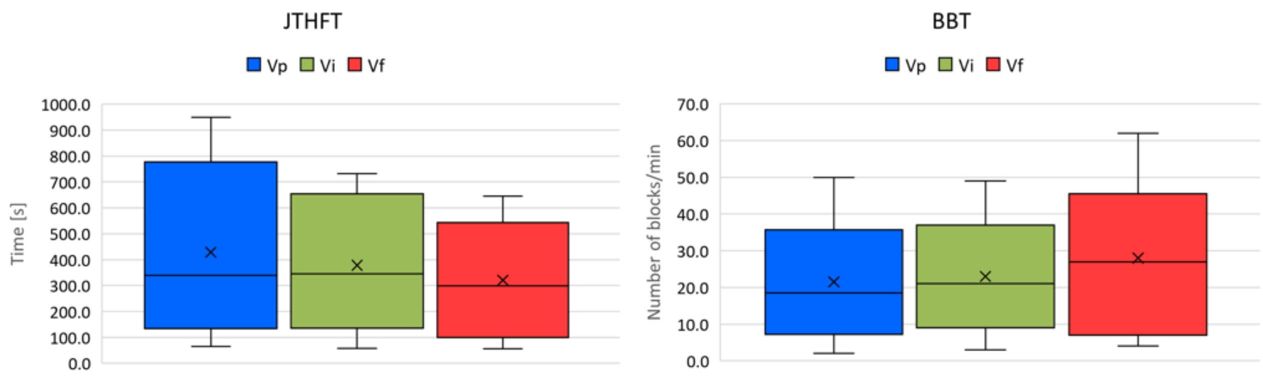

Figure 4. Visualization of the dependencies between evaluations, test types, and groups. Within parentheses, the percentage of time played with easy and medium adjustment of the game parameters is given. The following code was used to identify the participants: CP/OBPP+age+hand+group.

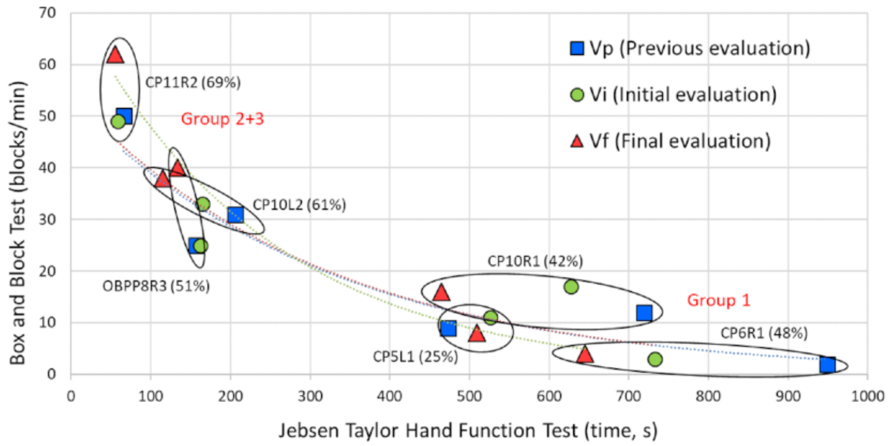

Discussion

The main finding of this study is the categorization of the parameter adjustments into 5 levels of difficulty, which may be of high interest to a therapist who has to decide on the configuration of different exercises. Here, the *easy* and *medium* levels seem to be the most effective, as the final assessment tests show greater improvements for those children who played longer in these adjustment ranges.

Participants

The number of children in this study seems small at first glance, but given our conditions (being a common primary school that integrates 28 children with very different types of physical disabilities), we were fortunate to find 6 children of similar conditions and age and that they were allowed to participate in this study. However, their physical abilities were different because of different degrees of affection, so we decided to analyze them in 2 homogeneous subgroups of the same size, which turned out to be a positive decision, as can be observed from the results.

Intervention

Table 3 presents the results of play for each child and each type of exercise as relative values between the scores and the adjustments. In this way, it was possible to quickly observe in which cases the parameter settings led to better results (the higher the percentage, the more appropriate the parameter adjustment was to the child's capacity). The graphical representation of these values (refer to the graph in Table 4) led to a distinction of 5 levels of difficulty ranging from *very easy* to *very hard* and reveals that most exercises were played with settings that led to achievements of 70% to 100% for both values (upper right part of the graph in Table 4). This means that the objectives were achieved in most cases and that the time given was sufficient, neither too short nor too long. We also observed that in those cases, the children played with more fun and enthusiasm. In the other ranges, they performed worse and felt frustrated or bored. When the time limit was not considered a challenge, as the highest score could be achieved without much effort, the setup seemed too easy. When the goal of an exercise could not be achieved within the given time limit, the participants became stressed and frustrated, so adjustments were probably too difficult. These observations led us to consider the range between 70% and 100% as a *medium* difficulty level, which could be the optimal range of adjustment.

Figure 1 visualizes 4 typical cases showing cases of play that were too easy, too hard, and just right. Participant CP5L1 achieved a 100% score in less than half of the given time limit, so this could be considered a *very easy* adjustment. In the diving exercise, the same child needed the full amount of time given but was unsuccessful, so the configuration appeared to be *very hard*. CP6R1 achieved the score within the given time, so the configuration of this exercise was considered well suited for this child; we would call it an optimal setup. CP10L2, in the beginning, required the entire time given and achieved very low scores. After readjustment, the child never failed and quickly achieved the goal. Both situations were not ideal, too difficult at first and too easy afterward.

During the intervention, adjustments were made to the parameters of the game based on subjective observations because at that time, the therapist did not have a graphic display of the results available on the web. The adjustments made were expected to be optimal; however, subsequent analysis showed that not all children received an adequate adjustment to their abilities. For example, we noticed an incorrect setting for the participant CP5L1, both in the training sessions and in the intervention sessions, which could possibly have been avoided. Therefore, we consider it crucial that a therapist has an *objective* measure to verify whether a game setting is well adjusted for each participant. We are convinced that if we had had a tool that showed the range in which a child was playing, our adjustments would have been made more quickly and accurately.

In addition to the general results, it is worth mentioning some differences among the 4 types of exercises (or minigames) inherent in the game. Of them, 3 (75%) are aimed at arm movements (rowing, climbing, and chopping), and the child can fully concentrate on them because the avatar does not change its position when the child's position changes. Instead, the dive exercise is fully controlled in 3D; that is, each corporal movement translates into a change in the position of the avatar in the virtual space. This exercise was created to train trunk stability; however, it turned out to be the most difficult to control, especially for the youngest and most affected children. Therefore, this exercise produced frustration in some cases, especially for CP5L1. Here, we set the goals to low values, because we noticed that children avoided this exercise. They liked the chopping exercise best, which has a great animation with a sparkling axe and logs falling to the sides. Climbing and rowing were the 2 easiest exercises, and the children got much faster after learning how to do them.

Data Analysis of the Exercise Results and JTHFT and BBT Assessments

The results obtained in the 3 evaluations of the JTHFT and BBT showed clear improvements for almost all children, especially between V_i and V_f (before and after the intervention with the video game): a reduction in time for the JTHFT and an increase in the number of blocks for the BBT (refer to the column $V_f – V_i$ in Table 5).

The results of group 1, which includes children with lower capacities, clearly differ from those of group 2+3, which can be observed in the difference in mean values for both groups. Group 1 had longer times for the Jebsen tests and moved fewer blocks in the BBT (3 to 5 times fewer blocks). The difference in means can be considered significant despite the small sample size; after checking for normality through Levene test, all P values were <.05 for the 3 assessments (JTHFT: V_p, P=.02; V_i, P=.002; and V_f, P=.002; BBT: V_p, P=.03; V_i, P=.04; and V_f, P=.01).

However, the improvements in both tests achieved through the intervention were different: group 1 improved their results in the JTHFT more than group 2+3. In V_f, the average times achieved were about 5 times longer, but the improvement compared with V_i was 89.1 seconds, which was 3 times better than the improvement of group 2+3 (26.9 s). For the BBT, this was the other way around: after the intervention, group 2+3 achieved moving 11 blocks more than those moved before the intervention (+13%), whereas group 1 did not show any improvement caused by the game or related to the game.

An important correlation can be observed when contrasting the data obtained from the BBT and JTHFT evaluations with the time they played in the *easy* or *medium* difficulty range. As can be observed in Figure 3, the children who played most of the time with this configuration (refer to the percentages within parentheses) were the ones who achieved the best evaluations in either the BBT or JTHFT.

Looking at the individual cases, it can be observed that the improvement between the initial and final BBT ratings is best for CP11R2 (who played 69% of the time with *easy* or *medium* settings) and very high for OBPP8R3 (who played 51% of the time on *easy* or *medium*). CP10L2 played 61% of the time at those ranges and improved similarly in the BBT and JTHFT. CP10R1 (42%) and CP6R1 (48%) improved more in the JTHFT. Finally, CP5L1 unfortunately had *very hard* settings for her abilities, and as a result, she was the only child who did not improve, neither in the BBT nor in the JTHFT. As explained before, the reason was probably the young age and the general difficulty of the diving exercise, which was already set to the minimum possible goal for this child.

From these results, we understand that a correct adjustment range generates a certain challenge that leads to a longer playing time and highly motivates the player to reach the goal (a fact frequently mentioned in the literature and also called “flow” [34,35]). This is optimal from the therapeutic point of view, as overexertion and underload are avoided while achieving the highest possible level of motivation.

Comparing our proposed level adjustment in Table 4 with the generally published guidelines for game level adjustment, we observe a great coincidence. For example, Sepulveda et al [34] presented the ratio between player performance (*Cp*) and expected performance (*Ep*), as a method to measure the general performance or quality of adjustment:

$$Performance = Cp / Ep \quad (3)$$

A value next to 1 means that the challenge is appropriate for the player, and with an error range set to 0.2, a value <0.8 indicates the game is too difficult and a value >1.2 means the game is too easy. If we apply this formula to our data, the relation pct_{goal} / pct_{time} would be equivalent to *Cp*, with *Ep=1*, the ratio expected and desired by the therapist. With this, our *very easy* level can reach up to 3.3, *easy* up to 2.3, *medium* between 1.4 and 0.7, *hard* down to 0.4, and *very hard* down to 0.3. Therefore, compared with Sepulveda et al [34], we apply a larger and asymmetrical error margin, which is 0.3 for the harder adjustments and 0.4 for the easier adjustments. This is also graphically confirmed in the figure in Table 4, where most settings fall on the harder side. It has to be mentioned here that this classification should be confirmed or refined in more extensive follow-up studies.

Many publications can be found in the area of automatic and dynamic difficulty adjustment of game levels, as reviewed by Zohaib and Hideyuki [35]. It would be interesting to apply our ranges to one of the proposed algorithms and test whether they could be useful for an automatic adjustment of exercise games for people with disabilities. Furthermore, to the best of our knowledge, there are no publications on the adjustment of the level of play for people with motor disabilities; most approaches consider "accessibility," for example, the studies by Bierre et al [36], Cairns et al [37], and Carr et al [38], but this is not the same. Accessibility deals with different disabilities and adapts interfaces. Making a game "easy" does not necessarily guarantee that people with disabilities can play it. Game level adjustment goes beyond accessibility, as an accessible game still needs to adapt to the players' abilities like any other game to challenge the player; only the rules should not be the same as those for abled people.

Limitations

As stated before, on some occasions, the Kinect has difficulty capturing the smallest students, and specific problems were detected in handling the main character of the game, which led to some frustration. We are currently developing a new version of the game based on Kinect One, which has much better detection possibilities.

Furthermore, it is necessary to perform tests with larger population groups and analyze the changes that would appear at a longer intervention time. For future studies, it is important to assess whether benefits are maintained in the long term and analyze motivation. Currently, we are conducting a long-term study on the same game but using an improved web interface that visualizes the range in which the users are playing. In this way, readjustments can be made according to an objective measure and, if necessary, after each session.

Conclusions

The use of video games is considered a viable intervention to carry out in physical therapy sessions in the school environment. We observed that when the parameters were not well adjusted, the play time was short, which led to less changes in motor function (proved with the BBT and JTHFT evaluations).

The adjustment of the game seems to be related to the motor benefits found, so it would be appropriate to have access to the patients' game performance data easily and continuously to be able to modify the parameters in time and to work within the adjusted range. Therefore, we consider it a good option to use the criteria established in this study to achieve an adequate adjustment, seeking that the child performs most of the game in the range between 70% and 100% of the goal and time. However, exhaustive tests must be performed now to prove these values.

Acknowledgments

This work was supported in part by the Spanish and European Social Funding Committee provided through the Europe 2020 program for the employment of young people (Reference Number PEJD-2017-PRE/TIC-4825). The funder did not play a role in the design, conduct, or reporting of this study. The authors thank all children for their participation and their parents for their consent.

Abstract

Background: A widely applied and effective rehabilitation method for patients experiencing spatial neglect after a stroke is "visual exploration training." Patients improve their ipsilesional bias of attention and orientation by training exploration movements and search strategies toward the contralesional side of space. In this context, gamification can have a positive influence on motivation for treatment and thus on the success of treatment. In contrast to virtual reality applications, treatment enhancements through augmented reality (AR) have not yet been investigated, although they offer some advantages over virtual reality.

Objective: This study aimed to develop an AR-based app (Negami) for the treatment of spatial neglect that combines visual exploration training with active, contralesionally oriented rotation of the eyes, head, and trunk.

Methods: The app inserts a virtual element (origami bird) into the real space surrounding the patient, which the patient explores with the camera of a tablet. Subjective reports from healthy elderly participants (n=10) and patients with spatial neglect after stroke (n=10) who trained with the new Negami app were analyzed. Usability, side effects, and game experience were assessed by various questionnaires.

Results: Training at the highest defined difficulty level was perceived as differently challenging but not as frustrating by the group of healthy elderly participants. The app was rated with high usability, hardly any side effects, high motivation, and entertainment. The group of patients with spatial neglect after stroke consistently evaluated the app positively on the dimensions of motivation, satisfaction, and fun.

Conclusions: The Negami app represents a promising extension by adding AR to traditional exploration training for spatial neglect. Through participants' natural interaction with the physical surrounding environment during playful tasks, side effects as symptoms of cybersickness are minimized and patients' motivation appeared to markedly increase. The use of AR in cognitive rehabilitation programs and the treatment of spatial neglect seems promising and should receive further investigation.

Introduction

Spatial neglect is the dominant disorder after a brain lesion of the human right hemisphere [1,2]. The most common cause of spatial neglect is a large stroke in the right middle cerebral artery area that affects a perisylvian network consisting of the superior/middle temporal cortex and the parietal and ventrolateral frontal cortexes [3]. Affected patients behave as though the left side of their surrounding space no longer exists. The patient's eyes and head are sustainedly oriented to the side of the brain lesion (ie, mostly to the right side) [4,5]. When searching for objects, the patient's visual and tactile exploration is shifted to the right side. Accordingly, objects or people located on the left side are ignored and not found. Many therapeutic approaches to spatial neglect thus entail exercises (eg, search training on large projection screens) and activities (eg, reading and copying tasks, picture descriptions) that require increased and active turning of the patients toward the neglected contralesional side [6-9]. In this training, termed "visual exploration training" or "visual scanning training," exploration movements are improved, and compensatory search strategies are practiced, leading to improvements in neglect behavior in important everyday situations.

A critical component of neurorehabilitation and its success is related to patients' motivation to train [10]. Improving the latter is one of the main aspects of recent rehabilitation efforts known as "gamification" [11,12]. Gamification describes the application of game design elements in a nongame context to motivate desired behavior. Treatment motivation in stroke rehabilitation can additionally be increased by gamified feedback (ie, giving feedback about the performance in the corresponding task by awarding points) [13].

The principle of gamification is further emphasized when combined with virtual reality (VR) methods. The principle of active exploration training in spatial neglect has already been extended by several VR approaches. Nonimmersive VR procedures, in which a virtual environment is displayed on a monitor with which the patient interacts without being immersed in it, have been successfully used in group studies for therapeutic purposes [14-16]. On the other hand, immersive VR procedures, in which the patient becomes part of a virtual 3D environment surrounding them by means of VR goggles, have also been developed, gearing toward active exploration scenarios. Recent proof-of-concept studies have shown that healthy participants and patients who have had a stroke perceive this technique as highly motivating and enjoyable [17-19]. Moreover, immersive VR applications have already been tested with individual patients with spatial neglect for treatment purposes [20,21].

Another promising way to increase training motivation in poststroke rehabilitation is through augmented reality (AR). AR describes the computer-generated addition of virtual elements to reality. The visual, real world is augmented by virtual images and figures via a video camera of an electronic device such as a tablet. The virtual addition takes place in real time in the sense of a live transmission and thus combines the real and the virtual [22]. Bakker and colleagues [23] developed the first game combining AR elements with visual scanning training in the context of neglect rehabilitation. It consisted of participants searching for virtual images projected onto a wall in the environment of a museum. Design decisions were made based on expert opinion as well as the opinion of patients with spatial neglect. Features to increase extrinsic motivation were rated as the most important design decision.

In this development and feasibility study, the application of an AR technique for the treatment of spatial neglect is further developed. It is based on the observation that visual exploration training seems to be particularly effective when combined with an active rotation of the trunk contralesionally [24]. An attractive extension of this treatment principle is the innovative app named Negami. This app is based on the principle that patients are playfully motivated to orient themselves to their neglected side of the real room by (1) following and (2) searching for a virtual element (in this case an origami bird), actively exploring space by turning their gaze, head, and trunk. In developing the game, special consideration was given to the age group to ensure high usability. Our goal was to develop a task that would motivate the patients and that they would enjoy. By eliciting the subjective views of both healthy elderly participants (aged 57 to 89 years) and patients with spatial neglect after stroke regarding our AR-assisted exploratory therapy app, we also aimed to uncover barriers to its use and make recommendations to improve the future development of therapies with AR.

Methods

Participants

Ten elderly neurologically healthy individuals with a mean age of 66 (SD 11.9) years, including 5 (50%) females, participated in this study. In addition, we included 10 patients, including 2 (20%) females, who were experiencing spatial neglect and left-sided hemiparesis after a stroke in the neurological right hemisphere —5 (50%) with infarction and 5 (50%) with hemorrhages. They had a mean age of 61.3 (SD 15.2) years and a poststroke interval of 138.4 (SD 192.1) days when they were tested for spatial neglect. More details of the patients are provided in Multimedia Appendix 1.

The inclusion criterion for the patients was the presence of spatial neglect after a stroke. In addition to clinical behavioral observations, diagnostic criteria had to be met in at least 2 of the following 4 neglect tests: the Letter Cancellation Test [25], the Bells Test [26], a Copying Task [27], and a Line Bisection Task [28]. All 4 neglect tests were performed on a Samsung S7+ tablet with screen dimensions of 285 × 185 mm. The severity of spatial neglect in the cancellation tasks was determined by calculating the center of gravity of the target stimuli marked in the search fields, known as the Center of Cancellation (CoC). A CoC value ≥0.08 indicated left-sided spatial neglect [3,29]. The Copying Task consisted of a complex scene consisting of 4 objects (fence, car, house, and tree), wherein points were assigned based on missing details or whole objects. One point was given for a missing detail and 2 for a whole object. The maximum number of points was therefore 8. A score higher than 1 (ie, >12.5% omissions) indicated neglect [27]. In the Line Bisection Task [28], patients were presented with 4 different line lengths eight times each (ie, 32 lines in total). The cut-off value for spatial neglect was an end point weightings bias (EWB) value ≥0.07 [30].

In the group of patients, the mean CoC on the Letter Cancellation Test was 0.42 (SD 0.28), the mean CoC on the Bells Cancellation Task was 0.38 (SD 0.29), the score on the copying test was 4.4 (SD 1.51), and the EWB score on the Line Bisection Task was 0.33 (SD 2.5).

Ethics Approval

All participants gave their informed consent to participate in the study, which was conducted following the ethical standards of the 1964 Declaration of Helsinki. This study was also approved by the ethics committee of the University Clinic of Tübingen (373/2021B02).

The Negami App

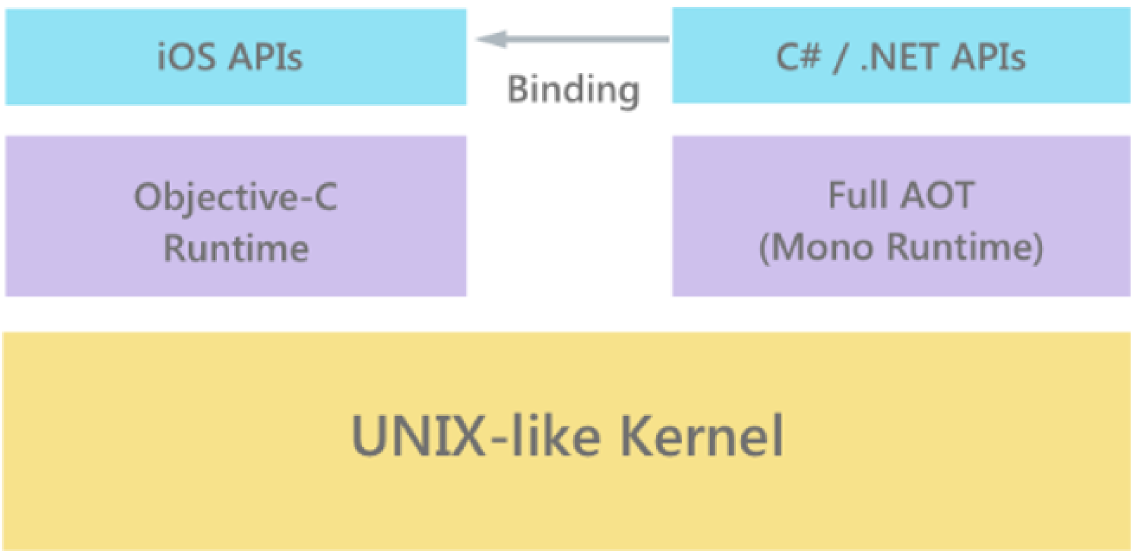
Overview

Negami [31] is a mobile app that enables the treatment of spatial neglect using gamified AR. It is optimized for use on tablets but also works on smartphones. In this study, a 3rd generation Apple iPad Pro 12.9” was used to run the app and conduct the therapy sessions. Negami provides 2 modes (Task A and Task B), which are detailed in the subsequent section. In both tasks, the live video stream from the devices’ back cameras is displayed on the screen. Additionally, a virtual element (origami bird) is added (augmented) as a 3D object that must be followed (Task A) or searched for (Task B) by moving the tablet in 3D space. An overlaying crosshair user interface (UI) element provides visual feedback and guidance for the patient.

Technical Background

The Negami app can be achieved via the Negami website. The app was implemented in C# programming language using the open-source cross-platform framework Xamarin (Microsoft Corp) [32]. It allows the creation of native Android, iOS, and Windows apps by sharing UI and code across platforms. The Xamarin platform consists of Xamarin.iOS and Xamarin.Android projects, which are implementations of the Mono framework for iOS and Android, respectively. Mono is a cross-platform open-source .NET compatible software framework. Additionally, Xamarin includes the Xamarin.Forms library for the creation of cross-platform user interfaces using XAML (Extensible Application Markup Language). A UI created in Xamarin.Forms is automatically mapped to native controls on each platform during the build process. Xamarin was chosen for the development of the Negami app because it provides native runtime performance, which is important for game-based apps, as well as an abstraction layer over many platform-specific application programming interfaces (APIs), thus increasing development speed. Additionally, Xamarin offers a set of bindings for full access to all device-specific APIs (Figure 1). Apps built with Xamarin are compiled into native packages for each platform. For the Android platform, the written code is compiled down to Intermediate Language (IL), which is then just-in-time compiled to native assembly on app launch. On iOS, the app is fully ahead-of-time compiled into native ARM (Advanced Reduced Instruction Set Computer Machine) assembly code (Figure 1 [33]).

Figure 1. Architecture of an application developed using Xamarin.iOS (left) and Xamarin.Android (right) [33]. AOT: ahead of time; API: application programming interface.



Utilizing Xamarin, the implementation of the Negami app’s entire business logic and user interface could be shared across platforms. The development followed the Model-View-View-Model design pattern and applied other best practices such as the use of an inversion of control container for dependency injection, commands, and event aggregators. Additionally, the app’s functionality was verified using both unit tests and manual testing. To facilitate the data collection process, a data synchronization feature was implemented that regularly syncs the local SQLite database (which enables the app’s offline usage) containing metadata about each patient and app settings with a remote Microsoft SQL (Structured Query Language) database utilizing the Dotmim.Sync library. As the actual data for each completed exercise session were too large to be stored efficiently in a database, a file-based synchronization was implemented using the Azure Blob Storage (Microsoft Corp) service.

Unlike the business logic and UI elements, the AR aspects of the app had to be implemented in a platform-specific way because Xamarin provides no abstraction layer for these APIs. The implementation was only completed for the iOS platform. For this, the Apple ARKit platform [34] was used (through native bindings provided by Xamarin.iOS) to implement all AR-related logic, such as world tracking, placing and rendering of the objects in 3D space, and retrieving the current screen position of the bird. For Android, the Google ARCore library was utilized in the future to implement the same logic.

Design

Since the target group consists mainly of elderly people, the design of the app was tailored to their needs to facilitate the most positive user experience. The app was intended to reduce the distance and strangeness that this user group often feels from digital devices. We did not want it to feel like a monotonous, mandatory clinical treatment. Instead, we wanted patients to playfully find the motivation to work on their recovery.

A further aim was to ensure that patients—after discharge from inpatient treatment—can safely use the app to practice on their own or with family members to make further progress. This is achieved through short distances in operation and simple instructions and assistance. The same applies to large control buttons that are easy to reach even with shaky or stiff fingers. We also took into account that patients with spatial neglect ignore information on the contralesional side. For example, this was considered when placing and labeling the exercise buttons. Simple letters like “A” and “B” presented on the right tablet side were used instead of complex icons or text. Moreover, we took into consideration that patients with spatial neglect are often hemiparetic. Instead of holding the tablet from the right and left with both hands, hemiparetic patients can hold it with the unaffected hand from the bottom/center. However, if the tablet is too heavy for the patient to hold in this single-handed position, a loop with Velcro can be attached to the patient’s wrist, which, in turn, is attached to the middle of the back of the tablet to help the patient carry the weight.

In addition to the patients, there is another user group: the therapists. This group of users has different requirements for the app than the patients. Since therapists are often responsible for several patients concurrently, they need to treat patients as efficiently as possible. For this purpose, the app offers the therapist the possibility to easily adjust the corresponding performance level of each patient to their current treatment status. The development of each patient's skills is easily visible to the therapist. Further, the app offers the possibility to create a plan for independent therapy at home. The patient's progress thus is recorded and can be viewed by the therapist at any time, allowing them to make the exercises more difficult or easier depending on the patient's level of ability.

Tasks Provided by the Negami App

During the typical use of Negami, the participant sits in a chair or a wheelchair. If possible, the tablet is held with both the left and right hands. If the participant is hemiparetic, the tablet can be held from below with one hand positioned in the middle. Using arm movements in combination with trunk rotations, the tablet can then be moved to the left or right through real space (Figure 2). The participants perform 2 different tasks in succession.

Figure 2. Patient performing tasks of the Negami app. A virtual element (origami bird) was added (augmented) to the video stream of the surroundings produced by the camera of a tablet.

The patient's first task (Task A: "follow the bird") is to follow the virtual origami bird through real space. The patient's straight-ahead eye/head/body orientation is set as 0. Beginning at set point 0, the bird flies with random sinusoidal movements toward one side of space (in neglect patients toward the contralesional, neglected side). While doing so, the patient sees an orange circle in the center of the screen (Figure 3). The bird should be held in this circle while performing the task. As soon as the patient fails to successfully follow the bird and keep it in the circle during its flight, they are provided with an additional orientation aid. A blue compass needle appears showing the patient in which direction the bird is located (see Figure 3). The task is successfully completed as soon as the bird has finished its trajectory and the bird has been positioned centrally in the orange circle. During the performance, the patient receives auditory feedback. Every time the patient manages to get the bird into the orange circle, a short, bright tone is presented. If the patient manages to keep the bird continuously in the orange circle, the tone is presented every 2 seconds. When the task has been successfully completed, the patient receives feedback auditorily again through a different tone and visually through the change of the color of the circle to green.

At the end of a successful trial, the options "change angle" and "lead to point 0" are provided on the screen. If the patient/therapist wants to repeat the task, they can select "lead to point 0," and if the difficulty of the task must be varied, the patient/therapist can select "change angle." The patient/therapist has 3 different difficulty levels to choose from: easy, medium, or difficult (Table 1). The difficulty levels are saved as templates.

Figure 3. Task A: "follow the bird." The patient has the task to follow the flying origami bird and to keep the bird within the orange/blue circle (A). If the task is successfully solved the circle turns green (B).

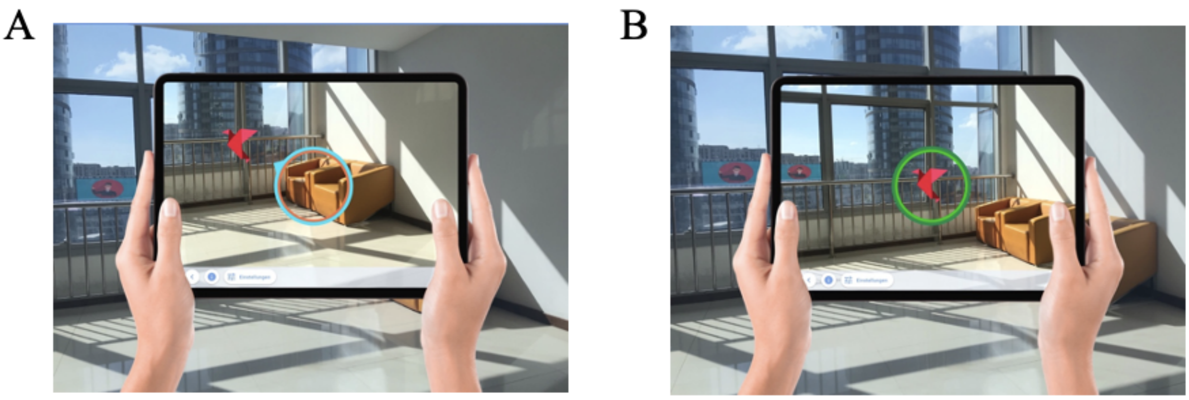


Table 1. Difficulty levels provided with Task A ("follow the bird")[a].

Level	Maximum distance of the bird's path	Speed of bird movement	Amplitude of bird movement
Easy	up to ±35°	2.3°/sec[b]	6.8°
Medium	up to ±55°	4.1°/sec	8.0°
Difficult	up to ±85°	8.1°/sec	11.3°

[a]Angular degrees are participants' space coordinates, starting from their straight-ahead eye/head/body orientation, which is set as 0.

[b]sec: second.

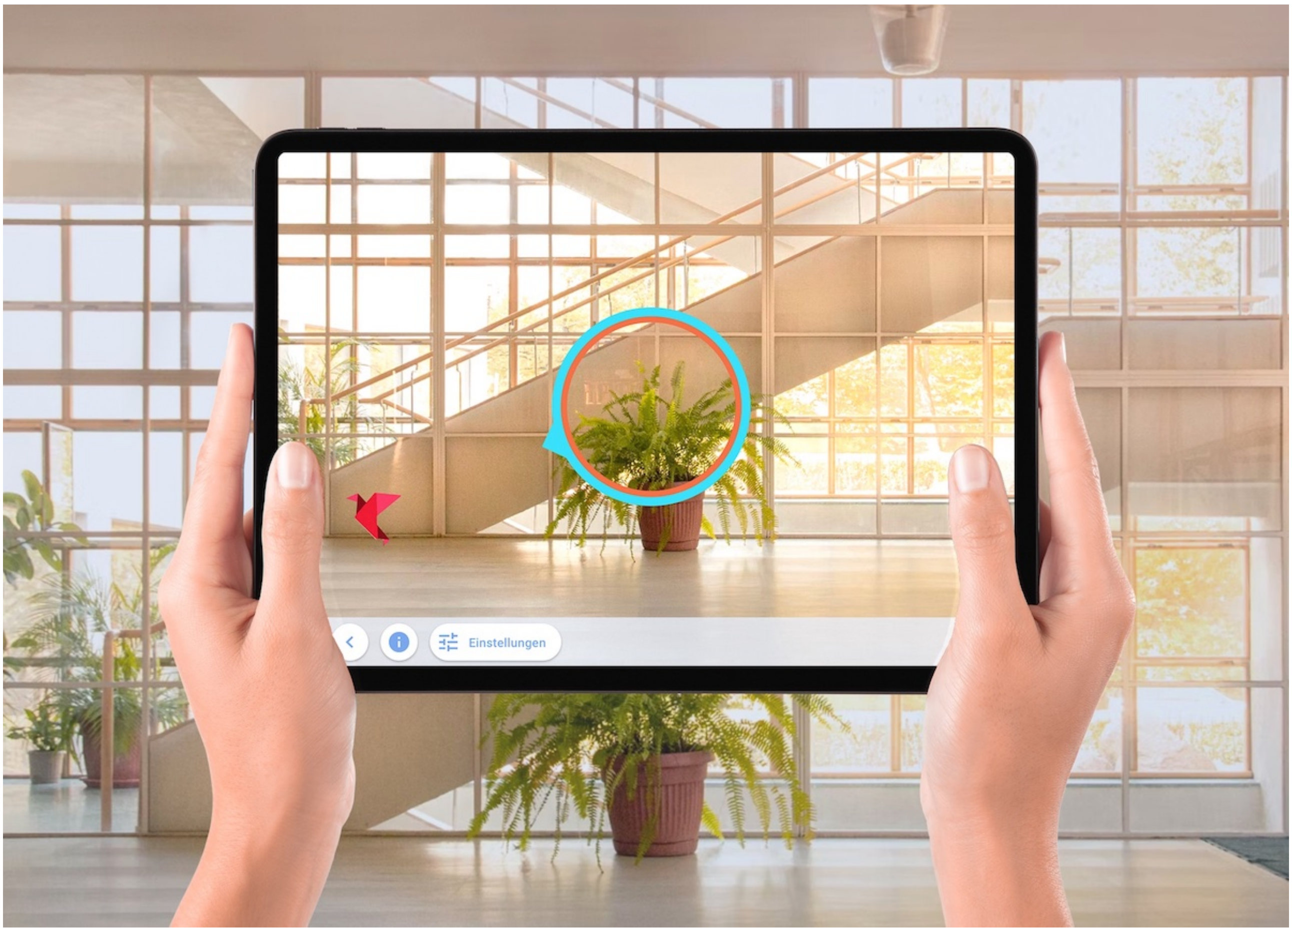
In the second task of the Negami app (Task B: "find the bird"), the therapist hides the virtual origami bird in the room surrounding the patient. For this purpose, the patient's straight-ahead eye/head/body orientation again is set as 0. Starting from this location, the therapist hides the bird somewhere on the left/right side of the patient without the patient seeing it. The best way to do this is for the therapist to step behind the patient and hold the tablet above the patient's head in such a way that they cannot see where exactly the tablet is pointing. The area within the bird that can be hidden by the therapist is predefined by the app depending on the chosen difficulty level of the task (Table 2). Once the therapist has positioned the bird in space by clicking on the center of the screen, they return the tablet to the patient's hand. The patient is then instructed to find the bird, and once found, to position it centrally into the orange circle. No time limit is given. Should the patient show difficulties in finding the bird, it is possible to provide the patient with orientation assistance by turning on the blue compass needle (Figure 4). The task is successfully solved when the patient finds the bird and places it in the center of the circle. As with Task A, the circle then turns green (Figure 3), and the patient hears a bright tone signaling the successfully solved task. After successful completion of the task, options "change angle" and "lead to point 0" are provided (see Figure 3) so that the task can be repeated or changed in difficulty.

Table 2. Difficulty levels provided with Task B (“find the bird”)[a].

Level	Extension of the area (along the horizontal dimension of the surroundings) within which the bird can be hidden
Easy	0° to −40° (or 0° to +40°)
Medium	−40° to −75° (or +40° to +75°)
Difficult	−75° to −90° (or +75° to +90°)

[a]Angular degrees are the participants’ space coordinates, starting from their straight-ahead eye/head/body orientation, which is set as 0. Negative values indicate positions to the participant’s left, while positive values indicate positions to the participant’s right.

Figure 4. Task B: “find the bird." The patient has to search for the bird that has been hidden by the therapist somewhere in the surrounding room (in this image, at the corner located at the foot of the stairs) and has to transfer it into the orange/blue circle.



Procedure

All neurological patients received training with Negami in their room in the ward of the respective rehabilitation facility. The healthy participants also received the training indoors for comparability. The healthy participants had 1 training session with Negami that lasted 20 to 25 minutes. They completed Task A in the first half and Task B in the second half, each at the highest difficulty level. If patients were not able to use both hands to hold the tablet due to hemiparesis, they were instructed to hold the tablet with the unimpaired hand only by grasping the tablet in the middle from the top or bottom. A video example of a patient working with Negami is shown in Multimedia Appendix 2. To assess feasibility, usability, and game experience, the System Usability Scale (SUS) [35], Simulator Sickness Questionnaire (SSQ) [36], and Perception of Game Training Questionnaire (PGTQ) [37] were administered to the participants directly after the training session.

To assess usability, the participants answered the 10 questions of the SUS through a 5-point Likert scale ranging from 1 (fully disagree) to 5 (fully agree). The mean score was calculated for each participant across all questions. To capture the presence of side effects of simulation technologies, the SSQ was applied. For this purpose, the presence of a series of symptoms grouped under “cybersickness” was tested by a 4-point Likert scale ranging from 0 to 3 (not at all, slightly, moderately, and strongly). The following 15 symptoms were recorded in total: general discomfort, fatigue, headache, eyestrain, difficulty focusing, increased salivation, sweating, nausea, difficulty concentrating, fullness of the head, blurred vision, dizziness, vertigo, stomach awareness, and burping. Again, the mean score was calculated across all items for each patient. Finally, the patients were asked via the PGTQ, which uses a 7-point Likert scale ranging from 1 (fully disagree) to 7 (fully agree), about how motivating, frustrating, challenging, and enjoyable they found the training with Negami to be. Since each of the 4 questions covers a different aspect of the perception of Negami, no mean value was calculated.

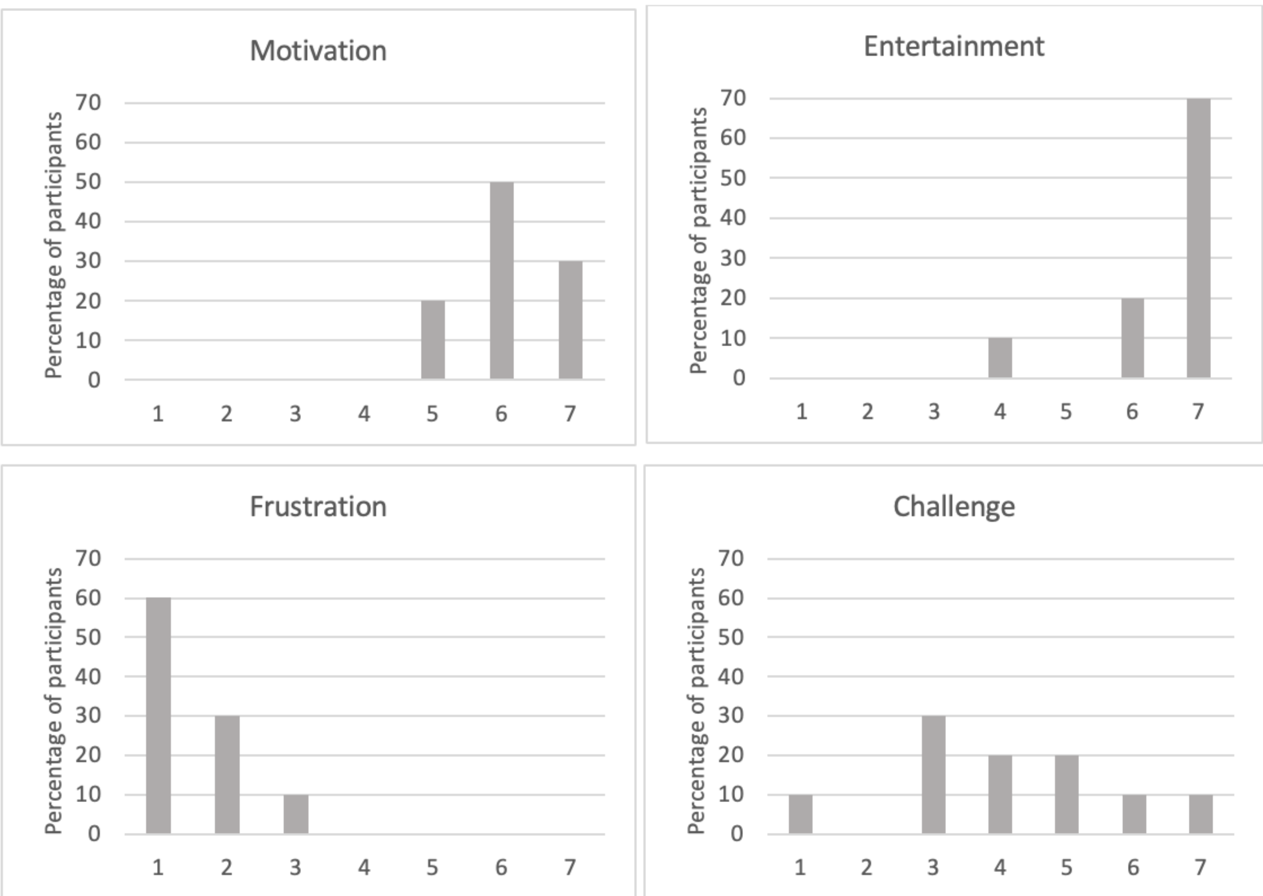
The patients with spatial neglect received a 2-week application with 5 training sessions per week. Each session lasted 20 to 25 minutes. As the healthy participants, they completed Task A in the first half and Task B in the second half. The tasks were always initiated for the patients with the easiest difficulty level. The criterion for success in advancing to the next difficulty level was that the task was successfully completed 3 times in a row. A return to a lower difficulty level was indicated when the task was not solved 2 times in a row. Upon completion of the treatment, subjective reports about the use of the Negami app were collected from the patients by using the following three questions: (1) How satisfied were you with the treatment? (2) How motivating did you find the treatment? (3) How much did you enjoy the treatment? The answer options varied from 1 to 6, with 1 being the best result. The patients were further asked whether they would recommend the treatment to others (yes/no) and in an open response format, whether they had any suggestions for improvement.

Results

Healthy Participants

The results of the healthy elderly participants from the SUS on usability resulted in a mean value of 4.3 (SD 0.6), indicating that the usability of the Negami app was rated on average as high to very high. Moreover, there were hardly any side effects detected, as assessed by the SSQ and indicated by a mean score of 0.8 (SD 1.32). More specifically, only 1 patient (10%) reported mild symptoms of fatigue, headache, difficulty focusing, and blurred vision. In addition, 2 (20%) other participants reported mild problems with strained eyes and focusing. None reported moderate or strong side effects. Finally, the PGTQ captured the dimensions of motivation, frustration, challenge, and entertainment during training with Negami. The healthy participants' evaluations on these dimensions are shown in Figure 5. The participants found Negami to be motivating (mean 6.1, SD 0.7) and highly entertaining (mean 6.5, SD 0.9). As indicated by a mean score of 1.5 (SD 0.7), the training was not perceived as frustrating. However, some participants found the training challenging, while others did not (mean 4.1, SD 1.7).

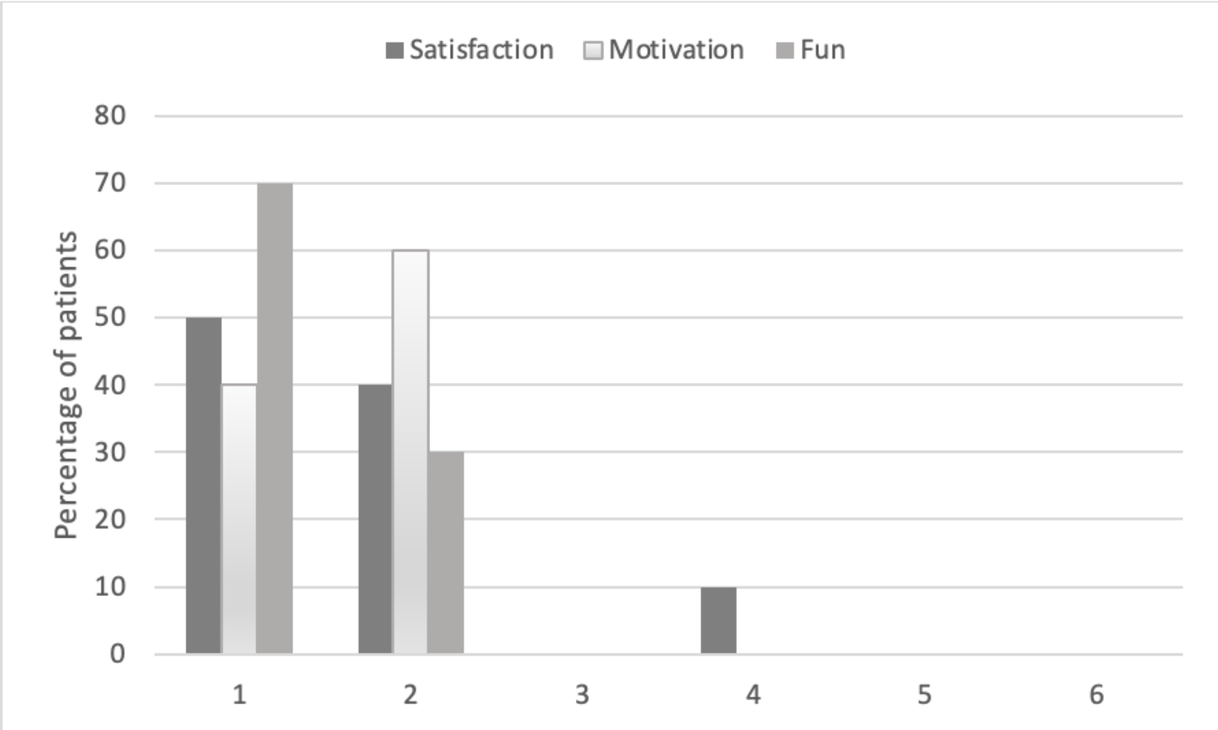
Figure 5. Percentage of healthy, older adults (n=10) evaluating training with the Negami app on the dimensions “motivation,” “frustration,” “challenge,” and “entertainment,” on a 7-point scale (1 = "I fully disagree"; 7 = "I fully agree").



Neglect Patients

An analysis of the reports by the patients regarding the use of the app revealed that all 10 patients recommended treatment with Negami. The patients' evaluation of the app treatment on the dimensions of fun, satisfaction, and motivation are shown in Figure 6. The results demonstrate that all patients evaluated the app treatment on all 3 dimensions with the best 2 scores. Only 1 (10%) of the patients chose a score of 4 on the dimension of satisfaction. Consistent with these very positive ratings by the patients with spatial neglect, the Spearman rank correlation coefficients between the dimensions of satisfaction, motivation, and fun and the severity of spatial neglect (expressed as the mean value of the CoC from the 2 cancellation tasks) were not significant (satisfaction: r=.21, motivation: r=.57, fun: r=.42; all P≥.086). Regarding suggestions for improvement in the open response format, 3 (30%) of the 10 patients with hemiparetic neglect reported that they had trouble holding the tablet due to the weight. They had to hold the tablet with 1 hand instead of both. One (10%) patient noted that older patients might be digitally overwhelmed with the treatment. All other patients had no suggestions for improvement.

Figure 6. Percentage of stroke patients (n=10) with spatial neglect evaluating training with the Negami app on the dimensions "satisfaction," "motivation," and "fun," on a 6-point scale (1 is the best score; 6 is the lowest score).



Discussion

Principal Findings

This study aimed to develop and assess the usability, side effects, and game experience of a new rehabilitation app (Negami) for patients with spatial neglect. By using AR, the app was designed to playfully encourage patients to actively explore space by turning their gaze, head, and trunk. Our investigation showed that Negami was perceived as motivating and entertaining by the healthy elderly controls. Training at the highest defined difficulty level was perceived as differently challenging but not as frustrating. The survey further revealed high usability and no to very low side effects such as headache, strained eyes, or blurred vision. Additionally, the second group evaluated in this study (ie, the patients experiencing spatial neglect after a stroke) consistently evaluated the app positively on the dimensions of motivation, satisfaction, and fun. Furthermore, we observed that the app and the tablet could also be used by patients with hemiparesis (by holding the tablet with the unimpaired hand only, grasping the tablet in the middle from the top or bottom). However, 3 (30%) of the 10 patients with hemiparesis complained about the heaviness of the tablet, so the use of even lighter devices seems beneficial.

Gamification and the Negami App

These positive results give us reason to believe that the new app could become a very useful tool in the treatment of patients with spatial neglect. Ogourtsova and colleagues [38] have shown that patient expectation of performance is the most important factor for acceptance of the use of VR technologies in rehabilitation. Therefore, when defining the 3 different difficulty levels of training with Negami, our focus was on ensuring that the easiest task could be solved relatively quickly even for patients with more severe neurological impairment. This could also be the reason why Negami was so well received by the tested patients who had a stroke. The use of different difficulty levels, as well as auditory and visual feedback on performance during training, are elements that supported the gamification of the Negami app. Gamification for the purpose of rehabilitation has been shown to have positive effects on the patients' engagement and motivation for their treatment [39]. Another reason for the positive feedback from both patients and healthy participants could be due to our app design in that we paid special attention to the age group, as 75% of patients who have had a stroke are aged over 65 years [40] and are typically not "digital natives" [41]. In implementing short distances in operation, simple instructions, and assistance, we aimed to ensure that this age group feels comfortable in dealing with an electronic device such as a tablet when using the Negami app.

AR Versus VR Techniques and Telerehabilitation

A third aspect that might have contributed to the positive ratings by the 2 groups tested could be the choice of the AR over VR technique. It is a frequent observation that the use of VR may evoke symptoms that are summarized under the term "cybersickness" [42]. These include symptoms such as drowsiness, headache, balance and coordination problems, nausea, and blurred vision. We observed that such symptoms were absent during the training with Negami. The reason for this could be that the risk of sensory mismatch concerning visual, vestibular, and proprioceptive information, which is considered one of the causes of cybersickness [43], is reduced to a maximum—if not completely avoided—when working with AR. The AR-based Negami app prompts people to move in the real world by actually moving their heads and bodies. The use of the tablet merely adds a virtual object to the real world. In this respect, manipulation is kept to a minimum.

Negami can also offer an advantage over VR games in terms of cost. The development of a VR system is often associated with high costs due to the need for dedicated hardware [42]. Since Negami is available online (see the Negami website), it can be easily downloaded to any available tablet or smartphone. This provides wide availability and ensures that additional costs are avoided. The use of already existing technical hardware also offers immense opportunities regarding remote/telerehabilitation. This is important because, in one-third of patients experiencing spatial neglect in the acute phase of the stroke, the disorder becomes chronic [44]. During their inpatient stay, patients are well cared for in terms of their recovery, but what happens after discharge from inpatient rehabilitation? An answer to that could be remote/telerehabilitation. Easy-to-understand instructions for the tasks in Negami can allow patients to practice independently from home. With online data storage, the therapist has external access to patients' treatment data and can monitor them remotely.

Limitations

One limitation of this study is the small sample size. We only could include 10 elderly neurologically healthy individuals and 10 patients experiencing spatial neglect and left-sided hemiparesis after a stroke in the right brain hemisphere. Therefore, testing the Negami app with a larger number of participants in a future study will be useful. It would also be desirable to evaluate the use of the app on the part of the therapists in the future. It should be further mentioned that Negami thus far can only be used on Apple devices. However, it is being further developed with the aim of being able to use on Android devices as well. The further development of all smart devices with different operating systems would also ensure the use of lighter devices, as 3 (30%) of the patients complained about the weight of the tablet. At this point, it should also be mentioned that very severely affected patients, who are not yet able to hold a tablet in the acute phase after a stroke, may not benefit from Negami initially, and other therapeutic approaches should be considered first for them.

Conclusion

AR represents a promising extension to the traditional "visual exploration training" for spatial neglect. The natural interaction with the environment during playful tasks appears to markedly increase patient motivation. An advantage of AR, as implemented in Negami, over immersive VR-based treatments may be that it minimizes the risk of sensory mismatch concerning visual, vestibular, and proprioceptive information, which is considered one of the causes of cybersickness.

Abstract

Background: While vestibular rehabilitation with virtual reality (VR) is becoming more popular every day, the disadvantages of this method are not yet clear.

Objective: The aim of this study is to examine the effect of the image to be used in vestibular rehabilitation with VR on the systems that provide body posture.

Methods: The study was carried out with 36 participants (18 women and 18 men) aged 18 to 30 years. To assess balance control components separately, a sensory organization test was administered to the participants in the presence of stressful and relaxing environment images with VR technology. The State-Trait Anxiety Inventory survey was also used to measure the stress values in the created environments.

Results: The State-Trait Anxiety Inventory survey revealed that while stressful videos significantly increased stress, relaxing videos reduced stress. Among measurements obtained in the presence of VR, significant decreases were observed mostly in the visual system data. A significant increase in vestibular system data (*P*=.01) was observed with a decrease in visual system data (*P*<.001) when the relaxing image was presented. Additionally, there was a significant difference in the somatosensory (*P*=.001), composite (*P*=.002), and visual system (*P*<.001) data in the presence of stressful videos.

Conclusions: Although the use of a VR system for vestibular rehabilitation is relatively new, no extant studies have examined how the image type used in VR can affect the integration of visual system data. Therefore, this study is unique in terms of showing the effects of the stress created by the change in the type of the image used in VR. When VR technology is used for therapeutic vestibular rehabilitation for patients whose balance disorder is due to the vestibular system, stress-free videos should be used. However, the use of stressful videos in VR technology will be beneficial in the rehabilitation of those with balance disorders due to the somatosensory system.

KEYWORDS

balance; computerized dynamic posturography; stress; vestibular rehabilitation; vestibular system; virtual reality

Introduction

Maintaining posture uses a complex mechanism involving the brain's processing of multiple sensory inputs from the visual, proprioceptive, and vestibular systems by the central nervous system [1]. Computed dynamic posturography (CDP), which is used to examine the effects of these multisensor inputs separately, is a kind of test that can be used to evaluate the mechanisms that ensure the protection of the individual's posture by using different test positions similar to those we often experience in our daily lives [2]. The sensory organization test (SOT), one of the CDP test protocols, is a test that can evaluate a person's ability to use inputs from the vestibular, somatosensory, and visual systems to maintain balance in different stimulus situations and to monitor the compensatory condition in case of balance deterioration [3].

Virtual reality (VR) can be defined as a computer-generated simulation of a 3D image or environment with which the user can interact. Recently, the scope of VR use has expanded greatly, and it is being used in many areas, especially in rehabilitation programs, where it is increasing the effectiveness of vestibular rehabilitation. Studies have shown that a VR protocol may be a safe option to improve postural control and quality of life in individuals with vestibular disorders [4-6].

The classical stress response is a negative feedback system mediated by the hypothalamic-pituitary-adrenaline axis [7]. Studies have found that balance is affected in people who are under stress [8-10]. According to Saman et al [11], stress may affect central vestibular function either directly through the effects of cortisol and corticosteroids on ion channels and neurotransmission in the brain or indirectly through stress-related neuroactive substances. Gliddon et al [12] observed a significant increase in postoperative salivary cortisol levels in guinea pigs undergoing unilateral vestibular deafferentation.

One of the most widely used clinical tests for the measurement of anxiety is the State-Trait Anxiety Inventory (STAI) survey (Multimedia Appendices 1 and 2). The survey test, which evaluates stress immediately after an individual has undergone a test in a research or clinical setting, was administered, and the Turkish validity form, the reliability of which had been ascertained before, was filled in. There are questions in the inventory that increase and decrease the anxiety score [13,14].

Additionally, in the study by Seinfeld et al [15], increases in stress indicators (heart rate and skin responses) were observed in stress environments created by a VR system [16]. However, in some other published studies, the effect of stress was not considered in vestibular rehabilitation using a VR system. For this reason, the aim of this study is to examine the effect of the image to be used in vestibular rehabilitation with VR on the vision-proprioception-vestibular systems that provide body posture.

Methods

Participants and Recruitment

We calculated the sample size using power analysis. In the study, we set an α (type I error) of 5%, Cohen medium standardized effect size of 0.5, and power of 80% (with β [type II error] set to 20%). Power analysis revealed that a minimum of 28 patients were required. A total of 36 patients, 18 men (aged 23.33, SD 2.54 years) and 18 women (aged 21.66, SD 2.22 years) between the ages of 18 and 30 years (sample mean age 22.50, SD 2.50 years), were included in the final analysis. While individuals who were psychologically healthy and had no problems with balance in daily life in the preceding 1-year period were included in the study, those with eye problems, a fear of heights, dizziness in daily life, physical discomfort, or regular use of alcohol or drugs were excluded from the study.

Experimental Design

The study was conducted in the audiology clinic at the Istanbul Training and Research Hospital between February 23 and May 10, 2021. A NeuroCom device (Natus Medical Inc) was used to administer the SOT from among the CDP test repertoire.

The SOT measures how well the patient maintains equilibrium under 6 sensory conditions. Each condition is scored between 1 and 100, with an increased score indicating better stability. Each of the 6 conditions is repeated 3 times, and the duration of each test is 20 seconds. After 6 conditions (ie, 18 tests) the composite equilibrium score is then determined [16].

For the first 3 conditions, the force plates are fixed, and for the other 3 conditions, they move in anterior and posterior directions. In the first condition (baseline), the person is placed on the system such that all sensory information involved in postural control is available. In the second condition, the participant is tested with eyes closed (the visual information system is eliminated). In the third condition, the person's eyes are open, but the visual environment moves to present incorrect visual sequences. In the fourth to sixth conditions, the force plates are moved so that they act as what is referred to as a "sway referenced surface," making proprioceptive information inaccurate; hence, the subjects use visual and vestibular (or only vestibular) information to maintain their balance, in addition to having to overcome the inaccurate proprioception signals by relying on other systems and compensatory mechanisms. In the fourth condition, information from the visual and vestibular systems is evaluated. In the fifth condition, the eyes are closed. In this condition, information from the vestibular system is evaluated. In the sixth condition, inappropriate visual arrays are presented; thus, information from the vestibular system is evaluated [16].

Comparison of scores from the first 2 trials produces a "somatosensory score"; comparison of the score for test 4 with that from test 1 yields the "visual score"; comparison of scores from trial 5 to trial 1 reflects the "vestibular score." Comparing the sum of scores from the third and the sixth trials with the sum of scores from the second and fifth trials yields the "visual preference score" [17].

The SOT, one of the CDP tests, was administered to the participants in 3 different conditions generated using VR: in the control condition, in a stressful environment, and in a relaxing environment (Figure 1). An HTC VIVE VR system was used to generate the different environments. In the control condition, normalization values were determined by administering the SOT to the participants without wearing VR glasses (Figure 1).

To generate a stressful environment in the VR simulation, participants were raised to a height of 40 meters in a simulation of an elevator. Then, in the simulation, the elevator door opened, and they walked onto a platform that appeared in front of them. The end of the platform was mapped to the test area of the CDP device. When they arrived at this position, the SOT was administered to the participants while they saw VR images from a simulated height of 40 meters (Figure 1).

In the relaxing environment, while participants were waiting for the test on the CDP device, a meditation application was opened in VR. The SOT was administered while the participants were in the relaxing scenery (Figure 1).

Considering that the participants could adapt to the test, the tests were applied to each participant starting from a different condition. This aimed at preventing possible adaptation. A participant who completed one condition rested for at least 1 hour, after which another condition was applied.

After the tests, the participants took the STAI survey. Certain questions in the survey could increase or decrease the anxiety score. For each question, a score between 1 (or –1) and 4 (or –4) is assigned in accordance with the positive or negative characteristics of the question. The highest score is 80 and the lowest score is 20. The higher the total anxiety score, the higher the anxiety level of the person taking the survey [13].

Figure 1. Three different visually generated test environments.

Ethics Approval

The study was approved by the Non-Invasive Clinical Research Ethics Committee of Istanbul Medipol University (923/2020). All individuals participating in the study received explanations of the aims of the study, how long it would last, and practices and expectations. Participants then signed the consent form.

Statistical Analysis

The minimum subject size was estimated using G*Power (version 3.1; Heinrich-Heine-Universität Düsseldorf). The data analysis of our study was performed using SPSS (version 22.0; SPSS Inc). Descriptive statistics included mean and SD values. Normality of the distribution and homogeneity of the data were analyzed with the Kolmogorov-Smirnov test. A triple comparison of the groups (control condition [CC], stressful condition [SC], and relaxing condition [RC]) was carried out using the Friedman test. CC-RC, CC-SC, and RC-SC comparisons were made using the Wilcoxon signed-rank test. The statistical significance level was set to a *P* value of ≤.05 when analyzing the results of the Wilcoxon signed-rank test. In the Friedman test, statistical significance level was set to a *P* value of ≤.017.

Results

Triple Comparisons

Significant differences were observed in the visual system ($P<.001$) and somatosensory system ($P=.001$) data in the triple comparison of SOT data obtained in different stress environments (Figure 2). While no significant difference was observed in the vestibular system ($P=.03$) data, a significant difference was observed in the composite ($P=.002$) values (Figure 3). While a significant difference was observed in stress values ($P<.001$), there was no significant difference in the preference values (Figure 4).

Figure 2. The sensory organization test and visual and somatosensory system data.

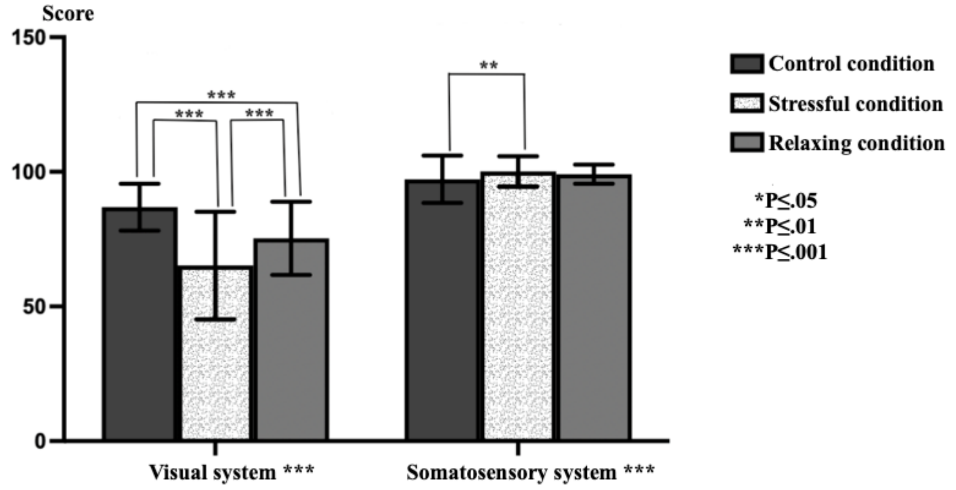

Figure 3. The sensory organization test for the vestibular system and composite data.

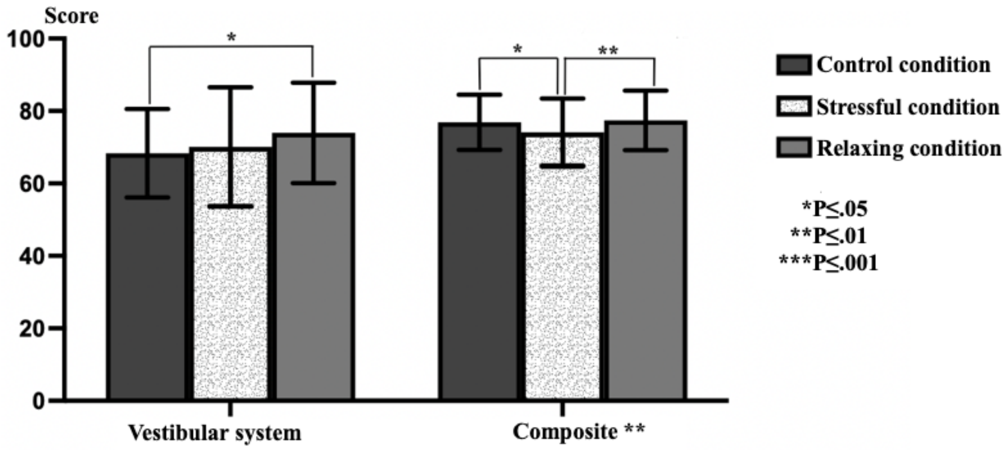

Figure 4. The sensory organization test, preference scores, and survey stress data.

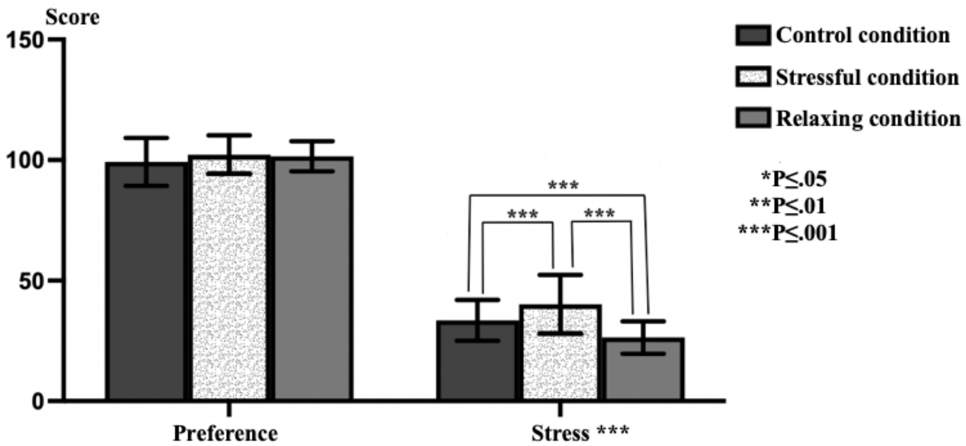

Dual Comparisons

Significant differences were observed in visual system data in pairwise comparisons between the cases (CC-RC and CC-SC, *P*<.001; RC-SC, *P*=.001). A significant difference was observed when comparing the CC and SC environments (*P*=.002) in the somatosensory system data. A significant difference was observed when comparing the CC and RC environments (*P*=.01) in the vestibular system data (Table 1). No significant difference was observed in the comparisons made with preference data. A significant difference was observed when comparing the CC and SC environments (*P*=. 02) and the SC and RC environments (*P*=.005) in the composite data. When only the stress data were evaluated, a significant difference was observed when comparing the CC and SC environments (*P*<.001), CC and RC environments (*P*<.001), and SC and RC environments (*P*<.001; Table 2).

Table 1. Dual and triple comparisons of visual, vestibular, and somatosensory system data in 3 different cases.

	Control condition (CC), mean (SD)	Stressed condition (SC), mean (SD)	Relaxed condition (RC), mean (SD)	*P* value (CC-SC-RC)	*P* value (CC-SC)	*P* value (CC-RC)	*P* value (SC-RC)
Visual system	86.88 (8.70)	65.22 (19.98)	75.30 (13.61)	<.001	<.001	<.001	.001
Vestibular system	68.36 (12.20)	70.11 (16.46)	73.97 (13.87)	.03	.43	.01	.12
Somatosensory system	97.22 (8.79)	100.16 (5.64)	99.11 (3.52)	.001	.002	.21	.10

Table 2. Dual and triple comparisons of preference, composite, and stress data in 3 different cases.

	Control condition (CC), mean (SD)	Stressed condition (SC), mean (SD)	Relaxed condition (RC), mean (SD)	*P* value (CC-SC-RC)	*P* value (CC-SC)	*P* value (CC-RC)	*P* value (SC-RC)
Preference	99.19 (9.95)	102.25 (8.03)	101.55 (6.27)	.50	.12	.30	.97

Discussion

Principal Findings

The aim of the study was to investigate the effect of stress on the systems that provide data for maintaining posture. The SOT was administered to the study participants in different stress environments generated with VR. The changes in visual, vestibular, and somatosensory systems were examined with the SOT. Our results indicate that stress, especially presented visually, has a significant effect on the systems that protect posture.

Wuehr et al [18] took people to a height of 40 meters with a VR-based elevator simulation and observed specific changes in subjective fear levels, muscle activity, and balance control. In our study, like that of Wuehr et al [18], the SOT was administered by raising people to a height of 40 meters in an elevator simulation with a VR system as an instant stress source. When we examined the change in stress in the participants using the STAI survey before and after the test, we found that the participants were affected by stress in the presence of a stressful video. In the presence of a relaxing video, we found that the stress level was significantly lower than in the control group. Thus, we proved that our image selection is effective for assessing stress factors.

VR, which we use as an instant stress generation tool, has been used frequently in clinical studies with the development of technology in recent years [19]. In addition, its use in vestibular rehabilitation is increasing [20]. It has not been specifically reported in the literature whether VR has an adverse effect in VR-based vestibular rehabilitation or whether it has an adverse effect on the systems that provide data for maintaining posture [21]. Micarelli et al [22,23] reported that symptoms of nausea, oculomotor stress, and disorientation decreased over time in people participating in a vestibular rehabilitation program with VR. Both studies saw a significant reduction in nausea, oculomotor stress, and disorientation in the first to fourth week of the rehabilitation program with VR [22,23]. However, the instantaneous effect of VR and the effect of the video type used on treatment were not investigated in these studies. In our study, when we looked at the instantaneous effect of VR on the systems that maintain posture by comparing the CC and RC environments and considering the results of the SOT, we found that VR application does not directly cause stress, but rather makes the person feel more comfortable than normal. However, we also observed that VR had a negative effect on the visual system while in this condition. Although there was no negative effect on the somatosensory system, we observed a significant increase in the values of the vestibular system. With the decrease in values for the visual system and the increase in those for the vestibular system, there was no significant decrease in the composite value, which is the general balance score. We believe that VR-based vestibular rehabilitation will be a successful process based on these findings. To avoid potential side effects from staying in a virtual environment for a long time during this process, special attention should be paid to the effect on the visual system, cyber sickness, dizziness under visual stimuli, nausea, and imbalance [24,25].

In Öztürk’s [25] study, individuals were evaluated with cervical vestibular-evoked myogenic potentials and video head impulse tests in the presence of visual illusions. The amplitudes of the vestibular-evoked myogenic potentials increased in cases where visual illusions were presented, and gains in some semicircular canals increased significantly. This showed that the vestibular system works more efficiently when there is a decrease in the consistency of the data obtained from the visual system [25]. In this study, the increase in vestibular system data is compatible with the visual stimulus provided by wearing the VR device.

In a study by Smyth et al [26] , healthy individuals with the highest cortisol response to psychosocial stress—that is, those who were most affected—had less-impaired postural sway when exposed to visual movement [26]. This is consistent with the findings of our study, in which the somatosensory system performed better when the VR image containing the stress stimulus was used, because in healthy people, minor oscillations are modulated by the ankle, which is part of the somatosensory system.

Psychological effects are common in patients experiencing vertigo or dizziness. In particular, the fear of falling and the resulting stress and anxiety seriously impair the quality of life of these individuals [27]. Eagger et al [28] found that patients with vestibular symptoms had higher social stress and trait anxiety scores than those without vestibular symptoms. The balance-stress neuroanatomical link has been defined as follows: the nucleus tractus solitarius has been shown to have extensive connections with the vestibular nuclei, both directly and through indirect projections through the parabrachial nucleus, which provides major inputs to the limbic system, including the enlarged central amygdaloid nucleus, infralimbic cortex, and hypothalamus [29]. Because of this connection between the vestibular system and the limbic system, the stress factor should be taken into account when planning treatment for individuals with vestibular symptoms. Choosing less stressful images during the vestibular rehabilitation phase, especially near the end of the study, will aid in the recovery of vestibular systems.

Studies have shown that stress has an effect on the systems that maintain posture [7,9,11]. In line with the findings of the literature review, this study found that stress has a significant effect on these systems and that the stress effect provided by VR is primarily due to the effect on the visual system. When comparing the RC and SC environments, there was a significant decrease in visual system data and composite scores, accompanied by a significant increase in stress values. When we compared the visual system values of the CC and SC environments, we found a significant decrease as a result of stress, as well as a significant change in stress. Similarly, a significant increase in somatosensory values was observed with stress. This result shows the importance of the image used in vestibular rehabilitation. Confidence in the somatosensory system increased significantly when the participants watched a stressful video, while confidence in the vestibular system increased significantly when a relaxing video was shown. Thus, data on which group would be more effective for use in vestibular rehabilitation with VR, and the appropriate images to be used, should be highlighted.

Limitations

The SOT is not normally administered while wearing VR glasses. However, to investigate the effects of VR on balance while wearing these glasses, the SOT was used with relaxing images. To investigate the effect of image selection, a stress-inducing image, rather than a relaxing image, was used.

Conclusions

Our study investigated the effects of stress on the systems that protect posture and how much each of the systems is affected by stress, and the effect on individuals of using VR technology to provoke stress. Our results show that the visually created stressful environment had a significant effect on balance. In individuals with balance disorder, it would be more beneficial to use stressful images if the problem relates to the somatosensory system and to use less stressful images if it is related to the vestibular system. To obtain more successful and quicker results in the treatment processes for individuals with balance problems, it is necessary to focus on the stress condition and its effect on patients. In addition, the decrease in visual system data as a result of the stress we induced visually and the effect of rehabilitation with VR in people whose visual system contributes to their balance disorder should be the subject of further studies.

Abstract

Background: Neurological rehabilitation is technologically evolving rapidly, resulting in new treatments for patients. Stroke, one of the most prevalent conditions in neurorehabilitation, has been a particular focus in recent years. However, patients often need help with physical and cognitive constraints, whereby the cognitive domain in neurorehabilitation does not technologically exploit existing potential. Usually, cognitive rehabilitation is performed with pen and paper or on a computer, which leads to limitations in preparation for activities of daily living. Technologies such as virtual reality (VR) can bridge this gap.

Objective: This pilot study investigated the use of immersive VR in cognitive rehabilitation for patients undergoing inpatient neurorehabilitation. The goal was to determine the difference in rehabilitation effectiveness between a VR serious game that combines everyday activities with cognitive paradigms and conventional computerized cognitive training. We hypothesized the superiority of the VR serious game regarding cognitive abilities and patient-reported outcomes as well as transfer to daily life.

Methods: We recruited 42 patients with acute brain affection from a German neurorehabilitation clinic in inpatient care with a Mini Mental Status Test score >20 to participate in this randomized controlled trial. Participants were randomly assigned to 2 groups, with 1 receiving the experimental VR treatment (n=21). VR training consisted of daily life scenarios, for example, in a kitchen, focusing on treating executive functions such as planning and problem-solving. The control group (n=21) received conventional computerized cognitive training. Each participant received a minimum of 18 treatment sessions in their respective group. Patients were tested for cognitive status, subjective health, and quality of life before and after the intervention (Alters-Konzentrations-Test, Wechsler Memory Scale—Revised, Trail Making Test A and B, Tower of London—German version, Short Form 36, European Quality of Life 5 Dimensions visual analog scale, and Fragebogen zur Erfassung der Performance in VR).

Results: Repeated-measures ANOVA revealed several significant main effects in the cognitive tests: Tower of London—German version (*P*=.046), Trail Making Test A (*P*=.01), and Wechsler Memory Scale—Revised (*P*=.006). However, post hoc tests revealed that the VR group showed significant improvement in the planning, executive control, and problem-solving domains (*P*=.046, Bonferroni *P*=.02). In contrast, no significant improvement in the control group between t_0 and t_1 was detected (all *P*>.05). Furthermore, a nonsignificant trend was observed in visual speed in the VR group (*P*=.09, Bonferroni *P*=.02).

Conclusions: The results of this pilot randomized controlled trial showed that immersive VR training in cognitive rehabilitation had greater effectiveness than the standard of care in treating patients experiencing stroke in some cognitive domains . These findings support the further use and study of VR training incorporating activities of daily living in other neurological disorders involving cognitive dysfunction.

Introduction

Background

The primary goal of neurorehabilitation is to restore or preserve critical function, thereby enabling patients to participate in daily life. Neurological diseases can lead to severe disabilities. This requires the patient to make great effort in rehabilitation. For example, stroke is one of the leading causes of disability. It is estimated that 33% to 42% of stroke survivors require assistance in managing activities of daily living (ADL). Reduced ability to manage ADL is often long term, with 20% of patients being unable to manage ADL independently 5 years after a stroke [1,2]. Even patients with only mild stroke have unmet rehabilitation needs and require support in managing ADL [3,4]. This also raises the question of whether there should be more ADL-focused therapies in principle, because the study by Rejnö et al [1] showed that there is a continuous decrease in ADL independence over time after a stroke; the proportion of patients who can independently manage ADL 3 months after a stroke decreases by about 3% per year, so that 5 years after the stroke, only just over 80% of the group of independent patients can independently manage ADL [1].

Furthermore, stroke is associated with a substantial economic burden, creating a cost of €60 billion (US $67.2 billion) in the European Union [5]. Wilkins et al [6] highlighted that these costs are far greater when including indirect costs from the subsequent burden on society by lost employment and expenses related to the need for multidisciplinary, extensive rehabilitation. This points to the great need for more effective rehabilitation interventions that support patients in regaining their ability to participate and manage everyday life independently.

ADL, such as making coffee or preparing lunch, require multiple motor and cognitive processes to achieve their functional goals. Seemingly trivial activities demand several temporally overlapping cognitive functions such as planning, problem-solving, recall, and execution [7]. Toth et al [8] demonstrated in collaboration with 36 occupational therapists that the 20 most critical instrumental ADL were closely related to different cognitive functions in older adults. Cognitive domains that have been frequently discovered in this context are memory, executive functions (EF), attention, visuospatial abilities, and language. They also found that, for instance, in grocery shopping, making and keeping medical appointments and medication management EF were the most demanded cognitive domains, whereas paying bills, making a phone call, and making and keeping medical appointments were identified to require language the most [8]. In addition, there exists a correlation between ADL performance, multimorbidity, and quality of life [9]. Therefore, it would be beneficial if neurorehabilitation methods emphasized preparation for everyday life to reduce morbidity. One component of this process is improving the cognitive skills required to handle ADL. With the findings of Toth et al [8], it would be beneficial if rehabilitation explicitly addresses patients' requirements in everyday life and provides training, especially on the more complex instrumental ADL and its cognitive functional domains.

However, computerized cognitive training (CCT), or pen-and-paper training, is the standard practice in German rehabilitation facilities. It involves training in isolated domains, including attention, working memory, EF, and language. They are economical and efficient tools for delivering therapies. Still, its use is recommended only with restrictions by national guidelines for treating EF in various diseases, for example, in the stroke guidelines [10].

Furthermore, researchers discovered insufficient evidence of computer-based training in a second-order meta-analysis in neurorehabilitation [11]. The authors concluded that the processes initiated by CCT are often limited to near-transfer effects. The effects remained within the scope of the trained task regardless of the far-transfer measure, study population, or cognitive training application used. However, a far-transfer effect is crucial for later-stage rehabilitation and return to daily life. This report aligns with the above-referenced stroke guidelines, advising caution using computer-based training owing to the limited evidence on its effectiveness. Although Gajewski et al [12] demonstrated in their clinical trial that some far-transfer effect occurs when conducting combined PC and paper-and-pencil training, a transfer effect on ADL was not detectable.

Instead, customized virtual reality (VR) training is suitable for multidomain ADL training [13,14]. VR is defined as images and sounds created by a computer that seem almost indistinguishable from the real world and users can interact with via sensors [15]. Although it can be experienced nowadays with purpose-made head-mounted displays (HMDs) placed on the head in front of the eyes for a fully immersive experience, the interaction with the virtual world is mainly carried out with 2 hand controllers. VR enables a combination of principles from occupational therapy, neuropsychology, and ADL, resulting in an ecologically valid training setting for many individuals with neurological impairments who want to regain their ability to participate in daily activities. Although insights exist concerning the acceptance of immersive HMD-VR in patients with stroke [16] or older adults [17], knowledge about the processes of cognitive rehabilitation facilitated by immersive VR needs to be expanded.

One concept that is becoming more widespread in neurorehabilitation is serious games (SG) [18]. SGs are defined as games developed not only for entertainment but also for serious learning purposes and can be considered a nonpharmacological, gamified approach to treat and evaluate [19] a patient's executive dysfunction in an ecologically valid way [20]. SGs and VR have already been combined, as Faria et al [21] demonstrated. They trained EF in immersive VR with a virtual city, Reh@City, including attention, memory, visuospatial abilities and other EF, in performing ADL and found that this approach boosts cognitive rehabilitation and leads to better results in contrast to conventional cognitive rehabilitation methods [21]. A systematic review of the assessment and treatment of EF with VR in clinical populations and healthy participants concluded that VR is a promising tool [22]; however, more research is necessary, as the authors cited only a few trials on this topic. Training systems focused on ADL have the potential for better transfer to the real world after rehabilitation. Still, more evidence on the interrelation between SGs, ADL, EF training, and immersive VR [22] is necessary.

Investigating VR-based cognitive rehabilitation involves research of a multitude of groups. The number of publications in scientific journals has increased almost exponentially since 2004 [23]. The 3 most frequently studied diseases in VR-based cognitive rehabilitation are stroke, dementia, and mild cognitive impairment. Jahn et al [13] noted in their systematic review of publications about VR and cognitive rehabilitation that there is promising evidence for the functionality of this approach. However, current research findings still struggle with several issues, including group sizes being too small (N=6-34 participants, with 89% of reviewed trials having N<20 participants per intervention arm), the lack of randomization (eg, no randomization at all), or suboptimal statistical analyses (no group-by-time interaction analysis reported).

Maggio et al [14] found in their review of VR for cognitive rehabilitation that VR training in neurorehabilitation has measurable effects on executive functioning, visuospatial abilities, speech, attention, and memory skills. In particular, executive functioning and depression at discharge from stroke rehabilitation are strong predictors of functioning at the time of discharge and the following 12 months, as Shea-Shumsky et al [24] found in their study that executive functioning was a strong predictor of ADL capacity to a more significant extent than mental status. It is a strong signal that problems with EF are involved in issues regarding functionality in everyday life and that viable training is helpful and necessary [24].

Objectives

In this paper, we present the results of a pilot clinical randomized controlled trial in patients undergoing neurological treatment after acute brain injury. The trial compared two treatments: (1) a novel immersive VR intervention to treat cognitive dysfunction, specifically EF, presenting ADL in the form of an SG, and (2) conventional computerized cognitive rehabilitation training in inpatient care at a German rehabilitation hospital. VR intervention includes training in a virtual kitchen or garden, simultaneously targeting various cognitive domains, including planning, attention, and problem-solving. Furthermore, interaction with the virtual environment was enabled using HMD-VR to fully immerse users. The trial was conducted to investigate whether training with a VR-SG produces measurable effects in different cognitive domains in patients after acute brain injury and whether the potential effects outperform, are similar to, or are inferior to traditional training methods, specifically CCT.

We hypothesized that VR training will significantly improve cognitive performance and outcomes related to quality of life and general health compared with our control condition throughout the 4-week treatment. Therefore, this study addressed the following objectives:

- The primary objective was to assess the impact of an ADL-based VR-SG on patients’ cognitive abilities after acute brain injury throughout a 4-week treatment period and compare it with a conventional CCT treatment.
- The secondary objective was to assess the impact of an ADL-based VR-SG on self-reported outcomes, quality of life, state of health, and affect and compare it with conventional CCT treatment.
- The tertiary objective was to assess the impact of an ADL-based VR-SG on the actual transfer of learned abilities in VR to daily life and reality compared with conventional CCT treatment.
- The exploratory objective was to investigate the extent to which an ADL-based VR-SG is suitable for cognitive rehabilitation from phase C onward.

No changes to these objectives were made after trial commencement.

Methods

Participants

Participants were screened and recruited for enrollment at the Asklepios Neurologische Klinik Falkenstein clinic in Königstein im Taunus, Germany. The patients were transferred to the rehabilitation clinic directly from the emergency hospital (rehabilitation phase A) or had already undergone early rehabilitation (rehabilitation phase B). The differentiation to which unit a patient was admitted was based on the Barthel index: it was first developed by Mahoney and Barthel in 1965 [25] and Colin et al [26] and Shah et al [27] modified it over the years. The original 10-item form consists of 10 scales describing ADL, including feeding, bathing, grooming, dressing, bowel and bladder control, toilet use, transfers (bed to chair and back), mobility, and stair climbing. The rating describes the independence of patients to perform the named ADL on a scale from 0 to 10, with a maximum of 15 points for the transfers and mobility scale. The maximum score was calculated by summing up the results of all the scales. A maximum score of 100 indicates that patients have no difficulty managing the described ADL, whereas a score between 30 and 70 indicates the patient’s ability to conduct rehabilitation phase C in Germany. All patients were admitted to the rehabilitation phase C unit and had subacute stroke syndromes. The trial was planned using a parallel design.

The admission interview at the rehabilitation clinic and records of newly admitted patients undergoing rehabilitation were used to recruit the sample. A phase C status qualified patients to participate in the clinical trial, and a transition to phase D during study participation was possible. None of the patients started earlier or later than phase C. All participants were required to be legally competent and of age and had to undergo inpatient neurological rehabilitation treatment at the neurorehabilitation clinic because of acute brain affection (eg, cerebral infarction, intracerebral hemorrhage, subarachnoid hemorrhage, subdural or epidural intracranial hemorrhage, traumatic brain injury, brain tumor, meningitis or encephalitis, and hypoxic encephalopathy), had to have full functionality for at least one arm, had known adequate or corrected eyesight in the central field of vision, and had to give written consent to participate. Patients were also screened for cognitive performance using the Mini Mental Status Test (MMST) [28]. The score obtained had to be >20 out of 30 points. The cut-off value was chosen because some cognitive impairment was expected in this sample, and scores of 27 to 30 (no cognitive impairment) would not properly represent the sample of patients undergoing neurorehabilitation. Patients were excluded if they had present or prior psychiatric comorbidities or disorders and a known overreaction to visual stimulation leading to seizures. Once patients eligible for the study were identified, they were targeted by trained study personnel and informed of the opportunity to participate. In this course, the content and objectives of the study are explained.

Materials: Training Tools

For the trial, 2 different treatment methods were applied. The control group received CCT used in routine care at the rehabilitation center at least 3 times a week for 30 minutes each session, in this case, Freshminder. Freshminder is a cognitive training program with multiple training paradigms, focusing on attention, planning, and memory (Figure 1). Training was conducted on a PC with a keyboard and mouse. Users must interact with the application by clicking objects or deciding by pressing a key on the keyboard. In this study, the following tasks were considered: pearlfish (vigilance and working memory), picture series (memory), step sequence (action planning), task switching (flexibility), and double play (divided attention). For example, in the pearlfish task, participants had to click on fish carrying pearls. Participants had to discriminate which fish were holding the pearls and identify the fish at the correct time so that the pearl fell appropriately into the box at the bottom of the sea. This exercise trained selective attention, visual perception, and visuomotor skills. All exercises were adapted to the patient's performance by changing the difficulty and level at the beginning of each task. This was adapted by the therapist in charge. Patients received information about their performance during the training tasks. They could choose from a subset of exercises with the therapist, ensuring that all exercises were performed at a well-balanced frequency.

Figure 1. Computerized cognitive training exercises, representing the exercises of Freshminder; upper images: Doppelspiel (double play) and Perlenfische (pearlfish), bottom images: Schrittfolge (step sequence) and Aufgabenwechsel (tasks switching).

The VR group received treatment with an early version of Teora mind, conceptualized and developed by the medical device manufacturer Living Brain, a cognitive training in immersive VR. Teora mind is a certified medical device of risk class IIa according to Medical Device Regulation (EU) 2017/745. The certification procedure was executed by Notified Body TÜV Süd in 2021. The SG integrates ADL and cognitive training methods in a playful way to improve cognition and transfer into daily life and consists of realistic scenarios for training specific abilities.

The participants were trained in a virtual garden and kitchen scenario. Patients were asked to make coffee for multiple people in the kitchen. Therefore, they had to actively implement all the necessary steps for serving coffee, including filling the coffee machine with beans and water, changing the coffee filter, choosing a mug, and considering whether the coffee had to be served with milk and sugar (Figure 2). Other exercises included sorting groceries according to their categories, for example, beverages, fruits and vegetables, and durable food for stock, or sorting out the refrigerator according to specifications, such as spoiled food. A time pressure component was added with increasing difficulty. All activities were implemented in real time and through patient interactions with the virtual environment.

Figure 2. Virtual reality training scenarios, upper images: virtual garden scenario, showing action planning board (left) and greenhouse with user harvesting cucumbers (right); bottom images: virtual kitchen scenario, showing user refilling coffee machine with coffee beans (left) and start screen when entering the kitchen (right).

In the garden scenario, patients were asked to plant seeds to grow strawberries, tomatoes, and cucumbers. In the growth phase, users had to ensure that there was always sufficient water in the bed and that popping weeds did not destroy the seedlings, which required watering the bed with a watering can. After successfully growing fruits and vegetables, users can produce juices from the harvested food. Participants had to plan their activity by first sorting picture cards describing each action step on a board in what they thought was the correct order. Next, they were required to confirm their orders. Finally, the system reported whether the order was correct or incorrect and indicated the steps that were arranged incorrectly. The exercise could begin only after the right order was achieved. The complexity varied depending on the difficulty level; at the highest level, planning was omitted and the activity had to be started immediately.

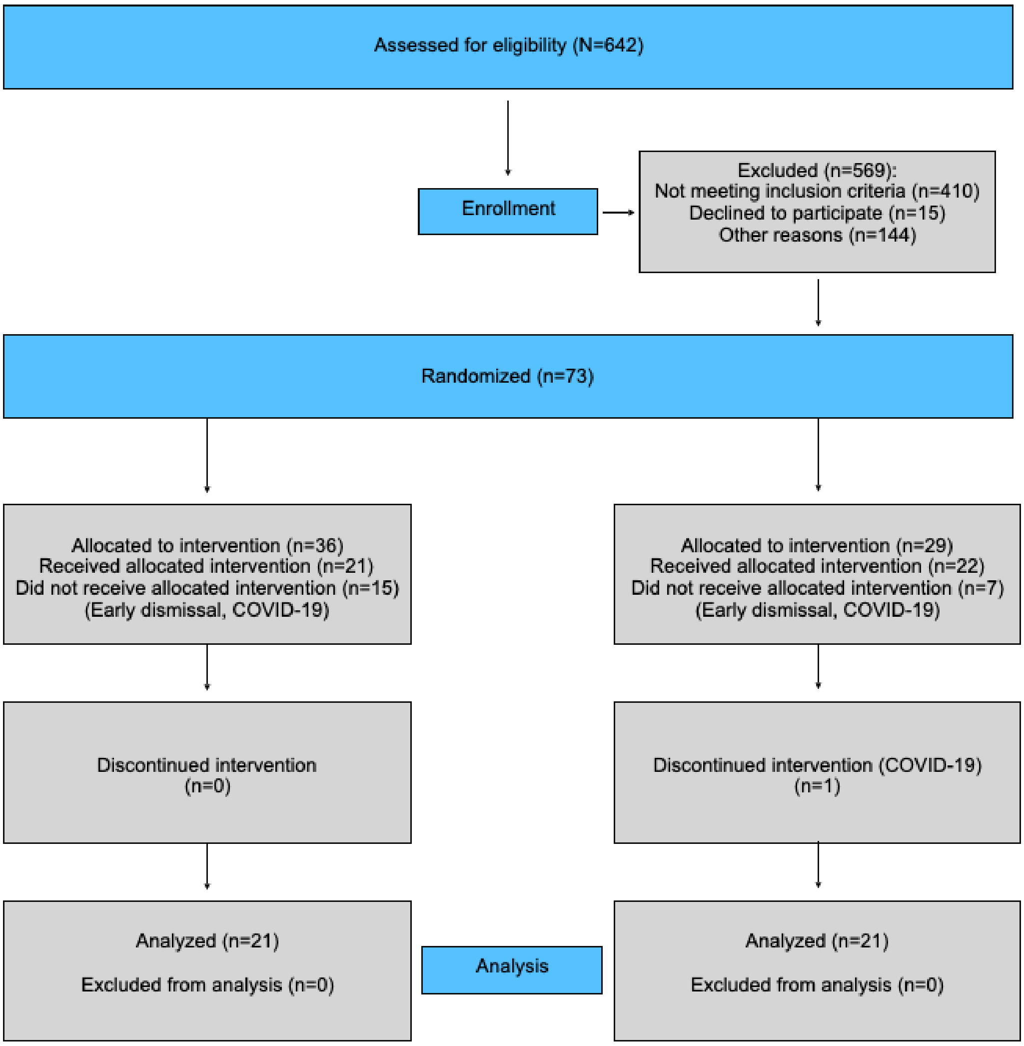
The main cognitive domains targeted by this VR training are EF, in particular action planning, problem-solving, selective attention, and working memory. The specific pieces of training themselves do not primarily focus on a single cognitive domain but rather on training the ADL, which typically comprises multiple cognitive domains simultaneously. Similar to the CCT intervention, the difficulty could be adapted to individual performance by changing to 20 different degrees of difficulty, which was adjusted by the therapist in charge. Patients received information on how they performed their training tasks in the VR application. In this trial, an early version, specifically designed for this clinical trial, was used. At that time, the medical device had not been introduced to the market. It was updated 2 times during the trial for minor bugs.

VR devices of the type Oculus Quest (manufacturer: Meta) were used for the trial conduction. The device is a stand-alone HMD, and additional technical devices for experiencing immersive VR are not required. In addition to the VR device, the study nurses and therapists in charge received a tablet (Samsung Galaxy Tab A) for monitoring ongoing VR activities; all VR procedures were mirrored on the tablet in real time. This allowed patient-therapist interaction despite the high grade of immersion, particularly in the first training sessions of benefit. Interaction in immersive VR was enabled by the hand controller used by the patients. The blue hands visually represented them and were congruent with the actual movement of the upper extremities. The controllers included multiple buttons, of which only 2 were necessary to use the VR software. Moving the head makes it possible to gain a complete overview of the virtual world. Through a visible white beam, users can assess what they are currently pointing at in a virtual environment. This allowed for the selection of objects. To introduce the patients to the technology and virtual environment, they went through a dedicated tutorial at the beginning of each treatment. High resolution pictures of the training are available in Multimedia Appendices 1-4.

Procedure

In the first 2 sessions, which lasted approximately 60 minutes each, comprehensive testing (Alters-Konzentrations-Test [AKT], Wechsler Memory Scale—Revised [WMS-R], Trail Making Test [TMT] A and B, Tower of London—German version [TL-D], Short Form 36 [SF-36], visual analog scale [VAS; EQ-5D VAS], and Fragebogen zur Erfassung der Performance in VR [FEPVR]) was conducted (t_0). The testing consisted of psychological tests conducted by a psychologist and self-assessed questionnaires. After completing the testing, individuals were randomly assigned to 1 of the 2 training groups by drawing from an urn, which was performed by the study nurse. Only the responsible investigator had access to the list of individuals in each group. Because of the nature of the study, it was impossible to ensure the blindness of the investigator responsible for the intervention and participants. The process of participant randomization is described in the flowchart prepared according to the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Figure 3), and we used an analog randomization process by drawing notes from an urn. The whole CONSORT checklist is available in Multimedia Appendix 5. Simple randomization was performed by the study nurse. The treatment was scheduled for 18 to 25 sessions with a duration of 30 minutes for the individual, based on the date of admission and the participant's immediate health and neurological condition. The sessions were conducted at least 3 to 5 days per week. Both groups received their allocated treatments from day 3 to day 20. A maximum of 25 treatment sessions were allowed.

Figure 3. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.



The study nurse instructed the intervention group on the device's functions and use before the first VR training session. This included the general operation of the device from the outside with the attached buttons (on-off button and volume control), especially the handling of the hand controllers. After receiving the instructions, participants went through a VR tutorial, consisting of training in basic functionality, a memory game, and a recycling game, in which they were familiarized with general handling in the first training session. This tutorial demonstrated the interaction with the VR environment, virtual objects, and the handling of the entire experience. The tutorial was developed and tested with stroke patients, leading to high acceptance in a group of patients with stroke and healthy older adults, indicating that it is suitable for introducing this critical user group to immersive VR [16]. In addition, the familiarization phase helps reduce possible effects due to unawareness about the technology and negative attitudes toward it [29]. During all training sessions, the study nurse was able to track the process on a tablet and was thus able to provide accurate, customized assistance if needed.

The control group was also instructed on the operation of the used computer if needed, and an introduction to the program, explaining the different tasks, before the first training session was conducted by the study nurse in charge. During all training sessions, the study nurse was close to the participant and was thus able to provide accurate, customized assistance if needed.

The patients remained statically seated in the same place throughout all training sessions to minimize the potential risks of injury. Locomotion was performed using only a controller in a virtual environment. The study nurse documented the task results during the training sessions (ie, the time needed to finish a task and other observations), in a separate, pseudonymized document. The patients could choose from the exercises themselves, with the therapist ensuring that all exercises were performed at a well-balanced frequency. All participants could stop the treatment at any time, for example, if they felt unwell during training.

Immediately after the seventh training session, participants in both groups were asked to complete the Positive and Negative Affect Schedule (PANAS) questionnaire and rate their current subjective health status using the EQ-5D VAS. After the final treatment session, the test battery was repeated (t_1). Furthermore, a survey regarding the overall VR experience was conducted using open-ended questions, and the patient was asked for suggestions for improvement and satisfaction with the application.

Dependent Measures

Overview

Each participant was comprehensively tested at 2 points: before treatment (t_0) and immediately after the last session (t_1). The focus was on investigating the impact of the 2 cognitive training methods on diverse cognitive abilities. We tested the patients regarding working memory, selective attention, planning, attention, task organization, cognitive flexibility, and problem-solving. We also examined their quality of life, affect, and health status. In addition, a new measurement tool was tested to evaluate subjective performance in a situation similar to VR training to determine the extent to which the VR training was transferred to reality. The test battery included the following tests.

AKT Measure

The AKT [30] is a psychometric procedure that measures concentration ability and vigilance. The test was developed and standardized specifically for older people and is therefore adapted to their needs in terms of comprehensibility, task difficulty, and resilience requirements. Participants had to differentiate a figure at the top of the test sheet from a series of similar figures and cross it out. In this trial, we used the German version.

TMT A and B Measure

The TMT [31] is a cognitive test for measuring EF, particularly visuomotor abilities, which are essential for executing ADL properly [24]. In TMT A, patients had to connect numbers in ascending order; in TMT B, they had to connect numbers and letters in ascending and alternating order. The test has been standardized for patients with cognitive disorders undergoing neurological rehabilitation and is often used for neurorehabilitation screening and diagnostics.

TL-D Measure

The TL-D is a transformation task that captures convergent problem-solving thinking and planning processes [32]. The objective of the task is to transfer 3 different-colored balls from an initial state to a specified target state in a minimum number of moves. The test consists of 20 tasks of varying severity and has been standardized in a sample of patients with neurological diseases; we used the German version of the test.

WMS-R: Number Span Forward and Backward

The WMS-R measures different memory functions [33]. In this study, a subset number span was used. First, the therapist reads a series of numbers of increasing length out loud. Depending on the task, the patient was then asked to recall the numbers in the correct order, either forward or backward. The WMS-R has been tested and standardized in patients with neurological and psychiatric disorders.

SF-36 Measure

The SF-36 questionnaire assesses patients' health-related quality of life and consists of 36 items [34]. It measures 8 dimensions of subjective health: physical functioning, physical role functioning, physical pain, general health perception, vitality, social functioning, emotional role functioning, and psychological well-being. The SF-36 has been standardized in various patient populations; we used the German version of the instrument in this trial.

EQ-5D VAS Measure

Scientists use EQ-5D instruments developed by EuroQol for many different diseases. The EQ-5D VAS is a VAS in the standard layout of a vertical 20-cm scale with a range of values from 0 to 100, asking respondents to rate their current health status on the scale. The higher the rating, the better the indicated health status. The tool has been used in more than 117 countries and standardized for multiple patient groups.

FEPVR Tool

The VR performance instrument is a measurement tool to assess how well everyday activities can be performed and what effects training in VR has on daily performance. The test consisted of questionnaires, individual actions that were actively performed, and observation forms for therapists to rate patient activities. These activities included, among others, actively sorting laundry, planting strawberries, self-assessment of the ability to plan an action, and quantitative and qualitative feedback on the training experience. Our research group developed this tool specifically for this trial; however, it has yet to be validated in a large clinical sample. Therefore, the use was experimental. Book et al [35] and Graessel et al [36] developed and published a similar testing tool.

PANAS Trial

For this trial, we used the German version of the PANAS [37]. This questionnaire measured positive and negative affective states and traits. The patient rated the intensity of a sensation or feeling on a 5-point scale from “not at all” to “extremely.” Twenty items were presented.

Power and Statistical Analysis

Statistical analyses were performed using SPSS 29 (IBM Corp), with statistical significance set at $P<.05$. We performed repeated-measures ANOVA and post hoc tests to detect inner-subject and between-group changes between t_0 and t_1.

Comparing the VR and control groups in terms of cognitive performance and health-related measures involved group mean comparisons from 2 independent samples. Power calculations (power analysis tool GPower [Heinrich-Heine-Universität Düsseldorf, release 3.1.9.6 for Mac OS X]) revealed that our sample size of n=21 per group was sufficient to detect a standardized estimated population mean difference of f=0.25, which is considered a medium effect size, with a power of $1 - \beta = .88 - \alpha = .05$. This shows that our small sample size did not constrain the detection of between-group effects at a conventional power goal of 0.8 with a medium effect size of f=0.25.

Ethics Approval

Approval for this pilot trial was obtained from the local Ethics Committee of the Regional Medical Association Hessen, Germany, under approval 2020-1768-fMP. The VR training Teora mind is a certified medical device (class IIa) in line with the European Medical Device Regulation and therefore obtained approval to conduct this trial from the state authority Bundesinstitut für Arzneimittel und Medizinprodukte under the file number 94208-5660-12543. All regulatory approvals were obtained before the recruitment of the first patient.

Results

Baseline Characteristics

The recruitment process started on November 1, 2020, and the last patient completed the treatment on March 31, 2022. We initially planned to include 52 patients but decided to close the study when we reached 42 patients finishing all treatment sessions because this sample size was large enough to calculate repeated-measures ANOVA. Further extension of the trial was not possible due to administrative reasons. A total of 21 patients received the novel VR treatment, whereas the other 21 received control CCT. Furthermore, 33% (14/42) of the patients were female. Patients in the control group were, on average, aged 67.3 (SD 4.6) years at trial participation, while the VR group had a mean age of 68.3 (SD 14.5) years at trial participation; no statistical difference between both groups regarding age was found (P=.69). Detailed information on the brain damage of the included participants is found in Table 1. For more detailed information on the demographic characteristics, mean performance, and SD for all sample measures in this clinical trial, please refer to Tables 2 and 3.

Of the 642 patients receiving treatment at the center at the time of trial conduction, 73 patients were primarily included for participation, of which 42 (14 female patients) completed all treatment sessions. However, 31 patients were not able to complete the minimum treatment number for the following reasons: COVID-19 (n=4), early dismissal (n=12), psychiatric comorbidities not detected earlier (n=3), and treatment discontinuation due to a high incidence of COVID-19 cases at the trial center (n=12).

Of the 42 included patients, 17 (28%) had a right-sided pathology, 22 (52%) had left-sided pathology, and 3 (7%) had damage occurring in both brain hemispheres.

Table 1. Types of brain damage.

Brain region	Patients, n
Cerebral infarction	33
Brain hemorrhage	3
Subarachnoid hemorrhage	2
Basal ganglia hemorrhage	4

Table 2. Demographic characteristics of control and VR[a] group.

Variable	Control group (n=21)	VR patients (n=21)	*P* value
Age (years), mean (SD; range)	67.3 (4.6; 59-74)	68.3 (14.5; 36-93)	.69
MMST[b], mean (SD; range)	26.95 (2.04; 24-30)	27.05 (2.11; 24-30)	.97
Sex, n (%)			.67

[f]SF-36: Short Form 36.

Nausea and Motion Sickness

Of the 21 patients in the VR group, none reported problems with motion sickness or associated nausea, and no treatment had to be stopped due to motion sickness or nausea. This is congruent with the results of our feasibility trial with patients with stroke and healthy older adults, where we demonstrated that applying specific principles in VR development, such as having complete control of all motions in VR, reduces the risk of experiencing motion sickness and is feasible for use in special needs groups such as patients with stroke [16]. Patients in the control group using CCT reported no negative side effects. The patients conducted, on average, 18.7 (SD 0.99) successful treatment sessions.

Treatment Satisfaction

Patients were asked as part of the FEPVR tool to rate the treatment satisfaction on a Likert scale ranging from 1 (*very dissatisfied*) to 7 (*very satisfied*). Both groups reported a tendency toward high acceptance and satisfaction with both treatments (M=5.7). The treatment also created the impression that it helped against the present condition in both groups (VR: M=5.5, CCT: M=5.7), rated from 1 (*I completely disagree*) to 7 (*I fully agree*).

Adverse Events

While the trial was conducted, no severe adverse event or adverse event was linked to the intervention in either group; nevertheless, we had to report adverse events as the clinical trial was conducted amid the COVID-19 pandemic in 2020 and 2021. Owing to the general incidence of infections in Germany, 4 patients included in the trial were infected with SARS-CoV-2 and were isolated and excluded from the study.

Survey Completion

Of the patients who completed the study, 97% (41/42) of the participants completed all the questionnaires and tests, with only occasional missing items or tests. This might be explained by the fact that all surveys were conducted in the presence of a therapist or neuropsychologist working and trained in the clinic.

Cognitive Tests

To evaluate the impact of both treatments on cognitive status, subjective health, and quality of life, we used *SPSS Statistics* (version 29, IBM) and calculated repeated-measures ANOVA. For the comparisons between the 2 groups between the pre- and posttest, repeated-measures ANOVA and Bonferroni post hoc test indicated that TL-D scores significantly differed in the VR group after the intervention (P=.046). Table 4 presents the results of all other conducted tests. As a nonsignificant trend emerged in the TMT A (main effect: P=.01; time by group interaction: P=.09) and WMS-R (main effect: P=.006; time by group interaction: P=.18) results, a post hoc test was also performed. No further post hoc tests were performed for the other variables.

Table 4. Clinical parameters of the virtual reality (VR) and computerized cognitive training groups before and after the intervention.

Measure and time point	Control group[a] (n=21)	VR group[b] (n=21)
TMT[c] A scores, mean (SD; range)[d]		
Pretreatment	93.7 (47.83; 36-205)	80.95 (47.84; 39-200)
Posttreatment	89.95 (55.2; 26-257)	61 (22.87; 32-135)
TMT B scores, mean (SD; range)[e]		
Pretreatment	326.9 (216.7; 91-853)	292.24 (244.26; 96-1056)

[m]Repeated-measures ANOVA: no significant interaction detected (P=.52).

[n]SF-36: Short Form 36.

[o]Repeated-measures ANOVA: no significant interaction detected (P_{pain}=.28; P_{energy}=.69; P_{emo_wb}=.31; P_{soc_func}=.59; P_{gen_health}=.87; P_{phys_func}=.06; $P_{role\_lim\_phys}$=.88; $P_{role\_lim\_emo}$=.69).

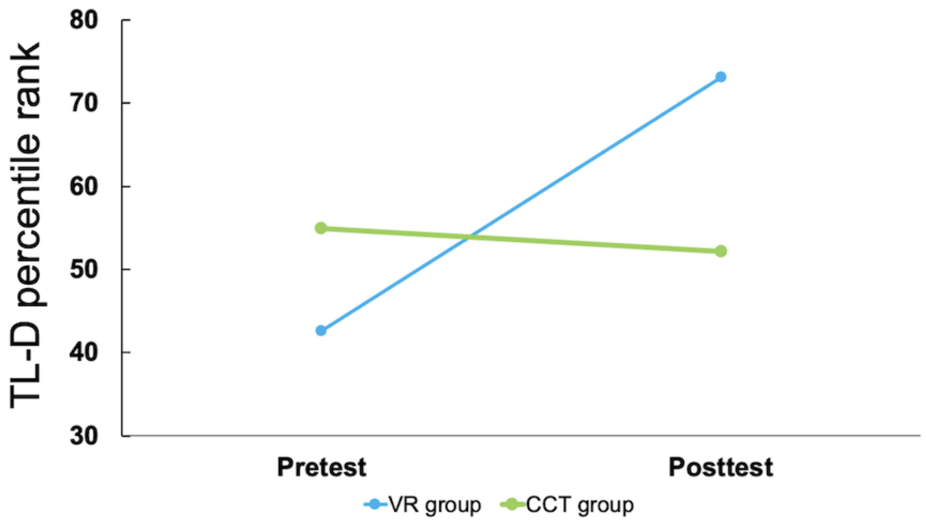
PANAS Trial

Patients were asked to describe their affects on the allocated treatment after 7 sessions of trial participation. Affect was measured with the German version of PANAS, and patients were asked to rate their affect immediately after treatment. An ANOVA was performed, resulting in $F_{1,36}$=0.879 (P=.63) for the positive affect scale and $F_{1,36}$=0.954 (P=.57) for the negative affect scale. The test results showed no difference between the intervention and control groups regarding positive and negative affect toward the kind of treatment received by both groups during the trial. Both groups reported high positive affect, with the VR group at mean 29.809 (SD 7.98) and the control group at mean 25.6 (SD 8.23), showing a slightly higher positive affect in favor of the VR group. Negative affect results were rated mean 15.95 (SD 8.59) in the VR group and mean 15.66 (SD 6.18) in the control group, showing similar negative affect ratings in both groups.

Summary

The critical effects for both groups are presented in Table 4, showing mean changes between t_0 and t_1 and the results of repeated-measures ANOVA for group effects. Figure 4 shows the mean changes for TL-D results in both groups.

Figure 4. Results of repeated measures analysis of variance Tower of London—German version (TL-D). CCT: computerized cognitive training; VR: virtual reality.



Discussion

Overview

To our knowledge, this is one of the few trials comparing immersive VR cognitive training, incorporating ADL and SG and focusing on the ability to perform ADL, with a multitude of cognitive domains and not single domains only, with CCT. In this randomized controlled trial, we aimed to determine the impact of both cognitive training in immersive VR and CCT on cognition and the ability to perform ADL in patients in inpatient neurological rehabilitation with an MMST score >20 in rehabilitation phases C and D, combining immersive VR with paradigms of neuropsychology and occupational therapy. In the patient group receiving VR therapy, we found a statistically significant improvement in executive functioning within the 4-week treatment interval. Some nonsignificant trends were detected for attention and processing speed, working memory, and subjective health. No significant changes were observed in the control group.

In recent years, VR systems found their way to neurological rehabilitation. However, being used most often for motor rehabilitation, only a few systems have been developed and evaluated concerning their impact on cognition in patients with acute brain affection. Furthermore, some developed trainings have only been used for research purposes but have yet to undergo more extensive testing or application in clinical practice. In addition, several cognitive trainings in VR were developed to target a specific cognitive domain, for example, memory [38] and attention [39].

Principal Findings

We compared the VR group with a control group using CCT, which represents care as usual in German rehabilitation facilities. Both groups were able to engage in their assigned interventions successfully. Despite our initial concerns regarding the number of sessions to be conducted in VR, no significant side effects were reported. All patients participated in all sessions required to complete the trial. Some initial hurdles had to be overcome, for example, mainly introducing older adult patients to an entirely new technology or ensuring continuous disinfection of all equipment, as the trial took place at a time when the COVID-19 pandemic situation in Germany was very tense. However, after the first treatment session, those problems were solved without further external intervention. Overall, the acceptance and usability of both technologies were observably high, which, in terms of the VR experience, is congruent with the results of our feasibility study using an earlier version of the software used in this trial [16].

The demographics between the 2 groups were similar: not significantly different in age and pathology but with a larger proportion of male participants in the trial. The trial's sample size was too small to make far-reaching statements, but clear tendencies provided the first indication of training effects that opened up room for further research in a larger trial.

We detected the effects of immersive VR on different cognitive functions in patients with acute brain affection receiving treatment during inpatient neurological rehabilitation. Comparing both groups by calculating repeated-measures ANOVA, we detected improvements in some cognitive domains in the VR group but no significant improvement in any cognitive function in the control group. By conducting the TL-D, specifically assessing problem-solving and planning, we found significant improvements from pre- to postintervention phase in the VR group, and the Bonferroni post hoc test also verified these significant improvements with a medium-sized effect of η^2=0.135. Oliveira et al [40] conducted a trial to investigate the impact of VR on ADL in stroke rehabilitation. They found that VR training resulted in better tests measuring EF, global cognition, attention, and memory training. This partly overlaps with the results of this study. We also observed improvements in attention, processing speed, and subjective health status in the VR group. However, these did not become significant in the repeated-measures ANOVA, while the scores for the named variables persisted at the t_0-level after the treatment in the control group. No significant improvements and differences between groups were detected in concentration and memory in both groups.

The improvements in subjective health state are of interest for further research, as Domínguez-Tellez et al [41] ascertained in their systematic review that VR interventions for upper limb rehabilitation were a part of improving quality of life. They hypothesized that an improvement in the actual pathology leads to better abilities for carrying out ADL, and an improvement in quality of life goes hand in hand with a higher grade of participation. The higher levels of subjective health state in the VR group (mean 62.86, SD 21.03) compared with the control group (mean 46.84, SD 25.01) after the intervention, with an improvement on the EQ-5D VAS-scale of 13.81 points in the VR group and 1.34 points in the control group between t_0 and t_1, although not significantly different, showed a tendency toward the impact of VR treatment when considering the significant improvement in TL-D scores in the VR group and the resulting implications for participation in daily life. More thorough research is necessary to better understand the interrelationship between these constructs and the results of the SF-36 subscales.

Looking at the results the VR group achieved in planning and problem-solving (TL-D), we would have expected to notice a significant difference in TMT results as well, as both tests are positively correlated [42]. TMT specifically measures cognitive flexibility, alternating attention, sequencing, visual search, and motor speed, which overlap with the measured domains of TL-D, predominantly measuring planning and problem-solving. The missing significant improvement in the abilities measured by TMT in this trial raises the question of how specifically the VR training stimulates particular cognitive skills. We still see a tendency for improvement in these cognitive abilities, as the VR group achieved more improvement between t_0 and t_1 than the control group, as measured by TMT A. We found a nonsignificant trend in the repeated-measures ANOVA (P=.09). As we expected a correlation between TL-D and TMT results, we calculated a Bonferroni post hoc test, which resulted in a significant improvement in the VR group (Bonferroni P=.02). This is only a trend, which cannot be used to draw far-reaching conclusions. Nevertheless, it is interesting, as this might correlate with the significant improvement in TL-D measures in the same group. Nevertheless, it would be interesting to investigate in a larger trial if an optimized version of the training software leads to more diversified and measurable effects.

In addition, other studies cited in this paper have reported further improvements in multiple cognitive subdomains. In our study, significant improvements were found only in the EF. One explanation for the difference in results is that both groups received only 1 therapy to treat cognitive dysfunction rather than simply augmenting the existing treatment. A 2017 Cochrane Review found that in many studies, VR therapy was added to traditional treatment, resulting in a higher total amount of therapy [43]. Therefore, it cannot be said with certainty whether VR therapy alone is causal for the improvement in these studies or whether the overall increased measure of treatment compared with the control group is the determining factor. The fact that each group in our study received only 1 cognitive rehabilitation treatment means that the effects can be more precisely attributed to a single treatment method.

When developing the software used in collaboration with occupational therapists, neuropsychologists, neurologists, and patients, we were particularly faced with the lack of proximity to daily life of current CCT, which led us to the question of how we could depict everyday life and its challenges in a way that is easy to understand, therapeutically beneficial, and motivating, so that patients could adhere to training over a more extended period. The results showed the VR training used in this trial. The following components have played a significant role in its development and could provide a directional indicator for further development of new training methods for cognitive rehabilitation.

The results of this trial helped us formulate hypotheses on why VR-based training might lead to better results in cognitive rehabilitation than PC-based interventions:

Ecological Validity

In rehabilitation, particularly when focusing on returning to daily life, it is vital to have ecologically valid training simulations, for which VR is well suited [40,44]. In our application, we presented a garden and kitchen scenario to simulate activities and situations in which subjects found themselves after rehabilitation. In reality, as it is either dangerous or unavailable, it is often not viable to let patients train in real-life settings. VR enables stimulation with settings as close as possible to reality, potentially facilitating a more effortless transfer from training to reality.

The results of this trial indicate that high ecological validity is beneficial for training cognition. Patients in the VR group achieved significantly higher scores in planning and problem-solving than their counterparts in the control group. In addition, they reported better scores in terms of speed and health status than the conventionally treated patients. This is congruent with the results of Faria et al [21], who examined the benefits of immersive ADL simulation in neurological rehabilitation [21].

Gamification and Immersion

Gamification adds games or game-like elements to encourage participation or engagement. Engagement is a crucial component of rehabilitation; in patients with stroke, it increases the rate of rehabilitation and rehabilitation outcomes of survivors of stroke [45]. The VR experience relies to a great extent on the grade of immersion. Immersion describes the effect of a virtual environment that causes the user's awareness of being exposed to illusory stimuli to fade into the background to such an extent that the virtual world is perceived as real. High-grade immersion can be created using HMD-VR. The user wears device-like goggles on the head over the eyes, effectively masking the actual environment.

Combining these 2 aspects and adding up the feature of receiving immediate feedback from the virtual environment on performance leads to increased motivation and, subsequently, patients stuck with the treatment longer [43]. Yoshida et al [46] discussed motivation in patients with subacute stroke and discovered that it is mainly influenced by extrinsic reward factors (eg, positive feedback provided by therapists). However, if basic psychological needs are met, for example, autonomy or competence, which play a critical role in stroke rehabilitation, the motivation pattern switches from extrinsic to intrinsic [46]. Long after an acute event, improvements in rehabilitation can still be achieved, and patients' self-perception regarding the improvements is paramount.

On the Right Dosage

Participants in this trial received a treatment dosage of 18.7 sessions over 4 to 6 weeks, each lasting 30 minutes (9.35 hours per participant). Other trials reported an average intervention duration of 13.3 hours [39,40,47-50], ranging from 4 to 24 hours, with a session duration of 30 to 60 minutes, 3 to 5 times a week. Our dosing was sufficient to achieve a measurable effect in some domains and was also oriented toward the care reality in German rehabilitation hospitals. To attain more significant outcomes in multiple domains, it would be interesting to see if other training tasks in immersive VR create an effect on cognition and if a varying number of treatment sessions beyond inpatient care leads to different results than those reported here. On the basis of the results of this trial, we conclude that 18 to 19 sessions over 30 minutes are sufficient to achieve a measurable treatment effect. Still, we cannot determine whether fewer sessions would create similar effects if more treatment automatically leads to more significant outcomes and if those effects vary between patient groups. More extensive trials with blinding, subgroups, and longer treatment duration are necessary to answer this question.

Transfer to Daily Life and How to Measure it

One end point of this trial, which we were not able to meet, was to identify whether the treatments in both groups induced transfer effects on daily life by examining if patients in either group were in a better state to perform instrumental ADL, such as preparing food or handling the washing machine, after the intervention. While designing this trial, we noted that standardized neuropsychological testing batteries are well suited to test particular cognitive domains and performance therein, but that daily life is more complex—it can not be reduced to 1 or 2 cognitive processes at the same time—and that functional capabilities of managing everyday life as the end goal of rehabilitation are not sufficiently represented by those testing batteries when focusing on cognitive rehabilitation [40]. Therefore, we developed a testing tool, FEPVR. It was used for the first time in this trial, and we faced some issues with properly capturing the ADL. We plan to publish the battery and its manual in a revised version, including experiences from use in this trial so that further development and testing by other research groups is possible.

Limitations

Although this study provides valuable insights into the impact of immersive VR on cognitive rehabilitation, several questions remain unanswered. Specifically, we identified the following limitations that should be considered: future research in this field should be conducted with larger sample groups. This randomized controlled pilot study builds a profound understanding of the potential immersive VR can have in neurological rehabilitation for cognitive impairment in patients with MMST scores >20, affected by stroke, to the largest extent. Conclusions cannot be drawn for patients below this cut-off score. We also need more information on the manifestation of training effects, for example, if the measured results are still the same 6 to 12 months after the intervention and if an actual transfer effect to ADL occurs. Therefore, long-term studies with follow-up over multiple years are necessary.

The applied VR environment was limited to only 2 training scenarios inspired by ADL. More training scenarios replicating other ADL should be developed and tested in future studies.

Even though there are findings about the application of VR in rehabilitation of other patient groups, for example, multiple sclerosis, psychiatric disorders, and pain management [51], the application used here has chiefly been tested in the rehabilitation of patients with acute brain affection. Therefore, the evaluation needs to consider patients from the abovementioned groups to draw further conclusions in other patient groups.

Conclusions and Outlook

Our group of psychologists, software developers, 3D artists, neurologists, and occupational therapists has developed a new form of immersive VR-based cognitive rehabilitation training. After proving the feasibility and acceptability in stroke patients with stroke, we demonstrated the initial therapeutic effects of a novel immersive VR training on EF in patients undergoing inpatient neurological rehabilitation. Data were collected over 18 months, including multiple recruitment pauses due to the COVID-19 pandemic between 2020 and 2022. The supervision of patients was necessary for conducting treatment, but it was administered by trained therapy assistants, freeing time for neuropsychologists and occupational therapists. None of the patients in the VR group had previously been exposed to VR, but that did not diminish their excitement about receiving the experimental treatment and getting the most out of it.

It was reported earlier that combining cognitive training with physical activity leads to even better results; for example, a group of older adults with mild cognitive impairment showed more significant improvements in multiple cognitive domains when receiving combined therapy than physical or cognitive training alone [52]. Investigating whether the treatment effects of VR-based cognitive training can be increased by additional full-body physical training would be an interesting research topic for future trials. We also intend to depict everyday life in VR even more with new training scenarios, a higher level of gamification, and using techniques to personalize the treatment itself to a greater extent.

Our goal is to ensure that treatments in neurorehabilitation are improved and that all parties involved profit from new developments. The excellent acceptance, low side effects, and initial therapeutic effects of immersive VR treatment presented here offer new therapeutic options, for example, applying SG in routine therapy [53]. The results of this pilot trial show that a short but intense period of treatment leads to measurable improvement in EF, a manifold construct consisting of behavioral and higher-order cognitive skills necessary for independent functioning and carrying out everyday life, such as shopping, managing money, and preparing meals [3,8]. It would be interesting to determine if these results can be extended if patients continue treatment at home and increase the overall number of treatment sessions.

Temehy et al [4] explored the needs of patients with stroke after discharge from rehabilitation; they discovered that patients often not only need physical rehabilitation but also psychological services, comprising cognitive rehabilitation. Shipley et al [54] cite a patient who says, “it should have been a formal process to gain access to a psychologist, and it would have been beneficial from an earlier time point, such as from the acute hospital.” Access to qualified and trained neuropsychologists in Germany is difficult, as the *Gemeinsamer Bundesausschuss* (Federal Joint Committee) states that only 1100 neuropsychologists in outpatient care are available. The 2019 German Society for Neuropsychology list contains even fewer specialists with only 350 practitioners in outpatient settings [55]. This shortcoming highlights the need for complementary treatment approaches. This is in line with what the COVID-19 pandemic has uncovered: the need for digitized rehabilitation tools, bringing the general problem of accessibility of rehabilitation services to center, for example, for people living in rural areas or simply an insufficient number of neuropsychologists or occupational therapists in Germany, which prevents the actual implementation of necessary aftercare in neurological rehabilitation with a regular high number of treatment sessions for manifesting rehabilitation progress. Further development of video game–based rehabilitation approaches with digitized platforms to bring care home should be the focus of other groups active in this field, which is also emphasized by Ong et al [56] and Salisbury et al [57], who stated that VR is a promising technology to foster home care and shorten hospitalization. As prices for HMD-VR devices continuously decrease and the acceptance of digitized treatments in Germany increases, it augments the chance that access to VR-assisted rehabilitation will become more accessible and a standard in a wide range of treatment settings.

Abstract

Background: Serious games have the potential to transform the field of cognitive assessment. The use of serious game–based cognitive assessments in prison environments is particularly exciting. This is because interventions are urgently needed to address the rapid increase in the number of currently incarcerated older adults globally and because of the heightened risks of dementia and cognitive decline present in this population. Game-based assessments are assumed to be fun, engaging, and suitable alternatives to traditional cognitive testing, but these assumptions remain mostly untested in older adults. This is especially true for older adults in prison, whose preferences and needs are seldom heard and may deviate from those previously captured in studies on cognition and serious games.

Objective: This study aimed to understand the design preferences of older adults in prison for a game-based cognitive assessment.

Methods: This study used reflexive thematic analysis, underpinned by critical realism, and applied the technique of abduction. Overall, 4 focus groups with a total of 20 participants were conducted with older adults (aged ≥50 years; aged ≥45 years for Aboriginal and Torres Strait Islander people) across 3 distinct prison environments in Australia.

Results: Self-determination theory was used as a theoretical foundation to interpret the results. Overall, 3 themes were generated: *Goldilocks*—getting gameplay difficulty *just right* through optimal challenge (the first theme emphasizes the participants' collective desire for an individualized optimal level of difficulty in serious gameplay), *Avoiding Childish Graphics*—gimmicky gameplay can be condescending (the second theme raises the importance of avoiding immature and childlike gameplay features, as some older end users in prison felt that these can be condescending), and *A Balanced Diet*—meaningful choice and variety keeps game-based assessments fun (the third theme highlights the strong user preference for meaningful choice and variety in any serious game–based cognitive assessment to maximize in-game autonomy).

Conclusions: The collection of these themes provides novel insights into key game design preferences of marginalized older adults.

Introduction

Assessing Cognition Through Serious Games

Gamification stands as one of the most promising solutions to enhance the user experience of traditionally monotonous tasks [1]. The process of gamification includes applying game design elements such as challenges, scoring, graphics, and narratives to nongame environments (eg, psychometric testing) to increase engagement and motivation [2]. When gamified tasks are embedded into an immersive user experience, they are typically referred to as *serious* games. Serious games present users with unique and exciting environments to complete objectives that go beyond entertainment [3]. An emerging area of research is the study of serious games for cognitive assessment. Although there are well-evidenced benefits of using traditional cognitive assessment tools (proven psychometric validity, high sensitivity to neurological disease, etc) [4-6], they are often seen as boring and repetitive by users [7]. This can reduce task engagement [2] and affect the reliability of the performance data collected [1,8]. People also report test anxiety and self-stigma regarding low literacy or education levels when performing traditional cognitive tests [9-12]. In addition, there is evidence that some widely used neuropsychological tests are not culturally safe [13-15].

Serious games have the potential to transform the field of cognitive assessment. Game-based assessments appear to be suitable alternatives to traditional tasks given their potential to improve motivation and enjoyment and support individuals to produce their best effort, without making them feel overly bored, anxious, or distracted [1,16]. Recent studies have indicated that the experience of playing digital cognitive games was perceived as less stressful, more interesting, and more enjoyable when compared with standard cognitive tasks [2,3]. Serious games can also offer a brief, cost-effective, and scalable substitute for more traditional assessment methods [8,17]. In addition, serious games might support more ecologically valid assessment through realistic context and gameplay by engaging cognitive processes in a way that is more similar to a real-life situation [18].

Although the user benefits of enhanced motivation, engagement, and enjoyment are promising, they are not automatically derived through gamification. In recent years, some gamified cognitive assessments have assumed that, because something is presented as a game, it is fun. In a systematic review (conducted in 2021) of game-based cognitive assessments [1], less than half of the games included in the study evaluated any aspect of gameplay or user preference. Furthermore, although many studies have reported the positive effects of serious games on enjoyment [8], additional findings suggest that some games do not increase engagement, with Birk et al [19] concluding that their gamification actually reduced task engagement when compared with a traditional task. These findings suggest that serious games that assume user enjoyment and engagement overlook the complexity of end-user preferences. Poorly designed and executed serious games can be expensive and ineffectual and are unlikely to result in a more enjoyable and motivating experience than traditional tasks [1,16,19,20]. If games are to be used as cognitive assessment tools, they must first be designed with the end user's enjoyment and motivation in mind. Furthermore, ensuring that a game-based assessment is culturally safe to play is critical [21]. This means acknowledging the context in which a serious game will be played by a user and ensuring a relevant level of sensitivity to the distinct backgrounds, beliefs, and experiences of target users [21]. These are essential steps in justifying the use of a serious game, especially in the context of cognitive assessment.

The Cognitive Health of Older Adults in Prison

There has been a rapid increase in the number of people aging in prisons across the world in the last decade [22]. One area of particular concern for older adults in prison is age-related cognitive decline. There is evidence indicating that cognitive deficits are considerably underdetected in prison environments [23], and when they are detected, they are often managed informally or inadequately [24,25]. Studies on cognitive impairment in Australia, France, and the United Kingdom reported high levels of potential cognitive decline, with impairment rates of 15.3% (Australia) [26], 19% (France) [27], and 13% (the United Kingdom) [28] found in samples of people aged ≥50 years (≥45 years for Australian Aboriginal and Torres Strait Islander people) in prison.

Cognitive impairments lead to poor outcomes for older adults in the criminal justice system [23,29] and those transitioning out of prison [30]. Unidentified cognitive impairment can hamper a person's ability to navigate the prison system and reduce their capacity to access (and routinely engage with) health and aged care services during incarceration and after being released from prison [31]. People with cognitive impairment are also prone to manipulation and coercion in prison, including physical and sexual trauma, peer pressure, and victimization [32]. People with cognitive impairments in prison can also have their symptoms perceived by staff and peers as purposefully obstructive or combative, resulting in punishment [33,34]. In addition, after being released from prison, people who have substantial cognitive impairments are less likely to adapt to *life on the outside* without appropriate support [24,25], resulting in increased risks of recidivism, homelessness, and hospitalization [30].

Although prison staff view early screening and diagnosis of dementia as a priority area for prison dementia care reforms [23,29,35], there still exists very limited cognitive assessment of older adults in prison, often because it is resource intensive. The use of a serious game for cognitive screening in prison appears to be a potential solution to the growing need for an effective and affordable cognitive assessment to support older adults in prison presenting with or at risk of cognitive deficits.

Conceptualizing Motivation to Play Games in Prison Using Self-determination Theory

If gamification promises to enhance user motivation to undertake cognitive assessment, but gamification does not always fulfill this promise, then a way to understand what increases (or decreases) a person's motivation is necessary. A prominent theory used to understand a person's motivation is self-determination theory (SDT). In SDT, the basic needs that ought to be satisfied to produce motivation, enjoyment, and overall well-being are competence (ie, experiencing mastery over challenges), autonomy (ie, doing something owing to an individual's own volition), and relatedness (ie, experiencing meaningful social relations). In addition to helping researchers understand motivation generally, SDT has also been applied specifically to understand the motivation to play digital games [36-38]. The theory has been useful in explaining how game features relate to basic psychological needs and thus how game design and development decisions can increase (or decrease) user motivation and enjoyment [39]. Games have been shown to directly enhance motivation through features and gameplay [38].

In the video game context, competence refers to being challenged at the optimal level. For instance, a player will experience low competence if the challenges are very great (eg, game controls are difficult to use or enemies are very numerous) [37]. Autonomy may include the feeling of free choice to play a desired game and make choices within the game (eg, choosing which level to complete). Autonomy may also be satisfied when a user can design their own playable character and feel empowered to do things that they cannot do in real life. Relatedness can be achieved by playing with others, either in person or via the web [36]. Relatedness or a sense of belonging or connection can be satisfied by achieving team goals (eg, defeating the enemy together) or through healthy competition (eg, racing each other in Mario Kart).

SDT is a helpful framework to understand the motivation to play a serious game–based cognitive assessment in prison. Specifically, it provides a theoretical foundation to understand a specific user group's fundamental psychological needs [40-42] and map these needs to tailored game design preferences [37,38]. In doing so, it ensures that a game is designed appropriately with the end user's enjoyment, motivation, and well-being in mind [39]. Using SDT to query game design preferences and acceptability is an important exercise capable of expanding knowledge about desired user preferences for a serious game in prison.

Objectives of This Study

A critical first and ongoing step in developing suitable game-based assessment is to collaborate with the target population for whom the intervention is intended [43-45]. This point is especially important for older adults in prison whose preferences, values, and needs may deviate from those previously captured in studies on cognition and game design [46,47]. It is essential to capture and embed end-user input into game design and development to produce a game that is relevant to and compatible with the lives of older adults who are in prison.

Thus, the purpose of this qualitative thematic analysis was to understand the design preferences for a cognitive game-based assessment for older adults in prison, in the context of the prison environment and future transition back to community. Using the theoretical framework provided by SDT, the user design preferences for and user acceptability of a serious game–based assessment can be hopefully understood in a way that is useful for game designers to develop a cognitive assessment that is motivating, culturally suitable, nonthreatening, and enjoyable.

Methods

Philosophical Approach

This qualitative study was informed by a critical realist philosophy [48-51]. Critical realism broadly assumes that there are things that have a real, objective existence *out there* (ie, an independent world exists beyond our own constructions). However, critical realism appreciates that knowledge is fallible; our understanding of the world is based on and filtered through our own personalized interpretations [52]. Thus, critical realism makes an important distinction between epistemological and ontological assumptions. That is, ontology (ie, what is real and the nature of reality) is not reducible to epistemology (ie, our knowledge of reality) [48]. In other words, the critical realist approach combines realist ontology with constructivist epistemology [52]. After assuming this position, we can make ontological distinctions between our unique experiences and observations of events, the actual events themselves (which can be different from our experience of them), and the underlying mechanisms or structures that produce events [53]. Once we perceive reality in this way, we are open to exploring and explaining social events through reference to these mechanisms and structures and their effects.

Using the philosophical position of critical realism for this study has 2 major benefits. First, the deeply individual and subjective game preferences of older adults in prison can be interpreted empirically. Such an exercise can (and should) have direct input into game design considerations regarding the features, preferences, and esthetics of the game development process. Second, a more theoretical and critical analysis of participants' observations and how the underlying mechanisms and structures may explain game preferences (and motivation for game-based cognitive assessments) can be undertaken. This second type of analysis is necessary to explore latent themes that may influence the success of a serious game–based intervention in the context of this complex population [54,55]. Considering both empirical observations and underlying mechanisms, simultaneously, and how they interact is critical to adequately design, develop, and deliver a game-based cognitive assessment for this marginalized population.

Sampling and Recruitment

Purposive sampling was used to produce representation across age, sex, and security level. Correctional staff identified and recruited potential participants after guidance from researchers to identify any older adults in prison, that is, aged ≥50 years (or ≥45 years for Aboriginal and Torres Strait Islander people). Aboriginal and Torres Strait Islander people are the Indigenous people of Australia, and relatively young ages are typically used in health, aged care, and policy settings to define *older adults* in this population, owing to population-level disparities in morbidity and mortality. Suitable participants were known to corrective staff through their day-to-day operations. Staff oversampled those who were potentially eligible for the study and shared the study information (study flyers and consent forms) with them. Consent forms were signed by participants in front of the prison staff. Potential participants were allowed to ask any clarifying questions to staff. After the consent forms were signed, these were sent back to the research team for confirmation of informed consent.

We are sympathetic with the criticism by Braun and Clarke [56] about saturation as a useful concept in reflexive thematic analysis underpinned by constructionist epistemology. As such, we do not discuss our sample in terms of saturation. However, given our commitments to critical realist ontology, it is important to confirm the sufficiency of our sample in terms of information power [57] to support validity claims [52]. Thus, according to the criteria stipulated by Malterud et al [57], our sample size of 20 participants across 4 focus groups (FGs) was deemed sufficiently powerful given the (1) applied aim of the study, (2) sample specificity, (3) use of established theory (eg, SDT), (4) high quality of dialogue, and (5) comprehensive analysis strategy. As is standard, participants received AUD $15 (US $10.05) for lost work time. Funds were deposited into the inmates' *buy-up* account.

Ethics Approval

Human research ethics approval was obtained from Corrective Services New South Wales Ethics Committee (D20/1014950), the University of New South Wales Human Research Ethics Committee (HC210546), Justice Health and Forensic Mental Health Network Human Research Ethics Committee (2021/ETH11114), and The Aboriginal Health and Medical Research Council (1873/21) before the commencement of the study.

Procedure

FG Approach and Schedule

We conducted 4 FGs, all of which were between 60 and 120 minutes long. All FGs were completed using internet-based audio-visual technology owing to the COVID-19 protocols. Sessions were led by the second author (AW), a neuropsychologist, and supported by RM and JH. FG questions were semistructured, and all 4 sessions followed a similar interview schedule. We were interested in game interventions but also more broadly in understanding people's interaction with prison and past health services and their personal experiences with these services. After the objective of our study was discussed with participants, we showed a serious game demonstration (Graze Invaders; designed by AW, LM, and MK). This was used to provide a grounded example of what a serious game–based cognitive assessment might look like, in turn, setting some parameters for targeted design while still enabling participants to be open and creative [58] (refer to the study by Povey et al [21] for similar approach). After the general discussion about health and the demonstration, we asked targeted questions about what people thought about the serious game and then asked them to provide their general preferences for games and scrutinize the suitability (eg, logistically) of a game-based cognitive assessment in prison.

Example questions include the following:

1. Do you remember ever being asked questions about your memory or thinking while you have been in prison?
2. Have you ever had a memory or thinking test before coming to prison, maybe from a psychologist?
3. Before entering prison, did you ever use a computer or tablet?
4. Did you ever use a computer/phone/tablet to play games?
5. What kinds of extra things make you enjoy games more?
6. Do you think there would be any issues with you and other older adults in prisoner using this sort of brain game technology?
7. Is there anything else about using a serious game in prison you might like us to consider?

Data Analysis

This study used reflexive thematic analysis in which the active role of the researcher in producing knowledge is emphasized, with themes conceptualized as meaning-based patterns, rather than summaries of data [59]. Reflexive thematic analysis is compatible with our overarching philosophy of critical realism [60], which can be used to accurately explore the participant's empirical world while engaging with underlying mechanisms and theories that can inform game design and development in the context of prison [44,61]. An abductive analytical approach was adopted to conduct this process. Abduction—also known as theoretical redescription—is a technique whereby empirical data are redescribed using theoretical concepts (in this case, SDT and game design research) [54,62]. Abduction has been defined as a process of "inference or thought operation, implying that a particular phenomenon or event is interpreted from a set of general ideas or concepts" [51]. Abduction raises the level of theoretical engagement beyond detailed description of the empirical entities but with an acknowledgment that the chosen theory is fallible [51]. This enables us to investigate participant observations in the context of latent, theoretical, and underlying mechanisms [51,53], which may be influencing game design preferences and motivations, while also ensuring that user observations and insights are still central to theme generation [56].

The analytical process followed the phases presented by Braun and Clarke [56,59,63]. Specifically, the first author transcribed and reread the interview transcripts and then coded and collated the interesting features of the data. Next, codes were added or updated deductively; that is, we explicitly analyzed our data through the lens of existing theory (namely, SDT). When we were satisfied with our coding, we used an abductive approach to combine and recontextualize existing codes. After coding and collating was completed, themes were drafted. These theory laden themes were analyzed to query any important underlying mechanisms, which may have been influencing the empirical observations. Finally, themes were organized and named in ways to appropriately portray the overall story of analysis. Using the process of abduction, all themes embody both the experiences of end users and relevant theories redescribing these observations in a context relevant to developing game design features [45].

Validity

While generating themes, the rigor and quality of the analysis can be enhanced by considering the types of validity (descriptive, interpretive, and theoretical) by Maxwell [52] and broad indicators of validity such as empirical adequacy, ontological plausibility, and explanatory power [64]. Interviews were transcribed verbatim and then reread to check the accuracy of the transcription by the first author (RM), who also conducted the primary analysis. This addressed the questions regarding descriptive validity. The predetermined group design differences (women vs men; Aboriginal vs non-Aboriginal; and aged 50-64 years vs aged ≥65 years) in the FGs were used to establish consistency and key differences [49] in participant accounts from varied perspectives. The FG questions were partially informed by existing theoretical accounts on serious game design (eg, questions about game design features and typical duration of a game-based assessment); however, given the nature of FG sessions, general and open-ended questions were also asked, which enabled participants to discuss general ideas together and form intragroup consensus organically. The second author (AW) and senior author (JH) acted as *critical friends* [65] to the first author (RM), who provided critical dialogue and challenged the first author's assumptions and explanations of phenomena at all stages of analysis (ie, initial coding, developing themes, and reviewing and naming themes). The use of the *critical friend* approach to thematic analysis underpinned by critical realism was conducted successfully by Goddard et al [44]. Finally, the applied basis for the research objectives (ie, to establish design preferences for an effective game-based assessment) produced clear practical utility [44,64] (this is discussed further in the *Limitations* section).

Results

Overview

Overall, 4 FGs with a total of 20 people were conducted with older adults (aged ≥50 years; aged ≥45 years for Aboriginal and Torres Strait Islander People) across 3 distinct prisons in New South Wales, Australia. Participants' characteristics are presented in Table 1.

Overall, 3 distinct themes were generated. The first theme emphasizes the participants' collective desire for an individually optimal level of difficulty in serious gameplay. The second theme raises the importance of avoiding immature and childlike gameplay features, as they can feel condescending to some older end users. The third theme highlights the strong user preference for meaningful choice and variety in any serious game–based cognitive assessment. According to SDT, the first theme relates to satisfying competence needs, whereas the second theme empathizes the need to avoid competence violations. The final theme is related to satisfying autonomy needs through meaningful choice.

Table 1. Participant characteristics.

Group; security classification and participants	Age (years)	Time served	Identified as Aboriginal	Sex
FG[a] 1; maximum security				
P1	52	<1 year	No	Female

[a]FG: focus group.

Goldilocks—Getting Gameplay Difficulty Just Right Through Optimal Challenge

There was considerable diversity in background, time served, education level, experience with computers and technology, and health status across the FG participants. This contributed to a variety of different expectations and preferences for what a serious game ought to be and the level of complexity that should be incorporated into gameplay.

One of the older men from FG4 felt that a simplified approach would be the most suitable:

> *I was in rehab 40 years ago...A couple of the blokes complained that it was a complicated program for simple people. And it should have been a simple program for complicated people. So, keep it simple stupid.* [Participant 3; FG4]

In contrast, one of the women from FG1, who had plenty of previous experience with games, was interested in a challenging game-based assessment:

> *I'm a games freak! So, yeah, I play...Obviously [it's good if] it gets harder, like to challenge us as you go, as you progress. Yeah, that would be good.* [Participant 2; FG1]

This desire for a challenge through gameplay emerged several times across FG1, FG2, and FG3:

> *You need a challenge to keep people interested.* [Participant 5; FG3]

However, FG4, which consisted of a group of older men (aged ≥65 years) residing in a Frail and Aged Unit, was keen to reiterate that whatever serious game was designed, it was best if it was "probably not too complicated" (participant 1; FG4).

One of the men in FG4 also added the following:

> *If you're happy doing it, I don't think it matters.* [Participant 3; FG4]

This highlighted that if the level of complexity in gameplay was appropriate, participants would be motivated to play it.

This desire for an optimal difficulty level [37,38] reflected a broad consensus across all groups that if the game provided a suitable challenge, it would be far more enjoyable.

When discussing a game he enjoyed, a participant from FG2 reflected the following:

> *Because you need skills to do it, it is pretty good.* [Participant 2; FG2]

What constitutes a challenge is likely to be different for each end user. For instance, the need for a technical and skill-based challenge by participant 2 in FG2 was not the preference of another member of FG2:

> *The other ones are too hard...I stay with Solitaire.* [Participant 4; FG2]

With this desire for different levels of difficulty, participants agreed about the need for challenge flexibility to ensure that game difficulty was suitable for each player:

> *As long as it challenges you, I'd probably stay with it.* [Participant 5; FG3]

> *...And if you can speed it up and slow it down, that gives people with no memory a better go at it. I can't remember things very well, so that adjustment of the speed level is pretty good. That's the only reason that I'd play that game.* [Participant 4; FG3]

According to SDT, participant observations and consensus about the need for optimal challenge reflect the need to satisfy the basic psychological need for competence [37,38]. In the context of games, optimal challenges can lead to a sense of efficacy and thus competence [39]. If a game is very easy, it becomes boring and reduces the likelihood of attentive engagement [66]:

> *If you lose interest early, it is doomed.* [Participant 5; FG3]

In contrast, if it is very hard, it can become frustrating and discouraging, thus also reducing the likelihood of motivation, engagement, and enjoyment:

> *My brain doesn't work that quick.* [Participant 4; FG2]

Optimal challenge is mediated by an individual's threshold for difficulty [39,66]. Difficulty creates the challenge that is essential for satisfaction of competence needs. However, the right level of difficulty will be vastly different across individuals, especially in the diverse prison context:

> *Maybe you can design the project that you're doing to different levels of how people want to react to these things.* [Participant 1; FG3]

Given the participants' need for optimal challenge, alongside the diversity in what challenge means for each person, a serious game–based assessment that can effectively differentiate game complexity appears to be important in the prison context to ensure that the challenge level is *just right* to address competence needs.

Avoiding Childish Graphics—Gimmicky Gameplay Can Be Condescending

Participants from FG2 and FG3 agreed that if a game did not have modern graphics or if it appeared childish, it was not playable and was even condescending:

> *No disrespect for who designed that game [the demo shown to participants] but that's a game for a 9-to-10-year-old...no offense but I couldn't play that...* [Participant 1; FG3]

> *I'm 60 years old and I use the phone and the graphics on the phone are better than that. You can't expect people to go back, to be honest.* [Participant 1; FG3]

It was clear that their expectations were for a game to feel more mature:

> *Your graphics are really bad [laughing]. Nintendo 64 was better than those graphics.* [Participant 1; FG2]

> *[The game needs to be] more realistic.* [Participant 5; FG3]

> *[And] more adult.* [Participant 1; FG3]

In contrast, the women from FG1 had a far more positive response to the serious game demonstration, with only 5% (1/20) of the participants finding the game to be problematic:

> *It's giving me anxiety.* [Participant 3; FG1]

> *[This game demo is good] because memory tests aren't usually fun.* [Participant 5; FG1]

> *I like it.* [Participant 4; FG1]

> *It's cute.* [Participant 2; FG1]

When queried about their general game preferences, the women in FG1 reacted positively to the ability to choose a character, even a character of the opposite sex. A participant suggested the following:

> *That's half the fun in it!!* [Participant 4; FG1]

The older men from the *aged ≥65 years* group were mostly indifferent to the game demonstration and did not comment about the graphics. They seemed to be more interested in functional issues connected to the game, such as whether it had audio and what the game was testing.

Although the openness to different game types varied across the groups, the strength of the aversion to *childish* games from several participants in FG2 and FG3 is important to be emphasized. Any game experience that makes a substantial portion of the target users feel condescended needs to be avoided:

> *I'd rather throw it out the window then just occupy my time with it. It has to be more than just the premise of being a game. In that regard, that's condescending. I don't consider myself unintelligent so, as someone said earlier, speak to me as an adult. Not as a ten-year-old kid. I understand there's people who have learning problems and all the rest of it, but do I have to be spoken to in the same manner as them?* [Participant 1; FG3]

Games that felt childish and immature appeared to violate competence needs in FG2 and FG3 for some participants [37-39]. Although these negative responses were not evident in FG1 and FG4, the need to avoid competence violations is of high importance for any game-based assessment. This is especially true for a cognitive assessment game in the prison context, where people already report feeling overlooked and unheard [40-42].

Furthermore, if people are worried about their cognitive health before completing the game-based assessment, any risk of competence violations must be minimized, otherwise feelings of self-stigma or shame may be exacerbated [9-11]. A participant reflected the following:

> *Just a thought. When you're planning for this...this is where psychs get it wrong...Say what you mean, mean what you say. We're grown men. Don't dabble around. Get to your point. Get your yes or no. Factor that in when you're planning this stuff. Don't treat humans like children. Nothing worse. It's patronising and condescending. Makes you feel stupider than you know you already are.* [Participant 2; FG3]

Thus, the need to ensure that game-based assessments in prison environments do not feel overly childlike or immature appears to have vital importance:

> *As far as games and all that, we had the Atari and Mario Brothers and all that. We played it with the kids. It's not just us playing. That was my involvement with games. But yeah, like the boys have said chess, backgammon, tiddlywinks, monopoly, we played all that. But I mean, games need to be more geared towards brain power, rather than just simplistic things like building blocks on top of other blocks like Tetris. But yeah, I got no problems with them.* [Participant 1; FG3]

Games that explicitly focus on *brain power*—such as quizzes, crosswords, and numeracy challenges—seem to be more aligned with the preferences and expectations of many participants in FG2 and FG3. In addition, there was no clear aversion to these types of *mature* games in FG1 and FG4, suggesting that they may be more appropriate for a wide range of older adults in prison.

A Balanced Diet—Meaningful Choice and Variety Keeps Game-Based Assessments Fun

Given the subjective nature of game enjoyment, a variety of different, and at times, contrary, game preferences were highlighted.

For example, when people were asked if they liked gaming features such as earning badges for performance achievements, there was a spectrum of opinions:

> *No, I don't want badges. I don't wanna know that.* [Participant 4; FG2]

This contrasted with views such as the following:

> *Oh, I love winning. I'm a really good winner! Yeah. That'd be cool.* [Participant 3; FG1]

Game variety appeared to be a key preference for participants:

> *It doesn't matter who you are, you can see on the screen, ok, I don't know how to do that, but I'd like to know, so I'll go and play that one...or, ok...I know how to do that, so I'll go play that other one.* [Participant 1; FG2]
>
> *Yeah, you got to have a variety.* [Participant 4; FG2]

Participants were also quick to acknowledge and discuss the purpose of the game, that is, to test different types of cognitive functioning (reaction time, memory, executive ability, etc). By acknowledging the primary purpose of the game, participants saw the opportunity to create a variety of gamified tasks addressing different design appetites within the groups and within themselves:

> *Yeah, you could have mind games, where you gotta think about what you're doing. And reactive games, where you gotta react to something and all that sort of thing...you could have literacy sort of games where you gotta think about what's being written and other games where you're using your reaction time and you're thinking about what's going on but you're not reading it.* [Participant 1; FG2]

When brainstorming about game design preferences, a participant from FG2 even suggested the technique of game customization to avoid amotivation and maximize meaningful choice:

> *Ohh, I just come up with a thing you can do for what you need. If you got someone who is getting dementia and they are retired, and you knew what their trade was, with the trade they'd done for work, you could ask them things like...let's say they done carpentry...Say, "what kind of tools would I need to build this kind of table and the process that I need to go through to start [to] build that table?" And you could see what their memory is from what they used to do. If you use to do something, your memory should recall, and you ask them something about that.* [Participant 2; FG2]

Another member of FG2 expanded upon this customization idea:

> *Going back to the building side of things, you could have a Mah-jong sort of game with building materials. Even engineering, you could do it with cars, make it like you gotta build a car or something.* [Participant 1; FG2]

Throughout the brainstorming conducted across a number of FGs, especially FG2, the game design technique of minigames emerged as a viable solution to address the need for variety and meaningful choice across the serious game.

When asked about the potential to use minigames, a participant positively reflected the following:

> *Like little minigames where, between what's going on around them, they're coming down like a map of different quests type thing? You're progressing through, or something, and play a little mini*

> *game...then move on and play another mini game? Yeah, that sounds good. To break the attention up. Yeah, yeah, that that would work.* [Participant 3; FG2]

This preference for different minigames reinforces the appetite for meaningful choice, a critical element of autonomy in the context of game design [37-39]. According to SDT, autonomy in digital games involves interesting options and volitional engagement [67]. Although choice and variety are critical design elements in most games, the strong desire for these elements by participants is important to be highlighted in the context of prison—an environment where autonomy is often thwarted [41].

Discussion

Principal Findings

This study aimed to qualitatively examine the design preferences for a serious game–based cognitive assessment among older adults in prison. Using an abductive approach underpinned by critical realism, we generated 3 distinct themes. They were (1) Goldilocks—getting gameplay difficulty *just right* through optimal challenge, (2) avoiding childish graphics—gimmicky gameplay can be condescending, and (3) a balanced diet—meaningful choice and variety keeps game-based assessments fun. These themes provide novel insights into the game design preferences of older adults in prison, whose voices have been seldom heard in the development of serious games so far. In addition, the production of these themes in the context of SDT and game design research should, we hope, provide a useful and actionable base for serious game designers to develop appropriate cognitive games that are acceptable and motivating for older adults within the unique prison context.

Within theme 1, it was clear that the competence needs for an individually optimal level of difficulty was a priority across all FGs. Regarding game design, this can be addressed by developers through dynamic game balancing [66,68]. Dynamic game balancing is a popular game design technique that overcomes variability in individual difficulty thresholds through real-time adjustment of game parameters, so that task difficulty adapts and eventually aligns with a player's ability [66]. This ensures that competence can be satisfied for a variety of users through optimal challenge [69]. The goal is to keep the user interested from beginning to the end. Dynamic game balancing is associated with high levels of user satisfaction [70] and feelings of competence, which predicates high levels of motivation and enjoyment [69]. The use of dynamic game balancing for serious game–based cognitive assessments is an emerging area, and potential complexities such as maintaining psychometric validity are yet to be fully considered [66]. Nonetheless, the technique appears to be theoretically capable of addressing the competence needs for optimal challenge highlighted by participants.

Theme 2 reflected the need to avoid competence violations by minimizing childlike game features, which made some participants feel condescended. In the context of SDT, game features offering opportunities for mastery that provide optimal challenges can satisfy competence needs by helping a player feel a sense of accomplishment and control [38]. However, the opposite can also be true. When people are tasked with playing a game that they believe is not suitable for them or does not align with their self-perceived level of capability, it can become boring, frustrating, and even insulting. This is an especially important consideration in the context of prison, where the need for competence is often thwarted, and people often distrust the prison system and report feeling disrespected by health and corrective professionals [71]. A noteworthy minority of our study participants highlighted that childish graphics made them feel condescended, and some members of our FGs appeared to be frustrated by the idea of playing a childish game for the purpose of cognitive assessment. We suggest that this frustration stems, at least in part, from a misalignment between some participants' self-perceived level of capability and the perceived inability of a game that looks and feels childish to meet this capability. We further suggest that this frustration, a common and natural response to perceiving a game as incompatible with one's intellectual capacity, can be exacerbated by the competence-thwarting prison environment, in which control is already difficult to achieve [72]. Thus, avoiding games that feel similar to *kids' games* and designing features that are more *adult* and *realistic*, which are *geared toward brain power* appear to be important to avoid competence violations and, more broadly, guard against overly negative responses to serious game–based assessments in prison.

Theme 3 highlighted the strong user preference for choice and variety, both of which satisfy the need for autonomy and can enhance intrinsic motivation [37,38,67]. Although the positive effects of choice can be complex and depend on a variety of factors (eg, cultural background), multiple studies have shown that choice has a beneficial effect on motivational outcomes such as effort and task performance [41,73]. Autonomy satisfaction has also been associated with better quality of life in prison [41]. However, both autonomy [74,75] and choice [76] are often difficult to attain in prison [41]. Therefore, ensuring that games are autonomy-focused through *meaningful choice* when they are restricted in real life may be particularly beneficial for this group. Minigames are an effective game technique to maximize choice and variety [38,39] and, as highlighted by participants, align well with the objectives of cognitive assessment. Thus, designing minigames with emphasis on user control appears to be a suitable way to maximize in-game autonomy for people from marginalized groups who may struggle to achieve autonomy in other aspects of their lives.

Limitations

This study has some important limitations. First, this study purposefully sampled end users from 3 different prisons in New South Wales, Australia. Although attempts were made to select a distinct variety of older adults in prison and in turn understand empirical observations in terms of prominent theories or underlying structures, the themes generated are not necessarily generalizable to other locations or user groups. Second, all FGs were monitored by a correctional officer owing to security protocols. This power imbalance may have affected the responses given by participants, particularly those who are highly reliant on staff, such as those in the Frail and Aged Unit. However, no evidence of this was observed during the FGs. Third, the method of analysis used in this study and our interpretation of data are underpinned by the philosophy of critical realism. It is entirely possible that a researcher informed by a different philosophical approach would interpret the empirical observations differently and thus make different truth claims. Similarly, results are reported using the technique of abduction. We have made attempts to be clear and transparent about our theory-focused interpretations and recontextualization of the data when producing our results. However, it is critical to acknowledge that our interpretations are inevitably based on our own beliefs and objectives. In addition, our chosen theories are fallible. To overcome this, we attempted to reduce biases and improve validity (refer to the *Validity* section); however, these attempts are not perfect. Moreover, they are not intended to remove the researcher completely from the qualitative process. With this in mind, it should be noted that the authors of this paper are focused on building a serious game for cognitive assessment that is suitable for use by diverse older adults in prison. We want the game to be successful and have likely interpreted participant observations and preferences to ask *how to make a serious game work* rather than *whether serious games work?* This does not mean we are certain that a game will be valid, feasible, or acceptable in prison. However, we certainly hope it will be, and this desire to design and develop a suitable serious game has informed this study.

Practical and Research Implications

A serious game–based assessment provides a novel challenge for game designers and developers. This is because the intended application of a serious game assessment is likely to be a relatively short (eg, 10-20 minutes) user experience, which is only *played* by users sporadically. The implication is that traditional game design focusing on intrinsically motivating features such as narrative and social connectedness may not be feasible or desirable. For instance, a complex and value-based storyline, with unique characters and quests, is likely very complex for an assessment that someone is going to undertake irregularly for 10 to 20 minutes. This tension has not been given much attention in the serious game literature from a user design perspective. Most of the previous studies on user preferences of cognitive game design has highlighted the importance of embedding intrinsically motivating game features without considering the complexity of embedding these features into a very short and sporadically played game-based assessment [77]. These traditional features may be desirable in long-form games focused on cognitive training or rehabilitation but are less suitable for the narrow and short objectives of a cognitive assessment. In contrast, other attempts to make game-based cognitive assessments have gamified traditional tasks in very basic ways. Although this may be more suitable to ensure psychometric validity, this process risks not being particularly engaging or fun. For instance, some previous attempts to digitize cognitive tasks or introduce simple gamification have been unsuccessful, with users reporting that, similar to traditional tasks, the experiences were tedious and boring [3,20,78,79].

Our study was guided in part by the need to address this tension. We were open with our participants about the typical length of serious games and the intended purpose of a gamified cognitive assessment (ie, to detect cognitive decline or dementia). This enabled users to provide practical design insights that reflect the unique parameters of serious game–based cognitive assessment. As such, the themes generated are consistent with the reality of serious game–based design and conform to the nuances of gamifying short and sporadic assessments while still highlighting game design features that are immersive, motivating, and enjoyable to our distinct user group. In this way, optimizing the challenge by balancing the difficulty level, avoiding childish features, and maximizing meaningful choice through minigames are unique user-generated design preferences suited to addressing user needs within a short and potentially infrequent serious game–based assessment in the prison setting.

Abstract

Background: Cognitive assessment using tangible objects can measure fine motor and hand-eye coordination skills along with other cognitive domains. Administering such tests is often expensive, labor-intensive, and error prone owing to manual recording and potential subjectivity. Automating the administration and scoring processes can address these difficulties while reducing time and cost. e-Cube is a new vision-based, computerized cognitive assessment tool that integrates computational measures of play complexity and item generators to enable automated and adaptive testing. The e-Cube games use a set of cubes, and the system tracks the movements and locations of these cubes as manipulated by the player.

Objective: The primary objectives of the study were to validate the play complexity measures that form the basis of developing the adaptive assessment system and evaluate the preliminary utility and usability of the e-Cube system as an automated cognitive assessment tool.

Methods: This study used 6 e-Cube games, namely, Assembly, Shape-Matching, Sequence-Memory, Spatial-Memory, Path-Tracking, and Maze, each targeting different cognitive domains. In total, 2 versions of the games, the fixed version with predetermined sets of items and the adaptive version using the autonomous item generators, were prepared for comparative evaluation. Enrolled participants (N=80; aged 18-60 years) were divided into 2 groups: 48% (38/80) of the participants in the *fixed group* and 52% (42/80) in the *adaptive group*. Each was administered the 6 e-Cube games; 3 subtests of the Wechsler Adult Intelligence Scale, Fourth Edition (WAIS-IV; Block Design, Digit Span, and Matrix Reasoning); and the System Usability Scale (SUS). Statistical analyses at the 95% significance level were applied.

Results: The play complexity values were correlated with the performance indicators (ie, correctness and completion time). The adaptive e-Cube games were correlated with the WAIS-IV subtests (*r*=0.49, 95% CI 0.21-0.70; *P*<.001 for Assembly and Block Design; *r*=0.34, 95% CI 0.03-0.59; *P*=.03 for Shape-Matching and Matrix Reasoning; *r*=0.51, 95% CI 0.24-0.72; *P*<.001 for Spatial-Memory and Digit Span; *r*=0.45, 95% CI 0.16-0.67; *P*=.003 for Path-Tracking and Block Design; and *r*=0.45, 95% CI 0.16-0.67; *P*=.003 for Path-Tracking and Matrix Reasoning). The fixed version showed weaker correlations with the WAIS-IV subtests. The e-Cube system showed a low false detection rate (6/5990, 0.1%) and was determined to be usable, with an average SUS score of 86.01 (SD 8.75).

Conclusions: The correlations between the play complexity values and performance indicators supported the validity of the play complexity measures. Correlations between the adaptive e-Cube games and the WAIS-IV subtests demonstrated the potential utility of the e-Cube games for cognitive assessment, but a further validation study is needed to confirm this. The low false detection rate and high SUS scores indicated that e-Cube is technically reliable and usable.

Introduction

Background

Cognitive assessment aims to measure multiple domains of cognition, including visuospatial abilities, working memory, language, attention, executive function, fine motor skills, and orientation [1]. One's cognitive abilities affect learning outcomes, physical and mental health, social behavior, and interaction with the environment [2-4]. Identifying impairment in any of these domains, diagnosing the cause, specifying the severity, and tracking the progression of the symptoms are the common purposes of cognitive assessment in clinical settings [5]. This paper presents an innovative technology called *e-Cube* for adaptive, automated cognitive testing and reports the evaluation results in terms of preliminary utility and usability.

There are standardized instruments widely used for cognitive assessment. The Wechsler Adult Intelligence Scale (WAIS) has been broadly adopted in clinical, research, and educational settings and is often referred to as a *gold* standard [6]. The WAIS Fourth Edition (WAIS-IV) is normed for the ages of 16 to 90 years. It comprehensively assesses cognitive abilities using 15 subtests that target various cognitive domains [7]. This instrument is administered and scored by a qualified psychologist, taking approximately 60 to 90 minutes. This process is labor-intensive and costly [8]. The Stanford-Binet Intelligence Scales, Fifth Edition, is another standardized instrument commonly used in both clinical and research settings [9]. Several WAIS and Stanford-Binet Intelligence Scales subtests rely heavily on a person's verbal skills and, therefore, show limitations when administered using a non–native language version [10]. There are also nonverbal instruments aiming to eliminate cultural and language biases in the assessment. For example, the Raven Progressive Matrices consist of 60 items measuring the basic cognitive functioning of individuals, each of which is a visual geometric design with a missing piece [11,12].

The advancements in digital technologies have enabled researchers to explore computer-based methods for cognitive assessment. Computer-based methods can reduce the administrative burden, automate the scoring process, reduce cheating, and standardize test conditions once successfully validated [13]. A straightforward application is to convert a paper-and-pencil test into a computerized version while retaining the contents and formats. Q-interactive is a digital system initially developed for the WAIS-IV that uses 2 iPads, one for the administrator and the other for the test taker [14]. This digital version reduces labor-intensity but takes approximately the same time for a trained professional. Moreover, it can only automate some types of tests. In particular, one of the subtests, Block Design (BD), requires the examinee to assemble physical blocks to match the top surface with a given image displayed on an iPad. The administrator then has to check the correctness and input the results manually. In addition to the computerization of existing instruments, an increasing body of research has adopted the concept of computer- or tablet-based *serious games* to make the experience more engaging [15-17]. Some serious games use dynamic difficulty adjustment to achieve adaptive testing by tuning item difficulty autonomously [18,19]. However, most of the previously developed games for cognitive assessment do not include measurements of fine motor and hand-eye coordination skills.

Cognitive Assessment Using Tangible Objects

Cognitive assessment sometimes uses tangible objects to measure one's cognitive skills together with fine motor and hand-eye coordination skills. These skills are closely linked to many neurological diseases and brain injuries [20]. Existing research also suggests that the deterioration of fine motor control and coordination characterizes sensorimotor deficiencies in mild cognitive impairment and Alzheimer disease [15,21-23]. The BD subtest in the WAIS [5] and the Kohs Block Design test [24] use a set of cubes and require an examinee to place and assemble the top surfaces of the blocks to match the given image. Unlike the simple multiple-choice questions used in many other assessment instruments, the administrator has to inspect the correctness of the block manipulation visually while timing in these tests. This is labor-intensive and error prone owing to manual recording and subjectivity, possibly affecting the assessment results.

Automating the assessment using physical objects also involves additional challenges and requires technological innovations beyond what is expected for computerized tests. For example, a platform called ETAN supports the use of tangible user interfaces and physical objects for evaluating visuospatial cognition by implementing the Baking Tray Task [25]. Cognitive Cubes were designed to assess spatial and constructive abilities by asking users to build 3D shapes with the cubes. A pilot study involving 16 participants demonstrated that the Cognitive Cubes were sensitive to differences in cognitive ability [20].

SIG-Blocks and TAG-Game, developed for the automated assessment of cognitive and fine motor skills, were the previous research of this work [26-28]. Each SIG-Block, covered with simple black-and-white geometric shapes, can sense physical motions applied to it, detect adjacent blocks, and send sensor data to a local host computer in real time. TAG-Games are computerized games that use SIG-Blocks as a means of game control. In total, 3 types of TAG-Games, namely, Assembly, Shape-Matching, and Memory, were designed and tested. These games are all nonverbal and require hand manipulation of physical blocks. The TAG-Game technology is one of the few systems that can automate the administration and data collection of tasks involving physical object manipulation. However, despite its demonstrated potential, several challenges were identified in our previous research. Specifically, hardware costs, occasional technical failure, and high maintenance make the system unsuitable for broad and long-term adoption and use.

e-Cube Games for Automated Assessment of Fine Motor and Cognitive Skills

e-Cube is our latest technical innovation that converts the original TAG-Game system into a computer vision-based system using a set of plastic cubes and a webcam. The e-Cube system reduces the device cost from US $1500 to approximately US $50 (excluding a computing device needed for any computerized assessment), decreases potential technical errors, and nearly eliminates the maintenance burden. The entire system is fully autonomous and easy to use. In addition to these benefits, a new *adaptive* test environment was established based on the embedded algorithms for measuring play complexity and generating adaptive test items autonomously. These features enable personalized assessment based on an individual's real-time performance. e-Cube consists of 6 types of games: (1) Assembly, (2) Shape-Matching, (3) Sequence-Memory, (4) Spatial-Memory, (5) Path-Tracking, and (6) Maze. The first 3 were directly adopted and converted from TAG-Games, and the other 3 were newly created. New computational measures of play complexity were defined and implemented for each game.

The evaluation focused on testing 2 objectives. *Objective 1* was to validate the proposed play complexity measures that form the algorithmic basis of the adaptive games. Correlation analyses were performed between the developed play complexity measures and 2 performance indicators, mean correctness and mean completion time. *Objective 2* was to understand the preliminary utility and usability of the e-Cube system as an automated cognitive assessment tool. The non–age-corrected raw scores of 3 WAIS-IV subtests—BD, Digit Span (DS), and Matrix Reasoning (MR)—were adopted to compare their results with the e-Cube game scores. The WAIS-IV is a well-established instrument, and the 3 selected subtests measure the target cognitive domains of the e-Cube games. Specifically, the Assembly game was conjected to be related to BD as both require the assembly of block surfaces to match a given pattern. The Shape-Matching game requires the participant to find a shape that completes a pattern, so it was expected to tap the same cognitive abilities as the MR subtest. Sequence-Memory and Spatial-Memory were expected to be related to DS as they all target working memory skills. The remaining games, Path-Tracking and Maze, are timed games asking participants to give the shortest trajectory by reasoning, so they were both hypothesized to show a relationship with BD and MR. The *hypothesized relationships* between the e-Cube games and the WAIS subtests are summarized in Table 1. The false detection rate of the system determines whether it produces reliable and accurate data. Usability was evaluated by administering the System Usability Scale (SUS) to all participants upon the completion of the assessment session. The SUS is a 10-item questionnaire measuring usability with high validity and reliability and, thus, used as a measure of perceived usability [29-31].

Table 1. The 6 e-Cube games with their associated task descriptions and the expected associations with the Wechsler Adult Intelligence Scale, Fourth Edition (WAIS-IV), subtests (Block Design [BD], Digit Span [DS], and Matrix Reasoning [MR]).

e-Cube game	Task	WAIS-IV		
		BD	DS	MR
Assembly	Assemble multiple cubes to match the top assembly configuration	✓		
Shape-Matching	Manipulate 1 cube to complete the pattern with 1 missing piece			✓
Sequence-Memory	Memorize a sequence of geometric shapes and reconstruct it using 1 cube		✓	
Spatial-Memory	Memorize a spatial assembly of geometric shapes and reconstruct it using cubes		✓	
Path-Tracking	Trace a connected path between 2 blue dots using a single cube	✓		✓
Maze	Navigate through a maze to reach a goal point from a starting point using a single cube	✓		✓

Methods

e-Cube Games

System Overview

The e-Cube system consists of a set of 9 cubes with 1.2-inch–length edges, a place mat with a brown rectangular region in the center, a computing device with a display, and a webcam with a custom-designed stand (Figure 1). The cube's 6 faces are distinctive black-and-white geometric shapes, including squares, strips, and triangles representing 4-, 2-, and 1-fold rotational symmetry (Figure 2). The cubes preserve the same design as the SIG-Blocks [28]. When the system turns on, the camera automatically detects the corners of the brown rectangular area on the place mat. This area is called the *play area*, where the cubes are expected to be placed and manipulated. The laptop with the connected webcam displays the cubes in the play area after perspective transformation projecting the original camera view onto a 2D plane and tracks their movements in real time [32]. This autonomous transformation offers flexibility in the camera location.

The e-Cube system requires the accurate identification of the top-surface images of the cubes. Individual box-shaped regions are assigned for placing the cubes (Figure 1), wherein the geometric shape and orientation detection algorithm is executed. The embedded algorithm first detects the black-and-white regions within each box to check whether a cube exists. It then identifies a polygon using the Ramer-Douglas-Peucker algorithm [33]. Finally, the specific shape and orientation of the detected polygon are determined. This simple strategy makes the system robust and reliable under different illumination conditions and limited computing capabilities. The e-Cube system can run reliably on a relatively low-end computing device, such as Intel Core i5-7200U (2.5 GHz, 3 M cache, dual core, and 4 threads).

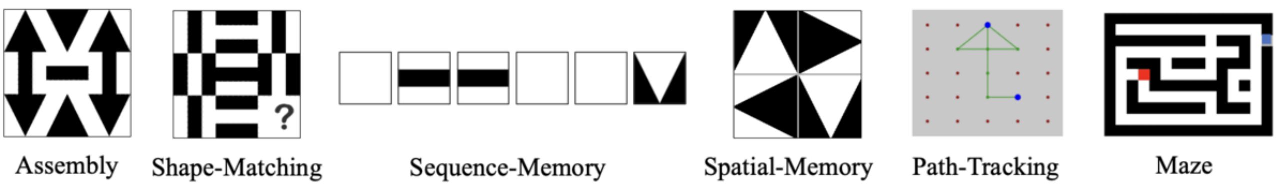
Game Design

We developed 6 e-Cube games: Assembly, Shape-Matching, Sequence-Memory, Spatial-Memory, Path-Tracking, and Maze. We directly converted the 3 TAG-Games (Assembly, Shape-Matching, and Memory) into the vision-based e-Cube versions (Assembly, Shape-Matching, and Sequence-Memory) [26]. Spatial-Memory, Path-Tracking, and Maze were newly added.

Table 1 presents the tasks associated with each game, and Figure 3 shows an example item for each e-Cube game. Assembly asks the player to match the given assembly figure displayed on the screen using 4 or 9 cubes, similar to the BD subtest of the WAIS-IV. Shape-Matching involves items with assembly patterns, each missing 1 piece, and the player completes the pattern using a single cube. Sequence-Memory and Spatial-Memory require the player to memorize a sequence or an assembly of geometric shapes. In Sequence-Memory, each shape is displayed for 1 second and then disappears. In Spatial-Memory, an assembly pattern of 2, 3, or 4 geometric shapes is displayed for 5 seconds. The items in the Spatial-Memory game are similar to those in Assembly, whereas visible outlines around individual shapes are added, as shown in Figure 3, to assist perceptual segmentation of the pattern [34]. Path-Tracking and Maze use only 1 cube with its white square facing up. In these 2 games, the vision algorithm detects the center of the white square and tracks it continuously on the screen; no assigned box-shaped regions are shown on the screen. Path-Tracking displays a green connected path between 2 blue dots, and the player must trace the path by moving the cube from one blue dot to the other on a 5 × 5 grid via the shortest path. The Maze game asks the player to find the shortest path of mazes shown on the screen by moving a cube from the start (blue) to the end (red).

Figure 3. Sample items for the 6 games.



Computational Measures of Play Complexity

Overview

The e-Cube system aims to dynamically adapt to individual differences in cognitive skills by generating test items autonomously based on one's real-time performance. To do so, a computational method to measure the difficulty of each item is required. The previously defined measures of play complexity presented in the studies by Lee et al [26,35] and Jeong et al [28] were highly correlated with the participants' performances measured using completion time or accuracy. These measures captured the complexities associated with individual geometric shapes without considering the spatial complexity of the assembly patterns. For example, the 3 assembly patterns shown in Figure 4 had the same complexity value using the previously defined measures. As our previous study used a handcrafted set of items, we could select the items where their difficulties could be clearly differentiated using the previously defined measures. However, for generating adaptive test items, the complexity measures must capture the difficulties associated with both the individual shapes and the assembly patterns.

Figure 4. Items formed by the same geometric shapes but with different play complexity (with identical compositional complexity but different configurational complexity).

To address this limitation, we defined new complexity measures for the 6 e-Cube games. Two mathematical concepts were applied: (1) the Shannon entropy and (2) the gray-level co-occurrence matrix (GLCM). The Shannon entropy measures the uncertainty, randomness, or disorder existing in the data [36] and is calculated as

where p_i is the probability of the ith event. When the probabilities are evenly distributed, the Shannon entropy is calculated as $H=\log_2 n$. The GLCM was originally proposed to classify image texture in grayscale [37,38]. For an image with an $m \times n$ dimension and L gray level, the GLCM of the image (f) is defined as an $L \times L$ square matrix such that

where Δx and Δy are typically defined as the horizontal, vertical, or diagonal position differences between the 2 adjacent pixels [37]. Horizontally adjacent pixels can be paired along 0° or 180°; vertically adjacent pixels can be paired along 90° or 270°; and diagonally adjacent pixels can be paired along 45°, 135°, 225°, or 315°. On the basis of the Shannon entropy and the GLCM, the computational measures of play complexity for the 6 e-Cube games are defined in the following sections.

Play Complexities of Assembly, Sequence-Memory, Spatial-Memory, and Shape-Matching

The play complexity of the items in Assembly, Sequence-Memory, and Spatial-Memory is computed using

where C_{compos} represents the compositional complexity associated with individual shapes (ie, the number of shapes and their rotational symmetry), C_{config} captures the configurational complexity associated with the orientation and color differences among the shapes in the way that they are arranged, and k is a sigmoid function defined as

If C_{config} is small, a small k leads to a lower impact of C_{compos} on C_{play}. For example, if an item is formed only by identical triangles (large C_{compos} and small C_{config}), C_{play} will still be small owing to k.

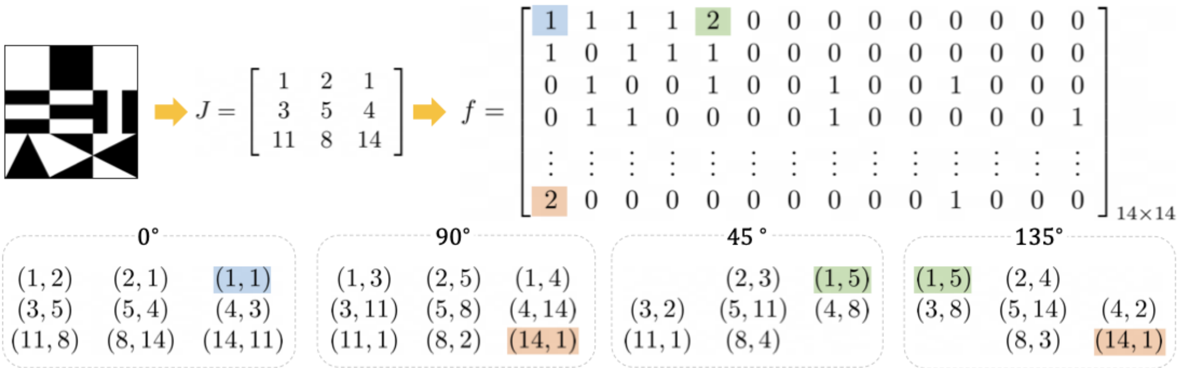
The Shannon entropy forms the basis of C_{compos} such that

where Q is the total number of shapes in the item, m_i is the number of available distinctive shapes among the 6 faces of a cube (m_i=6 if all faces of a cube are different), and r_i is the number of distinctive orientations obtained by rotating this shape 90° (r_i=1 for squares, 2 for strips, or 4 for triangles). The 3 images in Figure 4 have the same C_{compos} value.

The GLCM was adopted for capturing the configurational disorder (C_{config}) [39]. Figure 5 illustrates how it is obtained for an Assembly item. First, all geometric shapes used in each item are represented as J with the indexes corresponding to each shape defined in Figure 2 and its location. Second, all adjacent pairs along the 0°, 45°, 90°, and 135° directions on J are extracted. For example, the second row in J is (3, 5, 4), and the ordered pairs along 0°, including the circulant pair, are (3, 5), (5, 4), and (4, 3). Once all pairs are obtained, the number of each pair is imposed on the location in a 14-by-14 matrix f, that is, the GLCM, following equation 1. As shown in Figure 5, there are two (1, 5) pairs that correspond to 2 in the (1, 5) coordinate in f and one (1, 1) pair that corresponds to 1 in the (1, 1) coordinate. The weighted entropy [40] based on f is then calculated using

where

Figure 5. Gray-level co-occurrence matrix computation of a given 3 × 3 Assembly item.



The weight $w_{i,j}$ estimates the configurational complexity of 2 adjacent elements based on their colors and orientations. To compare the differences among these 14 distinctive shapes, 3 IDs were assigned to each shape to categorize its geometric shape (square, strip, or triangle), color, and orientation (Figure 2). Regarding the IDs, 2 was assigned to the weight if the 2 adjacent shapes had different colors and orientations, and 1 was assigned otherwise.

In Shape-Matching, as the player was asked to find a single shape that best completed the pattern, more shapes used in the pattern do not necessarily indicate greater difficulty in the pattern. Therefore, we only used the configurational complexity to estimate the item difficulty such that C_{play}=C_{config}, where C_{config} is defined as the summation of the weighted entropies based on the 3 GLCMs estimating how frequently a pair occurs horizontally, vertically, and diagonally.

Play Complexities of Path-Tracking and Maze

Path-Tracking and Maze do not use the geometric shapes of the cubes and, instead, use a single cube for creating a path. Therefore, the aforementioned method is not applicable. The play complexity of Path-Tracking adopts the network complexity based on the Shannon entropy [41], given by

where V is the number of vertices and a_i is the associated vertex degree. For Maze, the play complexity is defined as

where C_m is the maze complexity using equation 5 and C_s and C_l are calculated using

C_m reflects the complexity of the maze itself, but the complexity of solving a maze should also consider the start and end locations. The solution logarithmic complexity (C_s) in equation 7 represents the complexity caused by the vertex degrees, where L is the total length of the shortest path solved by the A* algorithm [42] and s_i is the degree of each grid in this solution. The solution length complexity C_l in equation 7 captures the length of the shortest path. In equation 6, the 0.4 value is multiplied to make the complexity values comparable with those of other e-Cube games. In addition, C_s + C_l is multiplied by 10 to balance with the range of C_m.

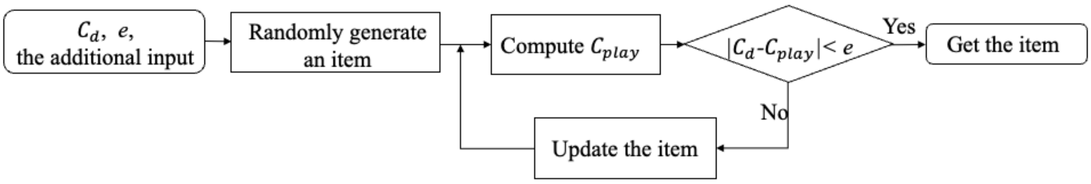
Adaptive Game Generators

The computational measures of play complexity form the basis of the adaptive algorithms, which can automatically generate test items. On the basis of the concept of dynamic difficulty adjustment, we created an adaptive e-Cube system that can adjust the item difficulty based on a player's performance measured using correctness.

The game begins with an item with a predefined low complexity. If the player answers the first item correctly, it proceeds to the next item with a higher complexity; otherwise, a new item with the same complexity is generated. If 2 consecutive incorrect answers are received, the complexity reverts to the midpoint between the latest correctly answered item complexity and the current incorrectly answered item complexity. The difference between the current and the next complexity value is referred to as a step size that can be either positive, 0, or negative. The game ends at a predefined highest complexity level or when the absolute value of the step size becomes sufficiently small.

The item generators for all games except for Shape-Matching follow a similar process, shown in Figure 6. The system takes a desired play complexity value C_d and a small tolerance e as input and generates a new item with a complexity C_{play}, where $|C_d - C_{play}| \le e$. Apart from C_d and e, additional input is needed in these games except for Maze. This input is the dimension of the pattern (eg, 2 × 2 or 3 × 3) in Assembly and Spatial-Memory, the number of images to be displayed in Sequence-Memory, and the number of dots to be connected (referred to as nodes) in Path-Tracking. The following steps generate items: (1) the system randomly generates an item based on the inputs; (2) the absolute difference between C_d and C_{play} is computed, where C_{play} is the complexity of the current item computed using the proposed measure; (3a) if the absolute difference is smaller than e, the system outputs the current item and ends the process; and (3b) if the absolute difference is not smaller than e, the system updates one feature of the current item to make the item easier or harder and then goes back to step 2. The features of the item can be geometric shapes in Assembly, Sequence-Memory, and Spatial-Memory; the paths connected by nodes in Path-Tracking; or the position of the end point in Maze.

Figure 6. The flowchart of the item generators for Assembly, Sequence-Memory, Spatial-Memory, Path-Tracking, and Maze.



Shape-Matching uses assembly configurations with embedded patterns where the types of patterns are predefined in the item generator, such as symmetry and rotation. Shape-Matching generates items from a predefined pool. For example, the easiest pattern in the predefined pool is formed by 4 identical shapes, in which one of the shapes will be hidden from players and treated as the missing piece. The item generator for Shape-Matching randomly selects a shape to form the easiest pattern, which leads to different items with the same play complexity.

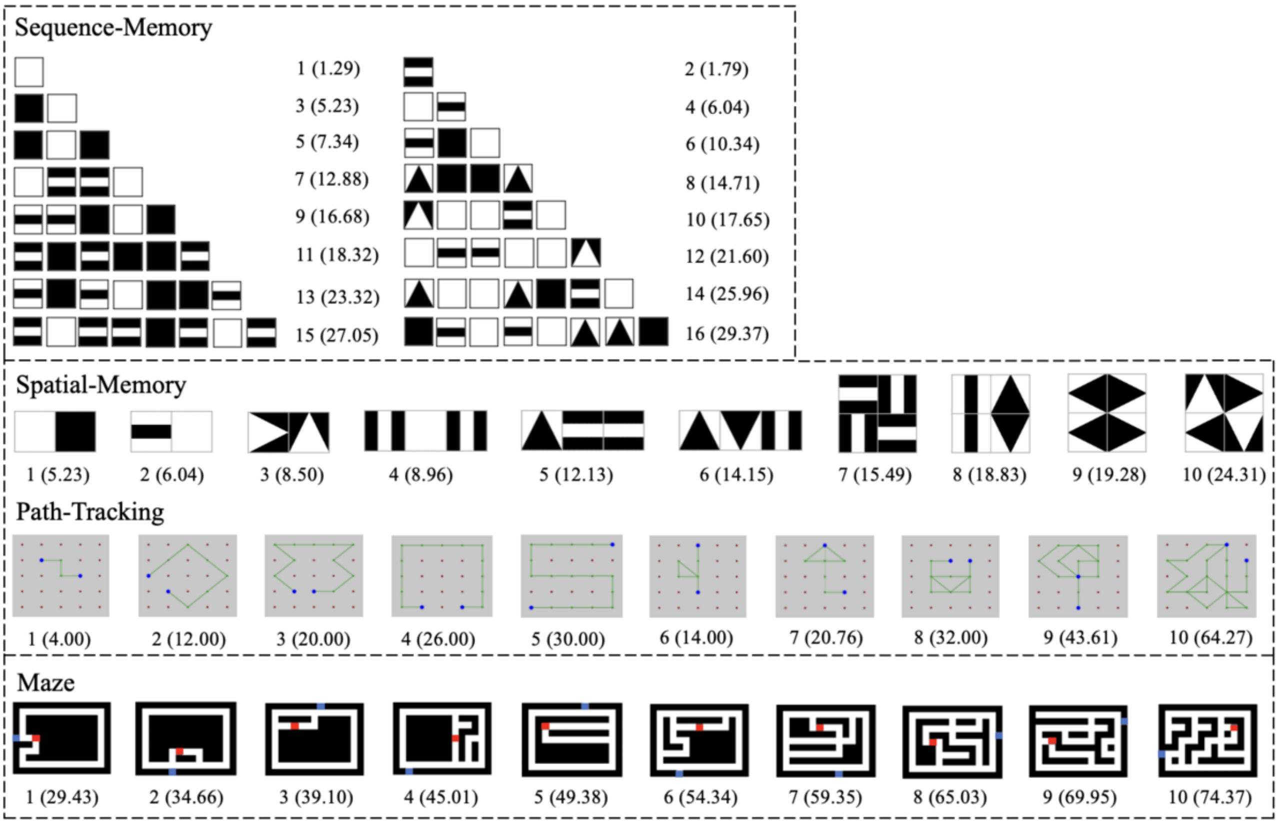
Evaluation of e-Cube

The evaluation study focused on the preliminary validation of (1) the proposed play complexity measures that form a basis for developing adaptive games (objective 1) and (2) the preliminary utility and usability of the e-Cube system as an automated cognitive assessment tool (objective 2).

Materials and Methods

The study used 2 versions of e-Cube games: e-Cube with the item generators (called *adaptive* e-Cube) and e-Cube with fixed items (called *fixed* e-Cube). Each participant was assigned to 1 of the 2 groups to experience the adaptive or fixed e-Cube games (ie, adaptive group and fixed group). The fixed games provided the same items for each player, whereas the adaptive games offered different items and different numbers of items based on the players' performance. The fixed versions of Assembly and Shape-Matching used the same items as in the study by Lee et al [26]. The fixed items of the rest of the games are shown in Figure 7.

Figure 7. Items with their ordering numbers and play complexity values in the fixed version of Sequence-Memory, Spatial-Memory, Path-Tracking, and Maze.



Objective 1 was tested by performing correlation analyses between the play complexity measures and performance indicators, including the mean correctness and mean completion time obtained by the participants for individual items in the fixed group. For objective 2, the correlations between the raw scores of 3 WAIS-IV subtests (BD, DS, and MR) and the 6 e-Cube games were analyzed to understand their relationships. We also investigated the technical reliability of the system using the false detection rate and usability based on the SUS results.

Protocol and Recruitment

This human participant study took place at Texas A&M University (TAMU). Bulk recruitment emails were sent to TAMU communities, and flyers were placed in buildings within the university for recruiting healthy participants aged 18 to 64 years. Once potential participants contacted the research team, a prescreening survey was sent via email to self-identify their eligibility before scheduling a visit. The prescreening survey consisted of 4 questions on age, date of birth, sex, and health conditions. Individuals who were beyond the target age range or had any of the following health conditions were excluded: stroke, other neurological diseases, low vision or blindness with aid, hearing loss or deafness with aid, or difficulties in arm or hand movements for manipulating small objects.

The sample size of a main trial is usually determined through a power analysis, where the variance is known from previous or pilot studies [43]. However, for this preliminary study, we applied the simplest method—sample size rules of thumb, which recommended samples of a minimum of 70 (35 per group) in pilot studies [44,45]. In our study, 80 participants (n=47, 59% male) were recruited and screened. All (80/80, 100%) were eligible and, thus, enrolled in the study. Informed consent and background information (ie, age and sex) were obtained from each participant. Most of the participants were randomly assigned to either the fixed or adaptive group, whereas efforts were made to balance the sex and age distribution between the 2 groups when we placed the participants in the groups toward the end. The fixed group included 48% (38/80) of the participants (23/38, 61% male), and the adaptive group included 52% (42/80) of the participants (24/42, 57% male). Owing to the convenience of recruitment and proximity to the study location, most participants were students from various departments and programs across the TAMU College Station campus, whereas several faculty and staff members, alumni of the university, and a few residents also participated. As a result, 82% (66/80) of the participants were aged between 18 and 30 years, 9% (7/80) were aged between 31 and 40 years, 2% (2/80) were aged between 41 and 50 years, and 6% (5/80) were aged between 51 and 60 years. There were no participants aged >60 years. Age mean, SD, and IQR; age distribution; and sex distribution are summarized in Table 2. We applied a chi-square test at a 95% confidence level to determine if there were differences in sex and age distribution between the 2 groups. The results showed no difference in the proportions of male, female, and intersex participants in the groups (χ^2_2=0.1, *P*=.76) and no difference in the proportion of age in the groups (χ^2_4=2.4, *P*=.50).

Table 2. Participant demographic data (N=80).

Characteristic	Participants	
	Fixed group (n=38)	Adaptive group (n=42)
Age (years), mean (SD; IQR)	26.71 (9.24; 22.00-28.00)	25.74 (8.50; 20.00-27.25)
Age range (years), n (%)		
18-30	31 (39)	35 (44)
31-40	4 (5)	3 (4)
41-50	0 (0)	2 (2)
51-60	3 (4)	2 (2)
>60	0 (0)	0 (0)
Sex, n (%)		
Male	23 (29)	24 (30)
Female	15 (19)	18 (22)
Intersex	0 (0)	0 (0)

The administration order between WAIS-IV and e-Cube was randomized. The order of the 3 subtests of the WAIS-IV followed the standardized protocol (BD, DS, and MR), whereas the order of the 6 e-Cube games was randomized. Upon the completion of both tests, the SUS was administered to each participant. The entire session took approximately 90 minutes: 50 minutes for e-Cube, 25 minutes for the WAIS-IV subtests, 5 minutes for the SUS, and a 10-minute break between e-Cube and the WAIS-IV subtests. Each participant was given a US $10 gift card upon the completion of participation.

Scoring System

The e-Cube games have not been standardized yet, and therefore, scoring methods are not finalized at this stage. We benchmarked the scoring methods used for the WAIS-IV subtests and our previous study [26] and modified them to suit the e-Cube games. The scoring of Assembly considers correctness, item size, and completion time—a 2 × 2 item that is correctly completed within 15 seconds or between 15 and 30 seconds yields 3 or 2 points, respectively; a 3 × 3 item correctly completed within 30 seconds, between 30 and 40 seconds, or between 40 and 60 seconds results in 4, 3, or 2 points, respectively. Shape-Matching, Sequence-Memory, and Spatial-Memory use correctness only as the scoring criteria—2 points for each correct answer and 0 for an incorrect answer. Scoring methods for Path-Tracking and Maze are based on correctness, completion time, and whether the path taken is the shortest. For Path-Tracking, the shortest path finished within 20 seconds, between 20 and 40 seconds, or between 40 and 80 seconds yields 4, 2, or 1 points, respectively; a correct path, but not the shortest, completed within 20 seconds or between 20 and 40 seconds yields 2 or 1 points, respectively. For Maze, the shortest path completed within 10 seconds, between 10 and 20 seconds, or between 20 and 40 seconds yields 4, 2, or 1 points, respectively; a correct path, but not the shortest, completed within 10 seconds or between 10 and 20 seconds yields 2 or 1 points, respectively. Others not satisfying the aforementioned conditions result in 0 points.

The adaptive e-Cube games require some additional considerations for scoring. If an item is generated with the same play complexity as the previous one answered incorrectly, the score for the correct answer is 1 point less than the score used in the fixed version. A total of 2 consecutive incorrect answers result in the system generating an easier item, and in this case, a correct answer for that newly generated item yields only 1 point.

Statistical Analysis

Correlations were computed to determine the relationships between the computed complexity values and participants' performance, the connections between the WAIS subtests and the e-Cube games, and the relationships among the 6 e-Cube games. We used the Spearman correlation to measure the monotonic association among them. The correlation is interpreted as "weak," "moderate," and "strong/high" when the coefficient is <0.36, between 0.36 and 0.67, and >0.67, respectively [46]. We used 2-tailed *t* tests to identify the mean differences in the game or subtest scores and the SUS scores between the 2 groups.

Ethics Approval and Informed Consent

This human participant study was reviewed and approved by the TAMU Institutional Review Board (IRB2019-1079D; approval date: December 22, 2020). Informed consent was obtained from all participants before taking part in this study.

Results

All enrolled participants (80/80, 100%) completed the entire session without withdrawal. The results and findings for objectives 1 and 2 are presented in the following sections.

Objective 1: Evaluation of the Measures of Play Complexity

The preliminary validity of the proposed play complexity measure (C_{play}) was evaluated by analyzing the correlations between the C_{play} values and the performance indicators from the fixed group participants. If the defined complexity measures properly reflected the difficulty associated with the individual items, participants would perform worse on the items with higher complexity values. Two performance indicators were used to evaluate the play complexity measures: (1) mean correctness and (2) mean completion time obtained for each item from the fixed group participants. The correlation analyses were performed at a 95% confidence level between the C_{play} values and all the mean values. The correlation coefficients *r* with *P* values and 95% CIs are shown in Table 3.

The C_{play} values showed strong positive correlations with the mean completion time in all e-Cube games, indicating that the items with higher C_{play} yielded a longer time to answer. Negative correlations between the C_{play} values and the mean correctness were found in Assembly, Shape-Matching, and Sequence-Memory, indicating that higher C_{play} items yielded lower accuracies. In Spatial-Memory, we found no substantial correlation between the mean correctness and C_{play}, mainly because of items 8 and 9 (Figure 7). The symmetry in these items seemed to make them easy to memorize, whereas it was not taken into account for the defined complexity measures. Without these 2 items, a correlation was found as r_8=–0.67 (95% CI –0.93 to 0.066; *P*=.06). A few participants correctly answered all the items in Path-Tracking (12/38, 32%; *P*=.58) and Maze (31/38, 82%; *P*=.07), and therefore, correctness did not yield any significant correlation with C_{play}.

Table 3. Correlations (Spearman r, 2-tailed *P* value, and 95% CIs) between the C_{play} values and the mean correctness and mean completion time for each item from the fixed group participants.

Game (*df*)	Mean completion time	Mean correctness
Assembly (20)		
r	*0.86* [a]	*–0.50*
P value	*<.001*	*.02*
95% CI	*0.67 to 0.94*	*−0.46 to 0.43*
Shape-Matching (10)		
r	*0.95*	*–0.75*
P value	*<.001*	*.009*
95% CI	*0.80 to 0.99*	*−0.94 to −0.23*
Sequence-Memory (16)		
r	*0.98*	*–0.95*

Objective 2: Evaluation of Preliminary Utility and Usability of e-Cube Games for Cognitive Assessment

Overview

The mean, SDs, and IQR values obtained from participants in each group for the WAIS-IV subtests (raw scores) and e-Cube games are summarized in Table 4. We also conducted a 2-tailed *t* test with equal variance (Cronbach α=.05) comparing the test scores from the adaptive and fixed groups to determine whether significant differences existed in mean scores between the 2 groups. The *t* test showed no significant differences in the mean scores of the 3 WAIS subtests—BD (*P*=.37), MR (*P*=.06), and DS (*P*=.18)—between the 2 groups. Group differences were found in Shape-Matching and Sequence-Memory, but not in other e-Cube games.

Table 4. Score statistics from the Wechsler Adult Intelligence Scale, Fourth Edition (WAIS-IV), subtests and e-Cube games.

	Fixed group, mean (SD; IQR)	Adaptive group, mean (SD; IQR)	2-tailed *t* test (*df*)	*P* value
WAIS-IV raw score				
BD[a]	50.95 (11,26; 41.00-60.00)	53.02 (9.35; 47.75-60.00)	–0.90 (78)	.37
DS[b]	28.34 (4.86; 24.75-32.00)	29.98 (5.83; 26.00-34.00)	–1.36 (78)	.18
MR[c]	21.55 (2.45; 11.00-14.00)	22.62 (2.49; 21.00-24.00)	–1.93 (78)	.06
e-Cube score				
Assembly	54.37 (11.10; 48.75-62.00)	58.52 (12.52; 51.75-67.25)	–1.56 (78)	.12
Shape-Matching	*16.53 (1.84; 16.00-18.00)* [d]	*14.67 (2.86; 13.00- 16.25)*	*3.42 (78)*	*.001*
Sequence-Memory	*20.63 (4.63; 16.00-24.00)*	*17.98 (3.83; 15.00-20.25)*	*2.81 (78)*	*.006*
Spatial-Memory	17.21 (2.16; 16.00-18.50)	16.88 (2.93; 15.00-19.00)	0.57 (78)	.57
Path-Tracking	26.95 (5.83; 24.00-31.00)	26.21 (7.54; 22.00-31.25)	0.48 (78)	.63
Maze	22.47 (6.27; 18.75-26.25)	22.12 (5.18; 17.00-26.00)	0.28 (78)	.78

[b]DS: Digit Span.

[c]MR: Matrix Reasoning.

[d]Italics indicate that a difference existed.

Relationship Between e-Cube Games and WAIS-IV Subtests

We presented the expected relationships between the e-Cube games and the WAIS-IV subtests in Table 1. The evaluation results are shown in Tables 5 and 6, which list the correlations between the e-Cube scores and WAIS-IV subtest scores in the fixed and adaptive groups, respectively. The 2 groups showed somewhat different trends in results. In both groups, Assembly and BD were moderately correlated, as expected in Table 1. Shape-Matching was expected to be correlated with MR, and the results from the adaptive group agreed with this. The Shape-Matching results from the fixed group showed a weak correlation with BD but no correlation with MR. Sequence-Memory and Spatial-Memory were expected to tap working memory as assessed by DS, but only the adaptive version of Spatial-Memory was moderately correlated with DS. The adaptive version of Sequence-Memory and BD also showed a weak correlation. Path-Tracking and Maze were expected to be related to BD and MR, and only the adaptive version of Path-Tracking yielded the expected results. However, no correlations were found between both versions of Maze and any WAIS subtest. Another notable finding was that both versions of Sequence-Memory showed no significant correlation with DS. Overall, the results suggested that the adaptive versions better tap into the cognitive abilities assessed by the 3 WAIS-IV subtests.

We further analyzed the intercorrelations among the e-Cube games (Multimedia Appendix 1 for fixed games and Multimedia Appendix 2 for adaptive games). The adaptive e-Cube showed fewer intercorrelations than the fixed version. In the fixed version, most of the games were somewhat correlated except for Shape-Matching. Both versions of Path-Tracking and Maze were correlated with Assembly.

Table 5. Correlations (Spearman r_{38}, 2-tailed *P* value, and 95% CIs) between the e-Cube scores and raw scores of the Wechsler Adult Intelligence Scale, Fourth Edition, subtests in the fixed group.

Fixed game	BD[a]	DS[b]	MR[c]
Assembly			
r	*0.49* [d,e]	−0.20	0.10
P value	*.002* [d]	.23	.57
95% CI	*0.20 to 0.70* [d]	−0.49 to 0.13	−0.23 to 0.41
Shape-Matching			
r	*0.33*	−0.30	0.09[d]
P value	*.04*	.07	.57[d]
95% CI	*0.01 to 0.59*	−0.57 to 0.02	−0.24 to 0.40[d]
Sequence-Memory			
r	0.31	0.14[d]	0.26
P value	.06	.40[d]	.11
95% CI	−0.01 to 0.57	−0.19 to 0.44[d]	−0.07 to 0.54

Technical Reliability and Usability of e-Cube

The e-Cube technology operated smoothly without any substantial technical issues identified during the study. The false detection rate, defined as the percentage ratio of incorrect detections to the total number of detections, was approximately 0.1% (6/5990). We note that all the analyses and computations mentioned previously were based on the corrected data. To analyze the results of the SUS, the scores from the 10 items were converted into a scale of 0 to 100 [47]. The overall mean SUS score was 83.40 (SD 11.52). There was a significant group difference in the results. The mean of the SUS scores from the fixed group participants was 80.79 (SD 13.23), whereas the mean score from the adaptive group participants was 86.01 (SD 8.75). The 2-sample, 2-tailed *t* test with Cronbach α=.05 showed t_{78}=–2.10 (*P*=.04). The result from the adaptive group showed a significantly higher mean SUS score with a smaller SD than the fixed group. On the basis of the industry standard [48], the usability of both fixed and adaptive e-Cube games is considered grade A (ie, the games are acceptable).

Discussion

Principal Findings

We presented the design, development, and evaluation of the e-Cube system for automated cognitive assessment. e-Cube is a vision-based system converted from TAG-Games, a computerized system using a set of highly instrumented blocks [28]. e-Cube adopted a set of plastic cubes and a webcam instead, costing only approximately US $50. e-Cube also reduced the labor burden by generating adaptive items, detecting answers and behavior, and scoring autonomously. A total of 6 games—Assembly, Shape-Matching, Sequence-Memory, Spatial-Memory, Path-Tracking, and Maze—were designed using the proposed play complexity measures and adaptive item generators. The e-Cube technology and the adaptive games were evaluated by testing the 2 objectives. This human participant study was conducted on the TAMU campus, and thus, most of our study participants (66/80, 82%) were college students aged between 18 and 30 years, with only 18% (14/80) aged between 31 and 60 years. Therefore, the results must be interpreted considering the skewed age distribution and demographic characteristics.

Objective 1 was supported by the correlation analyses performed between the C_{play} values and the 2 performance indicators—the mean correctness and mean completion time obtained from the fixed group. We found that each game was correlated with at least one performance indicator. The C_{play} values of Assembly, Shape-Matching, and Sequence-Memory showed high correlations with both means. No correlations were found using the mean correctness in Spatial-Memory, Path-Tracking, and Maze. As discussed previously, correctness was not the dominant factor that widened the performance difference in Path-Tracking and Maze; thus, no correlations with correctness were found. For Spatial-Memory, 2 items involved symmetric arrangements of the geometric shapes—which made them easy to memorize regardless of the geometric complexity of the shapes. We used the same play complexity measure for both Spatial-Memory and Assembly, which appeared not to ideally reflect the difficulty associated with such memory tasks despite a high correlation in the mean completion time. This problem can be avoided at the software level by adjusting the algorithm for the item generator. Nevertheless, such symmetric images were rarely created in the adaptive version and, thus, are expected to have minimal effect on the assessment outcome.

To test the preliminary utility of the adaptive e-Cube games for cognitive assessment (*objective 2*), correlation analyses were performed between the scores from the e-Cube games and the WAIS-IV subtests. The adaptive games yielded more significant correlations with the WAIS-IV subtests than the fixed ones. This implies the potential utility of the adaptive feature of the e-Cube games based on the complexity measures. The adaptive version used a discontinuation rule (ie, the substantially small step size leading to the termination of the game), which possibly reduced the number of items in each game, fatigue, and unintended correct answers. For example, given a fixed number of items sorted by increasing difficulties, one may fail to answer correctly in the early items but can unintentionally provide correct answers in the later items. The automatic item generator in the adaptive games adjusts the item complexity based on real-time performance, enabling the system to generate a more appropriate assessment for everyone. Note that the administration of the WAIS-IV also applies the discontinuation rule in the subtests to minimize time [49]. The subtest is terminated when a participant fails to answer a certain number of consecutive items, which differs for each subtest. Intercorrelation analyses also showed that the games in the adaptive version were more independent of one another.

There were some other notable findings from the *objective 2* evaluation study. The mean scores of Shape-Matching and Sequence-Memory in the fixed group were higher than those in the adaptive group (Table 4). In the fixed group, we found that most of the participants (26/38, 68%) correctly answered items 1 to 7 and 9, whereas only 50% (19/38) answered item 8 correctly and 24% (9/38) answered item 10 correctly in Shape-Matching. This inconsistency resulted in a higher mean score in the fixed group, but the results were not correlated with MR. In contrast, the adaptive group showed a significant correlation between Shape-Matching and MR. Sequence-Memory and Spatial-Memory were evaluated to understand which game has a monotonic relationship with DS, but a correlation was only found between the adaptive version of Spatial-Memory and DS. DS measures verbal working memory, which relies on auditory recall of numbers, sequences, and orders. However, Sequence-Memory was performed through the visual recall of geometric images, and Spatial-Memory used visual-spatial images. This fundamental design difference may have led to a lack of correlation. In addition, the language differences in participants and how they differently affect DS scores were not analyzed in this study as we did not collect such background data. Some nonnative speakers mentioned slight difficulty in memorizing the numbers said in English during the DS subtest. This feedback was collected only informally. The Path-Tracking and Maze games were correlated with Assembly, implying that their game settings or measured cognitive outcomes were similar to those of Assembly. Furthermore, Maze was not correlated with any WAIS subtest.

We further analyzed the correlation between the composite scores of the 6 e-Cube games and those of the 3 WAIS subtests. The results were r_{38}=0.51 (95% CI 0.23-0.71; P=.001) for the fixed group and r_{42}=0.53 (95% CI 0.26-0.72; P<.001) for the adaptive group. When only 4 e-Cube games (ie, Assembly, Shape-Matching, Sequence-Memory, and Spatial-Memory) were considered, the results were r_{38}=0.50 (95% CI 0.21-0.71; P=.001) for the fixed group and r_{42}=0.59 (95% CI 0.34-0.76; P<.001) for the adaptive group. Path-Tracking and Maze did not result in any meaningful relationship with the WAIS, and thus, their potential utility in cognitive assessment requires further exploration.

The low false detection rate (0.1%) demonstrated the technical functionality of the e-Cube system. Regarding the usability evaluation (*objective 2*), the average SUS scores from participants in both the fixed and adaptive groups were acceptable based on the industry standard [48]. The adaptive games resulted in a considerably higher mean SUS score with a smaller SD than that of the fixed games. To understand the feedback for individual items, we combined the results from both groups and computed the average rate for each item. The results for the individual SUS items were uniformly positive. For the 5 even-numbered questions that were in a negative tone, such as "I found the e-Cube games unnecessarily complex," all rates were between 1 (*strongly disagree*) and 2 (*disagree*). For the odd-numbered questions that were in a positive tone, the rates were between 4 (*agree*) and 5 (*strongly agree*) except for the following question—"I think that I would like to use the e-Cube games frequently"—with an average rate of 3.8. This was mainly due to the e-Cube games taking relatively long (approximately 50 minutes) to complete at this preliminary stage. Most of our participants (73/80, 91%) were aged <40 years, so using the game frequently to track cognitive decline was unnecessary for them. We received the highest evaluation of 4.5 on the following item: "I found the various functions in the e-Cube games were well integrated among all questions."

Limitations

Most participants (66/80, 82%) were TAMU students aged between 18 and 30 years. The data from participants who were young, educated, and motivated do not represent the general population well. This may also explain why none of the participants withdrew from the study. Furthermore, additional demographic information such as education level, socioeconomic status, race, and ethnicity was not collected in this preliminary evaluation study. A larger-scale validation study will be needed to involve participants from various communities with diverse backgrounds.

The administration order of the 6 e-Cube games was randomized to control for an order effect. The test order can influence the test results and bring about different levels of fatigue [50], so a well-developed cognitive assessment usually requires a standardized administration order. Although order and fatigue effects were not found in some standardized tests [50,51], the impact of the administration order of e-Cube on the scores was not investigated.

The WAIS-IV DS includes Forward, Backward, and Sequencing, which measure auditory working memory and attention with information reordering. However, Sequence-Memory and Spatial-Memory rely on visual recall and do not require any manipulation of information. Therefore, DS may not be an ideal choice for validating these 2 games. Another measure, such as Spatial Span Forward in the Wechsler Memory Scale, Fourth Edition, may be selected to compare the results with those of Sequence-Memory and Spatial-Memory in measuring relevant working memory skills.

Future Work

The e-Cube technology was developed for fully autonomous administration and scoring of cognitive assessment targeting fine motor, hand-eye coordination, cognitive reasoning, and working memory skills. Building on our prior work [26,28], the technology was converted into a much simpler, cheaper, and easy-to-use form, thus showing potential for use in larger-scale research studies. Our long-term objective is for the e-Cube games to serve as a routine self-assessment tool used by individuals who require continuous monitoring of their cognitive health, such as older adults and people with mild cognitive impairment. Once fully established, e-Cube can also be adapted in clinical settings, especially for remote assessment without requiring in-person interactions with an administrator. Our future work will be geared toward this long-term objective.

This extended human participant study will involve diverse participants (eg, age, sex, education, and socioeconomic status) to better represent the general population. In this future evaluation study, the existing instruments for comparison must be revisited and selected to ensure that the measures match the target cognitive domains of individual e-Cube games. Future work will also aim to establish reliability via test-retest evaluation and the validity of self- and remote administration functions via comprehensive and comparative evaluations. The study to understand the user experiences may also be extended by including an additional set of questionnaires to compare traditional instruments and the e-Cube games to gauge their preference if the e-Cube system is proven to replace some of these. To further improve the technical performance, additional vision processing methods may be added to improve this rate, such as hand detection algorithms to prevent hand motions from interfering with block detection.

The rich data from the e-Cube games on patterns, speed, and characteristics of physical movements applied to the cubes can also be explored to further explicate individual differences and cognitive and fine motor deficits. Such behavioral data may hold important information about individuals, especially those with cognitive deficits exacerbated by fine motor deficits or other behavioral symptoms such as hand tremors. Furthermore, the data provided by e-Cube have the potential to assess one's cognitive skills in a more objective way than in standard clinical settings. Upon validating its utility as a cognitive assessment tool, our future research may explore the e-Cube games for screening of early signs of neurological diseases. For the e-Cube games to be used as a routine assessment tool, we will consider shortening and gamifying the assessment to make it more fun and engaging. Enhanced graphics and sound and visual feedback mechanisms may be added to the game design. For example, we may benchmark the features of Music Blocks and iSIG-Blocks [52,53], allowing the users to customize audio, tactile, and visual sensory feedback during the cognitive assessment. The current system runs on a low-end laptop with a webcam, whereas further developments can make the algorithms executable on a tablet or cell phone using their built-in cameras. This may further reduce the cost, make it suitable for self- or remote assessment, and support long-term adoption and broader use of the technology.

Acknowledgments

This work was supported by the National Science Foundation under grant 2002721. The authors thank Elisabeth S Ford for assisting with the human participant study and all study participants for their time and contribution to this project.

Abstract

Background: As an integral part of computer-assisted surgery, virtual surgical planning (VSP) leads to significantly better surgery results, such as for oral and maxillofacial reconstruction with microvascular grafts of the fibula or iliac crest. It is performed on a 2D computer desktop screen (DS) based on preoperative medical imaging. However, in this environment, VSP is associated with shortcomings, such as a time-consuming planning process and the requirement of a learning process. Therefore, a virtual reality (VR)–based VSP application has great potential to reduce or even overcome these shortcomings due to the benefits of visuospatial vision, bimanual interaction, and full immersion. However, the efficacy of such a VR environment has not yet been investigated.

Objective: This study aimed to demonstrate the possible advantages of a VR environment through a substep of VSP, specifically the segmentation of the fibula (calf bone) and os coxae (hip bone), by conducting a training course in both DS and VR environments and comparing the results.

Methods: During the training course, 6 novices were taught how to use a software application in a DS environment (3D Slicer) and in a VR environment (Elucis) for the segmentation of the fibula and os coxae, and they were asked to carry out the maneuvers as accurately and quickly as possible. Overall, 13 fibula and 13 os coxae were segmented for each participant in both methods (VR and DS), resulting in 156 different models (78 fibula and 78 os coxae) per method (VR and DS) and 312 models in total. The individual learning processes in both environments were compared using objective criteria (time and segmentation performance) and self-reported questionnaires. The models resulting from the segmentation were compared mathematically (Hausdorff distance and Dice coefficient) and evaluated by 2 experienced radiologists in a blinded manner.

Results: A much faster learning curve was observed for the VR environment than the DS environment (β=.86 vs β=.25). This nearly doubled the segmentation speed (cm^3/min) by the end of training, leading to a shorter time (*P*<.001) to reach a qualitative result. However, there was no qualitative difference between the models for VR and DS (*P*=.99). The VR environment was perceived by participants as more intuitive and less exhausting, and was favored over the DS environment.

Conclusions: The more rapid learning process and the ability to work faster in the VR environment could save time and reduce the VSP workload, providing certain advantages over the DS environment.

virtual surgical planning; virtual reality; Elucis; 3D Slicer; oral and maxillofacial surgery

Introduction

Malignant or benign tumors, advanced osteomyelitis, osteoradionecrosis, and complex fractures can lead to extensive bone and soft tissue defects with the need for reconstruction. Therefore, soft and hard tissue reconstruction is an important and commonly used procedure in oral and maxillofacial surgery [1]. Microvascular reconstruction with fibula or iliac crest bone transplants is one of the best options for mandible bone reconstruction [2,3], and it has the highest success rate and delivers the best functional and esthetic results [4,5]. Microvascular reconstruction has been performed using a conventional technique, specifically manual free transplant raising, adjustment, and insertion [6,7].

Given its numerous clinical advantages, a virtual surgical planning (VSP) approach prior to microvascular reconstruction of the jaw has seen increased popularity. This approach involves using preoperative medical imaging within computer-assisted surgery (CAS) applications [8,9]. The advantages of VSP include reduced ischemia, a shorter defect reconstruction time, a shorter surgical procedure [10], a shorter length of hospital stay [10], a lower number of necessary osteotomy revisions, an overall lower volume of bone removed, a lower rate of osseous injury [11], and a better match of removed bone volume to defect volume [12].

However, VSP is associated with a higher preoperative workload [8] and is therefore often delegated to younger fellows or technical staff [13,14]. Despite this, VSP still remains an integral part of the surgical process and should be done or supervised by the performing surgeon [15]. Furthermore, learning VSP is time-consuming and requires an appropriate amount of learning time, but these investments are required to ultimately achieve good clinical outcomes [15-18].

One of the main bottlenecks is the preparation of 3D models by segmentation [19]. This process is still performed on a 2D computer desktop screen (DS) with 2D controls, such as a mouse and keyboard [20], which however seems unsuitable per se for such a task [21]. Furthermore, working in a DS environment differs from working in a surgical site since the DS environment lacks stereoscopic vision, and the use of a mouse and keyboard does not resemble working with surgical instruments at all. This leads to discrepancies between the VSP performed in a DS environment and the surgery performed in an operating theater.

A potential way to overcome the disadvantages of VSP performed in a DS environment could be the use of virtual reality (VR) [22] since it offers stereoscopic vision, allows the user to work manually, and allows more focused work due to immersion [21,23]. VR environments better resemble realistic work routines in the operating theater, as users can rotate and flip anatomical structures and observe different intraoperative viewing angles [24], thus enabling an enhanced understanding of the anatomy [25]. Although VR more broadly has been applied to surgery, it has often been basic or partially immersive VR. This must be distinguished from enhanced, fully immersive, binocular head-based VR [26]. With the so-called second wave that began in 2012, this technology has significantly spread in the consumer market and must be distinguished from augmented reality–based systems, which have become widespread under the terms mixed or extended reality [27]. Areas of application for these new VR head-mounted displays (HMDs) are surgical education, surgical training, and surgical planning [28]. VR simulations have been shown to lead to an improvement in surgical skills among subjects [29]. VR was also used for the visualization of medical images in radiology [22]. Recently, VR has been used for spatial understanding [30] or in the course of multiuser conferences during surgical planning [31]. However, to our knowledge, the potential for performing all steps or substeps of VSP using VR HMDs has not yet been explored.

This study aimed to demonstrate the possible advantages of a VR environment through a substep of VSP, specifically the segmentation of the fibula (calf bone) and os coxae (hip bone), which is typically applied in oral and maxillofacial surgery, by conducting a training course in both DS and VR environments and comparing the results.

Methods

Cases

We retrospectively selected 78 (13 cases for every 6 participants) planning computed tomography (CT) scans acquired between 2015 and 2020 at the University Hospital RWTH Aachen originally intended for VSP for the mandible, maxilla, or other viscerocranial sites for microvascular reconstruction. The CT scans were first scored by 2 trained radiologists based on image quality (1, good; 2, moderate; 3, poor), bone quality (1, good; 2, moderate; 3, poor), and artifacts (1, none; 2, moderate; 3, plenty), and from this, a total score (range 3-9) was then derived for each case and radiologist. A mean value was then calculated for each case based on the 2 radiologists’ total scores.

Ethics Approval

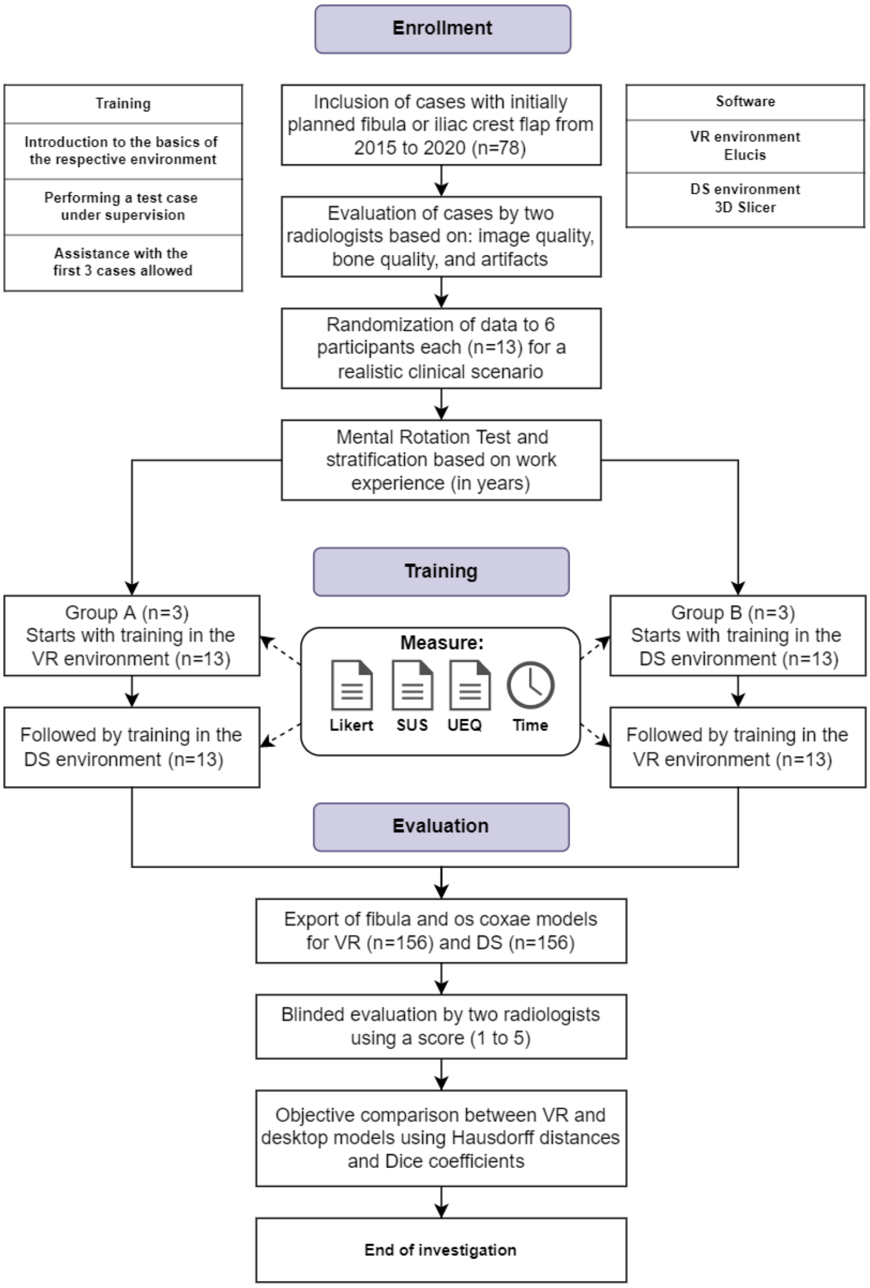
The local ethics committee of the Medical Faculty of RWTH Aachen University approved our study (approval number EK 471/20). The experimental protocol was carried out in accordance with the guidelines set by the Declaration of Helsinki. Informed consent was obtained from all participants involved in the study.

Study Design

A total of 6 novices in VSP (5 oral and maxillofacial surgery residents and 1 final-year dentistry student) took part in the study. Each participant’s age (mean 33.2, SD 2.6 years), gender (1 female, 5 males), surgical work experience (0-4 years), prior experience with computers, and prior experience with VR were recorded. Each participant performed a mental rotation test [32] before training to examine the influence of their baseline visuospatial ability on segmentation performance.

All novices received an introduction to the basic principles of the VSP application. The participants were stratified into the following 2 groups based on surgical work experience: Group A (4 years, 3 years, and 0 years in residency) and Group B (4 years, 2 years, and 1 year in residency). Group A was trained with 13 (3 cases for initial warm-up and 10 cases for autonomous training) randomly selected (for a realistic clinical scenario) cases per participant, first in the DS environment and thereafter in the VR environment. In contrast, Group B was trained with 13 randomly selected cases per participant, first in the VR environment and thereafter in the DS environment (Figure 1). This ensured that a potential learning effect gained in one environment and transferred to the other was evenly distributed between both [18,33]. The given task of the training was the segmentation of the fibula (a simpler model) and os coxae (a more complex model) of the right side of the body in the corresponding working environment. The participants were asked to carry out their tasks as accurately and quickly as possible. In the case of relevant bone defects, the left side was used.

Figure 1. Graphic illustration of the study protocol. A total of 78 computed tomography scans were included, scored by 2 radiologists for image quality, and randomized to 6 participants, who additionally performed a mental rotation test before training. Subsequently, the 6 participants were stratified into Groups A and B, each of which started with the virtual reality (VR) or desktop screen (DS) environment, respectively. During the training, Likert-type questionnaires were filled out, and segmentation time was measured. After training, the System Usability Scale (SUS), the User Experience Questionnaire (UEQ), and a final Likert-type questionnaire were administered. After training, all fibula and hip bone models were compared using the Hausdorff distance and the Dice coefficient, and additionally evaluated in a blinded fashion by the same 2 radiologists.



Each participant received an appropriate briefing in the corresponding working environment (DS or VR) with an explanation of all important functions, whereby the standard analog functions of both applications had to be used within a test case. Subsequently, the task was carried out based on a test case under the supervision of an experienced user who offered verbal guidance throughout each work step. The participants then started to work on the 13 cases. The opportunity to ask questions was allowed only for the first 3 cases to ensure a realistic clinical scenario. After each case, the procedure time was recorded (for fibula and os coxae segmentation, respectively), and a Likert-type questionnaire was completed [34]. All participants successfully completed the training. After completing the training for both environments, a final Likert-type questionnaire was completed. Additionally, for each application, the User Experience Questionnaire (UEQ) [35] and System Usability Scale (SUS) [36] were administered.

DS-based training was performed using 3D Slicer version 4.11.20210226 [37], and VR-based training was performed using Elucis version 1.4 (Realize Medical Inc). The VR hardware included an HTC Vive Pro with an HTC Vive Controller 2.0 (Valve Corporation). All training was done seated (Figures 2-5) at the same workstation (AMD Ryzen 3900X CPU with 64 GB of memory and an RTX 2080 Ti graphics card).

Figure 4. The classic desktop screen working environment (3D Slicer) with an already segmented os coxae (hip bone) model in yellow.

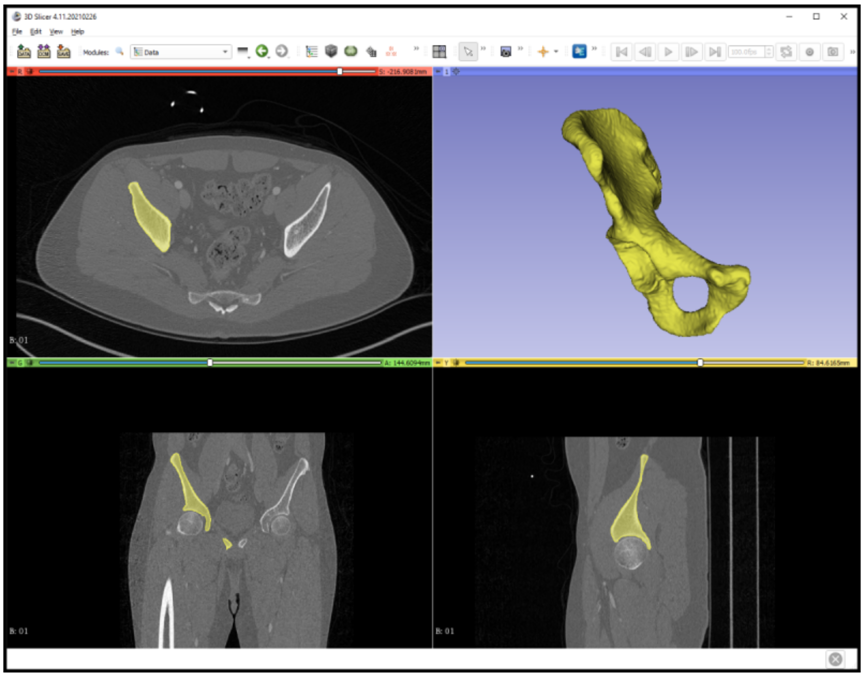

Figure 5. The desktop screen working environment from a third-person perspective.

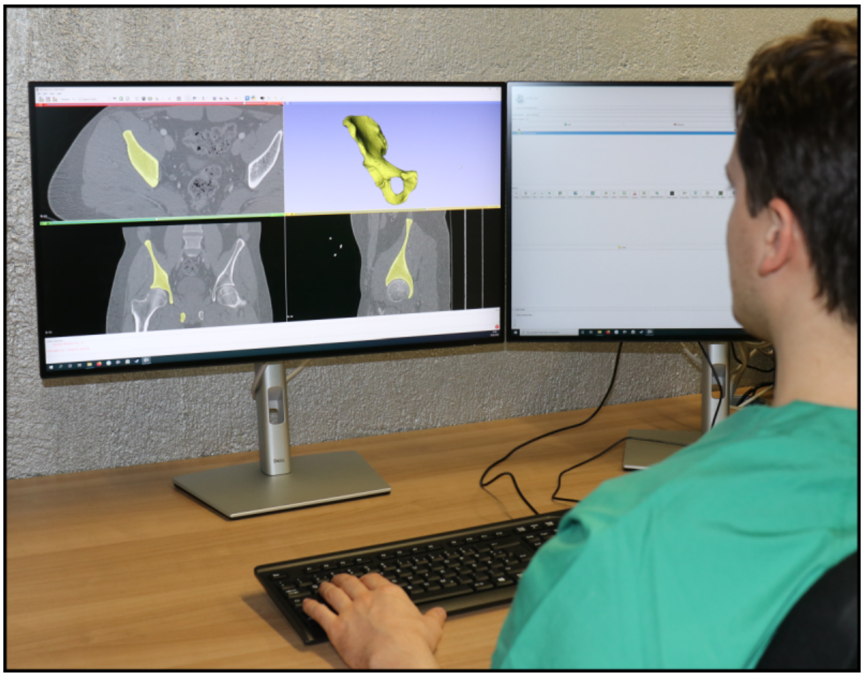


Evaluation

All segmented models of the fibula and os coxae (n=156) were assessed in a blinded setting by the same 2 trained radiologists using an absolute category rating (1, excellent; 2, good; 3, fair; 4, poor; 5, bad). Based on the evaluation of both radiologists, a mean value was calculated.

Afterwards, the postprocessing of all cases was performed using the 3D Slicer add-on Surface Wrap Solidify [38] to remove cavities in the models. This was necessary to avoid bias when comparing the volumes or surfaces of the models. Hausdorff distances and Dice coefficients [39] were then computed using the 3D Slicer add-on segment comparison [40] between the DS model and the VR model. Finally, intersection volumes (cm^3) between the VR and DS models were divided by segmentation duration (minutes) to calculate common segmentation performance (cm^3/min).

Statistical Analysis

Statistical analysis was performed using the programming language R (Version 4.1.1; R Foundation for Statistical Computing). A *P* value <.05 was considered significant. We used a *t* test, a Wilcoxon signed-rank test, or a chi-square test to assess differences between VR and DS. The training effect as a function of the environment was determined as the duration of task completion using a linear mixed effect model with the

R package lme4. For the model-based evaluations, a likelihood ratio test of the corresponding parameters was used to evaluate the relationships between dependent and independent variables. *P* values were adjusted for multiple testing using the Holm-Bonferroni method [41]. The 95% CIs were calculated by conventional bootstrapping with 1000 replications [42]. Plots were visualized using the R package ggplot2.

Results

Segmentation

The average overall radiologist ratings for the segmentation results were 1.40 (1, excellent; 5, bad) for the VR models and 1.29 for the DS models, and were not significantly different (Wilcoxon signed-rank test, *P*=.29). Similarly, there was no significant difference in radiologist assessment for the os coxae (VR 1.62 vs DS 1.39; Wilcoxon signed-rank test, *P*=.14) or fibula (VR 1.17 vs DS 1.17; Wilcoxon signed-rank test, *P*=.99; Table 1). Furthermore, regarding clinical use (models with a score ≤2/good), there was no relevant difference between VR and DS for all models, os coxae models, and fibula models (χ^2, *P*=.99, *P*=.99, and *P*=.99, respectively). Thus, the VR models are equally suitable for clinical use as the DS models.

Table 1. Results of metric evaluations and blinded assessments by 2 radiologists.

Model and characteristics (n=312)	VR[a] environment, mean (SD)	DS[b] environment, mean (SD)	Difference, mean (SD)
Os coxae (hip bone)			
Bone volume (cm^3)	341 (65)	329 (62)	12 (12)
Segmentation duration (min)	22.5 (13.0)	38.7 (22.6)	−16.2 (21.3)
Segmentation performance (cm^3/min)	19.2 (12.8)	12.0 (8.6)	7.2 (4.2)
Segmentation quality (range 1-5)	1.62 (0.76)	1.39 (0.63)	0.23 (0.78)
Hausdorff distance (mm)	N/A[c]	N/A	0.43 (0.19)
Dice coefficient (%)	N/A	N/A	0.96 (0.02)
Fibula (calf bone)			
Bone volume (cm^3)	60 (12)	58 (11)	2 (3)
Segmentation duration (min)	12.1 (8.0)	17.0 (11.1)	−4.9 (8.3)
Segmentation performance (cm^3/min)	6.5 (2.9)	4.7 (4.0)	1.8 (1.1)
Segmentation quality (range 1-5)	1.17 (0.38)	1.20 (0.44)	−0.03 (0.52)
Hausdorff distance (mm)	N/A	N/A	0.29 (0.12)
Dice coefficient (%)	N/A	N/A	0.96 (0.02)

[a]VR: virtual reality.

[b]DS: desktop screen.

[c]N/A: not applicable.

In contrast, the segmentation results from the VR environment were considered better than those from the DS environment by the participants themselves for both the os coxae models (7-point Likert scale [1, strongly disagree; 7, strongly agree], VR 5.5 vs DS 4.0) and fibula models (7-point Likert scale, VR 5.8 vs DS 5.1; Table 2). For the os coxae, the mean Hausdorff distance between VR and DS was 0.43 (SD 0.19) mm with a Dice coefficient of 96% (SD 2%). For the fibula, the mean Hausdorff distance between VR and DS was 0.29 (SD 0.12) mm with a Dice coefficient of 96% (SD 2%) (Table 1). The mean segmentation time of the os coxae models was 22.5 (SD 13.0) minutes for VR and 38.7 (SD 22.6) minutes for DS, and that of the fibula models was 12.1 (SD 8.0) minutes for VR and 17.0 (SD 11.1) minutes for DS (Figure 6; Table 1).

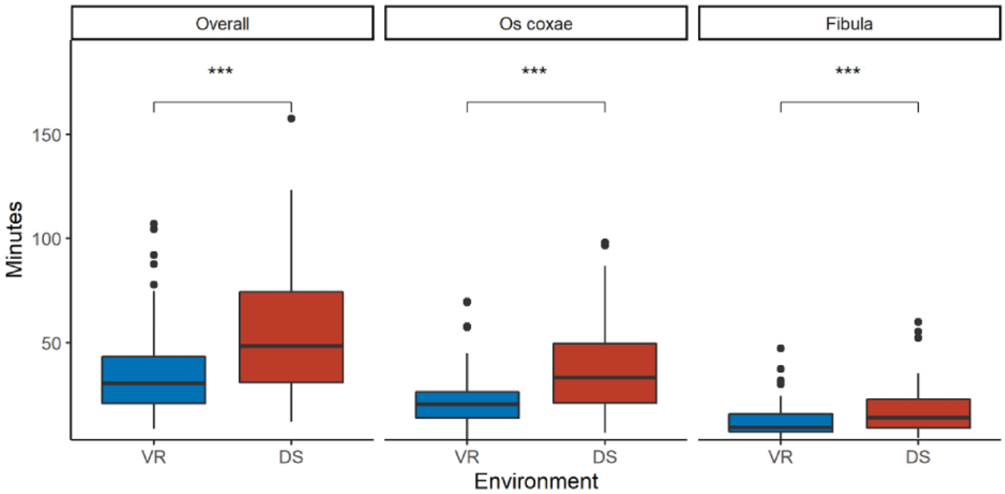
Table 2. Results of the Likert-scale questionnaire after each of the 13 training cases.

Likert (7-point) questions	Score in the VR[a] environment (n=78), mean (SD)	Score in the DS[b] environment (n=78), mean (SD)	Difference, mean (SD)
I learned something through this segmentation process.	5.7 (1.2)	4.9 (1.2)	0.8 (1.2)
I feel exhausted after the segmentation process.	4.4 (1.5)	5.2 (1.5)	−0.8 (1.8)
I had to repeat steps during segmentation.	4.3 (1.6)	5.0 (1.6)	−0.7 (1.6)
I consider this fibula to be adequately segmented.	5.8 (1.1)	5.1 (1.2)	0.7 (1.2)
I find this iliac crest to be adequately segmented.	5.5 (1.1)	4.0 (1.6)	1.5 (1.6)
I was able to orient myself spatially well during segmentation.	6.3 (0.7)	4.4 (1.3)	1.9 (1.7)

[a]VR: virtual reality.

[b]DS: desktop screen.

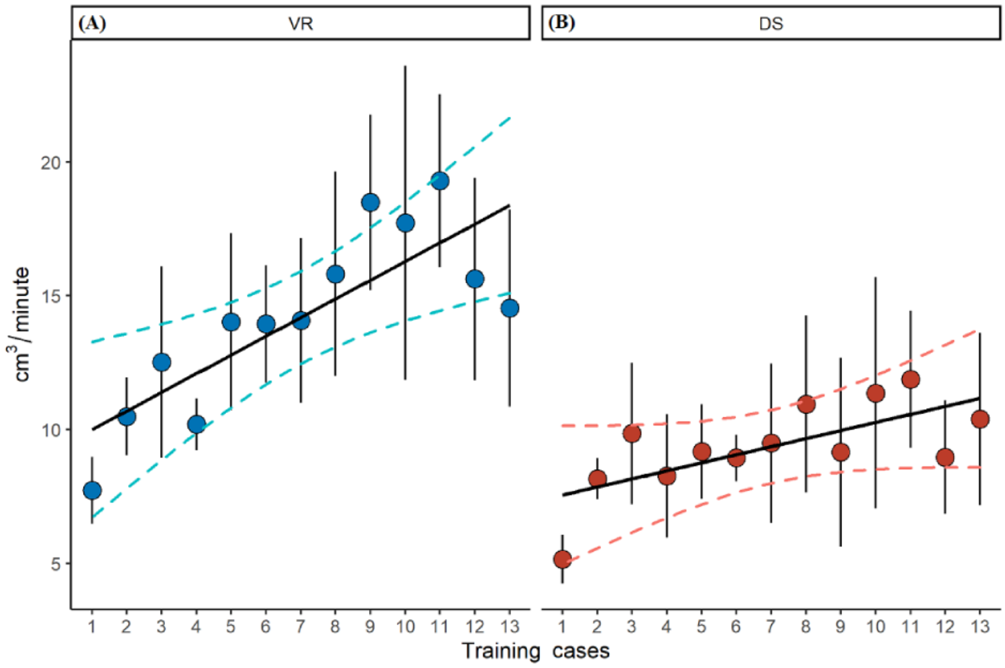
Figure 6. Comparison of segmentation time in minutes between the virtual reality (VR) environment (Elucis) in blue and the desktop screen (DS) environment (3D Slicer) in red shown as box-and-whisker plots. Box-and-whisker plots: boxes represent the IQR, thus representing 50% of data (Q1-Q3); the lower whisker is defined as Q1 − 1.5 × IQR; the upper whisker is defined as Q3 + 1.5 × IQR; the horizontal line in the middle of the box represents the median; and points are outliers. Additionally, the significance level of the respective Wilcoxon signed-rank test is shown above. The y-axis shows the segmentation time in minutes, and the x-axis shows the environment (VR vs DS). ****P*<.001.



Training Curve

The linear mixed effect model (adjusted for work experience, mental rotation test, CT quality, segmentation quality, and training group) showed a significant increase in segmentation volume per minute (cm^3/min) for the VR environment (β=.86; *P*<.001). While the training effect for the DS environment was not significant anymore after *P* adjustment (β=.25; *P*=.26; Figure 7). Lower CT quality had no influence on the segmentation process (*P*=.25). Segmentation performance was significantly higher in the VR environment than in the DS environment for the os coxae models (mean 19.2, SD 12.8 vs mean 12.0, SD 8.6 cm^3/min; paired *t* test, *P*<.001) and for the fibula models (mean 6.5, SD 2.9 vs mean 4.7, SD 4.0 cm^3/min; paired *t* test, *P*<.001; Table 1). These results correlated with the results of the Likert-type questions concerning the learning effect, exhaustion, and the perceived need to repeat steps (Table 2).

Figure 7. The segmented volume (cm3) per minute over the course of the 13 training cases in the (A) desktop screen (DS) environment and (B) virtual reality (VR) environment. The error bars represent the standard error of the mean, and the individual points are the mean values for the corresponding training case. The black line represents a linear model, and the dashed lines represent the 95% CIs of the model.



Environment

Overall, the participants clearly preferred the VR environment over the DS environment in a poststudy questionnaire (Tables 3 and 4). The UEQ results showed that the participants assessed the VR environment to be better in terms of attractiveness, dependability, efficiency, novelty, perspicuity, and stimulation (Figure 8). The SUS results showed that Elucis was rated 83.3 (95% CI 75.3-90.8) and 3D Slicer was rated 30.4 (95% CI 20.1-38.3).

Table 3. Results of the Likert-scale questionnaire after completion of training.

Likert (7-point) questions	Score in the VR[a] environment (n=6), mean (SD)	Score in the DS[b] environment (n=6), mean (SD)	Difference, mean (SD)
Segmentation in this environment was easy for me.	6.5 (0.5)	3.8 (1.9)	2.7 (2.0)
I would prefer this environment for VSP[c].	7.0 (0.0)	2.5 (0.5)	4.5 (0.5)
This work environment seems intuitive to me.	6.8 (0.4)	2.3 (1.0)	4.5 (1.0)
I suspect this work environment will continue to be the gold standard in clinical practice for VSP.	6.7 (0.8)	2.2 (0.8)	4.5 (1.4)
Monoscopic (DS) or stereoscopic (VR) vision in this environment made segmentation easy for me.	6.7 (0.5)	2.2 (1.2)	4.5 (1.5)
I prefer learning segmentation with a mouse and keyboard (DS) or VR controller (VR).	6.7 (0.5)	2.3 (0.8)	4.3 (1.2)
I found learning segmentation easy in this environment.	6.3 (0.5)	3.2 (1.2)	3.2 (1.2)
I felt the training scheme was appropriate for learning in this environment.	6.2 (0.8)	5.7 (1.5)	0.5 (1.5)
I felt the number of cases to learn segmentation was sufficient in this environment.	6.3 (0.8)	5.3 (1.2)	1.0 (1.7)
I had fun while learning segmentation in this environment.	7.0 (0.0)	3.8 (1.9)	3.2 (1.9)

[a]VR: virtual reality.

[b]DS: desktop screen.

[c]VSP: virtual surgical planning.

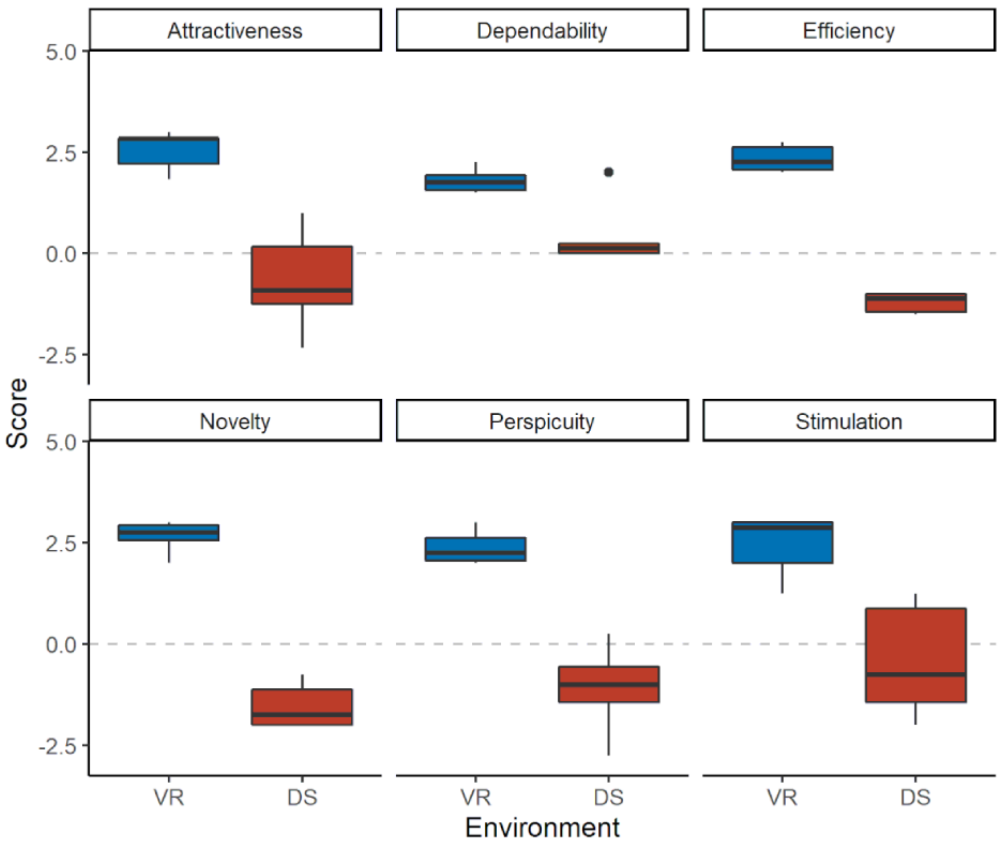
Table 4. Comments of the participants comparing the virtual reality and desktop screen environments.

Participant No.	What aspects of the VR[a] environment do you prefer over the DS[b] environment?	What aspects of the DS environment do you prefer over the VR environment?
1	Spatial vision, working with controllers, similarity to OP site.	Plausibility (you don't have to take off the HMD), work more precisely with the mouse at times, other applications usable.
2	Similarity of actions to surgical activity, stereoscopic vision, good spatial and anatomical orientation.	Island tool.
3	3D perception, rotating and handling the dataset in your own hands, direct segmentation in rendered state; you can directly see the result of segmentation without segmenting in 2D layers.	The possibility of labeling each voxel separately in each layer, if desired; thus, higher accuracy is possible.
4	Intuitive handling, spatial representation, fast learning progress.	Conventional desktop workplace.
5	Very intuitive in comparison, optimal spatial orientation, orientation also with regard to the future operation area, faster learning.	It was possible to use "ADD" function in difficult cases (e.g. calcified vessels in direct neighborhood); calcified vessels and bones often have similar Hounsfield units and cannot be visualized separately in Elucis.
6	Easier to learn, 3D environment easier to control, better spatial overview, much better control.	Lower acquisition costs.

[a]VR: virtual reality.

[b]DS: desktop screen.

Figure 8. User experience questionnaire (UEQ) comparison between the virtual reality (VR) environment (Elucis) in blue and the desktop screen (DS) environment (3D Slicer) in red shown as box-and-whisker plots. Box-and-whisker plots: boxes represent the IQR, thus representing 50% of data (Q1-Q3); the lower whisker is defined as Q1 − 1.5 × IQR; the upper whisker is defined as Q3 + 1.5 × IQR; the horizontal line in the middle of the box represents the median; and points are outliers. The Y-axis shows the UEQ score, and the X-axis shows the environment (VR vs DS). A total of 6 categories were examined (attractiveness, dependability, effectiveness, novelty, perspicuity, and stimulation).



Discussion

VSP in a traditional DS environment is still considered the gold standard, despite its disadvantages, such as being tedious and time consuming [43]. This negates the benefit of time saved in the operating theater due to additional time spent on VSP [13,14]. In this context, VR is a promising approach that might attenuate the mentioned disadvantages of VSP performed in a DS environment.

In this study, the processes of learning VSP, using segmentation as a surrogate parameter, between traditional DS and fully immersive VR environments were compared, as segmentation is a common substep in VSP, a bottleneck in terms of time [19,44], and a crucial factor that determines the accuracy of the final computer-aided design (CAD) result [45]. In general, segmentation is important for not only oral and maxillofacial surgery but also many other medical specialties that require 3D models created by segmentation for the subsequent steps in CAD [45]. Therefore, segmentation was used as a surrogate parameter to measure performance in VR compared to performance in a traditional DS environment during a structured training course. For a representative number of cases (n=156), all participants had to create models of the fibula and os coxae, which are commonly used for microvascular reconstruction of the mandible [2,3], in both environments.

Many studies have shown that VSP is beneficial to patients [14,46]. However, VSP is only feasible if the surgeon is proficient in VSP software. For this reason, the process of learning how to operate such CAS-related software has already been the subject of research in the literature. For example, learning curves upon repetition have been found for VSP for the treatment of orbital fractures or in orthognathic surgery [15,47]. In addition, differences in learning curves when it comes to CAD programs used in dentistry have been found between different software and professional groups (students, technicians, and dentists) [18,33]. Furthermore, the learning curve has been shown to be a function of the complexity of the task for model creation using CAD [48]. However, all these studies used applications in a 2D DS environment, where a computer mouse and keyboard were utilized. This type of work environment is counterintuitive to surgeons who are accustomed to ambidextrous, manual, and visuospatial activity while being very focused. In contrast, VR is more similar to surgical work and therefore offers a promising approach.

The results of our study showed that working in a VR environment is significantly more efficient than working in a DS environment. At the same time, VR has a much faster learning curve (Figure 7). To have a comparable measure between models with different volumes, we used segmentation volume per minute (cm^3/min), assuming that it significantly reflects the number of attempts to solve the task during the acquisition of cognitive and motor skills [48]. At the end of the training program, this was almost twice as high in the VR environment compared to the DS environment. To account for a transfer effect from one method to the other due to the crossover study design, we split the groups in correspondence to similar studies [18,33] and adjusted our model for training method order. To exclude bias from the multiple steps of the VSP as described in other studies that have evaluated the learning process for an entire VSP/CAS based on the final surgical outcome [15,49], we focused on the process performance itself. The measurable stronger learning effect in the VR environment was also perceived by the participants (Table 2). This is important, as the faster learning of CAD software, such as that for VSP, is also accompanied by increased planning and surgical accuracy, and improved anatomical understanding of the target structures [15,47]. Independent of segmentation performance, it is assumed that for different DS software, with correspondingly longer training periods, the differences will eventually cease to exist [33]. However, this does not explain the large differences observed between the DS and VR environments.

These differences can be explained by the principally different natures of the DS and VR environments. Subjects in our study reported a high degree of anatomical orientation in the VR environment compared to the DS environment (P<.001). One reason for the superior anatomical orientation might be the possibility of obtaining different viewing angles in the VR environment. Specifically, Cha et al demonstrated this advantage [24]. Furthermore, in our study, subjects preferred to work with both hands using 2 VR controllers, appreciated the advantages of stereoscopic vision, and preferred the intuitive perception provided by the VR environment, which might explain their preference for the VR environment over the DS environment overall (Table 3). In summary, this study highlighted the benefits of spatial perception and working in 3D in a VR environment with good orientation in terms of the anatomy and strong similarity to surgical work. Similar results have been found in the use of nonfully immersive VR for CAS of the liver [21]. In the literature, various approaches to using at least nonfully immersive VR in the medical context can be found. For example, stereoscopic monitors have been used in oral and maxillofacial surgery to determine facial soft tissue or orbital volumes [50,51]. Furthermore, they have been used in neurosurgery to train surgeons to resect intracerebral tumors [52] and assess surgical risk as a rehearsal before surgeries [25,53].

Yet, all of the aforementioned approaches lacked the full immersion that comes with using VR HMDs and controllers in both hands, as in our study. In our setting, users held control elements in both hands and worked with them within arm's reach (Figures 2 and 3). This could be another reason for the rapid learning and efficiency of working in VR, as proprioception can then be used. Therefore, subjects felt particularly comfortable, and the highest precision could be achieved [54]. In contrast, working with a computer mouse and keyboard in the DS environment does not allow this. For complex models (os coxae) in comparison to simpler models (fibula), this advantage was even more pronounced in VR than in DS. In addition to the advantages of the stereoscopic visualization of complex models in VR [55], the reasons for this are that complex models require more commands for their implementation [48] and, at the same time, bimanual work in VR is particularly faster [56].

Regarding the segmentation quality of the os coxae model, a certain discrepancy between the radiologists' evaluations and that of the subjects appeared to be a shortcoming, as the subjects tended to overestimate themselves. However, this had no impact on clinical practice, since with a given clinically relevant score of ≤2 (good or excellent), we found no significant difference between the 2 environments. A possible reason for this overestimation could be that in the VR environment by default, usually only 1 slice (axial, coronal, or sagittal) was displayed. In contrast, all 3 slices were displayed in parallel in the DS application. One solution would be to display all 3 slices by default in VR. In addition, a different perception of the 3D models (stereoscopic during segmentation by participants vs monoscopic during evaluation by radiologists) could have influenced this. Another reason could be the resolution capacity of the used VR HMD, causing individual voxels to be blurred. Improved hardware or better delineation of individual voxels in the single-layer view could probably solve this.

Overall, our results suggest that the intrinsic feedback learning effect of VSP, which a surgeon achieves by multiple repetitions of VSP and consecutive surgeries [15], could potentially be at least partially replaced by a training program in this manner for novices in VSP. Therefore, the results of our study suggest that VR should be the environment of choice, given its similarity to actual surgical activity. Furthermore, subjects consistently reported less fatigue and more enjoyment while working in the VR environment (Tables 2 and 3). This was also in line with the SUS results, which clearly rated VR better than DS. The reduced exhaustion can be explained by the shorter time needed to complete the task and possibly by the manual 3D interactions in VR, resembling the surgical working environment more realistically (Table 2). Participants perceived the VR software to be superior to the DS software according to the UEQ results for multiple qualities of experience (Figure 8) and preferred the VR environment over the DS environment (Table 3). This was in line with the results of a study on VR user interfaces for medical marking on 3D models [57]. Yet, these differences are surprising, since both applications basically fulfill the same task.

Experiencing the burden of today’s required levels of documentation, surgeons have long been demanding to spend less time at the computer [58]. This could probably also explain the poor rating for the DS environment, which is similar to the typical unpopular work on a DS computer. However, VR has a more playful character, which might explain the higher ratings for the VR environment. However, this clear difference in rating also shows that VSP applications should be adapted to the needs of surgeons. VR seems to meet these requirements, at least in the case of our test persons. In this context, the following things should be considered. Using a VR environment can lead to VR sickness. However, this was not reported by any of the participants, probably because they were sitting and no dynamic scenes were used [59]. In addition, it should be considered that older adults take longer to adapt when learning new technologies [60]. In this regard, studies have shown that older adults also adapt well to VR [61]. Unlike DS with the use of a keyboard and mouse, in the performance of VSP by older adults, VR can be advantageous, as VR is closer to actual surgery due to the immersive environment, stereoscopic vision, and bimanual working. Another point that needs to be considered is cost. Such a system would have to be acquired first. On the other hand, the use of VR, as shown in our study, is time-saving and could thereby reduce the overall cost of VSP. However, an investigation of cost was outside the scope of our study.

Trials featuring the completion of VSP in a nonfully immersive manner have been described to be very promising in the field of liver surgery [21]. However, to our knowledge, no studies have yet assessed VSP performed completely in fully immersive VR. Future studies should address, aside from segmentation, the other steps of full VSP, with the goal to perform VSP completely in VR.

Apart from the approach shown in our study, semiautomated or fully-automated segmentation algorithms are increasingly being used to accelerate or completely take over segmentation [20]. Yet, our study is concerned about which is the better working environment to perform any kind of VSP. This is even more important since the most common segmentation algorithms require a high amount of time for manual postprocessing [45], and the sole use of fully automated algorithms has still not gained general acceptance in clinical practice due to their high sensitivity to image-related artifacts, a resulting inadequate structure recognition, and a low functional stability [20]. In the future, however, artificial intelligence and VR could be combined, especially to further accelerate tasks in VR.

We not only demonstrated the feasibility of segmentation in VR but also highlighted the advantages of this. Possible explanations for these findings are the more intuitive work interface provided by the VR environment, the better spatial orientation, and the stereoscopic vision [21], which were perceived as great advantages for the purposes of VSP.

Through the crossover design, the subjects represented their own control group, and with a total of 312 experiments, the study achieved good internal validity. To improve the generalization of the results, that is, the external validity, we performed the study with subjects having different surgical experience. However, a greater diversity of subjects could lead to different results. The external validity should be evaluated in a further study, and a multicenter study is preferred to include subjects with experience from other clinics. However, this does not diminish the significance of this study. As with the various phases of drug studies, it is worthwhile to first examine the internal validity. Based on the findings of this study, a subsequent study for good external validity can be planned with more subjects but fewer examinations per subject. Furthermore, it should be considered that 2 different software programs (3D Slicer and Elucis) were compared with each other. Although both programs have a comparable command set, a slight impact cannot be excluded. However, this would not explain the large differences observed.

In contrast to the DS environment, the VR environment offers a more rapid learning curve, provides the ability to work faster, results in increased time saved, and is less exhausting when engaging in segmentation as an important substep of VSP. The VR environment was rated by participants to be easier to learn and to be their environment of choice, possibly due to its similarity to actual surgical activities. Therefore, VR-based VSP could be better integrated into clinical practice. This study can serve as a basis for investigating other common substeps of VSP.

Acknowledgments

We thank Rainer Röhrig for his valuable feedback and suggestions. We would like to thank Justin Sutherland and Sonya Deveau from Realize Medical Inc for providing us with a free license of Elucis to be able to perform this study.

Abstract

Background: The capacity of health care professionals to perform clinical procedures safely and competently is crucial as it will directly impact patients' outcomes. Given the ability of head-mounted virtual reality to simulate the authentic clinical environment, this platform should be suitable for nurses to refine their clinical skills for knowledge and skills acquisition. However, research on head-mounted virtual reality in learning clinical procedures is limited.

Objective: The objectives of this study were (1) to describe the design of a head-mounted virtual reality system and evaluate it for education on clinical procedures for nursing students and (2) to explore the experience of nursing students using head-mounted virtual reality for learning clinical procedures and the usability of the system.

Methods: This usability study used a mixed method approach. The stages included developing 3D models of the necessary instruments and materials used in intravenous therapy and subcutaneous injection procedures performed by nurses, followed by developing the procedures using the Unreal Engine (Epic Games). Questionnaires on the perception of continuance intention and the System Usability Scale were used along with open-ended questions.

Results: Twenty-nine nursing students took part in this questionnaire study after experiencing the immersive virtual reality (IVR) intervention. Participants reported largely favorable game perception and learning experience. Mean perception scores ranged from 3.21 to 4.38 of a maximum score of 5, while the mean system usability score was 53.53 of 100. The majority found that the IVR experience was engaging, and they were immersed in the game. The challenges encountered included unfamiliarity with the new learning format; technological constraints, such as using hand controllers; and physical discomfort.

Conclusions: The conception of IVR for learning clinical procedures through deliberate practice to enhance nurses' knowledge and skills is promising. However, refinement of the prototypes is required to improve user experience and learning. Future research can explore other ways to use IVR for better education and health care purposes.

Introduction

Overview

Generation Z students are well recognized to have different learning needs and preferences than previous generations [1]. With the advancement of medical technology and treatment, coupled with dynamic clinical settings, the ability of nurses to perform clinical procedures safely and competently is of paramount importance. The issue of ensuring competency prior to performance on actual patients remains crucial for patient safety. Therefore, new teaching strategies are needed to bridge the teaching-learning gap to create an effective learning environment. The use of technology to meet the challenges of medical education has been well documented [2,3]. Simulation sessions using manikins in clinical laboratory settings have been established for more practice. However, these simulation sessions are usually conducted in small groups and are labor and resource intensive. Studies also suggest that these conventional teaching methods do not fully meet the needs, interests, and learning preferences of Generation Z students [4,5]. The novel discovery of virtual technology has been explored for its effectiveness in enhancing students' learning in nursing education [3,6,7].

Immersive virtual reality (IVR) is highly visual and conducive to procedure-focused learning. IVR provides first-person active learning where learners can interact with 3D objects and characters [8]. With immersive 3D virtual reality (VR), learners can perform clinical procedures in a real clinical environment. It is well established that IVR as a medium of instruction facilitates interaction and immersion [9]. This enhances learning through the learner's psychological constructs, such as presence and agency. Presence forms the conditions, and agency gives autonomy of control to gain experience through immersive technology [9]. In designing IVR training, it is important to understand the factors influencing learning. Factors such as perceived realism, usability, and learning are crucial to learners' attitude toward the use of VR [10]. Hence, VR features, learning experiences, usability, and learning theories that guide the learning process are vital constructs when designing an IVR training environment [10].

The transformation of nursing education has been rapidly evolving with the advancement of VR technology. IVR allows learners to obtain repeated hands-on practice to understand concepts and master procedures, exercise their problem-solving skills, and develop confidence prior to managing actual patients in clinical settings. IVR allows learners to practice safely without risk to patients and empowers them for self-directed and regulated learning. IVR was reported to be used frequently to teach procedural-practical knowledge [11]. Although there have been nursing VR simulations conducted to improve technical knowledge and proficiencies, these studies focused mainly on linear step-by-step intervention, and the order of the steps played an important role [12,13]. Systematic reviews evaluating the effectiveness of IVR report that it improved knowledge and learning experiences, but the reviews' findings were inconclusive for skills, satisfaction, confidence, and performance in health care education [14-17].

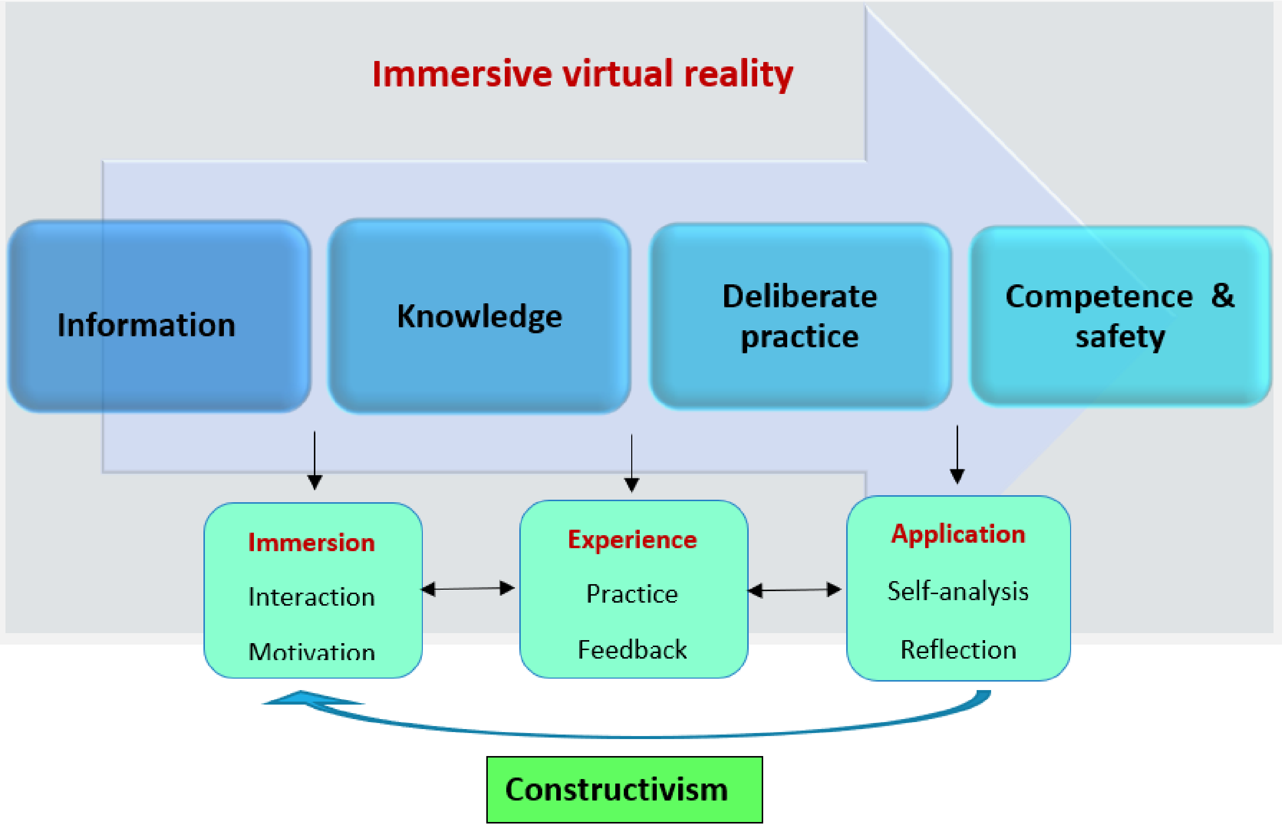
Theoretical Framework

The conceptual frameworks that guided this study are cognitivism, constructivism, and experiential learning through deliberate practice [18]. Cognitivism theory has been used for information processing in the context of VR. Learning in VR involves immersion, interaction, imagination, motivation, and transformation of new knowledge to enhance problem-solving capability [18,19]. Through the constructivism approach, students engage with the environment and are actively involved in building a scaffold for their learning to construct and develop new skills and meaningful knowledge [20,21]. Experiential learning refers to knowledge creation through the acquisition and transformation of experiences [22]. Through first-hand individual experiences using IVR, students are motivated to learn more in a safe and convenient environment for practice. The interaction with a task in VR allows the construction of learning experiences via abstract, active, and reflective processes of the experiential learning cycle [21,23]. With experiential learning and timely built-in feedback, students will be able to work on areas that they need to improve through self-analysis and reflection and achieve competence through meaningful learning.

Deliberate practice is the repetitive performance of a cognitive or psychomotor task in a focused domain combined with rigorous skills assessment [24]. Through deliberate practice, students learn new knowledge, analyze, reflect, and problem-solve cyclically for self-improvement [22,25]. With mastery of their experience, students can use deliberate practice, receive feedback on their own performance, improve self-efficacy, and construct new knowledge through experience, as shown in Figure 1.

The aims of this study were (1) to describe the design of a head-mounted virtual reality system and evaluate it for education on clinical procedures for nursing students and (2) to explore the experience of nursing students with head-mounted VR for learning clinical procedures and the usability of the system.

Figure 1. Conceptual framework for learning clinical procedure using virtual reality.



Methods

Design and Implementation of IVR Clinical Procedures

Design and Development

Overview

In this study, 4 key elements were considered when designing the VR prototype to create an engaging and immersive experience for users. The first element was accessibility and inclusivity for all learners and involved software components, adjustable height, and visual and audio design to minimize cybersickness. The second element was locomotion and navigation to allow the learners to navigate the virtual space intuitively. The third element was visual fidelity; the graphics were designed in a detailed and realistic way to provide good immersion for the IVR experience. The fourth element was motion tracking, where the learner's head and hand movements were detected to allow real-time interaction. An additional consideration was the degrees of freedom and interactivity whereby the learner was given control of their learning [9].

A real-time 3D creation tool, Unreal Engine 5 (Epic Games), was used to support the development of the IVR procedures, which reinforced the real-time interaction of the learner, clinical instructor, and patient in a virtual ward [26]. The design and development of the IVR clinical procedures were a close collaborative effort among the nursing school, health care institution, and IT experts in a systematic process. First, the faculty and nurse clinicians discussed and created clinical scenarios and consolidated common errors, critical steps, and safety issues pertinent to each procedure during the developmental stage.

Then, students accessed the proposed immersive simulation of the clinical procedures by wearing a 3D VR headset with 2 handheld controllers (Oculus Quest 2; Reality Labs), shown in Figure 2. Using the Oculus Quest, each student could visually experience a typical clinical session modeled after a real laboratory with its procedures, which they might have experienced before in their typical laboratories. The simulation was highly interactive, leveraging the handheld controllers for the left and right hands to enable and engage the students in executing the same simulated procedures vividly seen in their facilitated laboratory demonstrations. With the rich visual media and interactive experience, students could practice the simulated virtual procedures in their own time and space without mental stress, external distractions, fear of hazardous consequences, or creation of any clinical waste.

Within the IVR program, 3 stages for playing using the scaffold learning approach, namely, the orientation, practice, and assessment modes, were developed.

Figure 2. Oculus Quest (with 2 hand-held controllers).

Orientation

New users were guided by a tutor and an instructional video on the features and safety aspects of using the IVR clinical procedures for learning. When they put on the Oculus Quest 2 for the first time, they were required to complete virtual tutorials on how to maneuver the controllers, how to perform handwashing by rubbing 2 hands together using the controllers (Figure 3) and putting on and removing gloves to optimize their gaming experience.

Figure 3. Hand hygiene.

Practice Mode

Visual cues were provided when the learners learned how to proceed from one step to the next. With the built-in checklist, ample opportunities were given for the learners to learn from their experiences. With timely feedback based on the student's responses, they could rationalize their actions and reactions and thus decide the next course of action or repeat the session. Finally, after the learners gained confidence through practice, made sense of the procedures, and built on their prior learning, they were ready for assessment. No cues were given, and the students could see their results and repeat the practice when required. This approach aimed to allow the construction of knowledge through experience and deliberate practice. It boosted self-regulated learning, as learners could adjust their learning according to their own pace to either move to the next level or remain in the practice mode until they were ready for assessment [27].

Assessment Mode

No cues were provided, as this was a simulation of an actual clinical situation. The learner was expected to proceed according to what they had already learned and practiced. Reward systems were incorporated, with a maximum of 3 stars when the learner completed the procedures correctly. Deliberate practice and timely feedback on the learner's performance were integrated into the case scenarios and situations to develop critical thinking and problem-solving abilities. Each IVR experience lasted 15-20 minutes to ensure no learner fatigue.

Implementation

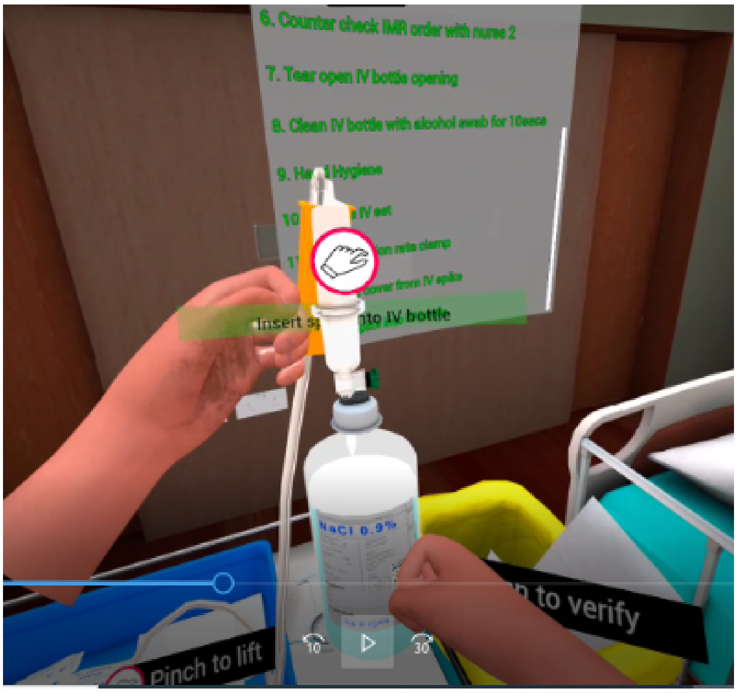
Figures 4 and 5 illustrate the subcutaneous injection and intravenous therapy procedures. In each scenario, the learners performed the procedures using the 2 handheld controllers. They also interacted with the patient and clinical instructor during critical steps such as checking identifiers and the "5 rights" when administering medication to ensure patient safety. The learners could click on a text box, and the patient would reply verbally with prerecorded responses. For example, if the learner asked, "May I know what your name and NRIC number are?" the virtual patient would reply, "My name is Ahmad, NRIC number is S1234567x." An electronic scanner and medication record were created to provide realism for learners to check the patient and medication prior to the administration.

The virtual simulation of administering a subcutaneous injection (Figure 4) included the critical component of checking the correct instruments and materials, type of insulin, and techniques in withdrawing air prior to withdrawing the correct unit from the vial. The appropriate injection site and any complications were identified, such as pain, edema, erythema, temperature, and lipohypertrophy. Critical components, such as checking patient identifiers, hand hygiene, the correct 5 rights, and injection techniques, had to be performed correctly to pass the procedure.

For the intravenous therapy procedure (Figure 5), learners studied critical concepts such as using the correct fluids and the accurate rate of infusion when administering intravenous therapy. Safety aspects, such as maintaining aseptic techniques while spiking the drip set and connecting to the intravenous plug, and steps to prevent phlebitis were incorporated into the scenarios. The learners were also expected to examine the risk of air embolism by checking the intravenous tubing.

Figure 4. Subcutaneous injection.

Figure 5. Intravenous therapy.



Evaluation of IVR Clinical Procedure

Study Design

This usability study used a mixed methods approach using convenience sampling. The recruitment and intervention of participants took place from June to August 2021 upon receiving approval from the institutional ethics review board.

Participants

The participants comprised undergraduate nursing students in their second academic year who had completed the pathophysiology and pharmacology modules and the Nursing Practice 1 and Clinical Experience Practicum 1.2 modules.

Data Collection

To achieve the aims of the study, three questionnaires were administered to the participants, which collected the following information: (1) basic demographics and past VR experience, (2) perception of continuance intention, with an instrument developed by Roca et al [28], and (3) the System Usability Scale (SUS) developed by Brooke [29]. To maintain consistency, we explained how to use the head-mounted device and how to put it on to ensure it was in good working condition. Any device issues were rectified, and then the participants brought the IVR device home for 2 weeks of testing on their own time. Upon returning the device, they were invited to complete the questionnaires.

The scale for perception of intention to continue was adapted from Roca et al [28] and had the following subscales: (1) usefulness, (2) cognitive absorption, (3) ease of use, (4) system quality, (5) confirmation, (6) satisfaction, and (7) continuance intention. All items were rated on a 5-point scale (1=strongly disagree to 5=strongly agree), except for item 1 on the system quality subscale, which was scored in reverse. The subscales adapted in this study had Cronbach α values of .81 (usefulness), .94 (cognitive absorption), .93 (ease of use), .68 (system quality), .96 (confirmation), .96 (satisfaction), and .91 (continuance intention).

The SUS is a 10-item self-report measure investigating one's reaction toward IVR procedures [29]. Items were assessed on a 5-point scale (1=strongly disagree to 5=strongly agree). The participants had to rate themselves on items like "I thought the VR procedure was easy to use." For items 1, 3, 5, 7, and 9, the score is the scale position minus 1. For items 2, 4, 6, 8, and 10, the score is 5 minus the scale position. The scores for each item were summed and multiplied by 2.5 to calculate a total score ranging from 0 (lowest) to 100 (highest). There was no cutoff score, but higher total scores indicated higher levels of usability for the IVR procedures. The Cronbach α values for the scale ranged from .85 to .91 [30].

Quantitative Analysis

Descriptive statistics using percentages, means, and SDs were computed to examine the study variables using SPSS (version 28.0; IBM Corp) [31].

Qualitative Analysis

Qualitative data from the open-ended questions were imported into an Excel spreadsheet for coding. Content analyses were used to understand the users' experiences of the IVR procedure [32]. Two researchers (STL and WLL) conducted the content analysis and extracted the codes, categories, and themes [33]. The research team reviewed the frequencies of the coded themes to reach a consensus. Trustworthiness, credibility, and transferability were ensured by including all 29 participants' responses, selecting units of meaning, and presenting the findings in a rich and vigorous way (Multimedia Appendix 1).

Ethics Approval

Ethical approval was obtained from the National University of Singapore Institutional Review Board (NUS-IRB 2021-305).

The participants were briefed thoroughly, and the participant information sheet was provided prior to recruitment. Participants were informed that their participation was voluntary and that they could withdraw from the study at any time. Confidentiality and anonymity were ensured.

Results

Participants

In this study, 29 participants were recruited, and all completed the study. The mean age of the participants was 23.03 (SD 6.59) years, with the majority being female (n=18, 62%). There were 22 Chinese participants (76%), 3 Malay participants (10%), and 1 Indian (3%) participant, with 3 participants of other ethnicities (10%). Most had no experience using VR prior to the user testing (n=27, 93%).

Quantitative Analysis

As presented in Table 1, for perception on intention, all the subscales in the perception scale had a mean score greater than 3 (of a total score of 5). This indicated that the students had a positive perception of the quality and usability of IVR, which is a key determinant for their continuity intention. The subscale with the highest mean score was "cognitive absorption" (mean 4.05, SD 0.61), suggesting that the students enjoyed and found the IVR engaging. The top 2 items with the highest scores supported this notion: "I have fun interacting with VR procedure" (mean 4.38, SD 0.68) and "When I am using the VR procedure, I am absorbed in what I am doing" (mean 4.14, SD 0.74). From another aspect, the 2 items with the lowest scores were "It is easy for me to become skillful at using VR procedure" (mean 3.21, SD 1.01) and "I will frequently use the VR procedure in future" (mean 3.24, SD 0.95).

However, for the student's perception of the usability of IVR, the mean SUS score was 53.53 (SD 16.18). This score was below the acceptable score of 68, indicating that more work needed to be done to improve the usability of IVR. Two items with poor perception, that was, items with >10 participants, indicating "Do not agree for positively worded item" or "Agree for a negatively worded item," were "I thought the VR procedure was easy to use" and "I think that I would need assistance to be able to use the VR procedure" (Table 2).

Table 1. Perception scale (N=29).

Subscales or items	Mean (SD)
Usefulness	3.71 (0.92)
Using the VR[a] procedure can improve my learning performance	3.79 (0.90)
Using the VR procedure can increase my learning effectiveness	3.66 (0.97)
I find the VR procedure to be useful to me	3.69 (1.11)
Cognitive absorption	4.05 (0.61)
Time flies when I am using the VR procedure	4.00 (0.96)
Most times when I get on to the VR procedure, I end up spending more time than I had planned	3.69 (0.81)
When I am using the VR procedure, I am absorbed in what I am doing	4.14 (0.74)
I have fun interacting with VR procedure	4.38 (0.68)
I enjoy using the VR procedure	4.03 (0.82)
Ease of use	3.32 (0.86)
Learning to operate the VR procedure is easy for me	3.31 (1.04)
It is easy for me to become skillful at using VR procedure	3.21 (1.01)
My interaction with the VR procedure is clear and understandable	3.45 (0.91)
System quality	3.50 (0.53)
Number of steps per task is too many[b]	3.55 (0.63)
Steps to complete the task follow a logical sequence	3.62 (0.86)
The organization of information is clear	3.41 (0.98)
The VR procedure has natural and predictable screen changes	3.55 (0.91)
The VR procedure system is responsive	3.34 (1.01)
Confirmation	3.52 (0.84)
My experience with using the VR procedure was better than I expected	3.48 (1.12)
The service level provided by the VR procedure was better than I expected	3.55 (0.87)
Overall, most of my expectations from using the VR procedure were confirmed	3.52 (0.78)
Satisfaction	3.70 (0.87)
I am satisfied with the performance of VR procedure	3.31 (1.04)
I am pleased with the experience of using the VR procedure	3.83 (0.89)
My decision to use the VR procedure was a wise one	3.97 (0.98)
Continuance intention	3.46 (0.96)
I will use the VR procedure on a regular basis in future	3.34 (1.08)
I will frequently use the VR procedure in future	3.24 (0.95)
I will strongly recommend others to use it	3.79 (1.11)
Overall score	3.63 (0.63)

[a]VR: virtual reality.

[b]Scored in reverse.

Table 2. System usability scale (N=29). The total score was 53.53 (SD 16.18).

Items	Strongly agree or agree, n (%)	Neutral, n (%)	Strongly disagree or disagree, n (%)
Positively worded			
I think I would like to use VR[a] procedure frequently	14 (48)	10 (34)	5 (17)
I thought the VR procedure was easy to use	10 (34)	8 (28)	11 (38)
I found the various functions of VR procedure were well integrated	12 (41)	10 (34)	7 (24)
I would imagine that most people would learn to use VR procedure very quickly	11 (38)	10 (34)	8 (28)
I felt very confident using the VR procedure	8 (28)	12 (41)	9 (31)
Negatively worded			
I found the VR procedure unnecessarily complex	7 (24)	10 (34)	12 (41)
I think that I would need assistance to be able to use the VR procedure	13 (45)	6 (21)	10 (34)
I thought there were too much inconsistency on the VR procedure	6 (21)	7 (24)	16 (55)
I found VR procedure very cumbersome or awkward to use	9 (31)	8 (28)	12 (41)
I needed to learn a lot of things before I could get going with the VR procedure	8 (28)	9 (31)	12 (41)

[a]VR: virtual reality.

Qualitative Analysis

Overview

Key themes were derived from the content analysis of the open-ended questions on the questionnaires regarding the experience of using VR procedures for learning. The themes derived from the analyses included the usefulness of IVR, learning experiences using IVR, challenges encountered, technical glitches, and suggestions for improvement. Themes and frequencies from the content analysis can be found in Multimedia Appendix 1.

Usefulness of IVR

Participants were excited about the new experience of using IVR. They found that the realism and relevance to the clinical setting and the ability to interact with a virtual patient and clinical environment promoted immersion in experiential learning:

> *It is intriguing as a first-time user; hence it caught my attention from the start. I could practice the nursing procedures at my own comfortable pace and get back to practicing the procedures again on my own time. There was an improvement in terms of accuracy in the procedure as I practiced more often on my own. Having a virtual patient in front of our eyes helped mimic clinical settings.* [P11]

Participants appreciated this learning format and found it a useful resource for students to practice and learn at their own pace, time, and convenience. “I can see this being a very useful resource for students to practice and learn in their own time” (P15).

Learning Experiences

Participants reported that performing the procedure using IVR encouraged them to consciously revise the sequence for the procedure and ensure accuracy as they built on their knowledge and skill through practice. This experience enhanced their thinking skills as they reviewed their performance:

> *I liked that the VR prompted me to think through the sequence of steps I have to do before a procedure. It helped me revise the steps and rationale behind the steps. I also like that the VR tracks your activity and lets you know which step you have forgotten to perform.* [P3]

Some participants commented that learning on the VR platform allowed novice learners to correct mistakes without putting an actual patient at risk:

> *The fact that I can practice clinical skills anywhere is an advantage of VR. Also, I would not be causing any real patient harm if I tried something out for the first time.* [P23]

> *It will make me understand my mistakes there, so I will be more aware not to repeat them the next try or during real-life clinical procedures.* [P11]

In particular, the participants appreciated the important concepts that might be overlooked in real clinical settings. One of these aspects was performing the “5 moments of hand hygiene” for any patient encounter. With IVR, the participants could not proceed, and they could see the “dirt” visually on their hands. “The visualization of soiled hands was also very useful as I see the importance of hand hygiene” (P21).

Challenges Encountered

Participants reported some limitations of the IVR system. The participants shared that adapting to the device and controls took time. Some concerns included physical discomfort, such as feeling dizzy, and that participants could not complete the entire procedure in 1 sitting:

> *I could not complete the tasks because I felt dizzy after a certain amount of time, and though I do revise*

> *the steps before I put on the headgear to do the task.* [P27]

Some of them also commented on their unfamiliarity with the device and instructions. Moreover, others were unable to communicate with the virtual patient and had a decreased level of enjoyment in using IVR:

> *I feel like there can be clearer instructions, possibly step by step, during my first attempt of the procedure to refresh and familiarize myself with the items. I could not communicate with the patient, grasp objects, put on gloves, and check the patient's body.* [P18]

Technical Glitches

The most technical glitches involved the withdrawal and administration of the medication procedure. The participants shared that they experienced irritation when virtual items were not responding according to commands despite multiple attempts. This impeded their progress and learning as they needed to restart the procedures:

> *Some IT interface needs to be adjusted to smoothen the flow of procedural execution. Sometimes there is a glitch where the packaging of the alcohol swabs, needle, and IV line gets stuck to our hand, thus hindering our next steps.* [P26]

> *It was very frustrating that I could not inject the needle into the insulin vial and manipulate it too.* [P22]

Suggestion for Improvement

Three main areas for improvement were suggested: provide orientation and more specific instructions, include more audio and haptic feedback in the game, and optimize the controls and joystick. Some other suggestions included adding a progress bar to motivate students to practice, including more procedures, and extending the use to hospitals:

> *More instructions can be given. A good example would be IV priming, where additional instructions are taught to us.* [P5]

> *Please include more procedures...look forward to it. If it works well, this can be a good technology to bring into hospitals for staff re-education or enrichment purposes. And any updates to a particular nursing skill can be updated in the software as well...that will be excellent.* [P6]

Discussion

Overview

The objectives of this study were to describe the development and to evaluate the learning experience of undergraduate nursing students. Creating these 2 clinical procedures in VR involved multiple stakeholders, including multiple reviews and refinements prior to this study. A new teaching approach was incorporated to create an effective learning environment to promote competencies among nurses. This study was a timely development during the period of the pandemic, when there were movement restrictions, safe distancing, and physical segregation of staff and students. More essentially, this study met the learning needs of the next generation.

Principal Findings

This study indicated that undergraduate nursing students found IVR satisfying and most of them enjoyed the experience. They were most intrigued by the contextualization of the VR procedures and felt that the experience was better than they had expected. This result reflects findings in the broader literature [34]. Once in the VR environment, they were absorbed in performing the procedures and tended to spend more time than intended. One of the reasons could be the high degree of realism, as the VR environment was a close representation of the actual ward setting. The participants could interact with patients when guided by the clinical instructor, just like in real life. From the study, the scores in the perception scale and qualitative data showed that the participants were highly engaged and immersed and forgot the time when performing the VR procedures, which is congruent with other studies [35].

Some participants shared that when practicing at home with practice versions of necessary instruments and materials, they were only able to practice psychomotor skills and that there was no holistic patient experience. They liked the VR system as it simulated the actual ward with instruments and materials readily available. The high-resolution visuals were stimulating for the students as they performed the task. In addition, the VR procedures were rolled out during the COVID-19 pandemic, when in-person practice sessions were largely reduced. The lack of hands-on practice experience might be an impetus for students to embrace using technology for learning more readily. The students were keen to experience a new approach to learning and viewed it as a valuable learning opportunity.

In this study, most participants agreed that VR effectively allowed them to practice steps, enabled repeatable learning, and helped them form good habits, including hand hygiene habits, such as when they touched a patient or the environment with their hands and prior to performing any procedures. They were able to remain focused without being distracted by the external environment. In addition, IVR allowed the participants to proceed at their own pace and enabled them to construct new knowledge through the reflective thinking process. With the checklist embedded in the VR procedures, the students could receive timely feedback during their practice. Moreover, they had a sense of achievement when they completed the procedures successfully. The real-time feedback motivated the participants, and they strived to do better in each practice session. Such a feature is critical to enhancing learning, as Generation Z students look for instant results [4,5]. Most participants agreed that VR provided a good learning platform and that it helped them to be more focused on finer details to improve their competencies. The interactive clinical procedures were valuable as they encouraged self-regulated learning. The learners were able to develop new knowledge linked to previous learning when they eventually progressed from virtual practice to actual practice. This explains the willingness of undergraduate students to explore the IVR system, as it provided opportunities for them to put theory into practice and could improve their confidence in real-life practice [34].

Comparison to Prior Work

These findings are aligned with other studies showing that IVR is promising for improving engagement and motivating students to learn. Hence, this learning platform is suitable to be included as a teaching approach [36,37]. However, in this study, the ease of use and system quality of the VR procedures scored lower than the rest of the perception subscales. Similarly, the SUS also showed that more than half of the participants felt they required assistance to use the VR system, and that it was not easy to use. This signifies the importance of improving the efficiency and quality of the VR prototypes. The participants shared in their qualitative feedback that the controls were not intuitive and were confusing, as they were unsure which button to click. In addition, they reported technical issues, such as that the items kept sticking to their hands or dropping. This feedback helped the IT staff improve the procedures before implementing them for the entire cohort of students.

The participants expressed that they needed time to get used to and learn to use the VR device. Some used the VR set for a prolonged period, resulting in physical discomfort and cybersickness. This study highlighted that not all users find IVR comfortable, and that more refinement needs to be made to reduce technical difficulties. Therefore, IVR might not be suitable for everyone [38]. To ensure cyber safety, more precise tutorials and instructions should be developed to guide users. The user guide for the VR technology and the controllers will be revised. Maximum play duration and cautions and instructions for safety must be included in the orientation for users.

Finally, the participants also found the application lacking in audio and haptic feedback. They suggested including more cues by having vibration or buzzing when errors are made or having a visual dialogue box or audio prompt to inform players to increase interactivity. They shared that students would learn more if there were more challenging situations, such as including several types of intravenous solutions or insulins to stimulate students’ thinking. These ideas were valuable feedback for enhancing the learning experience, and the team has considered refining the prototypes.

Strengths and Limitations

The strengths of this study included, first, that all interactive clinical scenarios were reviewed and refined by the various parties. Second, faculty and students conducted several rounds of user acceptability testing to refine the prototypes prior to this study. Finally, developing the clinical procedures was a collaborative effort among clinical, academic, and IT professionals. All comments received were valuable, and improvements suggested by the participants were incorporated into the future refinement of the IVR procedures. The limitations included the IT professionals using Unreal Engine software for the first time, which led to teething issues. As they gained expertise in using the program, the IVR procedures significantly improved. Although the sample size was small, considering that it was a usability study, 29 participants was considered a sufficient size, and data collection for reviewing the design and evaluating its usefulness reached saturation. Going forward, more participants will be recruited to test the effectiveness of the IVR procedures.

Conclusions

IVR for simulating intravenous therapy and subcutaneous injection procedures was designed and developed for nursing students to perform the procedures at their own convenience and the time and place of their choosing. Our evaluation supports the feasibility of using IVR in learning clinical procedures. It highlighted the value of deliberate practice and scaffold learning via VR procedures. The study also supported the usability of the VR device, although improvements and revisions are needed for a better user experience. With the enhanced features, future research can examine the effectiveness of health care students’ learning clinical procedures at home using IVR. Given its portability and flexibility, IVR is potentially an effective adjunct to support health care students in learning and performing clinical procedures.

Abstract

Background: Simulation-based Advanced Cardiac Life Support (ACLS) or Advanced Life Support (ALS) training for health care professionals is important worldwide for saving lives. Virtual reality (VR)–based serious gaming can be an alternative modality to be used as a part of simulation-based ALS training.

Objective: The aim of this study is to investigate whether a VR-based ALS serious game module can replace classroom-based ALS lectures, the latter being part of existing conventional ALS training protocols in addition to skills training.

Methods: Participants were students from Acibadem Mehmet Ali Aydinlar University's Vocational School for Anesthesiology (N=29) randomly divided into 2 groups with 15 (conventional training group) and 14 (VR-based training group) participants each. Participants in the conventional training group had to complete the pretest consisting of multiple-choice questions at the beginning of the study. Afterward, they took part in an interactive classroom-based ALS lecture. The next step involved skills training with task trainers to teach them compression skills. Following this, the conventional training group was divided into Code Blue teams, each consisting of 5 participants for the simulation session. Two independent instructors evaluated video recordings in terms of technical and nontechnical skills. The score acquired from the manikin-based simulation session was considered the main performance indicator in this study to measure the learning outcome. A similar workflow was used for the VR-based training group, but this group was trained with the VR-based ALS serious game module instead of the theoretical lecture. The final stage of the study involved completing the posttest consisting of multiple-choice questions. A preference survey was conducted among the study participants. Mann-Whitney *U* and Wilcoxon signed-rank tests were used to analyze the 2 groups' performances in this study.

Results: The improvement in posttest results compared with pretest results was significant in the conventional training group (P=.002). Hands-on technical scores of the conventional training group were higher than those of the VR-based training group during manikin-based simulation, but total scores, including those for technical and crisis resource management skills, acquired from the manikin-based simulation session did not reveal any significant difference between the 2 groups. The results of the VR preference survey revealed that the majority of the participants prefer VR-based serious game–based training instead of classroom lectures.

Conclusions: Although hands-on technical scores of the conventional training group during the manikin-based simulation session were higher than those of the VR-based training group, both groups' total performance scores, including those for technical and crisis resource management skills, did not differ significantly. The preference survey reveals that the majority of the participants would prefer a VR-based ALS serious gaming module instead of lecture-based training. Further studies are required to reveal the learning outcome of VR-based ALS serious gaming.

KEYWORDS

Advanced Cardiac Life Support; virtual reality; serious game; randomized controlled trial; Advanced Life Support

Introduction

Advanced Cardiac Life Support Course (ACLS) developed by American Heart Association (AHA) and Advanced Life Support (ALS) course developed by European Resuscitation Council (ERC) with a similar content to ACLS, aim to train healthcare professionals in managing adult patients suffering from cardiac arrest. The target group consists of medical doctors, nurses, and paramedics [1-4]. Around 1.3 million candidates take part in ACLS or ALS courses worldwide every year [5]. These training sessions have to be repeated at certain intervals depending on local regulations or institutional requirements [6].

Participants learn how to deliver high-quality cardiopulmonary resuscitation (CPR) to adult patients and to manage cardiac arrest cases. Besides technical skills, another aim of these courses is to provide training for nontechnical skills, which are essential when working as a multidisciplinary team. Blended learning techniques including didactic lecture-based, video-based learning; serious gaming; and simulation-based training modalities are used for ALS training [1,2,5].

Like in other industries, serious gaming is becoming an additional training modality for simulation-based education for healthcare over the last decade. A significant amount of time is spent in lecture-based sessions, which are generally organized before hands-on training for ALS in order to teach cardiac rhythm interpretation, drug dosage, the defibrillation procedure, and differential diagnosis [6,7]. By using serious gaming modules for this aspect of training, the educators can reduce the time spent on theoretical lectures and alleviate logistical difficulties, such as coordinating the training with a clinician from the hospital [6]. Another advantage is the ability to minimize the instructors' workload by delivering these training sessions with virtual reality (VR) modules [6]. Besides immersive features and interactivity, serious gaming modules also provide learners the opportunity to improve their skills in a safe environment anywhere and anytime they want [8-13]. PC-based, tablet-based, and VR-based serious gaming modules for health care training are available commercially. Due to their immersive effect, VR-based serious gaming modules are now widely used in health care training [6-8,14-19]. As VR hardware has already become more affordable, significant growth of VR-based learning is expected [20]. With technological developments, the new generation of VR headsets is becoming more affordable than the older ones, which cost much more and required a cable connection to a PC with an expensive graphics card to operate. The new generation of VR headsets also eliminate the huge logistical and hardware requirements for using VR. Another advantage of such a VR-based serious gaming module is the ability to be used with wireless VR headsets without the need for a PC and an expensive cable-based VR headset. Therefore, Meta Quest 2 headsets (Meta) were used in this study [21].

It is obvious that nontechnical skills are as important as technical skills when performing an ALS procedure as part of the Code Blue team [22,23]. Nontechnical skills including teamwork, resource management skills, and situational awareness are very important competencies that are required when performing an ALS procedure, as ALS is a team-based procedure [22,23]. Several serious gaming modules for ALS training are available in the market [6,24]. The existing VR-based ALS serious gaming modules are mostly focused on technical skills when calculating the total score upon final evaluation of the ALS learning outcomes. Therefore, the development of a new serious gaming module for ALS training has been decided, which can also evaluate and score nontechnical skills of the trainee in parallel with technical skills required to perform ALS. The objective of this study is to investigate whether a VR-based ALS serious game module has the potential to replace classroom-based ALS lectures, the latter being part of existing ALS training protocols in addition to skills training.

Methods

Study Design

This study was designed as a randomized controlled trial comparing the results of a VR-based serious gaming module and conventional training for ALS. Pretest, posttest, preference survey outcomes and hands-on training scores of the participants, which is the main performance indicator of the study, were compared.

Recruitment

In total, 30 third-semester students of Acibadem Mehmet Ali Aydinlar University's Vocational School for Anesthesiology volunteered to participate in this study. Simulation-based ALS training is part of their regular curriculum. The participants were randomly divided into 2 groups, with 15 participants each in the conventional (hereinafter called "group C") and VR-based (hereinafter called the "VR group") training groups. The VR headsets were cleaned with an antiseptic solution before each training session.

Data Exclusion

Exclusion criteria for the study were having previously experienced VR-induced motion sickness or other medical conditions such as vertigo. One participant from the VR group was not able to attend at the study due to personal reasons and was excluded from the study.

Statistical Analysis

Mann-Whitney *U* and Wilcoxon signed-rank tests were used to analyze the 2 groups' performances in this study.

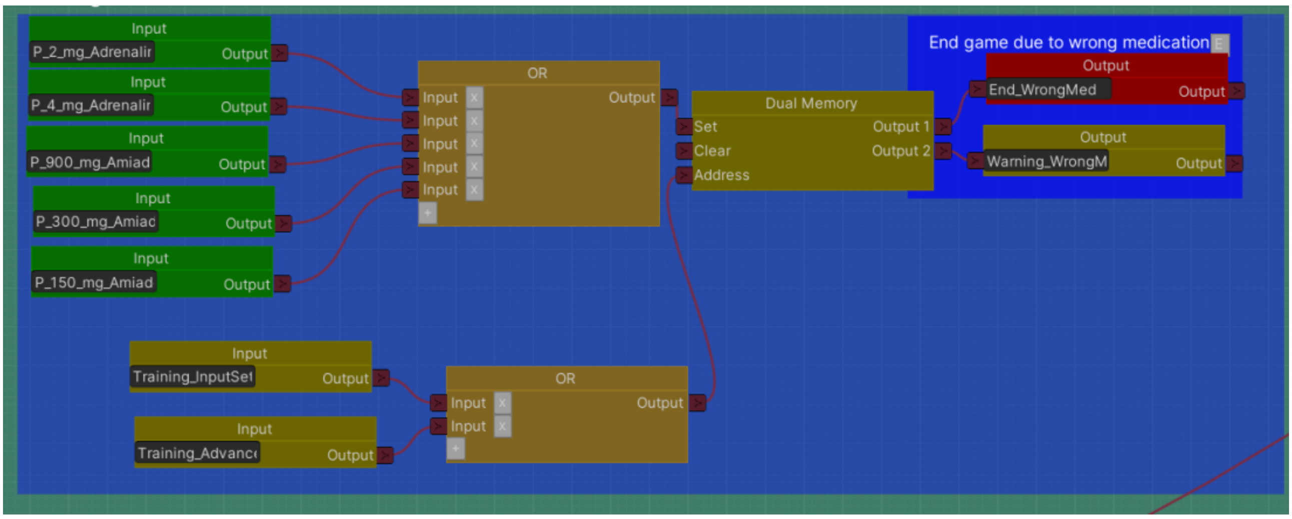
VR-Based Serious Gaming Module for ALS

The serious game module for ALS has been developed for this study and named "3DMedsim ALS VR." During the initial phase of development, the latest versions of international ALS or ACLS protocols from the AHA and ERC were reviewed together with the clinicians and software developers [1,2]. Crisis resource management (CRM) criteria adapted from those used in aviation and used for team-based training were also reviewed [22,25,26].

In the next phase, the development process of the VR-based gaming module was initiated. The VR-based serious game module developed for this study was designed to be compatible with the 2020 ALS algorithm of the ERC and AHA [1,2]. It comprises a learning management system and a learning record store (LRS), which allow users' credentials to be stored in a shared database [27-29]. The 3D visualization engine is also included and is integrated with the LRS to track the users' actions and generate experience application programming interface (xAPI) calls for each action carried out [28]. When the user triggers a predefined interaction with a significant object in the virtual environment, a xAPI event is automatically generated [27,30]. To enable this, a software library has been developed as a Unity extension, which makes the necessary xAPI web service calls to the LRS servers over the HTTP protocol. All user actions were defined in terms of actor, verb, and object parameters. The library automatically generates xAPI calls for each action, which are recorded by the LRS. The library can automatically generate xAPI calls for actions that have not been performed within a given time limit or in the proper order. Finally, the library also implements security and user authentication features required for record-keeping using the basic access authentication method included in the HTTP protocol standard.

To accelerate the development process and increase flexibility subsequently, a scenario building Unity plugin was developed [31]. This tool helps create and edit serious game scenarios as logic nodes outside of the virtual environment, independent from 3D objects. Thus, scenarios can be edited without altering Unity objects, which normally take the most time during the development process. The scenario building tool was only used during the development process and cannot be used by trainers to change the scenario flow during gameplay. The scenario building tool returns function calls to Unity in accordance with the logic flow, and these calls are linked to 3D objects as triggers for certain actions. As actions are triggered, they, in turn, trigger the next steps in the scenario until the serious game is over. A part of a scenario flow can be seen in Figure 1.

Figure 1. Screen capture of scenario logic flow.



The serious game consists of 3 different stages in multiple languages: basic training, advanced training, and a test mode. Initially, the serious game consisted of only training and test modes. However, during early testing, it became clear that a third stage was necessary, as the increase in difficulty and complexity was too much between the 2 modes. Another slightly more difficult training mode was added for this purpose. These stages can be completed in a virtual hospital or an examination room environment as seen in Figure 2.

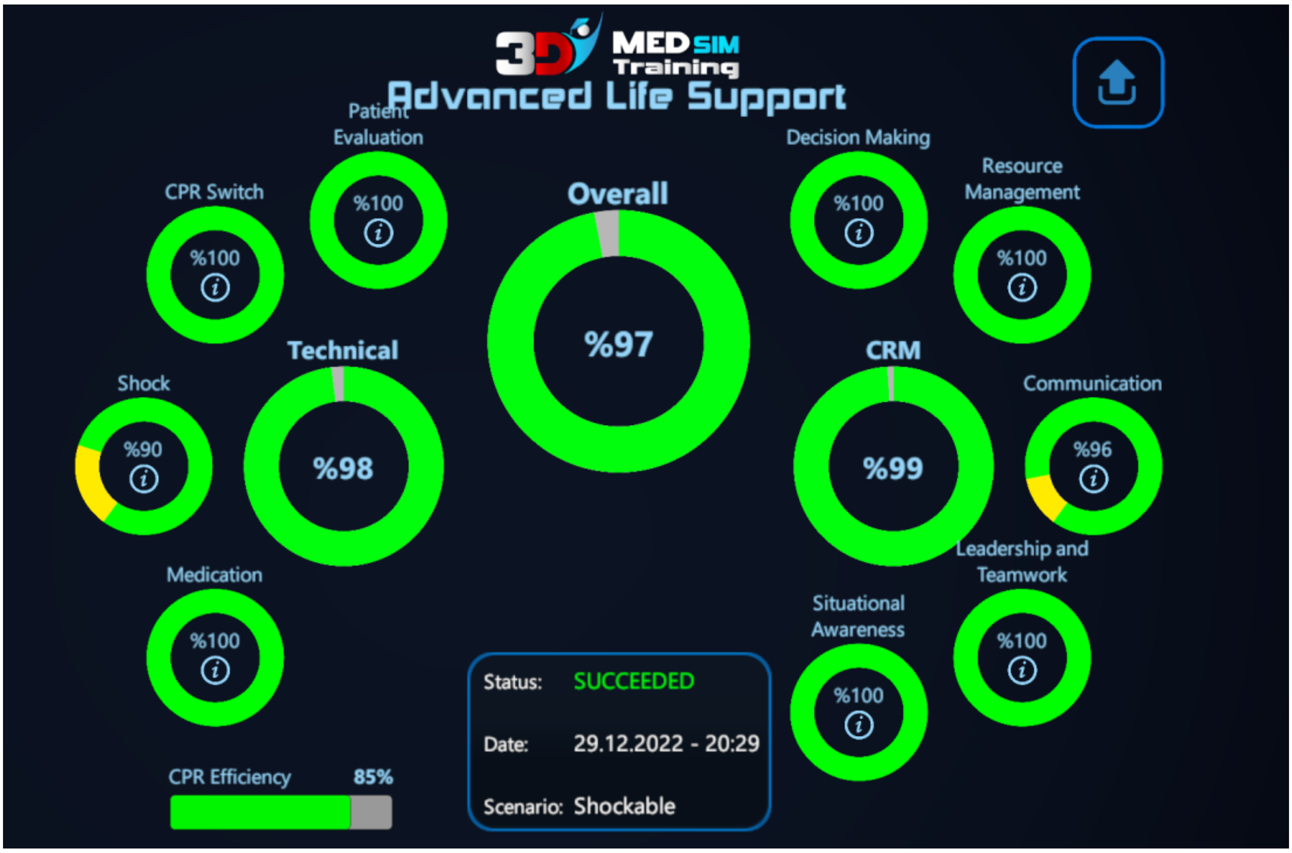
Figure 2. Screen capture from the virtual reality–based serious game for advanced life support.

The first stage, the basic training mode, is for beginners who wish to learn the fundamentals of the ALS algorithm. This version provides visual and audio guidance to the user at every step of the algorithm. An announcer verbally directs the user to perform specific actions, while corresponding buttons are highlighted on the interface. The user is not allowed to interact with anything that is not highlighted, and the risk of failure is thus eliminated. Additionally, time limits are removed, and the user is reminded to undertake the next step if user stays idle for a particular period.

The next stage is advanced training, which is intended for users who have completed the beginner-level training of the game. The advanced training version does not provide any visual or audio assistance, and the user is free to take any action; thus, mistakes are now possible. If users make significant mistakes or miss a time constraint, they receive a warning, but the game is not terminated.

The third stage is the test mode. The users' actions are evaluated on the basis of their order and timing during this mode. The evaluation is carried out under 2 categories: technical and CRM skills. The scores can be accessed by using the review section. Unlike the training stages, if the user commits a significant error, such as selecting the wrong rhythm, the game terminates with a warning indicating the mistake. The technical and CRM scores are segregated as shown in Figure 3. The subcategories of these grades are specified to pinpoint the users' errors during review.

Figure 3. Screenshot from the serious game showing technical, crisis resource management, and total scores of a trainee. CPR: cardiopulmonary resuscitation; CRM: crisis resource management.

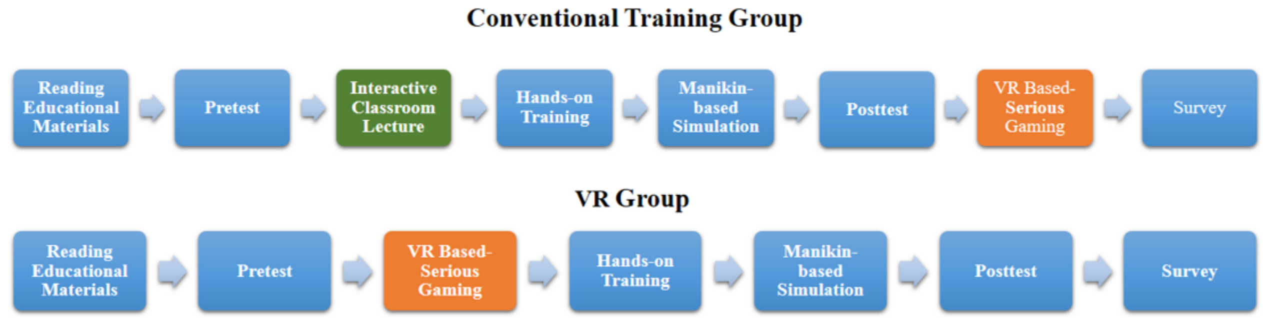


The total score of a participant was calculated as the sum of the technical and CRM scores during the game. The maximum total achievable score was 100, that for technical skills was 70 points, and that for CRM skills was 30 points. In order to avoid risk of failure due to problems concerning the content, scenario flow, and scoring, the first version of the game was presented to clinicians for evaluation. Depending on the feedback and critiques from the content experts, changes were made. The version used in this study is the second version of the software optimized depending on user feedback.

Study Flow

The details of the study flow are shown in Figure 4.

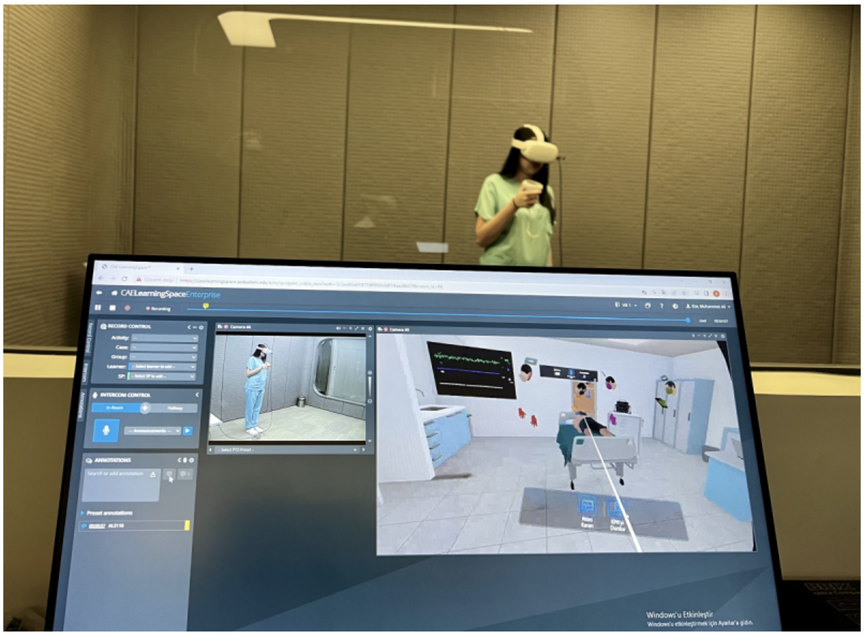
Figure 4. The study flow of the conventional training group and virtual reality (VR)–based training group.



During the initial stage of the study, all participants were asked to read the educational material sent to them. Then, both groups were asked to complete the pretest form shown in Multimedia Appendix 1.

The pretest and posttest consisted of the same multiple-choice questions, and the test content is aligned with the curricular content required for ALS training at Acibadem Mehmet Ali Aydinlar University. This test is being used to assess of ALS training at our university and is compatible with the content of the latest version of the ERC's training algorithm. The two-rounded Delphi technique was used with content experts when generating the pretest and posttest questionnaires. Group C participants took part in an interactive lecture with the instructors. VR group participants took part in a VR familiarization session and played 1 round of the VR beginner training mode followed by 1 round of the VR advanced training mode (Figure 5). The total time spent for these 2 rounds with VR training was equal to the time the other group spent during the classroom lecture.

Figure 5. Real-time video of the trainee and virtual reality–based advanced life support serious game screen recorded during training sessions.



Afterward, participants of both groups took part in a skills training session in order to learn effective CPR and ventilation with a CPR manikin (CPR Lilly Pro+, 3BScientific GmbH; Figure 6) [32].

Figure 6. Hands-on training sessions performed using Basic Life Support manikin (CPR Lilly Pro+, 3BScientific GmbH).

After the skills training, both groups took part in simulation-based ALS scenario using a patient simulator (Apollo Patient Simulator, CAE Healthcare; Figure 7) [33]. The participants were divided into Code Blue teams, each consisting of 5 participants during each simulation session. The content and flow of the scenario were identical to the scenario used for the VR-based ALS serious gaming module. The manikin-based simulation sessions of all participants were video recorded for evaluation. Two independent instructors evaluated the video-recorded performances of the participants during the manikin-based simulation scenario with the same scoring criteria used for the VR-based ALS serious gaming module. Following the manikin-based simulation session, all participants were asked to complete the posttest, which was identical with the pretest. Group C participants were given the opportunity to try the VR-based module at the end of the study; however, as the VR group participants were attending classroom-based lectures during their standard educational program, there was no need for them to take part in a classroom-based lecture at the end of the study. At the end of the study, all study participants were asked to answer the preference survey form shown in Figure 8.

Figure 7. Manikin-based simulation of an advanced life support scenario with a high-fidelity patient simulator (Apollo Patient Simulator, CAE Healthcare).

Ethical Considerations

This study has been approved by Acibadem Mehmet Ali Aydinlar University's Ethical Committee (approval number 2022-19/04). After being informed about the content of the study, the participants signed informed consent forms. The collected data were anonymized in order to safeguard participant information. No compensation was provided to the participants.

Results

The VR group's pretest scores ranged from 21 to 79 (mean 43.36, SD 15.47); those of group C ranged from 21 to 79 (mean 46.53, SD 15.05). The pretest scores did not differ significantly between the 2 groups (*P*=.62). The VR group's posttest scores ranged from 32 to 89 (mean 53.79, SD 14.01); those of group C ranged from 47 to 84 (mean 64.20, SD 9.96). The posttest scores were significantly higher in group C than in the VR group (*P*=.01). The results of the pretest and posttest are summarized in Table 1.

Table 1. Evaluation of pretest and posttest results (N=29).

	Total	VR[a] Group (n=14)	Group C[b] (n=15)	*P* value[c]
Pretest, range (median); mean (SD)	21 to 79 (45); 45 (15)	21 to 79 (44); 43.36 (15.47)	21 to 79 (45); 46.53 (15.05)	.62
Posttest, range (median); mean (SD)	32 to 89 (58); 59.17 (12.99)	32 to 89 (53); 53.79 (14.01)	47 to 84 (63); 64.20 (9.96)	.01
Difference[d] (posttest versus pretest), range (median); mean (SD)	–11 to 42 (13); 14.17 (13.30)	–11 to 32 (10); 10.43 (11.99)	–6 to 42 (16); 17.67 (13.90)	.19

[a]VR: virtual reality.

[b]Group C: conventional training group.

[c]Mann-Whitney *U* test.

[d]Wilcoxon signed-rank test. Overall difference in pretest and posttest scores: *P*=.001; difference in pretest and posttest scores in the VR group: *P*=.02; difference in pretest and posttest scores in the group C: *P*=.002.

A comparison of the mean pretest and posttest scores is shown in Multimedia Appendix 2. There was no significant difference in the pretest scores between the 2 groups (*P*=.62). The increase in posttest scores compared to that in the pretest scores was significant in both groups (*P*=.001). The increase in the posttest scores compared to that in the pretest scores was significant in the VR group (*P*=.02). The increase in the posttest scores compared to that in the pretest scores was significant in group C (*P*=.002). A significant difference was found between the posttest scores in the 2 groups, and the scores of group C were found to be significantly higher than those of the VR group (*P*=.01).

The score of the manikin-based simulation session, which was considered the main performance indicator in this study, was evaluated with the same scoring criteria of the serious gaming module. The scores of manikin-based simulation session are summarized in Table 2. The total score of each participant consists of the CRM score and the technical score depending on their performances in the manikin-based simulation session. The maximum achievable CRM score was 30, and the maximum achievable technical score was 70. The total score was calculated as the sum of the participant's technical and CRM scores.

Table 2. Evaluation of manikin-based simulation session scores (N=29).

	Total	VR[a] group (n=14)	Group C[b] (n=15)	*P* value[c]
CRM[d] (maximum 30), range (median); mean (SD)	3-16 (13); 12.84 (4.20)	13-16 (14.5); 14.45 (1.23)	3-16 (13); 11.33 (5.37)	.23
Technical (maximum 70), range (median); mean (SD)	44-69 (59.3); 57.11 (8.41)	44-60.5 (58); 53.80 (7.63)	51-68.25 (63); 60.20 (8.13)	.03
Total (maximum 100), range (median); mean (SD)	57-85 (66); 69.95 (9.37)	57-76.5 (72.5); 68.25 (8.81)	64-85 (66); 71.53 (9.89)	.53

[a]VR: virtual reality.

[b]Group C: conventional training group.

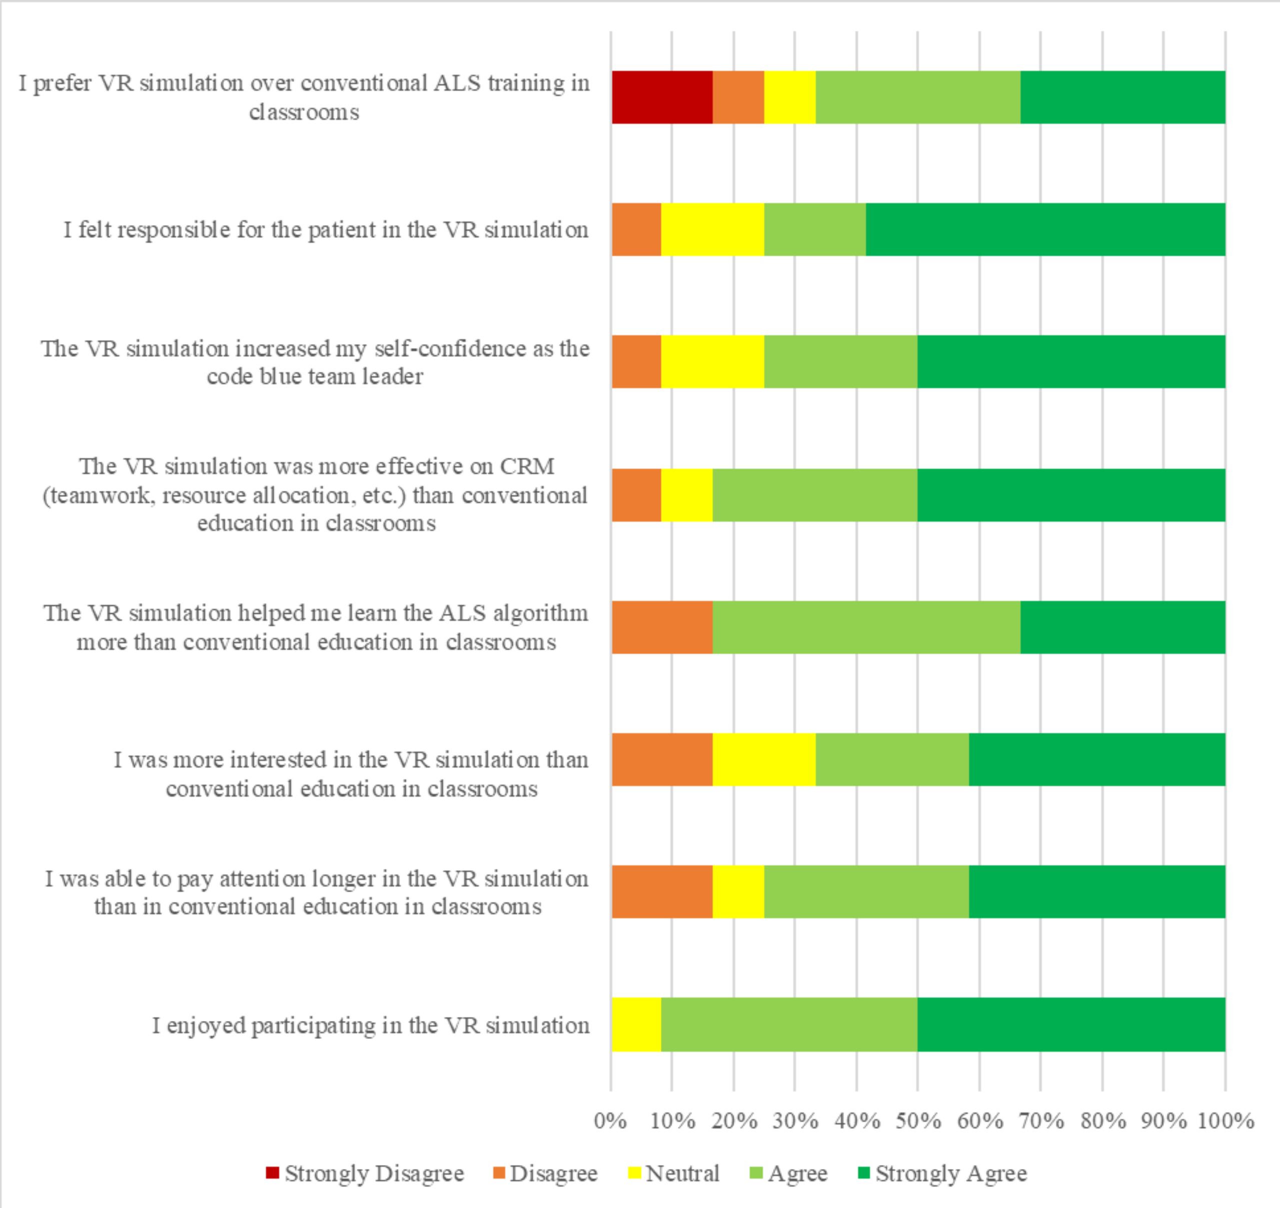
[c]Mann-Whitney *U* test.

[d]CRM: crisis resource management.

The VR group's CRM scores ranged from 13 to 16 (mean 14.45, SD 1.23); those of group C ranged 3 to 16 (mean 11.33, SD 5.37). CRM scores were not significantly different between the 2 groups (*P*=.23). Mean values of the CRM and technical scores of both groups during the manikin-based simulation session are shown in Multimedia Appendix 3. The technical scores of the VR group ranged from 44 to 60.5 (mean 53.80, SD 7.63); those of group C ranged from 51 to 68.25 (mean 60.20, SD 8.13; Multimedia Appendix 3). The technical scores of the conventional group were significantly higher than those of the VR group (*P*=.03). The VR group's total scores during the manikin-based simulation session ranged from 57 to 76.5 (mean 68.25, SD 8.81); those of group C ranged from 64 to 85 (mean 71.53, SD 9.89; Multimedia Appendix 3). The total scores of both groups during the manikin-based simulation session do not differ significantly (*P*=.53).

At the end of the study, a preference survey was sent to the participants to evaluate VR as a learning modality. The outcome of this survey is shown in Figure 8. More than 65% of the participants agreed or strongly agreed that they would prefer VR-based serious game–based training instead of classroom-based lectures before manikin-based simulation sessions. The survey also revealed that more than 80% of the participants agreed or strongly agreed that VR-based training is more effective for them in terms of teaching CRM skills. More than 70% of the participants agreed or strongly agreed that VR-based training also increased their level of self-confidence during the manikin-based simulation scenario. More than 90% of the participants enjoyed participating VR-based gaming.

Figure 8. Results of the preference survey.



Discussion

Principal Results

It has been investigated whether the use of serious gaming modules could replace lecture-based sessions that are mostly organized prior to medical simulation sessions. Several studies have compared serious games with lecture-based sessions in terms of providing knowledge to the trainees [10,30,34]. Several studies have revealed that learning outcomes in the serious gaming groups were significantly better than those in the lecture groups [10,26,30]. Depending on our results, the increase in the posttest scores compared to that in the pretest scores was significant in both VR group (*P*=.02) and in group C (*P*=.002). A significant difference was found in the posttest scores between the 2 groups, and the scores of group C were significantly higher than those of the VR group (*P*=.01). A significant difference was found between the technical scores during the manikin-based simulation session between the 2 groups, and the scores of group C were higher than those of the VR group (*P*=.03). CRM scores during the manikin-based simulation session were not significantly different between the 2 groups (*P*=.23): the mean score of the VR group was 14.45 (SD 1.23), whereas that of group C was 11.33 (SD 5.37). As the maximum achievable CRM score was 30, both groups had low CRM scores, indicating that participants may require extra additional training to improve their CRM performances.

The total score of manikin-based simulation session was considered the main performance indicator of the study for measuring the participants' learning outcome. The VR group's total scores during the manikin-based simulation session ranged from 57 to 76.5 (mean 68.25, SD 8.81), while those of group C ranged from 64 to 85 (mean 71.53, SD 9.89). According to the statistical analysis of the 2 groups' performances, the total scores during the manikin-based simulation session did not differ significantly (*P*=.53).

Comparison With Prior Work

The advantages of using serious gaming as an additional training modality for simulation-based education in health care have been revealed in several studies [6,9,10,34,35]. As CPR performances of trainees deteriorate after a certain time, refresher training is required to maintain knowledge [36]. It has been shown that VR-based serious gaming for ALS is an adequate method to sustain knowledge [36,37]. Serious game–based ALS training has the potential to prevent deterioration of knowledge between updates due to its potential to be used anytime or anywhere [36]. However, for skills training, there is still the requirement to take part in simulation-based ALS training at regular intervals to maintain motor skills. A unique feature of the VR-based serious gaming module, which has been developed for this study, is that the serious game automatically scores CRM skills of the trainees apart from technical scores. When serious gaming modules for ALS training available on the market are compared with the module developed for this study, the available serious gaming modules on the market are not capable of evaluating nontechnical skills in addition to technical skills.

Limitations

The first limitation was that only limited gameplay time for the ALS serios gaming module could be given to the VR group participants due to the busy schedule of the training center. The second limitation was that only the heads of the avatars could be displayed during the game, as wireless VR headsets available on the market can only provide limited processing power and memory capacity. The third limitation of the study was the limited number of participants. The fourth limitation was limited generalizability of our results due to this being a single-center study and recruiting only 1 type of participants.

Conclusions

After comparing posttest and pretest outcomes, all participants improved their knowledge, but the posttest scores of group C were higher than those of the VR group. Both groups' overall performances in the manikin-based simulation session did not differ significantly. The preference survey reveals that the majority of the participants would prefer a VR-based ALS serious gaming module instead of lecture-based education. The benefits of using a VR-based serious gaming module are the scalability of trainees' performances and its flexibility to be used anywhere and anytime by the users. Further studies are required to reveal the learning outcomes of VR-based ALS serious gaming. Future studies could further reveal whether the performance of the VR group may improve if more time were given for users to interact with the VR-based serious game.

Acknowledgments

The authors would also like to thank biomedical support team of Center of Advanced Simulation and Education of Acibadem Mehmet Ali Aydinlar University for their valuable support during this study. This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

The data sets generated during or analyzed during this study are available from the corresponding author on request.

Authors' Contributions

MEA was responsible for study conceptualization, methodology, and resources and drafting, reviewing, and editing the manuscript. AEÖ was responsible for the software and methodology. DK was responsible for study conceptualization, methodology, and reviewing and editing the manuscript. TU was responsible for the study methodology and data collection. Abstract

Background: Articulation disorder decreases the clarity of language and causes a decrease in children's learning and social ability. The demand for non–face-to-face treatment is increasing owing to the limited number of therapists and geographical or economic constraints. Non–face-to-face speech therapy programs using serious games have been proposed as an alternative.

Objective: The aim of this study is to investigate the efficacy of home therapy on logopedic and phoniatric abilities in children with articulation disorder using the Smart Speech game interface.

Methods: This study is a prospective single-arm clinical trial. Children with articulation disorders, whose Urimal Test of Articulation and Phonology (U-TAP) was –2 SDs or less and the Receptive and Expressive Vocabulary Test score was –1 SD or more, were enrolled. A preliminary evaluation (E0) was conducted to check whether the children had articulation disorders, and for the next 4 weeks, they lived their usual lifestyle without other treatments. Prior to the beginning of the training, a pre-evaluation (E1) was performed, and the children trained at home for ≥30 minutes per day, ≥5 times a week, over 4 weeks (a total of 20 sessions). The Smart Speech program comprised oral exercise training, breathing training, and speech training; the difficulty and type of the training were configured differently according to the participants' articulation error, exercise, and vocal ability. After the training, postevaluation (E2) was performed using the same method. Finally, 8 weeks later, postevaluation (E3) was performed as a follow-up. A voice evaluation included parameters such as maximum phonation time (MPT), fundamental frequency (F_0), jitter, peak air pressure (relative average perturbation), pitch, intensity, and voice onset time. Articulation parameters included a percentage of correct consonants (PCC; U-TAP word-unit PCC, U-TAP sentence-unit PCC, and three-position articulation test) and alternate motion evaluation (diadochokinesis, DDK). Data obtained during each evaluation (E1-E2-E3) were compared.

Results: A total of 13 children with articulation disorders aged 4-10 years were enrolled in the study. In voice parameters, MPT, jitter, and pitch showed significant changes in repeated-measures ANOVA. However, only MPT showed significant changes during E1-E2 (P=.007) and E1-E3 (P=.004) in post hoc tests. Other voice parameters did not show significant changes. In articulation parameters, U-TAP, three-position articulation test (TA), and DDK showed significant changes in repeated-measures ANOVA. In post hoc tests, U-TAP (word, sentence) and TA showed significant changes during E1-E2 (P=.003, .04, and .01) and E1-E3 (P=.001, .03, and .003), and DDK showed significant changes during E1-E2 only (P=.03).

Conclusions: Home-based serious games can be considered an alternative treatment method to improve language function.

articulation disorder; home-based therapy; serious game; children; speech; voice

Introduction

Articulation disorder is a condition characterized by difficulties in producing speech sounds due to a structural abnormality or a neurological or auditory cause. Among children aged 3-11 years, approximately 75% show an articulation problem that demands treatment [1]. Speech and language disorders reduce children's academic performance and can cause inequality in social and job opportunities in adulthood [2]. Early intervention in children with speech disorders can prevent several problems that may arise later. Effective speech therapy requires treatment sessions to be individualized, frequent, and intensive [3].

The goal of the treatment of articulation disorder is to train the patient to maximize verbal clarity in articulation to ensure an adequate understanding by the listener to increase the efficiency of the function of mutual communication, which would reinforce motivation toward linguistic expressions [4].

Conventionally, treating articulation disorder involves 2 main approaches: the phonetic approach, which focuses on the physiological aspects of the articulation problem, and the phonological approach, in which the treatment focuses on the linguistic aspects of the problem. The phonetic approach includes the phonetic placement method, sensorimotor training, paired-stimuli technique, motor skill learning, and biofeedback technique. The phonological approach to speech therapy includes various methods, such as the phonemic contrast method, cycle training, and Metaphon therapy. The critical point for children with articulation disorders is a suitable early diagnosis and interventions by specialists [5]. Prior to the treatment of articulation disorder, the clinician conducts assessments of voice and articulation to obtain data from the children. The most commonly used parameters for voice evaluation include maximum phonation time (MPT), frequency (F_0), jitter, relative average perturbation (RAP), pitch, intensity, and voice onset time (VOT). Moreover, commonly used parameters for articulation include percentage of correct consonants (PCC) regarding Urimal Test of Articulation and Phonology (U-TAP) and TA and the diadochokinesis (DDK) rate [6]. In principle, speech therapy is generally performed in face-to-face situations; however, the mode of delivery can vary depending on the situation [7]. Non–face-to-face speech therapy was initially proposed as an alternative method in countries with huge lands, such as the United States and Australia, even before the pandemic. In fact, studies have shown that this method can be effective in treating patients with neuro-lingual disorders, such as dysarthria and apraxia [8].

A computer-assisted home therapy has several advantages. It can offer personalized treatment to each patient, increase accessibility for residents in far-flung regions, and provide intensive training and autonomy, which is impossible when using conventional programs [9]. This could lead to increased treatment effects. A domestic study has found that applying non–face-to-face therapy to children with speech disorders who show articulation errors improved consonant accuracy of the target phoneme [10].

The definition of a functional game varies; nonetheless, it is generally known as a type of game to achieve a goal other than play using the same "motivational effect to cause voluntary participation," "fun," and "immersion" as in any game [11]. Smart Speech (Humanopia Co) is a functional game program for vocalization and articulation training designed to assist logopedics. The program allows repetitive and intensive treatments by way of the installed games. Jo et al [12] have treated adult patients with dysarthria using Smart Speech and observed significant positive changes in the following acoustic variables: pitch, intensity, jitter, RAP, and MPT. Additionally, they reported significantly increased scores for word-unit consonant accuracy, articulation accuracy, and sentence-unit consonant accuracy [12]. Currently, several studies have evaluated the efficacy for adults; however, only a few studies have assessed it for children.

This study investigated the efficacy of home therapy on logopedic and phoniatric abilities in children with articulation disorders using the Smart Speech game interface for speech therapy.

Methods

Ethical Considerations

This prospective single-arm clinical trial was registered and approved by the institutional review board of Jeonbuk National University Hospital (2019-02-026-015).

Participants

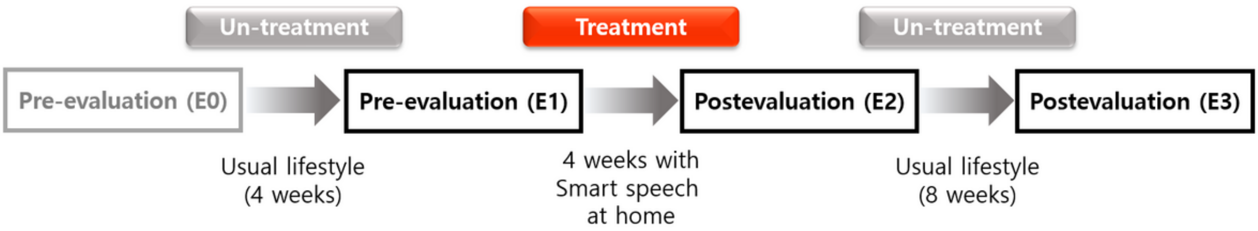
The study participants included children with articulation disorder who visited our institution's Department of Rehabilitation Medicine between September 2019 and January 2021. The participants were recruited via an advertisement. The inclusion criteria were as follows: (1) children aged 4 years or older and 12 years or younger; (2) U-TAP score of ≤–2 SD; (3) Receptive and Expressive Vocabulary Test score of ≥–1 SD; and (4) children showing no severe internal pathology without treatment. Before proceeding with the experiment, the participants and their guardians were provided with a full explanation regarding the purpose of the study, procedure, required time, and compensation, and only those who consented to participate were included in the experiment. Since it was a study involving children, signed informed consent was obtained from their guardians.

Study Protocol

Overview

This study was based on an exploratory design with the following phases: pre-evaluation 1 (E0), pre-evaluation 2 (E1), postevaluation 1 (E2), and postevaluation 2 (E3), in the given order (Figure 1).

Figure 1. Study protocol.



Pre-Evaluation 1 (E0)

Considering that the study participants were children, we conducted a preliminary evaluation (E0) to adapt the evaluation method before measuring the baseline (E1). The participants' voice, articulation, and alternate motion were assessed in the E0 phase.

Pre-Evaluation 2 (E1)

Before treatment using the Smart Speech program, following phase E0 and 4 weeks of usual lifestyle, the same variables as in E0 were assessed in the pre-evaluation 2 (E1) phase within 3 days.

Treatment and Postevaluation 1 (E2)

After the E1 phase and within 1 week, the same participants were provided with a laptop with the Smart Speech program and a microphone and were guided to perform the program at home for ≥30 min per day, ≥5 times a week, for the 4-week period (a total of 20 sessions). In addition, the participants were instructed to record the time of training on the set log during the 4-week period and have telephone counseling with the speech therapist once a week. After the treatment and within 3 days, postevaluation 1 (E2) was performed.

Postevaluation 2 (E3)

After E2 and 8 weeks of usual lifestyle, the same variables were assessed in postevaluation 2 (E3) to verify whether the changes induced by the treatment had been retained.

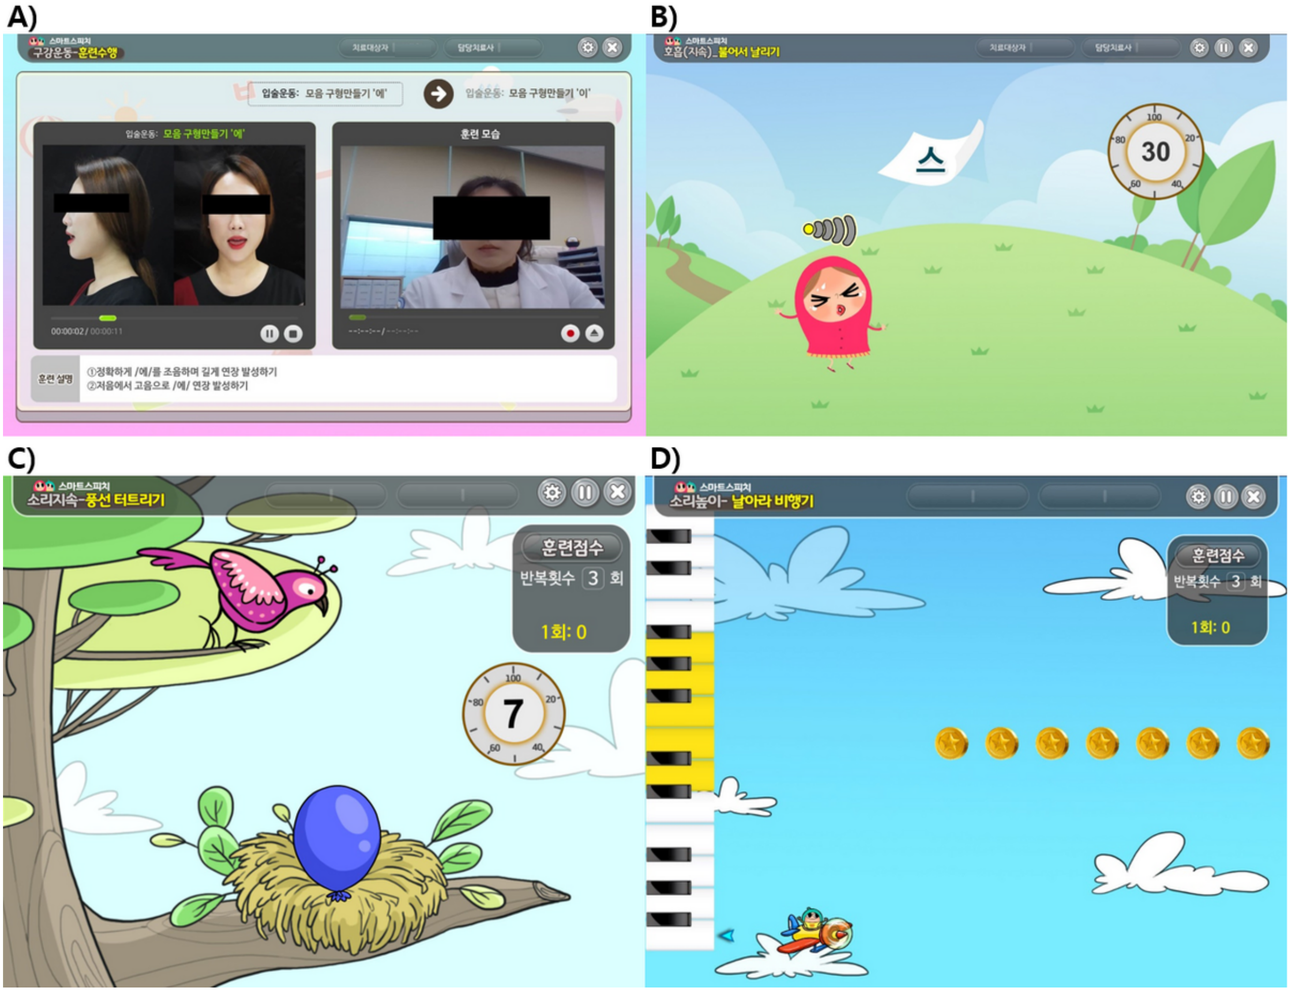
Intervention Procedures

The Smart Speech is a serious game program for vocalization and articulation training designed to assist logopedics. Structured games relate to oral exercise, breathing, vocalization, and articulation training. The game for vocalization training is subcategorized into sound duration, intensity, pitch, syllable, and word training. Before the intervention, the guardians are given the necessary instruction and training. Each session is designed to provide oral exercises, breathing, vocalization, word, and syllable training in the given order.

Oral Exercise Training

The training consisted of lip, tongue, and chin exercises. In addition, the participants were instructed to watch a recorded video and imitate what they saw while checking how they appeared on the screen. According to the participants' unique articulation errors and their ability to perform oral exercises, we could select the target of intensive training (Figure 2A).

Figure 2. Training program in Smart Speech. Training program in the Smart Speech (Humanopia Co, Korea). (A) In oral exercise training, participants are guided to follow the example on the left screen. They can check their appearance on the right screen and compare the differences with examples. (B) To improve breathing, participants keep breathing for a few seconds continuously so that the paper on the screen does not fall on the floor. (C) In sound duration training, participants can blow up balloons or blow out candles by maintaining a long vocalization in one breath. (D) Participants continued vocalization with the given pitch to fly the birds or airplanes seen on the screen in sound pitch training.



Breathing Training

The difficulty level was divided into easy, moderate, and difficult, and the duration could be selected. The training was performed by setting the difficulty level and duration based on the participants' articulation errors and vocalization ability (Figure 2B).

Speech Training

Duration

Increasing the MPT duration was used to train long vocalization maintenance in a single breath. As the duration and number of repetitions could be set, the difficulty level of the training was adjusted based on the participants' individual abilities (Figure 2C).

Intensity

We could train participants to maintain a suitable voice intensity for a set time by controlling the intensity. As the duration and number of repetitions could be set, the difficulty level of the training was adjusted based on the participants' individual abilities.

Pitch

Controlling the pitch was used to train the ability to maintain a suitable voice pitch for a set time. As the duration and number of repetitions could be set, the difficulty level of the training was adjusted based on the participants' individual abilities (Figure 2D).

Word-Unit Training

In the word-unit training, the user selected a target word to initiate the program and then could set the duration and number of repetitions. The training was designed to allow words containing the target phoneme as the initial, middle, or final consonant to be selected according to the unique articulation errors exhibited by the participants.

Syllable Unit Training

In the syllable unit training, the constituent programs allowed the vocalization of a sound with one or more syllables with consonants rather than the simple vocalization of vowels. The programs could be selected according to the phonetic and articulatory abilities of the participants.

Outcome Measurement

Instruments

The voice data were recorded at the Department of Rehabilitation Medicine Language Therapy Laboratory, where external noise was maximally prevented. The recording was performed using the SM48 microphone (Shure). The child was guided to hold the microphone at an approximately 10 cm distance from the mouth and to produce the voice in a relaxed state. For the recording and analysis of voice, the Computerized Speech Lab (Model 4150, CSL, Kay Elemetrics, Co) was used. The sample ratio for the voice files was as follows: CSL 11,025 Hz; multidimensional voice program, 50,000 Hz; voice range profile, 44,100 Hz; and real-time pitch, 50,000 Hz.

Intervention Environments

Since this study is a home therapy using serious games, treatment was conducted at home in the presence of guardians. Outcome measure was assessed at Jeonbuk National University Hospital by a skilled speech therapist with >3 years of clinical experience.

Voice Parameters

MPT (seconds) and F0 (Hz)

To measure the MPT using the real-time pitch module, the participants were instructed to vocalize/a/ for the longest possible duration. The F_0 was measured at the 3-second point from the initial vocalization along the entire stretch of the voice sample.

Jitter (%) and RAP (%)

Using the multidimensional voice program module, the participants were instructed to vocalize/a/ for ≥3 seconds three times to obtain the mean of triplicate measurements.

Pitch (Hz) and Intensity (dB)

To measure the pitch range using the voice range profile module, the participants were instructed to vocalize/a/ from the lowest range to the highest range he or she could make and, then, vocalize the same sound from the highest range to the lowest range. In addition, the participants were instructed to vocalize/a/ from the highest intensity of voice to the lowest intensity, while the intensity range was measured.

VOT

The participants were provided with a set of picture cards corresponding to the word list containing words with a plosive as the initial consonant (/p/, /p^h/, /p'/, /t/, /t^h/, /t'/, /k/, /k^h/, /k'/). Subsequently, they were instructed to look at the card to say or read the word. The word list contained the words used in a study by Gregory and Lee [13] on the development of Korean plosive sounds.

Articulation Parameters

U-TAP

The U-TAP was used to estimate the articulation accuracy of 43 consonants and 10 vowels at initial, middle, and final positions in words. The word picture cards were used, whereby the participants were instructed to look at the picture card and articulate the word. The sentence-picture cards were used, followed by the articulation of the sentence by the rater, whereby the participants were instructed to repeat after the rater.

Three-Position Articulation Test (TA)

The TA was used so that the participants could articulate words containing 2-4 syllables with 19 target consonants at the initial, middle, and final positions in words. The picture cards were presented, and the participants were instructed to articulate the respective words. In analyzing the U-TAP and TA results, the PCC was applied for consonant accuracy using the following equation for PCC calculation:

PCC (%)=the number of correctly articulated consonants/the total number of target consonants×100.

The PCC is widely used as an indicator of the level of articulation disorder because consonants generally reflect a multitude of articulation errors.

Alternate Motion Evaluation (DDK)

The DDK rate allows for the evaluation of the oral cavity structure and function and the oral exercise ability. After one or two demonstrations by the rater, the participants were instructed to articulate /p /, /t /, and /k / to determine the alternating motion rate and /p t k / for the sequential motion rate (SMR) within 5 seconds, as rapidly and regularly as possible. The number of syllables articulated per second was estimated.

Statistical Analysis

Evaluation results at each phase were comparatively analyzed to compare the treatment period with the nontreatment period of the functional game–based home therapy and verify the effects' retention. All voice data were analyzed using IBM SPSS Statistics (version 24.0; IBM Corp). Repeated-measures ANOVA (RM-ANOVA) was used to compare components of the voice and articulation parameters. The post hoc test was performed as planned with Bonferroni correction at $P<.05$ for variables showing significant values. The significance level was set at .05 in all analyses.

Results

A total of 13 children (9 males and 4 females) were investigated in this study. The mean age of the participants was 6.94 (SD 2.22) years, with their ages ranging from 4 years to 10 years and 5 months (Table 1).

Table 1. Demographic data of the participants.

Participant No.	Age (years)	Sex	U-TAP[a] (%)	REVT[b] receptive	REVT expressive
1	7	Male	93.02	106	98
2	6	Male	90.7	68	69
3	8	Male	93.02	97	96
4	7	Male	93.02	82	91
5	6	Male	93.02	73	69
6	4	Male	60.47	44	61
7	4	Male	48.84	59	47
8	7	Female	76.74	82	78
9	4	Male	67.44	61	48
10	10	Female	83.72	130	149
11	4	Male	67.44	54	60
12	4	Female	86.05	64	61
13	4	Female	79.07	36	47

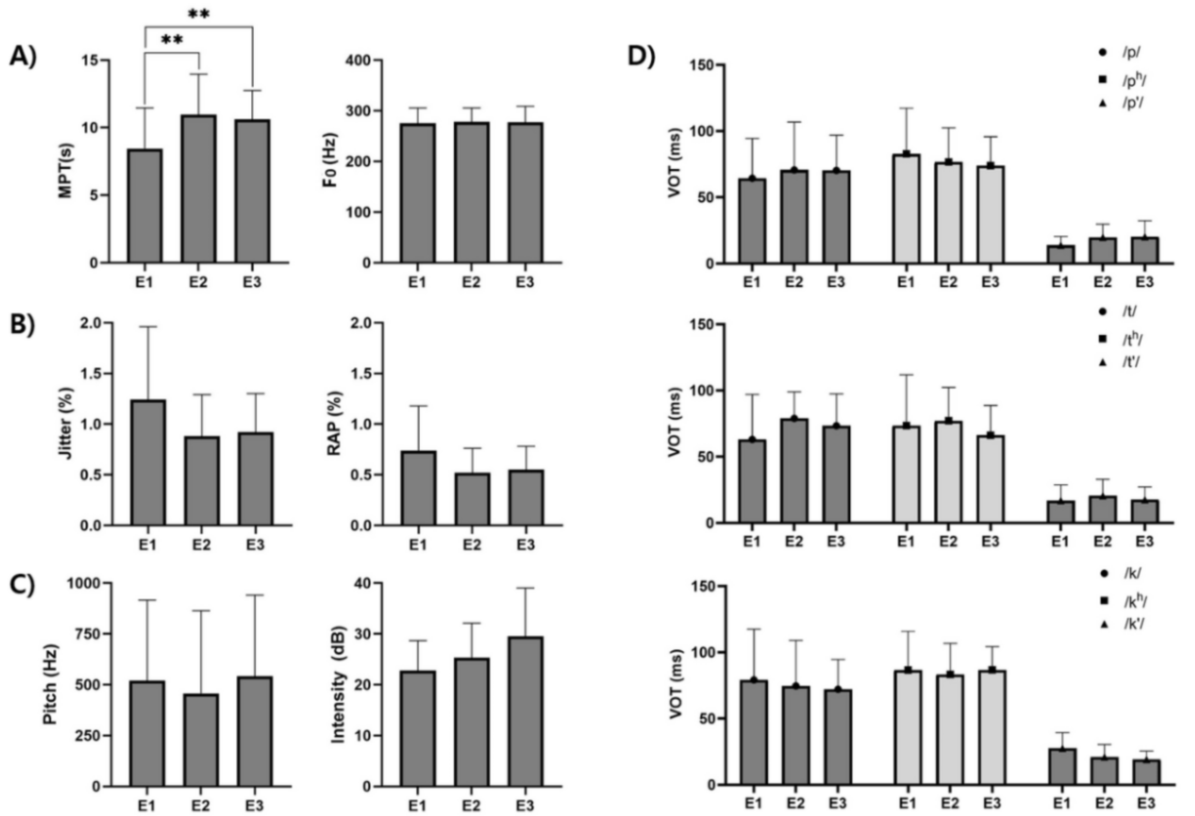
[a]U-TAP: Urimal Test of Articulation and Phonology.

[b]REVT: Receptive and Expressive Vocabulary Test.

Voice Parameters

A comparison between the treatment and nontreatment periods of functional game–based home therapy indicated a significant effect of the treatment in voice parameters (Figure 3).

Figure 3. Changes in voice parameters from pre to posttraining. (A) MPT and F0, (B) jitter and RAP, (C) pitch and intensity, and (D) VOT. Data are shown as mean (SD). Repeated-measures ANOVA (RM-ANOVA) with Bonferroni tests was used for statistical analysis. *P<.05, **P<.01. E1: pre-evaluation 1; E2: postevaluation 1; E3: postevaluation 2; F0: frequency; MPT: maximum phonation time; RAP: relative average perturbation; VOT: voice onset time.



MPT

The MPT showed significant variations across the 3 time points (E1-E2-E3, $P<.05$). In post hoc test, MPT showed differences between phases E1 (mean 8.44, SD 3.02 seconds) and E2 (mean 10.96, SD 2.99 seconds), indicating a significant increase after treatment. In addition, the difference of MPT between phases E1 and E3 (mean 10.62, SD 2.12 seconds) was significant to indicate that the treatment effects had been maintained until 2 months after the training ($P<.05$; Table 2).

Table 2. Post hoc analysis of outcome measures.

Variation	Overall Sig Diff[a]	Post hoc[b]		
		△(E1[c]-E2[d])	△(E1-E3[e])	△(E2-E3)
MPT[f]	.001	0.007	0.004	1.000
U-TAP[g] word	<.001	0.003	0.001	1.000
U-TAP sentence	.008	0.037	0.026	1.000
TA[h]	<.001	0.010	0.003	1.000
SMR[i]	.013	0.034	0.061	0.204

[a]Sig Diff: significant difference; analyzed by repeated-measures ANOVA.

[b]Post hoc: Bonferroni test ($P<.05$).

[c]E1: pre-evaluation 1.

[d]E2: postevaluation 1.

[e]E3: postevaluation 2.

[f]MPT: maximum phonation time.

[g]U-TAP: Urimal Test of Articulation and Phonology.

[h]TA: three-position articulation test.

[i]SMR: sequential motion rate.

Jitter and RAP

The jitter and RAP showed significant variations in RM-ANOVA were noted across the time points ($P<.05$). However, the post hoc test did not indicate significant values for jitter and RAP.

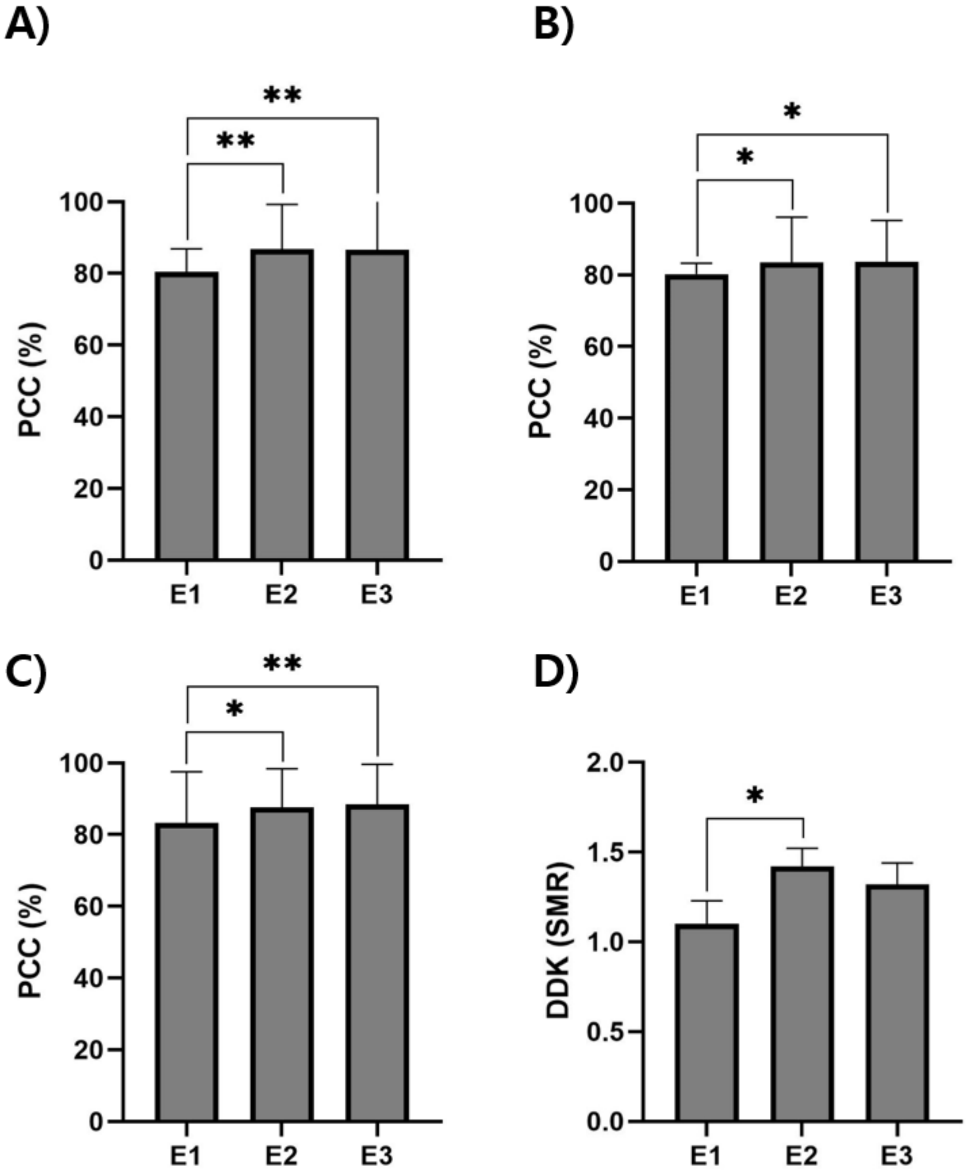
Other Parameters (F0, Pitch, Intensity, and VOT)

For other materials (F_0, Pitch, Intensity, and VOT), no significant difference was found between the time points.

Articulation Parameters

The functional game–based home therapy achieved a significant effect on articulation parameters (Figure 4).

Figure 4. Changes in articulation parameters from pre- to post-training. (A) U-TAP word, (B) U-TAP sentence, (C) TA, and (D) frequency of SMR /p t k / of DDK. Data are shown as mean (SD). Repeated-measures ANOVA (RM-ANOVA) with Bonferroni tests was used for statistical analysis. **P*<.05, ***P*<.01. DDK: diadochokinesis; E1: pre-evaluation 1; E2: postevaluation 1; E3: postevaluation 2; PCC: percentage of correct consonants; SMR: sequential motion rate (/p t k /); TA: three-position articulation test; U-TAP: Urimal Test of Articulation and Phonology.



U-TAP

The subcategories U-TAP word-unit PCC and sentence-unit PCC showed significant variations in analysis across the 3 time points (*P*<.05). The post hoc test revealed differences between phases E1 (word: mean 80.47, SD 6.38 per sentence; mean 80.23%, SD 3.07%) and E2 (word: mean 86.74, SD 12.55 per sentence; mean 83.49%, SD 12.62%), indicating a significant increase in the U-TAP after treatment. In addition, since there were significant differences between phases E1 and E3 (word: mean 86.51, SD 14.16 per sentence; mean 83.72%, SD 11.50%) and no significant differences between phases E2 and E3, it can be assumed that the treatment effects had been maintained until 2 months after the training (*P*<.05).

Three-Position Articulation Test (TA)

The subcategories TA PCC showed significant variations in the RM-ANOVA across the time points (*P*<.05). In the post hoc test, TA showed differences between phases E1 (mean 83.18%, SD 14.38%) and E2 (mean 87.50%, SD 10.89%), representing a significant effectiveness after treatment. In addition, as there were significant differences between phases E1 and E3 (mean 88.41%, SD 11.21%) and no significant differences between phases E2 and E3, it can be assumed that representing effectiveness until 2 months after the training (*P*<.05).

Alternate Motion Evaluation (DDK)

The SMR /p t k / of DDK showed significant variations across the time points (*P*<.05). In post hoc test, SMR showed significant differences between phases E1 (mean 1.1, SD 0.14) and E2 (mean 1.42, SD 0.1), indicating improvement of the articulation frequency per second for /p t k / after treatment (*P*<.05). However, no significant changes were found between phases E1 and E3 and phases E2 and E3 in the post hoc test.

Discussion

Overview

This study conducted a 4-week intervention applying the Smart Speech program consisting of functional games for logopedics to children with articulation disorder. The results of the speech program conducted in this study showed significant changes in both voice and articulation parameters. In voice parameters, MPT, jitter, and pitch showed significant changes in RM-ANOVA. However, post hoc tests showed significant changes between phases E1 and E2 and phases E1 and E3 in the MPT only. Other voice parameters did not show significant differences. In articulation parameters, U-TAP, TA, and DDK showed significant changes in RM-ANOVA. In post hoc tests, U-TAP and TA revealed significant changes between phases E1 and E2 and phases E1 and E3; however, DDK showed significant changes during E1-E2 only.

Several studies have confirmed the effectiveness of conventional treatment methods. However, there is a limitation in that children have to endure time and geographical restrictions for face-to-face treatment [14]. Although the optimum frequency of treatment remains unclear, Williams [15] has suggested that children with articulation disorders may require 30-40 sessions of treatment, depending on the severity and selected treatment method. Long-term intensive training may be effective in children with joint problems; however, economic or geographical constraints may make it difficult to provide treatment adequately [16]. In addition, the stress level in children could increase as the period of intervention increases; hence, a system without time constraints that minimizes training stress in children and allows a guardian's presence during training should be developed. The importance of home therapy with a parent has been emphasized in the study conducted by Bowen (1998) [17], which further described the available treatment techniques for therapists. The home-based serious game for school-age children enables more flexible scheduling while providing shorter but more frequent intervention sessions, thus, maximizing the usefulness of non–face-to-face treatment.

Computer-assisted logopedics would be advantageous in increasing the treatment frequency even if the treatment is not performed in a direct face-to-face session with a clinician. A computer-assisted home therapy could increase the treatment effects by providing personalized treatment to each patient allowing accessibility for residents living in far regions from the facility or center and, most importantly, providing intensive training and the autonomy that is not possible in conventional programs. Moreover, a familiar and natural environment could ensure psychological stability in children to maximize the treatment effects [18]. Logopedics using a computer program allows for a therapeutic approach at the desired level. As the participants can complete the task the clinician assigned without increasing the time of direct face-to-face treatment, the desired effects can be achieved more rapidly. Moreover, visual representations are provided, and the treatment effects and efficiency of the conventional programs can be improved. Voluntary training is essential in maximizing the treatment effects; however, it may not reach an adequate level because of physical or mental fatigue or lack of volition [19]. In contrast, functional games can motivate children through the added element of fun alongside the advantages of computer-assisted logopedics. Thus, a diversity of functional games for logopedics have been developed to allow the potentially tedious training to be conducted with enhanced focus and fun. The "Vox Games" in Brazil is a logopedics program for children's vocalization and speech training. "Dr. Speech" in the US offers logopedic-related games based on vocalization, including pitch and intensity. In addition, in Spain, Saz et al [20] have developed a logopedic program for vocalization and articulation training called "Comunica." In contrast, in Portugal, Grossinho et al [21] have developed "Visual Speech," a functional game for children with articulation disorder. In the Netherlands, Ganzeboom et al [22] had recently applied the "Treasure Hunters," a functional game of logopedics, in 5 patients with Parkinson disease or stroke and reported its positive effects on speech intelligibility. Hair et al [23] have developed the "Apraxia World," a game of logopedics for children with difficulty in speech production, and investigated the preference and satisfaction with using the game in 14 children with articulation disorder (4-12 years). Therefore, various speech therapy games have been developed based on each country's language, and "Smart Speech" is a serious game based on the Korean language.

Recently, various functional games have been applied in logopedics, whereas numerous computer-assisted logopedics for articulation disorder have been developed and tested; however, there is a comparative lack of studies investigating the clinical effects. Thus, this study applied a functional game–based home therapy to children with articulation disorder and, through preintervention and postintervention tests of voice, articulation, and alternate motion, investigated whether the therapy had positive effects on phonation ability and whether positive changes were maintained. In voice parameters, only MPT showed significant changes during E1-E2 and E1-E3 in post hoc study. Other voice parameters did not show significant changes. The ability to maintain vocalization is associated with the expiratory pressure in the respiratory organs. The MPT is a task of speech-motor evaluation that can predict the level of coordination among the muscles related to respiration, vocalization, articulation, and resonance [24]. Thus, the MPT results in this study indicated an increased ability of coordination in breathing and vocalization mechanisms by breathing and vocalization training through functional games. Breathing training of "Smart Speech" focused on expiration, and therefore, it positively affected the increase in phonation time. The acoustic analysis as voice parameters could be useful for identifying improvement in patients with cerebral palsy who showed dysphonia or dysarthria. For the articulation parameters, U-TAP and TA showed significant changes during E1-E2 and E1-E3, whereas DDK showed significant changes during E1-E2 only. It suggests that the effects of oral exercise and articulation training increased the PCC and DDK. In the "Smart Speech" program, oral exercise and speech training had many components that may have improved articulation rather than vocalization. It can be assumed that these factors made the following results. This coincided with the findings of Ahn [25], who reported the positive effect of oral exercise training on consonant accuracy, and with those of Lee et al [26], who applied an AR game–based word and sentence training to improve the word and sentence articulation accuracy in children with articulation disorder. Further, the results agreed with the findings of Lohman-Hawk [27], who reported that the DDK rate in patients with articulation disorder increased by 50% through treatment involving oral exercise training. Our findings suggested that functional game–based home therapy could prove useful in planning logopedic interventions in clinical practice. When children used Smart Speech programs at home, the guardians ensured proper treatment compliance. A clinical researcher contacted the guardian by telephone once a week to monitor the home-based therapy. It should be noted, however, that patients and guardians would be faced with difficulties in planning and conducting suitable training, and the participation and counseling of clinicians will be required.

Principal Results

In this study, children showed significant therapeutic effects in most articulatory indicators but did not show significant therapeutic effects other than MPT in negative indicators. A previous study on the VOT of children with functional articulation disorders has reported that the change in VOT according to the articulation position of plosives and vocalization type of children with functional articulation disorders was the same as that of ordinary children and that speech motor control skill was normally developed in the production of the plosives [28]. This suggests that speech problems in children with functional articulation disorders are more likely to occur owing to the decline of motor control of other articulation structures, compensation for speech motor control, and speech programming skills than in the upper laryngeal structure. The F_0 representing the frequency of vocal cords per second, the jitter representing vibration speed, and the shimmer representing vibration size are directly related to the anatomical structure of the larynx and can be affected by age or sex. This is more related to anatomical factors, and it is difficult to expect a significant therapeutic effect through training because it is less likely that children's articulation disorders will occur due to dysregulation of the upper and laryngeal structures [29]. The results of this study showed a correlation with previous studies and confirmed that the speech motor control or programming ability of articulation structures is likely to be sufficiently improved through a systematic home-based serious game. As the children who participated in this study did not have anatomical problems, it is highly possible that there was no problem with the tremor of the vocal cords. Except for 2 children, most participants showed initial evaluation for F_0 and jitter within the normal range. Thus, in this study, voice parameters may have shown no significant changes. Additionally, in the composition of the "Smart Speech" program, the treatment time of oral exercise and speech training was relatively longer than that of the breaking training, which would have affected the improvement of the articulation parameter.

Limitations

Our study had several limitations. First, the sample size was relatively small. The small sample size may have led to unstable results. Follow-up studies need to analyze a wider population. Second, this study was a single-arm, nonrandomized study. This study was designed as a randomized controlled trial, but it was difficult to set up sham groups because all guardians wanted treatment, and it was difficult to set up other home-based treatments to apply to control groups other than serious games. Therefore, the period of maintaining daily life without treatment was set as a control, and a single-arm design was adopted to assess and compare the period of home-based therapy as an experimental period. As there was no control group, follow-up studies, including the control group, are required to accurately verify the treatment effect. Third, the same treatment was performed regardless of the patient's baseline score, and there is a limitation in that selective treatment according to the patient's condition was not provided. Fourth, Children with a substantially wide range of age and severity were included in the study. In further studies, we need to narrow the scope of participants' age or seriousness of speech sound disorders. Fifth, In this study, we tried to analyze various indicators, but not all articulation parameters were measured due to limited time and human resources. In subsequent studies, we will perform as many standard assessments as possible and analyze the therapeutic effect in more detail by comparing initial and end time points. Finally, the follow-up period in this study was relatively short. Thus, further research is warranted to establish the long-term effectiveness of home-based serious games.

Conclusions

In conclusion, after applying a home-based serious game (Smart Speech) to children with articulation disorders, voice parameters showed improvement in MPT, and articulation parameters revealed improvement in all U-TAP, TA, and DDK. Therefore, home-based serious games are considered to be helpful in improving language function.

Abstract

Background: Virtual reality (VR) is a computer simulation technique that has been increasingly applied in pain management over the past 2 decades.

Objective: In this study, we used bibliometrics to explore the literature on VR and pain control, with the aim of identifying research progress and predicting future research hot spots.

Methods: We extracted literature on VR and pain control published between 2000 and 2022 from the Web of Science Core Collections and conducted bibliometric analyses. We analyzed the publication and citation trends in the past 2 decades, as well as publication and citation analyses of different countries, institutions, journals, and authors. For references, we conducted cocitation and burst analyses. For keywords, we conducted co-occurrence, clustering, timeline view, and citation burst analyses.

Results: Based on 1176 publications, we found that there was a continuous increase in publication and citation volumes, especially in the last 5 years. The United States was the most representative country, and the University of Washington was the most representative institution, with both having the most publications and citations. The most popular journal in this field was *Burns*, and Hoffman HG was the most productive author, leading many studies on patients with burn pain. The reference with the most citation burst was a study on the verification of new hardware in pain control. The keywords with the highest citation bursts related to various situations of pain such as “burn pain,” “wound care,” “low back pain,” and “phantom limb.”

Conclusions: VR has been applied in various clinical situations for pain management, among which burns and pediatric surgery have achieved satisfactory results. We infer that VR will be extended to more clinical pain situations in the future, such as pain control in wound care, low back pain, and phantom limb pain. New research hot spots will include the development of software and hardware to improve the immersive experience of VR for pain control. However, our work was based solely on English literature from the Web of Science database. For future studies, we recommend that researchers explore literature from multiple databases to enhance the scope of their research.

Introduction

Pain is an unpleasant sensory and emotional experience that can affect patients’ quality of life. Any form of harmful irritation has the potential to cause pain, and various medical procedures, including venipuncture and wound care, can result in temporary discomfort for patients. Moreover, chronic pain can have an even more substantial impact on individuals. It has been reported to affect more than 30% of people worldwide, and epidemiological studies have estimated that the prevalence of chronic pain is between 18% and 34.5% [1-3]. To a certain extent, continuous pain can adversely affect the patients’ family relationships and become the cause of both heavy social burden and economic burden [4-7]. The main clinical treatment for pain is medication, including paracetamol, opioids, etc. In addition, there are other interventions to relieve pain such as psychological interventions, acupuncture, massage, and spinal cord stimulation [8]. Because of the strong influence of psychological factors on pain perception, psychological intervention has become an important means of adjuvant drug treatment [9].

Virtual reality (VR) is an emerging technology in the psychological intervention for pain, which immerses users in a virtual 3D environment through a wearable screen [10]. In recent years, research has demonstrated that VR can effectively control pain by shifting attention [11]. Some researchers believe that VR influences memory, emotion, and attention, which can help alleviate pain [12]. Functional magnetic resonance imaging has provided evidence that VR can effectively reduce the activity of brain regions associated with pain [13], similar to the effects of opioids [14]. Due to its action mechanism, VR has shown significant efficacy in controlling acute pain and has been used in the management of pain during procedures such as burn wound care and acupuncture [15,16]. Additionally, VR has been applied to chronic pain management, where it creates a sense of presence in a new environment, improves mood, and diverts attention, ultimately reducing pain levels [17]. Chronic conditions such as chronic low back pain [18], chronic cervical pain [19], fibromyalgia [20], complex regional pain syndrome [21], and chronic neuropathic pain have also been targeted with VR-based interventions [22,23].

Despite the growing scientific literature on the use of VR in pain management, there is still a lack of studies on its development trends and hot spots, which can provide scientific guidance for researchers in this area. Bibliometrics is an analytical method that can generate a comprehensive view or quantitative parametric analysis of an entire research field or a specific scientific application area [24-26]. This study aimed to analyze the application of VR in the field of pain management in the past 2 decades using bibliometrics, to provide researchers with an overall research development trend and to help guide future research directions.

Methods

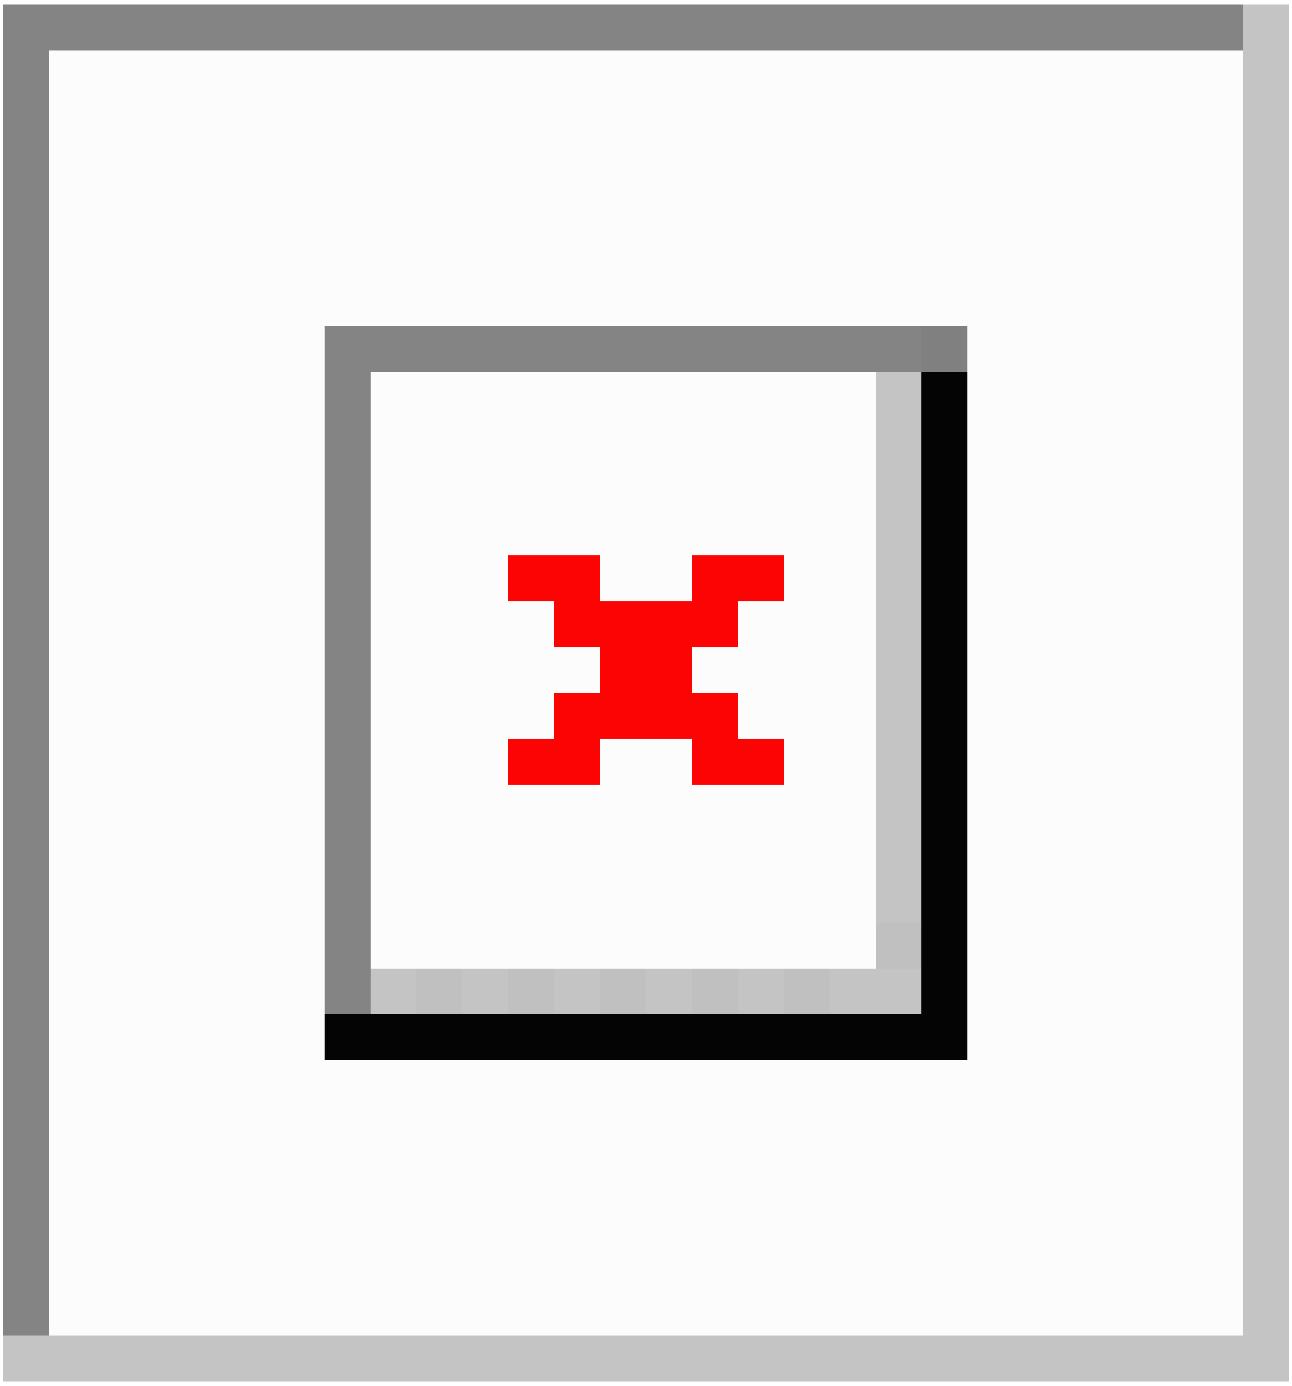
Search Strategy

We searched publications from the Web of Science Core Collection (WoSCC) for analysis. The search strategy was "((TS= (virtual reality)) AND ((TS=(pain)) OR TS= (painful)))." The search was conducted in April 2022.

Included and Excluded Criteria

This study included articles and reviews that were published from 2000 to 2022. The following were excluded: (1) non-English literature and (2) publications that are books, book chapters, meeting abstracts, letters, conference proceedings, editorial materials, etc. The screening process is shown in Figure 1.

Figure 1. The screening process of the selected literature in this study.



Data Export and Analysis

We obtained the information of these publications from the WoSCC through the above search strategy. CiteSpace (version 5.8.R3; Drexel University) and VOSviewer (version 1.6.11.0; Centre for Science and Technology Studies, Leiden University) were used for further data analysis. Quantitative and qualitative analyses were performed and presented in this study, including the following:

1. Annual trends of the publications and citations: these present the general trends in this field.
2. Publication and citation analyses of different countries and institutions: these aim to find the countries or institutions that have contributed more to this field and their partnerships. Researchers may choose to learn from or collaborate with them.
3. Publication and cocitation analyses of different journals: if a study published in journal A and another study published in journal B are both cited by a study published in journal C, then journal A and journal B are considered to have a cocitation relationship and the cocitation count is increased by 1. The definition also extends to the cocitation analysis of authors and references, which is described in further detail below. Journals with a higher number of publications and cocitations are considered as more important journals in the field. Researchers can pay attention to these journals to identify the research progress or publish their study in these journals in the future.

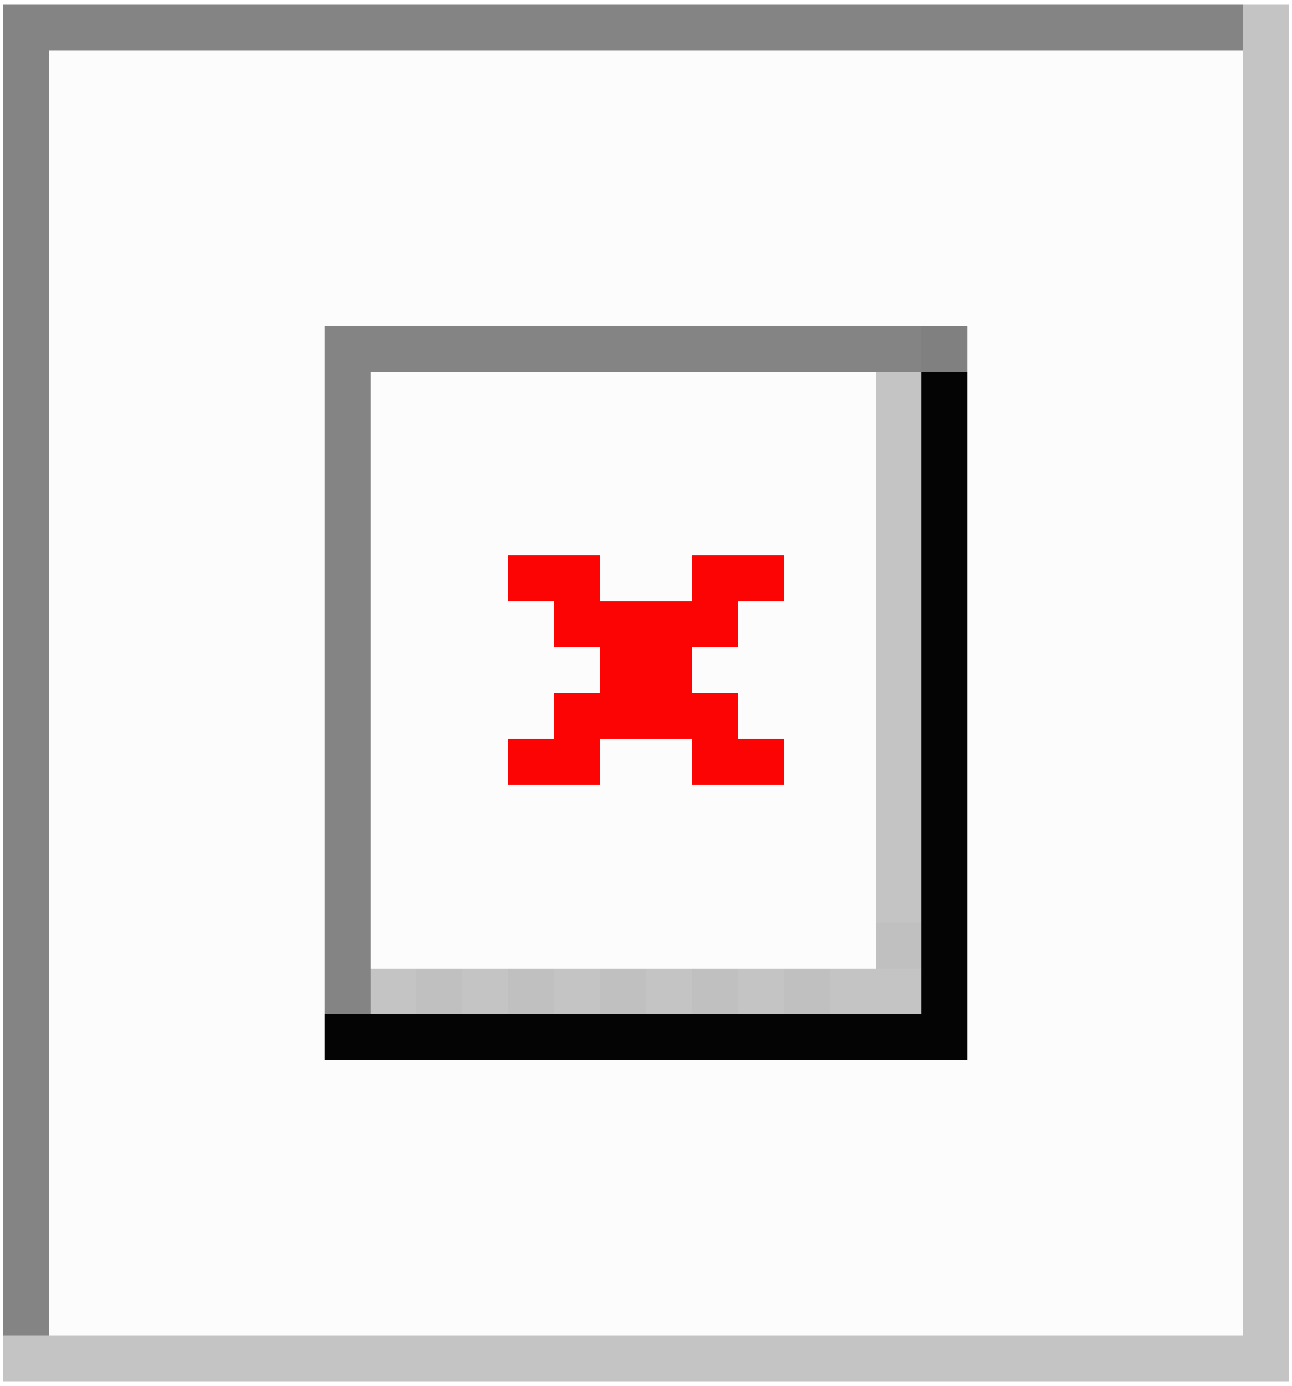
4. Publication and cocitation analyses of different authors: by identifying authors with a high volume of publications or cocitations, researchers can potentially connect with leading experts and stay informed about their research directions and progress.
5. Cocitation and citation burst analyses of references: references with a high number of cocitations can provide insights into the research hot spots of a field. These references are widely recognized and cited by authors in the field, indicating their relevance and significance within the research community. Researchers can use these references to identify key topics and focuses within the field. The citation burst analysis is an indication of the increase regarding researchers' attention to a reference over a given period of time, which is a very important indicator for identifying research hot spot trends.
6. Keywords analysis (co-occurrence, clustering, timeline view, and citation burst): we presented the keywords in the field based on co-occurrence and obtained the research hot spots in the field through the keywords that appear more frequently. Subsequently, those keywords were divided into several clusters, with similar keywords in each cluster, to capture the main research topics. By tracking these keywords through a timeline perspective, we gained a better understanding of the development and evolution in this field over time. Finally, by the analysis of citation bursts, we identified the research hot spots and trends in the field.

Results

Publication and Citation Trends

A total of 1528 publications were retrieved from the WoSCC. In all, 1176 publications were used for further analysis after excluding 41 non-English publications and 311 other publication types. Time trend analysis showed that from 2000 to 2021, the number of published papers increased from 3 to 234, which was statistically significant (2-tailed t_{22}=4.061, *P*=.001; Figure 2). The annual citation frequency had also increased from 3 times in 2000 to 5613 times in 2021, which indicated a similarly significant growth (2-tailed t_{22}=3.565, *P*=.002). In addition, publications and citations in the past 5 years showed a particularly rapidly growth, with an average annual increase of 42.75 papers and 1005.75 citations.

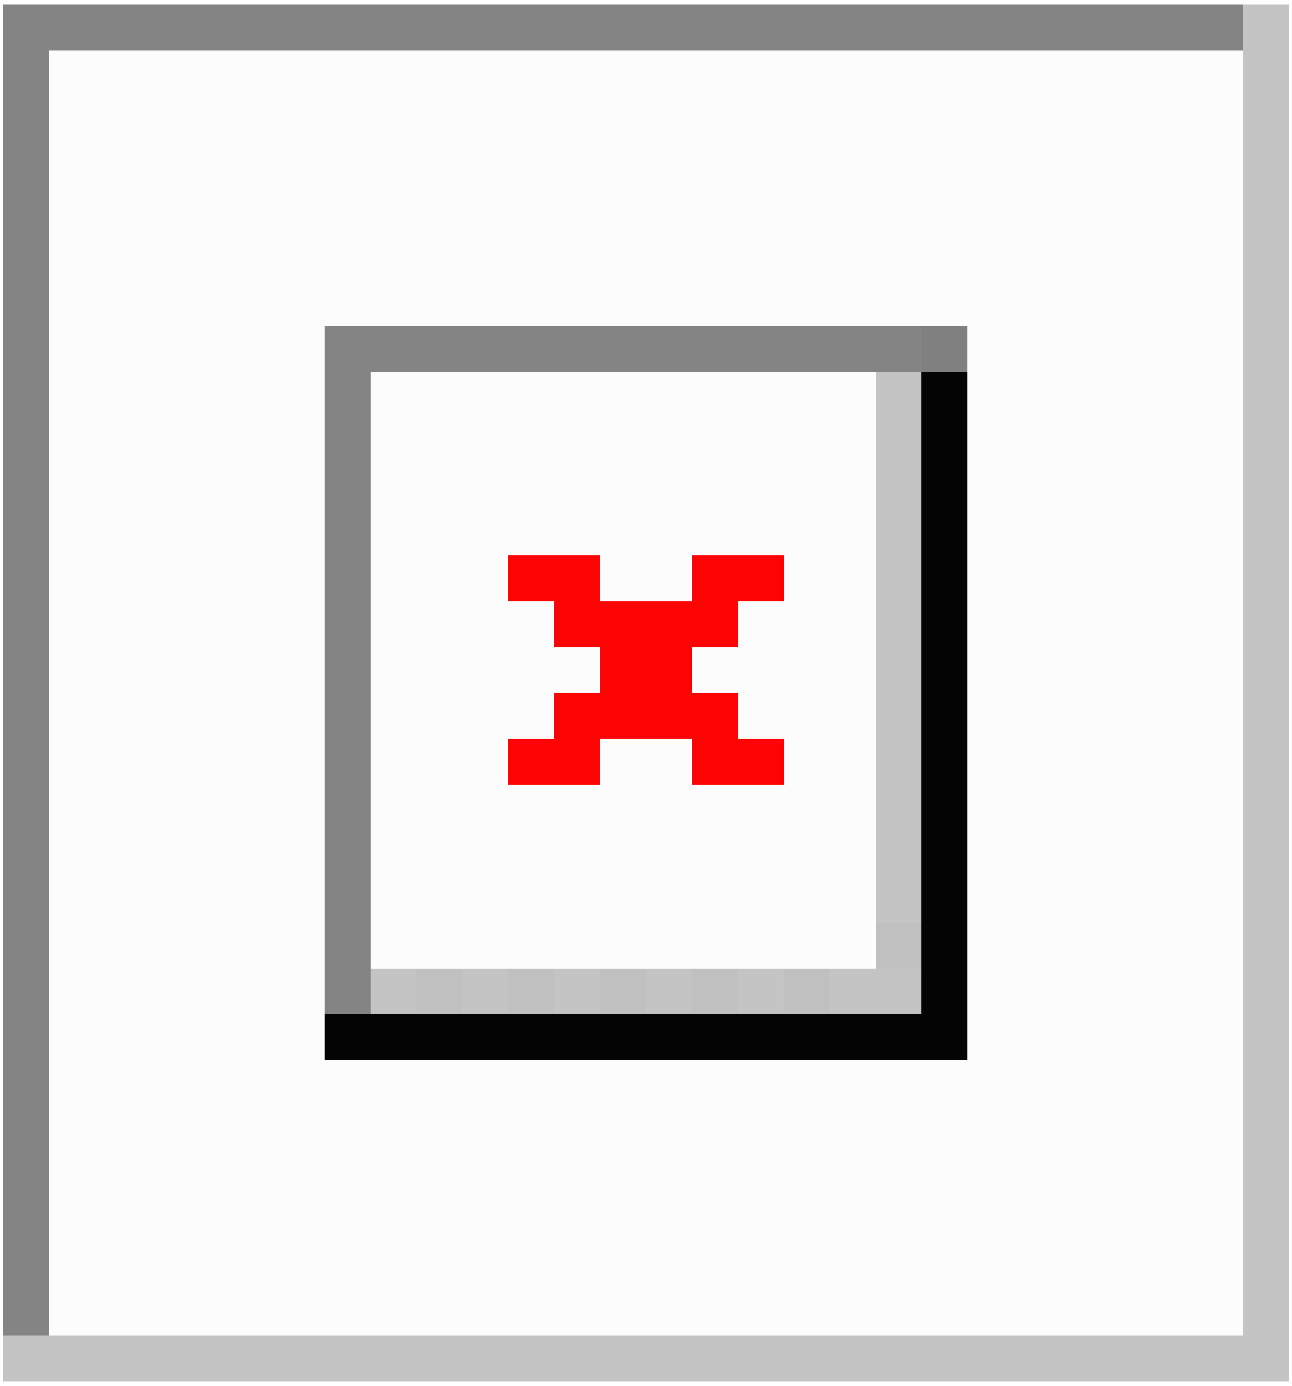
Figure 2. Annual trends of publications and citations.



Distribution of Countries and Institutions

In this study, all the included publications came from 69 countries. The top 11 countries with the most publications are showed in Figure 3A (each node in the figure represents a country). Of these countries, the United States (n=382) had the most publications, followed by England (n=97), Australia (n=89), Canada (n=86), and Spain (n=81). Furthermore, the country citation analysis is shown in Figure 3B. The lines between countries represent the mutual citation relationship between them (Figure 3B); more frequent citations are represented by thicker lines. A total of 1674 institutions participated in this research area, as shown in Figure 3C. In this figure, the institution that generated the most publications was the University of Washington (n=70), followed by the University of Barcelona (n=19), University of Queensland (n=18), University of Haifa (n=14), and University of Sydney (n=14). Similarly, we also analyzed the citation of institutions (Figure 3D). The top 5 countries and institutions with the most citations are summarized in Table S1 in Multimedia Appendix 1. Moreover, clustering analyses of countries and institutions are summarized in Tables S2 and S3 in Multimedia Appendix 1. A total of 5 and 12 clusters were found for countries and institutions, respectively. The top 5 countries and institutions in each cluster are shown in Tables S2 and S3 in Multimedia Appendix 1.

Figure 3. Distribution of countries and institutions. (A) Cooperation mapping of different countries. (B) Citation mapping of different countries. (C) Cooperation mapping of different institutions. (D) Citation mapping of different institutions.



Distribution of Journals

The included 1176 publications on pain and VR research came from 720 academic journals, of which the top 10 journals with the most publications accounted for 15.31% (180/1176) of the total publications, which can be considered as authoritative journals or mainstream journals in this field. Figure 4A shows the visualization results of the publications by different journals. Each node represents a journal, and a larger node indicates greater volume of publications. The cocitation relationship between journals is shown in Figure 4B. The line connecting the nodes indicates that there was a cocitation relationship between the 2 nodes. The top 10 journals with the most publications and cocitations are summarized in Table 1. Among the top 10 journals, 60% (n=6) were from the Q1 quartile and 30% (n=3) were from the Q2 quartile.

Figure 4. Distribution of journals and authors. (A) Publication mapping of different journals. (B) Cocitation mapping of different journals. (C) Cooperation mapping of different authors. (D) Cocitation mapping of different authors.

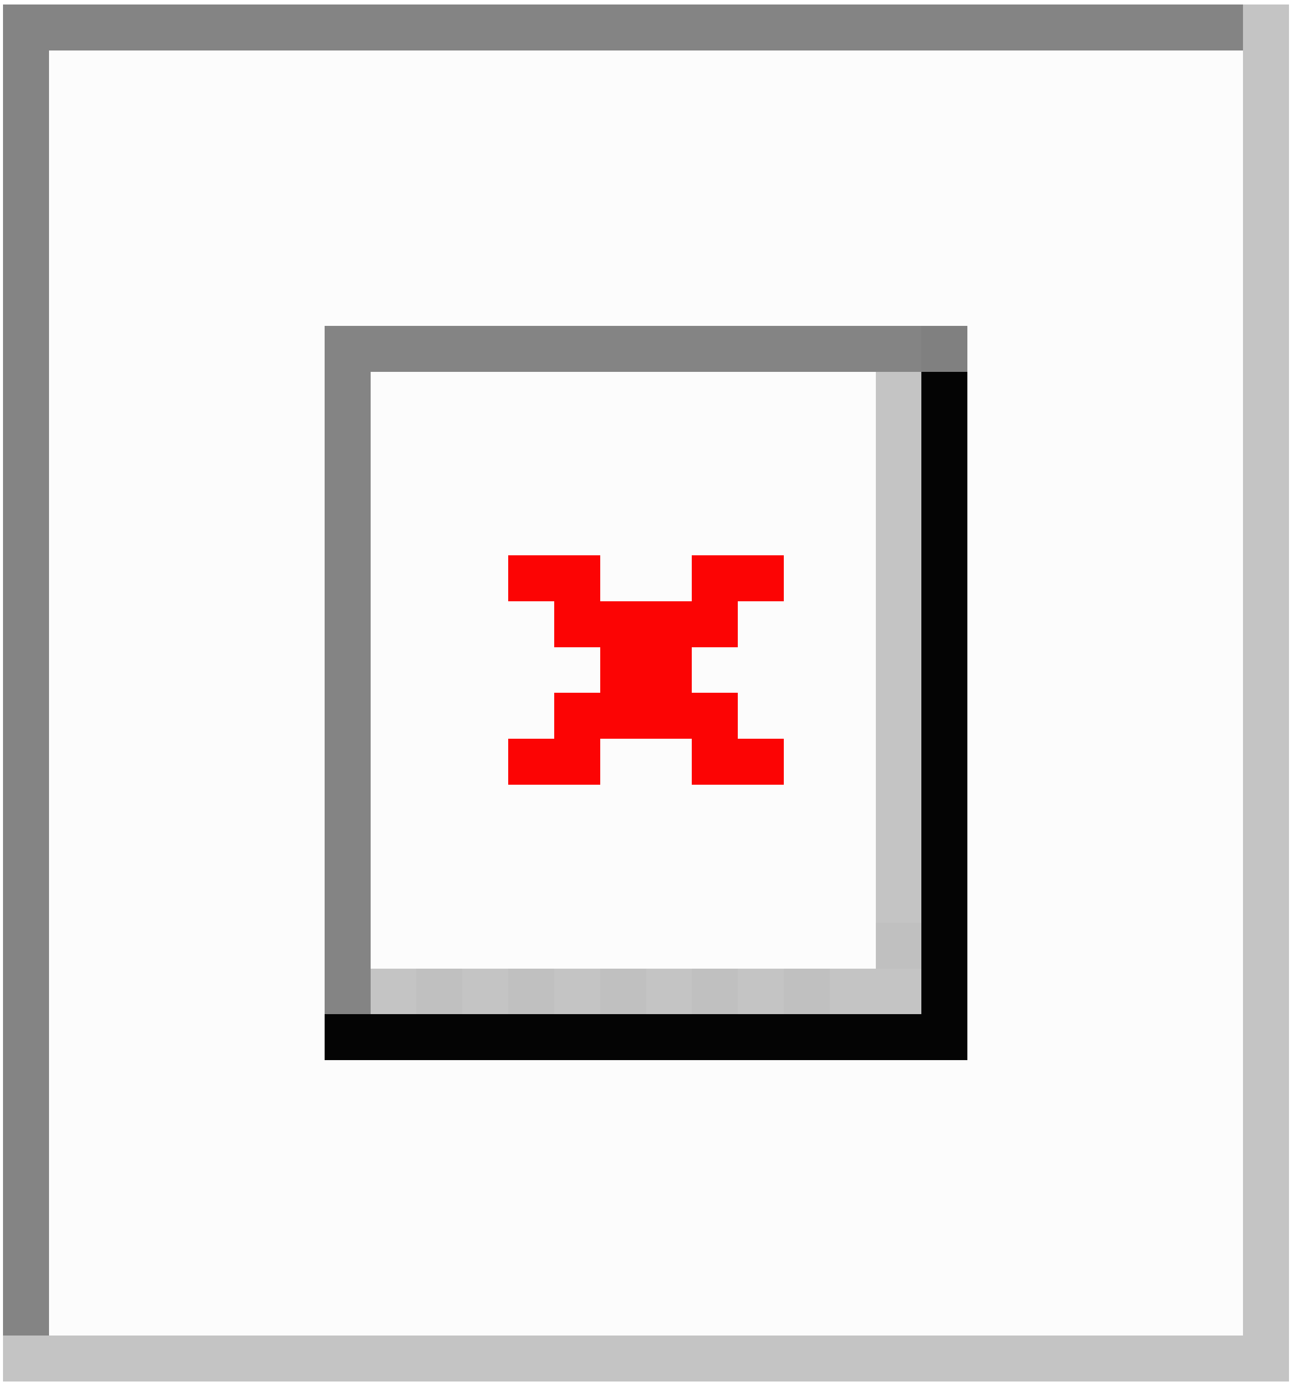


Table . The top 10 journals with the most publications and cocitations.

Distribution of Authors

The relationships between author and citation are showed in Figure 4C. Each node represents an author and the size of the node indicates the publication counts of the author. The lines between the nodes represent the citation relationship between authors: the thicker the line, the more citations there are between the 2 authors. Table 2 showed the top 10 authors with the most publications and their cocitations. For better visualization, we only included authors with more than 30 cocitations, and a total of 153 authors were included (Figure 4D). The top 10 authors with the most publications came from 4 countries (the United States, Spain, Italy, and Israel), and 7 (70%) out of 10 are American authors.

Distribution of References

We analyzed a total of 36,224 references from 1176 papers. The most frequently cited and cocited papers are summarized in Table 3. The cocitation relationships are visualized in Figure 5A. It is worth noting that the top 10 cocited references were all from the United States, and 6 of them were from Hoffman HG. We found that all the papers that were cocited the most were about pain control using VR technology.

Figure 5. Distribution of references. (A) Cocitation mapping of different references. (B) Top 25 references with the strongest citation bursts.

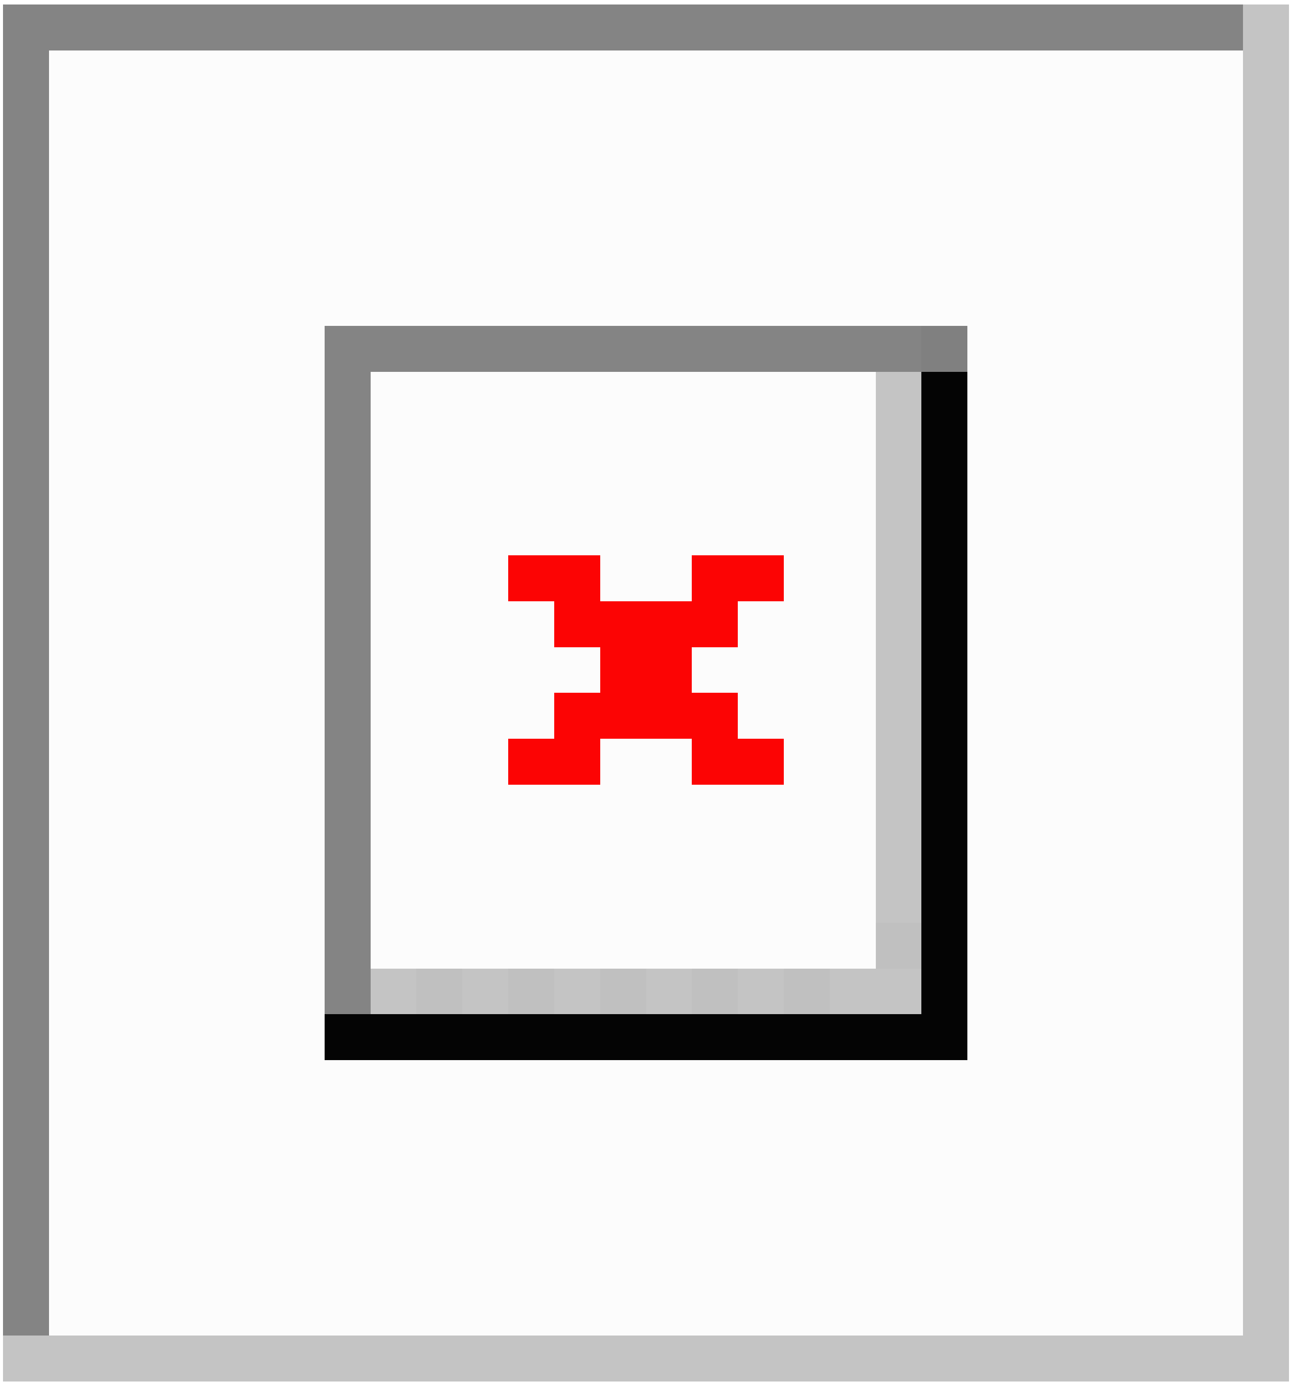

Figure 5B [9,11,13,29,31,34-36,38-54] shows the top 25 strongest citation bursted between 2000 and 200enting more citations and green ones representing fewer citations. A burst of reference means that this paper has been cited more frequently by other papers during this period. From the burst analysis of the references, we found that new directions and new hot spots in this field were constantly emerging and research interest in VR and pain had grown substantially. The burst of reference citations first started from 3 papers written by Hoffman HG in 2001, of which 2 were published in the *Clinical Journal of Pain* and the other in *Pain*. After a lapse of 14 years, the article published by Hoffman HG in *Cyberpsychology Behavior and Social Networking* in 2014 became the most persuasive one. These 3 journals were also among the top 10 journals in the field of VR and pain. Moreover, 8 of the top 25 strongest citation reference were published by Hoffman HG, which was sufficient to justify that Hoffman HG was a pioneer and leader in this field. The latest emerging authors were Mallari B and Arane K, who had published articles in the *Journal of Pain Research* and *Canadian Family Physician*, and these articles had received high citations recently.

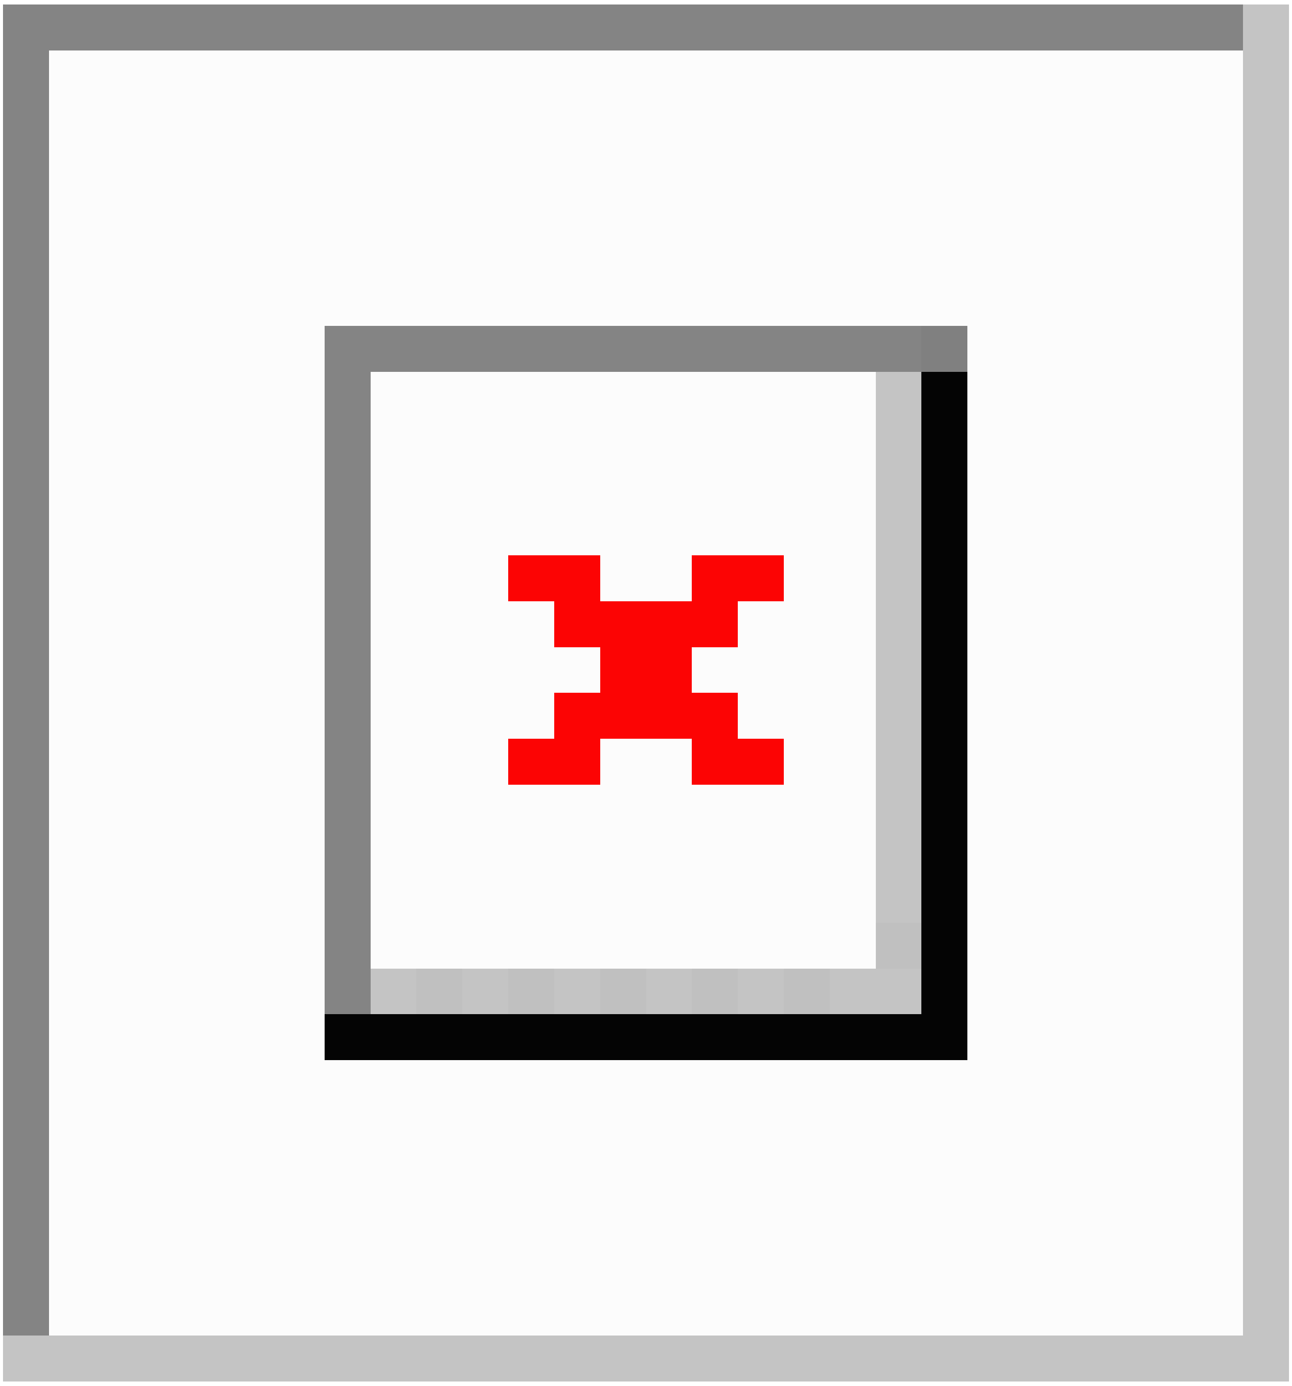
Keyword Analysis

The keyword co-occurrence analysis is shown in Figure 6A. The top 10 keywords and their centrality are summarized in Table S4 in Multimedia Appendix 1. The keyword with the highest number of occurrences was “virtual reality” with the highest centrality of 0.09, followed by “pain” with 348 occurrences and a centrality of 0.07.

Figure 6. Keyword analyses. (A) Co-occurrence mapping of different keywords. (B) Clustering mapping of different keywords. (C) Timeline view mapping of different keywords. (D) Top 25 keywords with the strongest citation bursts.



A total of 9 clusters were identified in the clustering analysis, and they are shown in Figure 6B. The *Q* value is 0.412>0.3, and the *S* value is 0.7018>0.7, indicating that the clusters were credible. The top 10 keywords in each cluster are shown in Table S5 in Multimedia Appendix 1. In the cluster, labels were derived from the keywords; a smaller cluster number indicates that the cluster contains more keywords.

The timeline view analysis is shown in Figure 6C. For better visualization, we only showed keywords with more than 18 occurrences. Each node represents a keyword, and only the year that the keyword first appeared was counted. The size of the nodes indicates the frequency of the occurrence. The lines between nodes refer to 2 keywords appearing in the same paper or several papers. For examples, “virtual reality” first appeared in 2000, and the node is the largest, indicating that “virtual reality” had the most occurrences from 2000 to 2022. “Pain” first appeared in 2003, and there is a connection between “virtual reality” and “pain,” indicating that these 2 keywords appeared in 1 or several papers in 2003 at the same time.

The citation burst analysis of the keywords is shown in Figure 6D. The most cited keyword was “wound care,” followed by “visual feedback,” “burn pain,” and “modulation,” indicating that the research on pain relief using VR technology was very popular in the field of burn pain. The latest hot keyword was "preoperative anxiety."

Discussion

Overview

With high incidence and prevalence, chronic pain has become the cause of both heavy social burden and economic burden. VR is a computer simulation technique that has been shown to help patients manage their pain, reducing unnecessary medication use and the numerous side effects. In this study, we analyzed the development process of VR in the field of pain management, as well as research hot spots and future trends. Our results showed that publications in this field grew rapidly, and the United States is now leading in this field. According to our research, the hot spot in this field was burn-related pain, and the representative keywords were "virtual reality," "burn," "surgery" and "pain control." This study provides systematic guidance and potential research directions for researchers in this area.

Principal Findings

VR was first popularized for pain control by Hoffman HG in 2000 [29,55]. Subsequently, publications in this field increased slowly from 2000 to 2017. After 2017, the publications increased rapidly from 63 in 2017 to 234 in 2021, with an average annual increase of 42.75 papers. We infer that there may be 2 reasons for this. First, according to the hype cycle of emerging technologies produced by the Gartner Group in 2015 [56], VR just ended the trough of disillusionment period in 2015 and was in the slope of enlightenment period. At that time, more and more organizations carried out in-depth research on VR technology [57]. The second reason is that as many technology companies such as Facebook, Sony, and other companies made huge investments in the VR field around 2016, VR technology has continued to improve. Additionally, there have been more ways for researchers to obtain VR technology while the cost has also become much lower [58]. In the future, with the continuous innovation of VR technology, we believe that the research on VR technology in medical treatment, including pain control, will become more and more popular. In terms of the global publications, the United States had published a total of 382 articles, accounting for about 32.5% of the 1176 selected articles, which indicates that the United States is the absolute leader in this field. In terms of the number of citations, US researchers topped the list with 12,454 citations, indicating that literature published from the United States are authoritatively reliable in the field of VR pain management, which is inseparable from the leading level of VR technology research. Other countries still have great potential for research in this field on the basis of this citation analysis.

The quality of articles published in this field was also high. Overall, 60% of the top 10 journals were from the Q1 quartile. The top 5 journals with the highest number of publications were *Burns*, *Journal of Burn Care & Research*, *Journal of Clinical Medicine*, *Journal of Medical Internet Research*, and *Frontiers in Psychology*. To sum up, papers in these journals were mostly about burn pain, which is the first application area of VR in pain control [9,29]. Hoffman et al [59,60] have done a lot on the application of VR in burns, and they have confirmed that VR is effective and feasible in pain control of patients with burn pain. However, the mechanism of VR analgesia has not yet been fully elucidated. Whether the analgesic effect can be improved through interaction in the field of burns is a research trend, and there is still a lot of research space in the field of burns [60].

Research Hot Spots

Combined with literature cocitation analysis and keyword co-occurrence analysis, the current research focus in the field revolves around 2 main areas: the control of burn-related pain and pain control during medical operations in children. Two important studies conducted by Hoffman et al [9,29] in 2000 demonstrated that VR can reduce pain perception in patients with burn pain during physical therapy and alleviate pain during burn wound care. Subsequent clinical experiments have consistently confirmed the pain-reducing effects of VR in procedures such as excision and hydrotherapy debridement for patients with burn pain [39,61-63]. Furthermore, Hoffman et al [64] provided additional evidence for VR's pain control capabilities in patients with burn pain by using functional magnetic resonance imaging to demonstrate a reduction in pain-related brain activity while using VR devices. Lee et al [65] used functional near infrared spectroscopy to analyze cerebral blood flow in patients with burn pain during VR experiences. They discovered a significant increase in oxygenated hemoglobin in the prefrontal lobe, suggesting that VR activates the prefrontal lobe to inhibit pain sensations.

Researchers have also been interested in understanding the factors that influence VR's pain control in patients with burn pain. Sharar et al [66] found that VR's analgesic effect remains consistent regardless of factors such as age, gender, race, burn wound size, or duration of treatment. However, a comparison study by Hoffman et al [67] showed that VR headsets with wider viewing angles result in a more immersive experience and better pain control compared to headsets with narrower viewing angles. In summary, the pain-relieving benefits of VR for patients with burn pain have been consistently validated, and future efforts should focus on optimizing the VR experience to further enhance pain control efficacy.

Moreover, VR has shown promising results in pain relief during medical procedures for pediatric patients. Beyond its application in burn-related scenarios, VR has been used for venipuncture, intravenous catheterization [68], lumbar punctures [69], and even preoperative procedures [70] to alleviate anxiety and minimize procedure-related pain in children. Compared to adults, VR is particularly effective in capturing the attention of children and can be applied in various clinical scenarios. Recent research has explored the use of VR for preoperative anxiety relief, postoperative pain management [71], pain control during vaccinations [72], anesthesia and tooth extraction [73], as well as pain management during emergency sutures [73,74]. In the future, VR is poised to play an important role in various pediatric medical operations.

Research Trends and Directions

The role of VR in pain control has been proven, and future research in this field aims to promote the application scenarios of VR pain control and enhance the user experience for patients to improve the analgesic effect. At present, in addition to the application of treating patients with acute burn pain, the analgesic effect of VR has been applied in the first stage of labor analgesia [75], wound care [76], cystoscopy [77], oral surgery [78], and postoperative pain management [79]. However, further studies are needed to confirm its effectiveness in different clinical scenarios such as gastroenteroscopy and puncture surgery. Patients with chronic pain, including chronic cancer pain, chronic neuropathic pain, and chronic low back pain, can also benefit from VR devices, which can provide pain relief and improve mood [80-83]. To manage chronic pain effectively, there is a need to develop more diverse VR software that caters to the needs of patients.

Improving the patient experience will also be a key focus for future research. As an immersive device, VR presents certain challenges. First, hardware equipment needs to be enhanced to provide a more interactive VR experience, as suggested by Yeo et al [84]. Second, the development of high-quality VR software specific to different pain types is crucial for enhancing the patient experience. Additionally, creating appropriate VR scenarios and games tailored to patients' needs will contribute to a better patient experience.

In conclusion, this study conducted a 2-decade bibliometric analysis of research on VR interventions in pain management. Currently, the research of VR in the field of pain has received extensive attention, and satisfactory results have been achieved in a series of fields such as burn pain and pediatrics medical procedure–related pain. It is remarkable that burn pain control is still a research hot spot in this field. The emerging trends include the application of VR in other departments related to pain and improving VR technology to enhance the patient experience. However, the mechanism of pain control with VR is not yet understood, and researchers are constantly working in this field, which will guide the development of more effective VR pain management technology.

Strengths and Limitations

This is the first bibliometric analysis of VR research in the field of pain. We provided scientific information in this field and predicted research hot spots and research trends to summarize the research status in this field and further promote the development of this field.

However, there are multiple limitations in our research. First, we only analyzed publications in the WoSCC and failed to exhaust all the publications on VR and pain control. Second, due to limitations of the analysis tools, we only analyzed the papers published in English and discarded other valuable books as well as non–article and review literature such as conference papers. Last but not least, our retrieval methods also have shortcomings, but they simplified the literature so that it is more in line with our theme, and simplicity was conducive to the development of our analysis and research. However, we still hope that future researchers can use more search terms to include some fringe literature in the analysis scope, which may be a useful recommendation for future treatment in this field.

Conclusions

Through bibliometric analysis and visualization, we provided an overview analysis of the field of VR for pain control. There were more than 60 countries participating in this field, and the relative research had been growing rapidly in recent years. The United States and the University of Washington were the representative country and institution, and Hoffman HG was the pioneer in this field. Through the analysis, we identified the hot spots in this research field, which included burn pain and pediatric surgery pain. More attention will be paid to the application of VR in various pain situations in the future, and more diversified software and hardware will be developed to improve the immersive experience of patients, making VR more distracting and more effective at reducing pain.

Acknowledgments

This study was funded by the Shanghai Key Laboratory of Peripheral Nerve and Microsurgery, National Health Commission Key Laboratory of Hand Reconstruction (Fudan University; grant 20DZ2270200), granted to XY; the National Natural Science Foundation of China (grant 82102640), the Medical Scientific Research Foundation of Guangdong Province of China (grant A2023195), the Nanshan District Health Science and Technology project (grant NS2023044), and the Nanshan District Health Science and Technology Major project (grant NSZD2023023), granted to GF; and the Science and Technology Commission of Shanghai Municipality (grant 22S31900100) and Yunnan Academician Expert Workstation (grant 202205AF150058), granted to SH. Abstract

Background: Exercise is effective for musculoskeletal pain. However, physical, social, and environmental factors make it difficult for older adults to persist in exercising. Exergaming is a new pathway that combines exercise with gameplay and may be helpful for older adults to overcome these difficulties and engage in regular exercise.

Objective: This systematic review aimed to determine the efficacy of exergaming to improve musculoskeletal pain in older adults.

Methods: The search was performed in 5 databases (PubMed, Embase, CINAHL, Web of Science, and Cochrane Library). The risk of bias for randomized controlled studies was assessed using the revised Cochrane Risk of Bias tool in randomized trials (RoB 2), and the methodological quality was assessed using the Physiotherapy Evidence-Based Database scale. Standardized mean difference and 95% CI were calculated using fixed-effects model meta-analyses in the Review Manager version 5.3 (RevMan 5.3).

Results: Seven randomized controlled studies were included, which contained 264 older adults. Three of the 7 studies reported significant improvements in pain after the exergaming intervention, but only 1 reported a significant difference between groups after adjustment for baseline (*P*<.05), and another reported a significant improvement in thermal pain between the 2 groups (*P*<.001). The results of the meta-analysis of the 7 studies showed no statistically significant improvement in pain compared to the control group (standardized mean difference –0.22; 95% CI –0.47 to 0.02; *P*=.07).

Conclusions: Although the effects of exergames on musculoskeletal pain in older adults are unknown, exergame training is generally safe, fun, and appealing to older adults. Unsupervised exercise at home is feasible and cost-effective. However, most of the current studies have used commercial exergames, and it is recommended that there should be more cooperation between industries in the future to develop professional rehabilitation exergames that are more suitable for older adults. The sample sizes of the studies included are small, the risk of bias is high, and the results should be interpreted with caution. Further randomized controlled studies with large sample sizes, high quality, and rigor are needed in the future.

Introduction

Background

The International Association for the Study of Pain defines pain as an unpleasant sensory and emotional experience associated with or resembling actual or potential tissue damage [1]. Pain is classified as acute, subacute, and chronic. Fewer than 4 weeks is acute pain, and the presence of 4 weeks to 3 months is subacute pain, and chronic pain is a condition that persists or recurs for more than 3 months [2]. The causes of pain in older individuals are often due to osteoarthritis, postherpetic neuralgia, diabetic neuropathy, spondylosis and radiculopathy, poststroke pain, and Parkinson disease [3]. According to data from the 2016 American Health Interview Survey [4], 20.4% of American adults have chronic pain, with 8% of American adults having a high impact on chronic pain [5]. The prevalence of pain increases with age [6]. Individuals aged 60 years and older are classified as older individuals by the World Health Organization [7]. Data from 1999 to 2019 showed that 57%-61% of community-dwelling older individuals reported intermittent or daily musculoskeletal pain [8]. By 2030, approximately 66% of people over the age of 65 years will have chronic pain globally [9]. Pain affects sleep and mood, increases the risk of falls, and reduces the quality of life [9-11]. It imposes a heavy burden on society [12].

Changes in the efficacy of analgesic drugs occur due to aging, such as a possible weakening in analgesic effect and a decrease in the efficiency of drugs acting on peripheral sensitization [13]. It is worth noting that medications may make older individuals more debilitated and adverse reactions occur more frequently [3]. Nonpharmacological treatments have therefore been used for pain relief. The efficacy of exercise in alleviating pain has been demonstrated [14], and exercising in nonpainful areas of the body has an analgesic effect on painful areas [15]. Older adults with poor physical function prefer to exercise at home at no cost [16]. However, the lack of supervision and motivation at home leads to low exercise adherence [17], which further leads to poorer treatment effects [18,19].

Technology can serve as an effective strategy to confront these challenges. Exergames are video games or virtual reality (VR) games that combine gameplay with physical training and are potential tools to make exercises more enjoyable and increase motivation and compliance for physical activity [20-23]. Results of systematic reviews showed that exergames could improve the activities of daily life [24], cognitive [25] and physical function [26], balance [27], walking speed [28], and depression [29,30] among older adults. There was some evidence of randomized controlled trials (RCTs) supporting the benefits of exergames for improving pain in older adults [31,32].

Research Gap and Aim

To our knowledge, 3 reviews have systematically summarized the effects of exergames on pain. A systematic review [33] included thirteen clinical studies, and the mean age of participants ranged from 23.9 (SD 6.8) years to 54.9 (SD 11.8) years. The 6 included controlled trials showed that interactive VR exergames may divert attention from pain and alleviate pain postmastectomy and ankylosing spondylitis, but the results were inconsistent for people with neck pain. The remaining 7 uncontrolled studies showed that interactive VR exergames reduced neuropathic limb pain and phantom limb pain, but did not affect nonspecific chronic back pain. A systematic review and meta-analysis [34] also showed that exergames can improve pain perception in females older than 18 years with fibromyalgia. However, a systematic review and meta-analysis [35] that included 7 RCTs concluded that there was insufficient evidence that exergames can improve musculoskeletal pain in the participants and the mean age ranged from 33.5 (SD 9.5) years to 80 years. The results of these reviews are inconsistent, as well as have some limitations. In the first place, they were not focused on older adults. Secondly, the included studies were not all RCTs. In further, some of them did not perform a meta-analysis and the results were not rigorous enough. Therefore, the purpose of this study is to review the efficacy of exergames for musculoskeletal pain in older adults.

Methods

Overview and Registration

The report of this systematic review and meta-analysis is consistent with the updated guidelines of the PRISMA (Preferred Reporting Items of Systematic Reviews and Meta-Analyses) 2020 Statement (Multimedia Appendix 1) [36]. The registration number is CRD42022342325.

Literature Search

A systematic literature search was carried out in 5 databases, PubMed, CINAHL (through EBSCO), the Cochrane Library, Web of Science, and Embase, from the inception to March 4, 2022. The combinations of Medical Subject Headings and free-text terms were used, and concepts included were exergaming, pain, and aged (see Multimedia Appendix 2).

Eligibility Criteria

The following were the criteria for including the articles: (1) participants' mean age was more than 60 years and they suffered from musculoskeletal pain; (2) game technology was used to enable participants to exercise; (3) the control group was either active control (other interventions but no gameplay) or passive control (eg, usual care, no treatment, or waiting list); (4) the pain was involved in clinical outcomes; (5) the article had been published in a peer-reviewed publication with a RCT; and (6) the articles were written in English.

Exclusion criteria were as follows: (1) reviews, editorials, conference abstracts, and protocols, or full text was not available; (2) incomplete information on the intervention; (3) outcome data for pain were not statistically analyzed; and (4) duplicate publications or no restrictions on the publication date.

Study Selection

A researcher searched the 5 databases according to the search strategies. Duplicates were excluded by EndNote 9X. Two researchers independently reviewed the titles and abstracts of records before reading the entire text for rescreening to identify the included literature based on the eligibility criteria. Any differences were settled through discussion or by consulting a third researcher.

Data Extraction

The data were extracted by 2 independent researchers using the self-developed form in Excel (Microsoft Corp), comprising study characteristics, participant characteristics, intervention details, attrition, supervision, adverse events, experience, measurement tools for the outcome, and the key results. Following that, the 2 researchers subsequently cross-checked. A third investigator was consulted in the event of a dispute.

Risk of Bias and Methodological Quality Assessment

The included studies' quality was evaluated using the revised Cochrane Risk of Bias tool in randomized trials (RoB 2) [37]. The risk of bias in 5 domains, including (1) randomization procedure; (2) deviations from intended interventions; (3) missing outcome data; (4) measurement of the outcome; and (5) selection of the reported result, was appraised using 3 degrees of "low risk," "some concerns," or "high risk." When at least one domain was considered to have "some concerns," but no domain was deemed to have "high risk," the study was labeled as having "some concerns of bias." When at least one domain was deemed "high risk" and many domains were deemed "some concerns," the study was deemed "high risk of bias" [37].

The Physiotherapy Evidence-Based Database scale was used to assess the methodological quality of randomized controlled studies. The scale is a specific instrument for clinical studies of physical therapy interventions [38]. It comprises 11 items related to the selection, detection, performance, information, and attribution bases domains. Research with a score lower than 4 is regarded as bad, 4-5 is considered fair, 6-8 is considered good, and 9-10 is considered excellent [39].

The assessments were conducted independently by 2 independent evaluators. One reviewer resolved the disagreement.

Data Synthesis

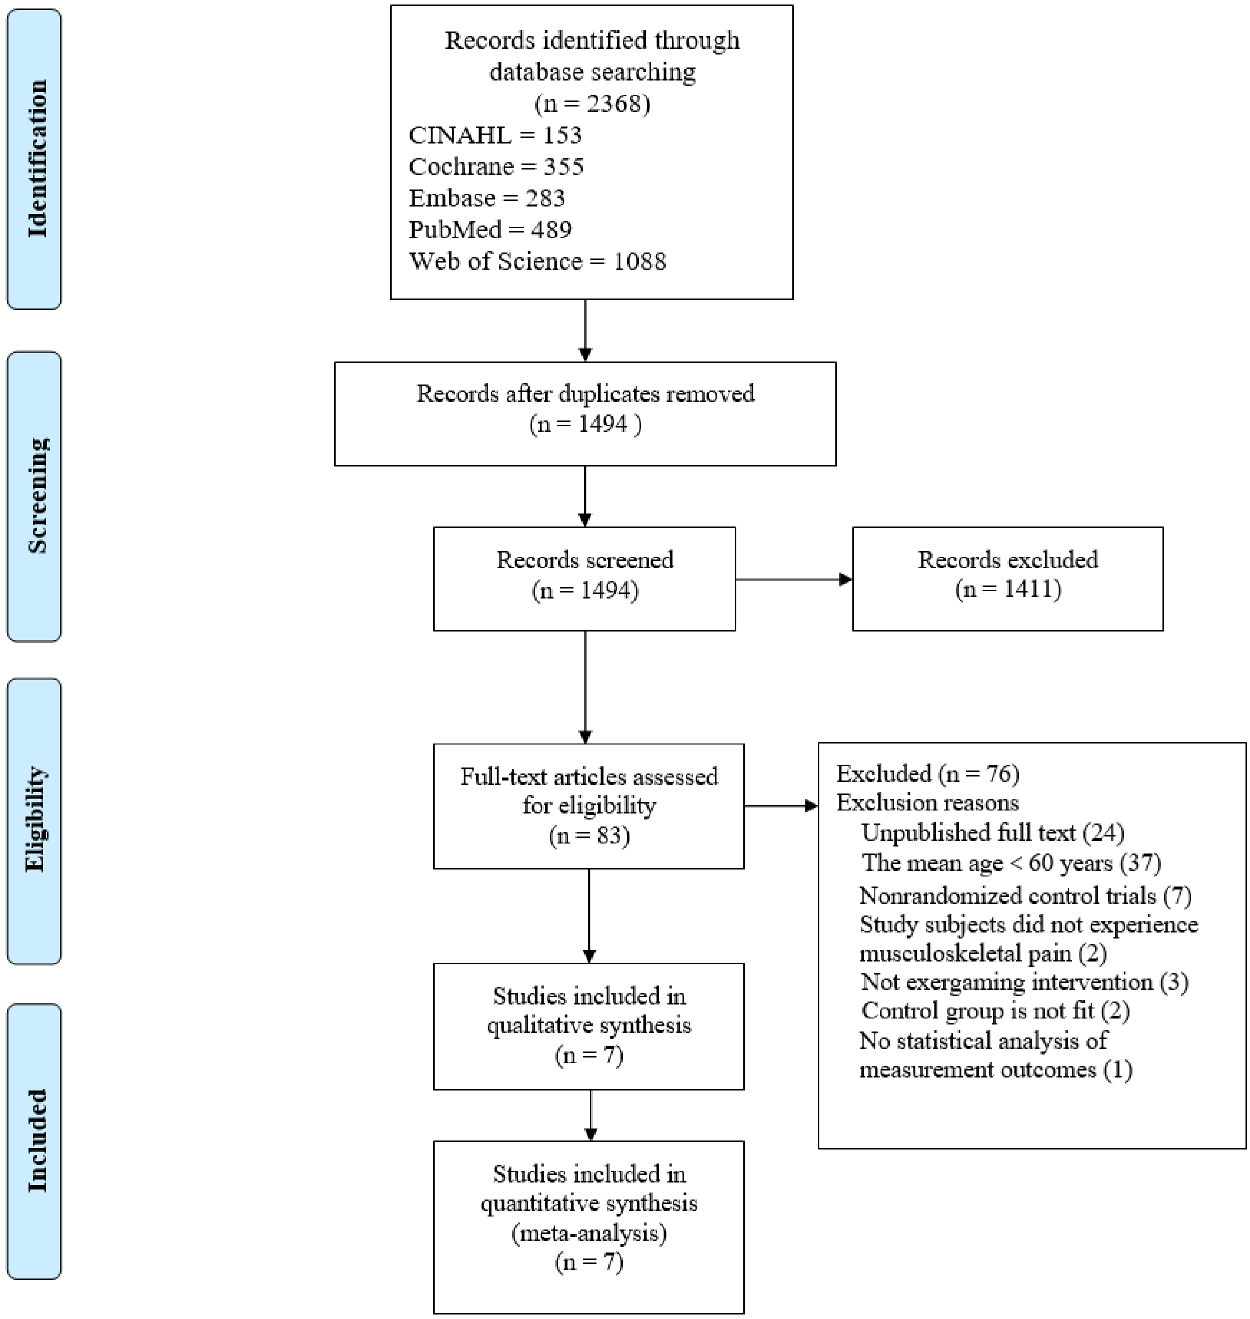
The equation ($Mean_{change}=Mean_{after}–Mean_{baseline}$) and ($SD_{change}=\sqrt{[SD^2_{baseline}+SD^2_{after}–\{2\times correlation\times SD_{baseline}\times SD_{after}\}]}$) were used to calculate the mean change and corresponding SD, and the correlation was set to 0.5. SDs were not given in the study and were obtained by converting the means, sample sizes, and *P* values of the changes in the intervention and control groups [40]. The effect size was measured by the standardized mean difference (SMD) corrected for small sample sizes (Hedges *g*) [40]. Hedges *g* estimates of <0.30, ≥0.30 and <0.60, and ≥0.60 were considered small, moderate, and large, respectively [41]. The heterogeneity among studies was quantified based on the I^2 statistic, with 0%-40% may not be important; 30%-60% may represent moderate heterogeneity; 50%-90% may represent substantial heterogeneity; and 75%-100% may represent considerable heterogeneity [42]. A fixed-effects model was used when I^2≤50%, otherwise a random-effects model was used. We performed subgroup analysis to explore which treatments were more effective or what nature of pain exergaming was more effective for. Meta-analysis was performed using Review Manager version 5.3 (RevMan 5.3). We did not perform a publication bias test because fewer than 10 studies were included [42].

Results

Study Selection

By searching the databases, 2368 records were found. After removing 874 duplicates, 1494 records were evaluated. A total of 1411 records were excluded according to the eligibility criteria. The remaining 7 studies were analyzed. The PRISMA flow diagram depicts the search and screening procedure (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items of Systematic Reviews and Meta-Analyses) flow diagram of study selection according to PRISMA [43].

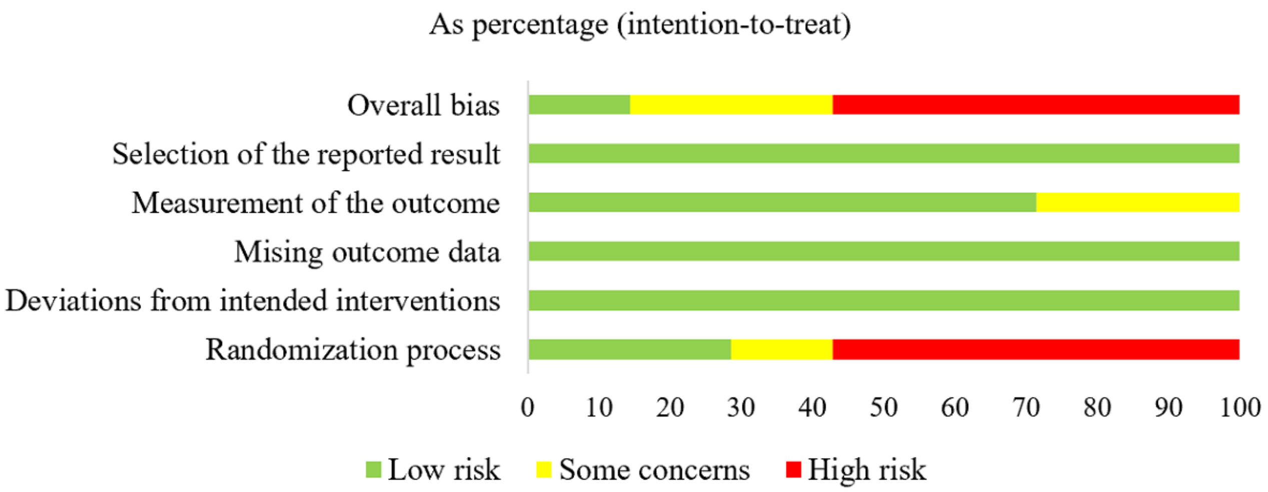


Quality Assessment

Figures 2 and 3 summarized the risk of bias assessment for the 7 studies that were included. One study (14%) was classified as "low risk" [44], 2 studies (29%) as "some concerns" [31,32], and 4 studies (57%) as "high risk" [21,22,45,46]. All studies were judged "low risk" for the domains "Deviations from intended interventions," "Missing outcome data," and "Selection of the reported result." Four studies (57%) were assessed as "high risk" for the domain "Randomization procedure" due to no report allocation concealment approaches, while 1 research (14%) was evaluated as "some concerns" related to baseline imbalance. Due to nonblind assessors, 2 studies (29%) were determined to have "some concerns" in the domain "Measurement of the result."

Figure 2. Risk of bias based on revised Cochrane Risk of Bias tool in randomized trials (RoB 2) [37].

Figure 3. The overall risk of bias in randomized controlled trials.



Physiotherapy Evidence-Based Database scores (mean score approximately 7, range 6-8) demonstrated good overall methodological quality. Monteiro-Junior et al [44] received the highest score of 8, while Stamm et al [46] had the lowest score of 6 (Table 1).

Characteristics of the Included Studies

Study Characteristics

Seven included studies were published in years from 2011 to 2022. They were conducted in Spain [22], England [31], Canada [21,45], Brazil [44], Germany [46], and Australia [32]. Study designs were RCTs (n=4) [31,32,44,45], pilot RCTs (n=1) [46], and crossover pilot RCTs (n=2) [21,22]. The sample size ranged from 14 to 60, with a total of 264, of which 137 were in the intervention groups and 127 were in the control groups.

Participant Characteristics

All participants had musculoskeletal pain, participants in 5 studies [22,31,32,44,46] had chronic pain, and participants in the 2 studies [21,45] had nonchronic pain. The average age of the participants ranged from 67.8 (SD 6) years [32] to 81.85 (SD 6.82) years [22]. The majority of participants were female, accounting for around 69% of the total.

Intervention Characteristics

Interventions were conducted in the nursing home [22], the university's physiotherapy laboratory [31], the hospital [45], the long-term care center [21], the center of rehabilitation [44], the laboratory [46], and the participant's home [32]. The Nintendo Wii, the Active Airlines serious game, the Interactive Rehabilitation and Exercise System, and the ViRST VR application were the main gaming platforms in the experimental groups. For a period of 4 weeks to 8 weeks, participants exercised for 210 seconds to 90 minutes every session, only once during the intervention to 3 times per week. In 1 study, participants in the control groups carried on with their regular activities. The other studies used traditional physical therapy.

In 4 studies, participants performed exergaming under the supervision of the first author [31], therapist [21,45], and physiotherapist [46]. In 1 study [32], participants performed unsupervised home exergaming, and the remaining 2 studies did not report whether supervision was implemented [22,44]. The number of attrition people ranged from 1 to 9 due to personal commitments and fear of COVID-19 infection. Adherence was reported in only 3 studies [21,32,44].

Most of the participants in the experimental group had a positive experience. The occurrence of adverse events was not reported in 3 studies [31,44,45], while 3 studies reported no adverse events during the intervention [21,32,46]. Two individuals in 1 study experienced unpleasant symptoms such as dizziness, eye pain, or disorientation [22]. Multimedia Appendix 3 depicts an overview of the included study characteristics.

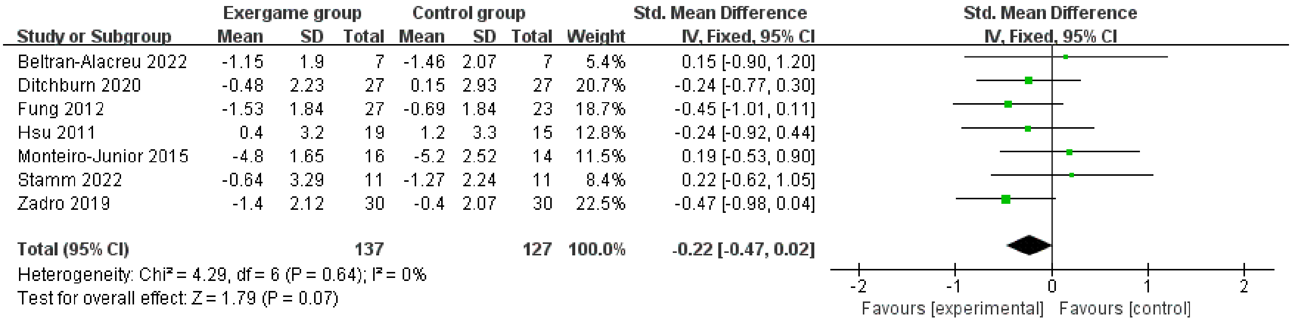
Results of Studies

The Effect of Exergames on Pain

The complete pain data was presented in 7 papers. A study [22] comparing the effects of using Active Airlines serious game and conventional exercise on pain using Visual Analog Scale (VAS) measurements after 4 weeks discovered that both experimental and control groups had significant improvements in chronic neck pain, but exergaming therapy was not superior to conventional exercise. Ditchburn et al [31] compared exercise using the VR rehabilitation system to traditional gym-based exercise, and the results of the study, measured at baseline and after 6 weeks using the VAS, showed a significant improvement in chronic musculoskeletal pain intensity in the experimental group, but no significant change in the control group, and no statistically significant difference between the 2 groups. The difference in improvement in thermal pain, including burning and hot, measured by Multi Affect and Pain Survey, was significant between the 2 groups. In the study by Stamm et al [46], the results measured at baseline versus 6 weeks later on the Numeric Rating Scale (NRS) showed that the improvement in chronic back pain was not significant in the experimental group using the VR system and those in the control group receiving traditional pain therapy, and the difference between the 2 groups was not statistically significant. Fung et al [45] investigated the effect of Nintendo Wii Fit gaming sessions on pain in posttotal knee replacement individuals, finding no significant difference between the 2 groups when compared to a control group receiving lower extremity exercise. Two research investigated the effects of exergaming combined with traditional exercise with regular exercise on pain perception, with Nintendo Wii used. Hsu et al [21] used the NRS and the pain bothersomeness of the upper extremity to measure the improvement of pain in people with upper extremity dysfunction in the experimental and control groups after 4 weeks of treatment and found no significant differences. Another study [44] reported significant improvement in chronic low back pain after 8 weeks of treatment in participants in both the experimental and control groups using the NRS, however, the difference between the 2 groups was not statistically significant. The study by Zadro et al [32] evaluated the effect of home-based exercise via Wii Fit U on chronic low back pain, measured by NRS at baseline versus 8 weeks later, with no statistically significant difference compared to usual activities, however, after adjustment for baseline, the results showed a statistically significant difference between the 2 groups.

A meta-analysis of data provided by VAS and NRS in 7 studies was performed and the overall results of this meta-analysis were inconclusive (SMD –0.22; 95% CI –0.47 to 0.02; P=.07; I^2= 0%; the fixed-effect model; Figure 4).

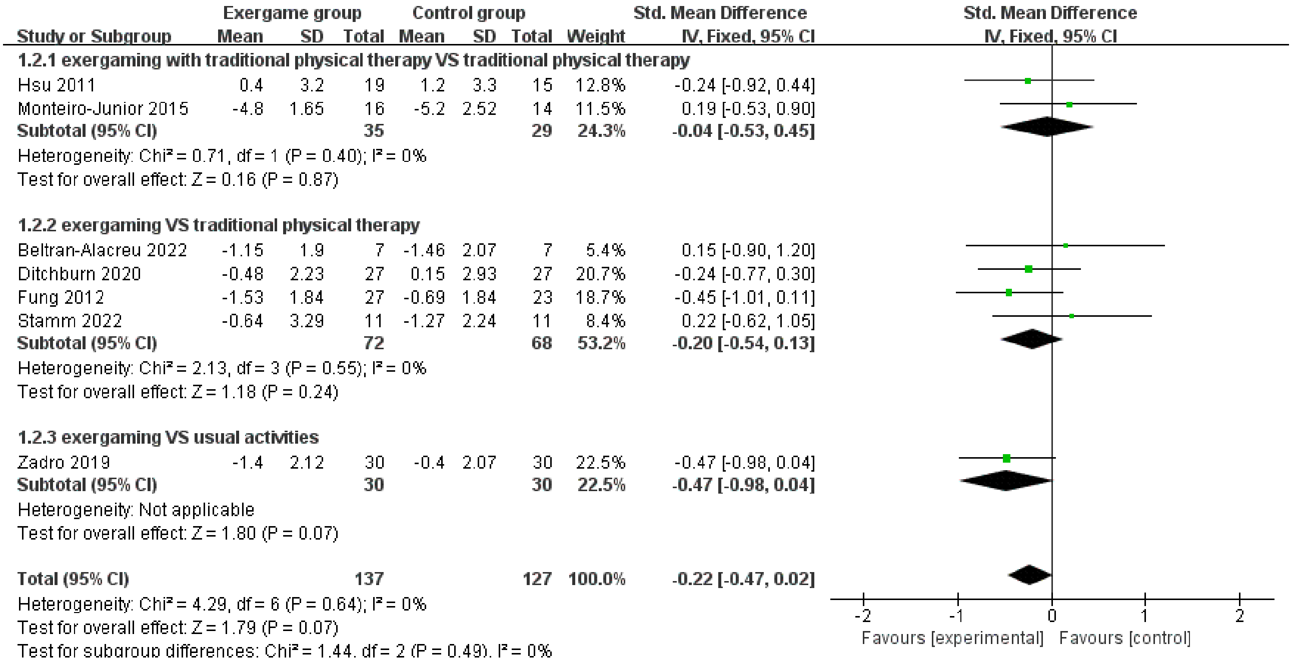
Figure 4. The effects of exergaming on pain perception.



Subgroup Analysis

We investigated the differences in the effects of pain perception on the comparisons. Subgroup analysis showed no significant effect of exergaming in combination with traditional physical therapy (SMD –0.04; 95% CI –0.53 to 0.45; P=.87; I^2= 0%; the fixed-effects model; Figure 5) or exergaming alone (SMD –0.2; 95% CI –0.54 to 0.13; P=.24; I^2= 0%; the fixed-effects model; Figure 5) on pain perception compared to traditional physical therapy. There was no statistically significant difference between exergaming compared to usual activities (SMD –0.47; 95% CI –0.98 to 0.04; P=.07; I^2= 0%; the fixed-effects model; Figure 5). The effect sizes for the 3 comparisons were small (<0.3), small (<0.3), and medium (≥0.3 and <0.6), respectively.

Figure 5. The effect on pain perception in the different the comparisons.



We conducted subgroup analyses to investigate the effects of exergaming on pain perception in participants with chronic pain or nonchronic pain. Subgroup analyses of the 7 studies revealed a nonsignificant difference in the effect of exergaming on chronic pain compared to controls (SMD –0.16; 95% CI –0.45 to 0.14; P=.29; I^2= 0%; the fixed-effects model; Figure 6). Similarly, there was no statistically significant effect of exergaming on nonchronic pain compared to the control group (SMD –0.36; 95% CI –0.80 to 0.07; P=.10; I^2= 0%; the fixed-effects model; Figure 6). Nevertheless, the effect sizes were small for chronic pain (<0.3) and moderate for nonchronic pain (≥0.3 and <0.6). We proceeded to investigate in depth the effect of exercise frequency on pain perception in participants with chronic pain. Subgroup analysis of the 5 studies showed no significant difference in the effect of exercise frequency of twice a week (SMD –0.16; 95% CI –0.64 to 0.32; P=.51; I^2= 0%; the fixed-effects model; Figure 7) and 3 times a week (SMD –0.16; 95% CI –0.53 to 0.22; P=.41; I^2= 35%; the fixed-effects model; Figure 7) on chronic pain compared to the control group, and the effect size was the same for both exercise frequencies (0.16).

Figure 6. The effects of exergaming on chronic pain or nonchronic pain.

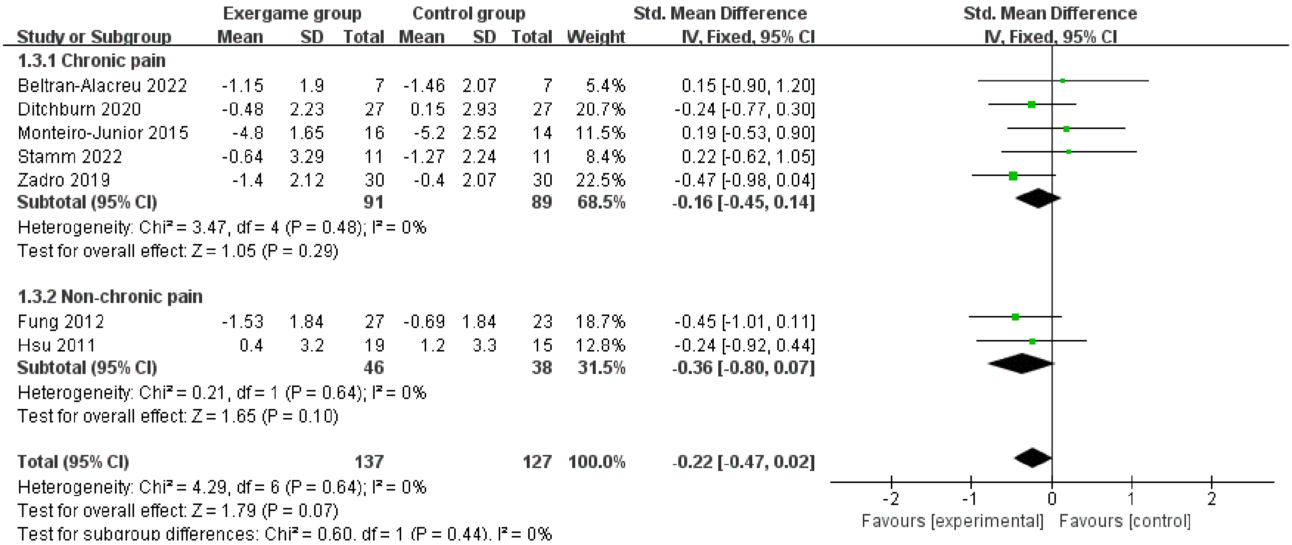


Figure 7. The effect of exercise frequency on chronic pain.

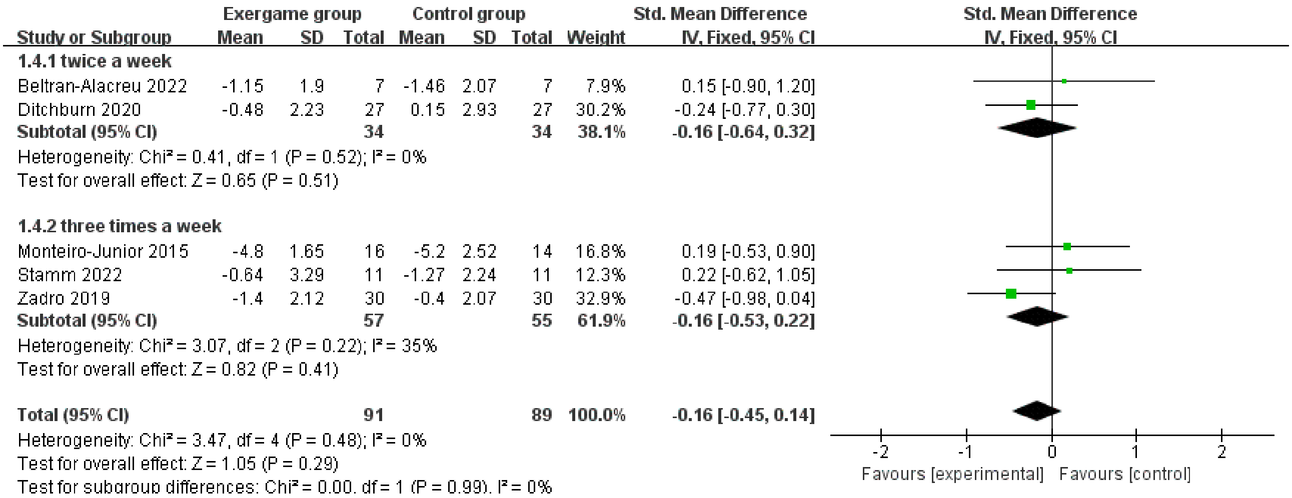

Discussion

Efficacy

This meta-analysis and systematic review focused on the effects of exergaming on musculoskeletal pain in older adults and included 7 randomized controlled studies. The main finding is that the effect of exergaming on musculoskeletal pain in older adults is inconclusive. The results of this study are similar to Collado-Mateo et al [35], and they concluded that exergaming is more difficult to improve musculoskeletal pain in older individuals compared to adults. Of the 7 studies we included, 1 study [32] adjusted for baseline reported a significant improvement between groups. Another study [31] showed significant differences between the experimental and control groups in terms of improvement in thermal pain. Furthermore, the quality of the evidence is low and the sample sizes in the studies were quite small. Further research is needed on the effect of exergames on musculoskeletal pain in older adults.

The highest mean effect size of –0.47 was observed for improvement in pain in the comparison of exergaming versus usual activities, although it was not statistically significant. In this comparison, only 1 study [32] was included and adjusted for baseline, which showed statistical significance. This suggests that exergames have some potential in the treatment of musculoskeletal pain in older adults and that future high-quality studies are needed. Exergaming combined with traditional physiotherapy compared to traditional physiotherapy alone yielded the lowest mean effect size of –0.04, but still favored the experimental group despite the nonsignificant difference between the groups. The results of the 2 included studies were contradictory. Hsu et al [21] examined older adults with upper limb dysfunction, and after 4 weeks, the pain did not improve within either group. In contrast, in the study by Monteiro-Junior et al [44], the pain was significantly improved within both groups after 8 weeks, but the difference between the groups was not significant and showed results in favor of the control group. First, the difference in the results of the 2 studies may be related to the disease experienced by the participants, with different duration of the intervention. Second, the results of the study by Monteiro-Junior et al [44] favored the control group, possibly because participants in the experimental group had to complete not only traditional strength and core training, but also exergame training through the Nintendo Wii, with a total training time of 90 minutes each time, 3 times per week, and higher exercise intensity, which may have made people difficult to obtain optimal results. The results of the network meta-analysis by Fernández-Rodríguez et al [47] suggested that core exercises, strength exercises, or mind-body exercises for less than 60 minutes at a time, at least once to twice a week, with exercise lasting 3 to 9 weeks, are the most beneficial treatment for pain and disability in adults with chronic lower back pain exercise program. Due to older adults tend to have lower endurance levels, they are more susceptible to sports injuries and overexertion and have difficulty tolerating high-intensity training. The sample sizes of the 2 studies were small and the results should be interpreted with caution. In the comparison of exergaming with traditional physical therapy, the mean effect size was –0.2. The results favored the experimental group. Overall, exergaming can be used as adjunctive alternative therapy to traditional physical therapy.

These studies included older adults with a variety of musculoskeletal pain. Most of the participants in the studies suffered from chronic pain (*k*=5) such as back pain (*k*=3), neck pain (*k*=1), musculoskeletal pain (*k*=1), and other nonchronic pain such as upper extremity dysfunction (*k*=1) and post total knee replacement (*k*=1). These can be explained by the results of epidemiological studies, in which the most common pain complaints were osteoarthritic back pain, especially in the low back or neck (65%), musculoskeletal pain (40%), peripheral neuropathic pain (35%), and chronic joint pain (15%-25%) [9]. The results from the subgroup analysis showed that the effect sizes of exergaming on improving nonchronic pain were greater than the effect sizes on improving chronic pain. The results of this study are inconsistent with those of Collado-Mateo et al [35] and the results may be due to age-related group differences, and our study focused only on the group of older individuals. More studies are needed in the future.

The mechanisms by which exercise ameliorates pain are unclear, with 1 suggestion being that exercise leads to an increase in stress pain thresholds and that adaptation of central inhibition occurs over time with exercise training [48]. A meta-analysis showed that increasing the frequency of weekly exercise was most likely to have a positive impact on patients with chronic pain [49]. However, our study results showed that exercise frequency of twice a week and 3 times a week had the same size of effect on chronic pain. There are no standardized criteria for exergaming intervention programs, and it is particularly important to develop an appropriate exercise program. From the RCTs included in this study, 4 weeks of the exercise was sufficient to significantly improve pain, at least twice a week, but not for more than 90 minutes per session.

Exergames Design

Most of the 7 studies tested commercial game platforms, with 1 study using a training rehabilitation-specific platform [31], and participants in the exergaming group experienced significant improvements in pain and for thermal pain, there was a significant difference between the 2 groups, the only 1 of the included studies to show a significant between-group difference for improvement in pain. Therefore, using professional rehabilitation exergames may be more effective than commercial games [23]. Professional exercise rehabilitation games are more specialized because they may be developed with the involvement of professionals in their design and can take into account the type of illness the users have, their needs, etc. Most commercial exergames are not suitable for the group of older individuals, about speed, required movements, amount of information, etc [50]. Therefore, in the future, commercial and medical rehabilitation professions should strengthen their cooperation to develop user-centered exergames for older individuals [51], thus improving the efficacy of exercise [52]. For older individuals, their physiological characteristics [53] and motivations for use should be considered. Older adults are motivated more by perceived health effects, the pleasure of the game, and the improvement of social confidence [20,54]. Wang et al [55] suggested that when designing exergames, first, aging characteristics should be included, paying attention to the decline of cognitive and physiological abilities associated with aging. Second, the game motion recognition should have higher fault tolerance. Third, the feedback should be clear. Fourth, consider the endurance of older individuals, pay attention to fatigue management and control the pace of the game. Fifth, it should have continuous action cues and tutorials. Sixth, it should be connected with reality. Seventh, reasonable use of body parts. Eighth, make good use of repetitive actions and reversible actions. Ninth, design advanced actions for the same game tasks. Lastly, designers should take advice from rehabilitation experts when designing exergames.

Supervision and Adherence

Except for Zadro et al [32], who studied unsupervised home exergame training and found a significant effect of exergaming on pain after adjusting for baseline, the majority of research participants were supervised during exergaming. Compliance among participants was higher but still lower than with supervised exergame training. A prior study indicated that while home exercise training relieved low back pain, supervised training improved pain intensity the greatest [56]. However, to the best of our knowledge, no studies have been conducted to compare unsupervised home exergaming with unsupervised home exercise in pain relief for older individuals. Exergaming, in general, remains a highly promising kind of training that allows participants to undertake unsupervised therapeutic exercises at home, capable of generating a remote rehabilitation environment. Older individuals who are frail or incapacitated can obtain therapy without having to travel vast distances, which may have significant cost-effectiveness benefits [22]. Because just 1 study on home exercise was included in this paper, the results were insufficiently persuasive. As a result, further research might be done in the future, and methods to promote adherence to unsupervised exergame training in older people at home could be pursued.

Security and Experience

Exergames are generally safe for older adults, although a few participants reported feeling uncomfortable, which may be related to the device and form of movement, such as wearing sensors to move the neck making participants feel dizzy, uncomfortable with their eyes, and disoriented [22]. From the reports of coaches and participants, it was found that exergames increased the fun and attraction of physical activity and made the game more enjoyable for the participants [21,45,46]. Previous research has also concluded that participants in the exergaming group had significantly more enjoyment of exercise than the other treatment groups [57]. Participants found exergames highly usable and the game challenging [22]. Exergames can increase participants' satisfaction and compliance [22]. Some studies [20,46] considered socialization as an important factor in improving adherence, as stated in previous studies [58]. However, participants in a control group in 1 study showed a higher acceptance of traditional exercise than exergames [31], possibly because participants in the control group had not experienced exergames. Overall, older adults have positive attitudes toward exergaming.

Limitations

It is the first systematic review of the efficacy of exergaming on musculoskeletal pain in older adults. Several limitations should be in consideration. When searching the literature, publications were limited to those in English and peer-reviewed ones. The small sample sizes of most studies were also a limitation. In addition, the overall risk of bias in the included studies was relatively high.

Conclusions

This paper systematically reviews the efficacy of exergaming on musculoskeletal pain in older adults. The available evidence is limited, and therefore, exergaming cannot yet be considered an effective intervention for improving pain in older adults. Exergames are safe and cost-effective. The playfulness and social components of exergaming may contribute to participant adherence. Increased collaboration between industries to develop specialized exergames for older adults should be considered in the future. Overall, exergaming can be used as a complementary alternative to traditional training. Future larger sample sizes and rigorously designed RCTs are needed to explore the effects of different exergames on older adults with musculoskeletal pain.

Abstract

The metaverse is gaining traction in the general population and has become a priority of the technological industry. Defined as persistent virtual worlds that exist in virtual or augmented reality, the metaverse proposes to afford a range of activities of daily life, from socializing and relaxing to gaming, shopping, and working. Because of its scope, its projected popularity, and its immersivity, the metaverse may pose unique opportunities and risks for mental health. In this viewpoint article, we integrate existing evidence on the mental health impacts of video games, social media, and virtual reality to anticipate how the metaverse could influence mental health. We outline 2 categories of mechanisms related to mental health: experiences or behaviors afforded by the metaverse and experiences or behaviors displaced by it. The metaverse may benefit mental health by affording control (over an avatar and its virtual environment), cognitive activation, physical activity, social connections, and a sense of autonomy and competence. However, repetitive rewarding experiences may lead to addiction-like behaviors, and high engagement in virtual worlds may facilitate and perpetuate the avoidance of challenges in the offline environment. Further, time spent in virtual worlds may displace (reduce) other determinants of mental health, such as sleep rhythms and offline social capital. Importantly, individuals will differ in their uses of and psychological responses to the metaverse, resulting in heterogeneous impacts on their mental health. Their technological motivations, developmental stage, sociodemographic context, and prior mental health problems are some of the factors that may modify and frame the positive and negative effects of the metaverse on their mental health. In conclusion, as the metaverse is being scaffolded by the industry and by its users, there is a window of opportunity for researchers, clinicians, and people with lived experience to coproduce knowledge on its possible impacts on mental health and illness, with the hope of influencing policy-making, technological development, and counseling of patients.

Introduction

In 2021, Facebook spent US $10 billion on its metaverse division, shipped 10 million virtual reality headsets, and rebranded itself as Meta [1]. The same year, 46 million users were logging onto the game platform Roblox every day, spending a total of 41 billion hours in this virtual world [2]. Concurrently, technology giants Apple, Microsoft, and Google have been developing their own metaverse-related infrastructures. While the idea of a metaverse is not new, the popularity of virtual worlds has boomed in the past few years, particularly during the COVID-19 pandemic [2,3].

The technology magazine *WIRED* defines the metaverse as an extension of "virtual reality—characterized by persistent virtual worlds that continue to exist even when you're not playing—as well as augmented reality that combines aspects of the digital and physical world” [4]. In virtual reality, users wear headsets to see a digital world in 3 dimensions. Through the avatars they embody, they can move in the virtual environment, have life-like interactions with other users, and control digital objects. In augmented reality, users see their real, physical environment, but digital elements are integrated through eyeglasses or a smartphone. Pokémon Go is an example of augmented reality: in this mobile game, the real-world locations of players are captured by their smartphone camera and overlaid with virtual creatures that they can interact with. Other devices combine elements of virtual and augmented reality, allowing users to simultaneously interact with virtual and real objects in “mixed reality” [5].

Although virtual worlds such as Pokémon Go and Roblox are already ubiquitous, the promise of the metaverse is to make these spaces more immersive and interconnected, and to extend their scope of application beyond play unto other aspects of daily life. Of late, there has been an emergence of virtual reality platforms such as VRChat, whose main purpose is to allow users to interact and socialize with others with their self-created 3D avatars. Increasingly, users of virtual worlds trade cryptocurrencies, which are digital currencies that function like money but are independent from states and central banks [6]. With cryptocurrencies, one can buy digital assets (eg, art, avatar apparel, and virtual estates) that are recorded on virtual ledgers as uniquely having one owner, and that are not interchangeable or duplicable; these assets are called nonfungible tokens [7]. Tying together a range of emerging technologies, metaverse platforms thus offer rich and vivid experiences, from games to new ways of socializing, working, learning, and shopping [4,8].

Will the metaverse impact mental health and illness? With every media revolution threatening to infiltrate people’s homes, whether the radio, TV, or the internet, there are concerns for mental health [9]. In line with popular views, a body of research points to potential harmful effects of digital media on depression, anxiety, and addiction-like behaviors [10-12]. However, in truth, cyberpsychology—the study of how humans and computers interact—paints a much more complex picture [13]. The mental health risks of digital media are far from universal and, at least in some cases, the adaptive use of technology may even contribute to improvement in short- and long-term well-being [14]. As interest in the possibilities of the metaverse continues to grow in the general population, we consider in the present viewpoint how this technology may impact mental health. We narratively present a selection of key articles from the literature on digital media to appraise the potential mental health risks and benefits of the metaverse and discuss directions for future research.

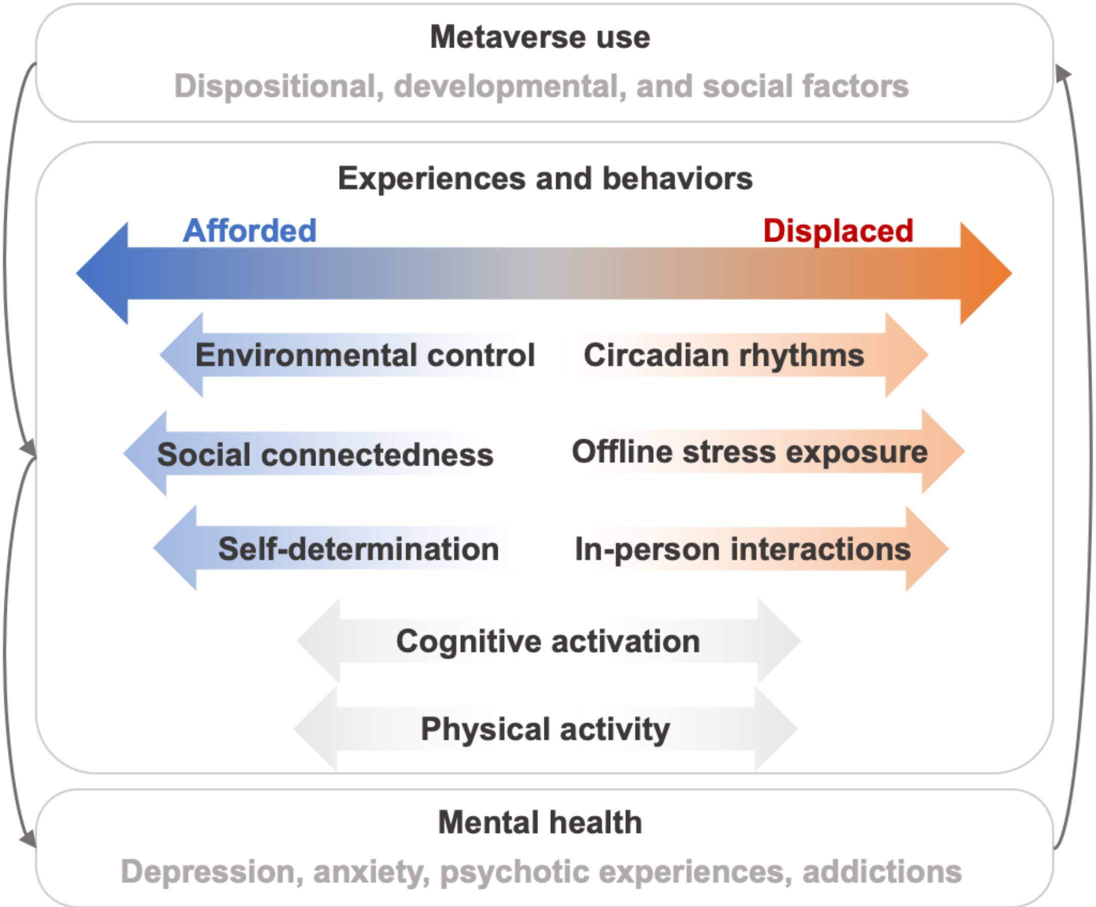
Virtual Worlds and Mental Health

Overview

Most research to date has examined exposure to digital media as a function of screen time, roughly defined as time spent on digital media and other screen devices. This body of literature generally shows that individuals who report greater screen time also report poorer mental health [15]. However, this association is likely to be confounded by other factors, such as preceding mental health conditions, occupational status, and lifestyle, to name a few. When individuals are studied as their own comparators, fluctuations in digital media use over time do not seem to predict changes in mental health [16-19], which goes against the hypothesis that higher screen time causes poorer mental health. However, the utility of screen time as an indicator of digital exposures is likely limited if the amount of time on digital media is not the primary mechanism by which digital media affect mental health. Media researchers have advocated for dropping the concept of screen time and focusing instead on more specific, theory-based measures of digital media exposures [14,16,20]. Limited research has investigated the mental health impacts of the metaverse, but many of the current platforms described as “metaverse” rely on virtual reality and are intended for internet-based gaming or socializing (see the *Introduction* section). The metaverse shares a number of characteristics with social media and video games: these include the possibility of interacting with other individuals in real time regardless of geographical location, the possibility of being anonymous, and the persistence of data over time [21,22]. Video games and virtual reality further afford vivid experiences that can be studied to better understand the potential psychological effects of immersion in the metaverse.

Thus, to anticipate how the metaverse will affect mental health, we can learn from the literature examining the mental health impacts of social media, video games, and virtual reality. From this state of knowledge, 2 broad categories of mechanisms, by which the metaverse may influence mental health, emerge: experiences or behaviors that are *afforded* by its use and experiences or behaviors that are *displaced* by it [9]. Below, we discuss these mechanisms in detail and summarize them in Figure 1.

Figure 1. Interplay among metaverse use, experiences, behaviors, and mental health. Participation in the metaverse may afford certain experiences and behaviors relevant to mental health, while displacing others. The type of use, as well as individual and contextual factors, likely influence these effects. Together, these mechanisms subsequently influence mental health outcomes. In turn, mental states reciprocally influence interactions with the metaverse.



Affordances of the Metaverse

Environmental Control and Self-representation

Virtual worlds of the metaverse have the potential to afford users a number of experiences susceptible of impacting their mental health. This begins with the environment of the person, on which the metaverse affords a unique degree of control: users can easily choose and navigate the environment of their choice, or even self-design the space they are in. Virtual reality relaxation exploits this affordance by bringing the user into restorative, pleasant environments such as lakes, forests, or rivers. According to a recent systematic review, there is preliminary experimental evidence that virtual reality relaxation is effective for improving mood and anxiety, at least in the short term [23]. Conversely, exposure to social stressors in virtual environments is associated with higher levels of subjective distress and paranoia [24], illustrating the potential influence of virtual environmental exposures on mental health.

Virtual worlds also afford users to choose their avatars' appearance and identity, which can influence how they perceive and interact with their surroundings. In an international survey of 142 regular users of video games, greater embodiment over an avatar was associated with lower awareness of bodily sensation during gaming sessions [25]. In a sample of 60 women from the UK general population, reducing avatar height during a virtual reality train ride was associated with increased levels of paranoia and negative social comparison [26]. Experimenting with self-representation in the metaverse may also participate in youth development: some authors have suggested that during adolescence, conducting identity experiments on the internet could help in the development of social competence [27]. However, strong investment in self-representation in virtual spaces could also cause harms, such as dissatisfaction with one's physical body. This risk has been documented in studies of social media usage, showing that people's investment in receiving feedback on their self-portrait photographs, and their comparisons with the photographs of others, may contribute to body dissatisfaction and drive for thinness [28,29].

Cognitive Activation and Physical Activity

The design of metaverse contents may be harnessed toward activating a person's cognitive functions in beneficial ways. Many games have been developed to encourage players to use their cognitive skills to solve problems [30]. In a randomized controlled trial of 72 US adults with major depressive disorder, a video game–based intervention was effective in improving sustained attention and global cognitive functioning compared with an active control [31]. The embodied navigation of virtual worlds, enabled by sensors that capture the user's movement in physical space, can also promote physical activity. This is the case of video games involving physical activity ("exergames"), which can produce significant improvements in cognitive functioning among clinical and nonclinical populations, according to a meta-analysis of randomized controlled trials [32].

Social Connectedness

Interpersonal relationships could be developed and maintained through the metaverse. The capacity to connect with others regardless of physical location enhance individuals' opportunities to join communities with shared interests, values, or identities. Members of marginalized groups and people living with mental health problems may benefit from these platforms for sharing knowledge and obtaining peer support [33-35]. Importantly, internet-based interactions can be experienced as meaningful. In an international survey of people using massively multiplayer online role-playing games (MMORPGs), respondents frequently reported high-quality relationships in their games, which sometimes transformed into friendships or romantic partnerships in the physical world [36,37]. MMORPG users also commonly play with their offline friends or romantic partners [37,38], suggesting that virtual worlds can foster both the formation of new relationships and the enhancement of existing ones. More research is needed to understand the extent to which these social affordances impact mental health, but arguably, they may be beneficial if they decrease a person's loneliness and increase their social capital [39].

Self-determination

Experiences of autonomy and competence in virtual worlds can fulfill the need for self-determination. In a survey of 672 MMORPG players, positive experiences associated with intensive gaming involvement included feelings of achievement, positive anticipation and stress (eg, "adrenaline rush"), enjoyable repetition and routine, positive social obligation, satisfying labor, increased confidence, and positive distraction, to name a few [40]. In samples of college students playing video games in experimental settings, experiences of autonomy and competence while playing were associated with gaming motivation and enjoyment [41]. For people experiencing disability, functional impairments, or social adversity in the context of mental health problems, digital spaces that operate under different parameters than the offline, physical world may thus provide invaluable opportunities for fulfilling the psychological needs related to self-determination.

Addictions

Because they repetitively afford rewarding experiences, virtual worlds can also be the object of addiction-like behaviors. Gaming disorder, which made its entry in the 11th revision of the International Classification of Diseases, captures how this may translate into mental health problems [42]. Gaming disorder is defined by persistent or recurrent gaming behavior, manifesting as impaired control over gaming, increased priority given to gaming (at the expense of other interests and activities), and continuation or escalation of gaming despite the occurrence of negative consequences. A meta-analysis situates the global prevalence of gaming disorder at 2%-3%, with the most common type being internet-based rather than offline gaming [43]. Attributing problematic gaming behaviors as constitutive of a mental disorder is subject to controversy [10,44]. But at the minimum, epidemiological and cross-cultural data show that some players engage in gaming in ways that negatively impact their well-being and functioning [43,45]. In the metaverse, immersive technologies broaden the scope of daily-life activities that can be performed digitally, raising the possibility of even greater absorption into virtual worlds and greater interference with functioning. Addiction is a particular concern considering that companies have a financial incentive to maximize virtual worlds' capacity to captivate users—something that can be facilitated by passively monitoring users' behaviors in the metaverse and by customizing their environment accordingly [46].

Displacement of Offline Activities

Circadian Rhythms

High engagement in the metaverse could be at the expense of other activities in the offline environment. According to the displacement hypothesis [47], excessive use of digital media causes harm to the individual by displacing time spent on other activities that are beneficial for mental health. Notably, participating in virtual worlds in the evening or at night may impair sleep rhythms because of delayed or reduced sleep time. According to a recent narrative review, previous observational studies support an association between greater use of screen-based media and poorer sleep outcomes in adolescents; however, experimental research does not consistently show that screen use has causal effects on sleep [48]. Three mechanisms could be responsible for the putative effects of screen use on sleep: disruption of the neurobiology of sleep due to light emitted by the screen devices, delay of sleep onset or reduction of total sleep time because of time spent on the screen device, and psychological stimulation caused by digital media content [48]. More evidence is needed to determine the causal effects of screens on sleep and whether the degree of immersion afforded by the metaverse will amplify these effects.

Offline Stress Exposure

Individuals may participate in virtual worlds to avoid or escape from anxiety-provoking situations of the offline world. In web-based surveys, avoidance and escapism are relatively commonly reported by video gamers as part of their motivations for gaming [36,45,49]. For example, in an international survey of internet-based gamers, participants endorsed some degree of "gaming to avoid challenges in [their] life rather than deal with them directly" (average item score of 2.46 on a scale of 1 to 5)—a finding that was consistent across North America, Europe, and China [45]. Recurrent avoidance of stressful situations may prevent a person from seeking to solve the problems or from learning to tolerate the stressors they face. However, it has been suggested that escapism through video gaming can also be an adaptive coping strategy that helps regulate or restore mood following exposure to stressful situations [50,51]. A systematic review of surveys conducted among video gamers found that escapism is cross-sectionally associated with both negative outcomes (eg, problematic video gaming, social anxiety, and loneliness) and positive outcomes (eg, social connection, enjoyment, and psychological well-being) [49]. Longitudinal studies are needed to better understand how escapism in the metaverse interacts with and affects a person's mental health problems over time.

In-Person Interactions

A related topic is how the potential displacement of in-person social interactions toward their digital equivalent influences mental health. As highlighted above, there is evidence that internet-based gaming can foster meaningful social interactions both digitally and offline. However, if high social involvement in the metaverse is accompanied by limited social interaction in the offline world, the net result may be an increase in social anxiety and a decrease in social skills in offline contexts [39]. This could explain why internet addiction was associated with a prospective increase in loneliness in a convenience sample of 361 college students in Hong Kong [52]. Potentially, for individuals living with social anxiety or low social skills, achieving connectedness through virtual worlds can simultaneously be a compensatory strategy and a perpetuating factor that constrains exposure to in-person social interactions.

The Importance of Individual and Contextual Factors

Overview

The effects of virtual worlds on mental health likely depend on individual and contextual factors. To begin with, virtual worlds and the technologies that support them differ in their features and affordances, including those discussed above: control of the avatar and environment, cognitive stimulation, social connectedness, and the satisfaction of other psychological needs. Users also have freedom in how they take advantage of virtual worlds' possibilities. Differences in digital media uses, and their relevance for mental health correlates, are frequently observed in the scientific literature. For example, in an experience sampling study of 44 adults with and those without psychosis in the United Kingdom, posting about feelings and venting on social media predicted higher subsequent paranoia, while posting about daily activities predicted lower paranoia [53]. Although such findings are correlational and subject to confounding, they reflect the heterogeneity of uses and mental health correlates for a given technology. This heterogeneity is perhaps best understood in terms of individual or contextual factors. Borrowing on the terminology of Valkenburg and Peter [54], factors that modify and frame the mental health impacts of digital media can be organized in 3 categories: dispositional, developmental, and social.

Dispositional and Developmental Factors

At the dispositional level, individuals' motivations and interests will likely influence how they engage with the metaverse. Among US school-aged children, boys generally report greater use of video games than girls, whereas girls report greater use of social media [55]. In an international longitudinal study of video game players, a person's increase in intrinsic motivation for gaming was associated with a subsequent improvement in their affect and life satisfaction; conversely, an increase in extrinsic motivation (ie, feeling pressured to play) was association with a deterioration of the same outcomes [16]. At the developmental level, age may moderate the mental health outcomes of metaverse usage as a function of the person's developmental needs and sensitivities, as well as age-dependent differences in motivations and profiles of use. To illustrate, early childhood is a crucial period for cognitive development, and there is tentative evidence from a Canadian study that a child's increase in screen time is associated with a decrease in their performance on developmental screening tests between ages of 24 and 60 months [56]. Adolescence is marked by social and identity development, and teens may be particularly sensitive to social acceptance and rejection in virtual worlds [57]. Some authors have also argued that digital experiences have the potential to contribute to agency, connectedness, and storytelling capacities that foster youth's identity development [58].

Social Factors

Social and economic factors are sources of inequalities in the access to metaverse-related technologies. Lower income or economic development is associated with reduced access to internet-connected devices, and in many emerging countries, women have lower access to the internet than men [59]. Given the cost of virtual reality headsets and related technologies, the rise in popularity of metaverse platforms may contribute to widening digital inequalities. Other sources of digital inequalities include older age, as older adults tend to be less autonomous and experienced in the use of new technologies [59], and physical disabilities, which to date have received little attention in the development of virtual reality hardware [60]. Digital inequalities are important to consider in the design of policies and the organization of services relevant to mental health care: these inequalities may translate into unequal access to digital mental health interventions, as well to health information and economic opportunities—all of which are determinants of mental health and recovery.

Virtual worlds are also a space where people can be exposed to bullying and discrimination. Exposure to cyberbullying is relatively common among the youth and has been associated with higher subsequent risk of psychological distress, suicidal ideations, and delinquency [61]. People in virtual worlds may feel emboldened to enact discriminatory and aggressive behaviors, as suggested by reports of sexual harassment, racism, homophobia, and transphobia within some video game communities [59,62,63]. Considering that 3D embodiment over an avatar, and its interactions with a virtual environment, can make internet-based interactions particularly vivid, one question that appears relevant for future research is to consider whether the metaverse risks magnifying the psychological impacts of internet-based bullying and discrimination.

People's offline environment may further influence how they engage with virtual worlds and their propensity for using them in a problematic, addiction-like manner. Socioeconomic disparities and other forms of social adversity could increase people's propensity for problematic metaverse use, for example, by motivating them to escape their stressful environment, or by constraining their access to alternative activities in their neighborhoods. Nagata et al [64] proposed that these effects of social adversity may explain, to some extent, why higher levels of problematic video game use are reported by adolescents in the United States who identify as Native American, Black, or Latinx, and by those with lower parental educational attainment.

Conversely, positive social interactions in the offline environment could be protective against the risk of problematic metaverse use. Illustrating this, a study of 250 MMORPG players found that higher levels of cultural consonance (ie, feeling successful in conventional society) and playing with offline friends were both cross-sectionally associated with lower levels of problematic gaming [38,65]. Similarly, in 2 samples of adult video game players, higher satisfaction of psychological needs in the offline world was cross-sectionally associated with lower levels of internet gaming disorder [66]. Young people's interactions with their parents may be particularly important in shaping how they engage with metaverse technologies. For example, a community-based study of 2974 children and adolescents in Singapore showed that higher parent-child closeness was subsequently associated with a decrease in their levels of pathological video gaming after 1 year [67]. Interactions with friends, family, and society in the offline world are thus relevant to understand individuals' engagement in virtual worlds. Together, these findings illustrate how individual and contextual factors, spanning dispositional, developmental, and social dimensions, may influence the mental health impacts of engagement in the metaverse.

Conclusions: Immersion in the Metaverse

When considered critically, the last 2 decades of research do not demonstrate universal harms of digital media on the mental health of the general population. The state of knowledge reveals many ways in which digital media may benefit or harm a person's well-being, whether as a function of technological, individual, or contextual factors. But popular concerns persist and will almost certainly grow if the metaverse fulfills its commercial and social ambitions. Perhaps what sets the metaverse apart from previous technologies is the greater immersivity it affords, compared with traditional social media and video game devices. Immersion seems to be a factor that could amplify many of the mental health impacts described above: with greater immersion may come greater displacement of bodily awareness, greater embodiment over one's avatar, greater sense of copresence with internet-based friends, and generally more vivid experiences. In turn, these features and experiences are likely to shape the motivations, affordances, and mental health risks associated with metaverse use.

It is too early to indicate whether the metaverse will broadly be a greater risk or benefit to mental health than previous digital media. Undoubtedly, virtual worlds are unprecedented in the scope of experiences and behaviors they can afford, and as such, in their potential to take a greater place in our daily lives. To adequately counsel patients and guide policies around the development and implementation of the metaverse, there is a need for timely and nuanced research on its opportunities and risks for mental health [68,69]. Arguably, previous research on digital media has often failed to achieve timely and nuanced knowledge production, partly due to the lack of clear theoretical frameworks and robust empirical methods [9,20]. Following these lessons, we believe a starting point is to examine the experiences and behaviors that are afforded and displaced by the metaverse, as well as the interplay of these effects with dispositional, developmental, and social factors. Collaboration among clinicians, researchers, individuals with lived experience, technology users, the industry, and other stakeholders will be crucial to successfully generate and translate this new body of knowledge. While metaverse technologies are in the process of being scaffolded and disseminated, psychiatry has a window of opportunity to think through conceptually and to strategically examine their risks and benefits for mental health.

Abstract

Game elements are increasingly used to improve user engagement in digital mental health interventions, and specific game mechanics may yield therapeutic effects per se and thereby contribute to digital mental health intervention efficacy. However, only a few commercial game–based interventions are available. We suggest that the key challenge in their development reflects the tension between the 2 underlying paradigms, health care and entertainment, which have disparate goals and processes in digital development. We describe 3 approaches currently used to negotiate the 2 paradigms: the gamification of health care software, designing serious games, and purpose shifting existing entertainment games. We advanced an integrative framework to focus attention on 4 key themes in intervention development: target audience, engagement, mechanisms of action, and health-related effectiveness. On each theme, we show how the 2 paradigms contrast and can complement each other. Finally, we consider the 4 interdependent themes through the new product development phases from concept to production. Our viewpoint provides an integrative synthesis that facilitates the research, design, and development of game-based digital mental health interventions.

Introduction

Background

Digital mental health interventions (DMHIs) are actively developed in response to the growing mental health crisis [1]. Some of the new interventions [2-6] use elements from entertainment games to improve user engagement and intervention effectiveness [7,8]. Using a game-based approach to pursue health-related aims requires developers to have competencies in both health care and game development; however, the 2 paradigms have considerable disparity in their goals. In health care, health-related aims are pursued by minimizing user interaction with the intervention, whereas entertainment products, largely oblivious to their health effects, seek to maximize user interaction with the content. This difference has led to specialized practices, institutions, and business models that are not readily compatible and challenge interdisciplinary development, which Mathews et al [9] succinctly describe as follows:

> *The "fail fast, fail often" mantra espoused by technology startups is frustrated by the confusing regulatory landscape of healthcare. This cultural clash is further exacerbated by the cautious, stepwise, and time-consuming process of healthcare innovation*

> *that is grounded in the risk-averse clinical principle of "first, do no harm."*

Existing models of intervention development [10-13], although comprehensive, do not sufficiently address the tension between health care and entertainment in the development of game-based DMHIs (gDMHIs). In this paper, we describe the tension and offer a framework to facilitate new product development and implementation.

The Treatment, Engagement, and Implementation Gaps in Digital Interventions

Mental disorders are common and cause distress and burden to both individuals and society [14]. However, most people with mental disorders remain untreated. The median treatment gap, defined as the difference between the prevalence of a disorder and those treated for it, is >50% for many disorders [15]. For instance, only a fourth of those living with anxiety disorders receive any treatment, with 1 (10%) in 10 receiving possibly adequate treatment [16]. The mental health care system is globally unable to offer sufficient interventions to address patients' needs.

Solutions to the mental health burden are increasingly sought from scalable digital interventions. The evidence of their effectiveness for both depression and anxiety is already substantial [17-19], and their effectiveness compares to that of face-to-face interventions [20]. Moreover, the treatments display a considerable dose-response relationship [17,18,21,22]: greater user interaction with the software-based intervention, that is, engagement, is associated with higher intervention effectiveness. However, digital interventions suffer from an engagement gap. High dropout rates and low user engagement are observed in digital interventions, particularly in self-guided programs [17,23-25], where 40% of the participants may drop out before completing a fourth of the intervention [23], and only 0.5% to 28.6% complete the entire intervention or continue its use [26]. As engagement is related to intervention effectiveness, there is a substantial need to ensure that users find the interventions interesting, motivating, and meaningful.

The engagement gap is also an indication of the implementation gap: researchers and developers struggle to transfer the effectiveness established in clinical settings to real-world environments [27]. The effectiveness of DMHIs in ideal and controlled research settings (efficacy trials) is almost double that in real-world settings (effectiveness trials) [18,28]. The intervention's clinical effectiveness in optimal circumstances does not guarantee real-world impact, which calls for paying more attention to how the interventions are designed and developed with both users and clinicians in mind.

Game-Based Approaches Seek to Increase Intervention Engagement and Effectiveness

Game-based approaches are increasingly developed with the ambition to improve user engagement with and the effectiveness of DMHIs [7,8]. This rationale reflects the immense popularity of digital entertainment games. Playing video games is a hobby for 71% of American youth and 65% of adults [29], and globally, there are >2.7 billion players [30]. Although youth and young adults are the most active players, the average player is aged 38 years, and those in their 30s still play, on average, >6 hours a week [31]. Digital games are a familiar, accessible, attractive, and engaging medium for the general audience.

Game-based interventions are currently developed for numerous psychiatric disorders, including depression [3], anxiety [2], attention-deficit/hyperactivity disorder (ADHD) [5], and autism spectrum disorder [6], and serious mental illnesses, including schizophrenia and bipolar disorder [4]. Fleming et al [8] suggested that game-based interventions can extend treatment reach, thus helping close the treatment gap and improve user engagement and intervention effectiveness. There are numerous game-based interventions in development [32], but only a few are in the market. To support their development, there is a considerable need for frameworks that address the particularities of the game-based medium and facilitate interdisciplinary collaboration.

The Aim of This Paper

There is a substantial need for DMHIs that are engaging, effective, and feasible, and game-based approaches have potential in this regard. In this paper, we offer an interpretive synthesis that integrates and contrasts the literature in 2 fields: health care and entertainment. First, we argue that the 2 fields are in tension, which challenges the development of game-based interventions. Then, we discuss how to negotiate the tension. We focus on 4 themes, namely the target audience, engagement, mechanisms of action, and effectiveness (TEME) framework. We conclude the discussion by reflecting on the themes through new product development phases. Aimed at researchers, developers, and designers working with game-based interventions, our paper facilitates interdisciplinary collaboration and the wise use of game-based elements to ameliorate mental health.

The Tension Between Health Care and Entertainment

The Paradigms Address Different Needs

We suggest that the engagement gap with DMHIs reflects a tension between health care and entertainment, which becomes especially apparent in game-based interventions. Our approach is built on the notion of the differentiation of society into subsystems such as law, economy, politics, religion [33,34], health care, and entertainment. The thorough history of the 2 paradigms is beyond the scope of this paper, but their differences can be summarized in the code that they specialize in. Health care is concerned with the code of health, focusing on identifying and classifying sources of disability and seeking remedies for them [35]. Moreover, health care has legitimized priority over the domain of health, manifesting in the authority of certified clinicians overviewed by regulatory bodies. Meanwhile, entertainment, also described as "audience-centered commercial culture" [36], is a societal subsystem focusing on the code of leisure. The value of entertainment manifests through its ability to attract and captivate the attention of the audience over time in the theater and through literature, music, and games. The freedom of expression prevails in these domains because of the low risk to audiences' health. The subsystem codes are associated with underlying universal human needs. According to the notions proposed by Max-Neef et al [37], health care addresses the existential needs of subsistence and protection by curing and helping, whereas entertainment responds to the needs of idleness, creation, and identity by offering fantasies, relaxation, and opportunities to have fun both alone and together with others.

The organizations catering to the same need differentiate into industries that share a high-level *raison d'être* and have specialized concepts, regulations, structures, competencies, and methodologies to support their work. This specialization both increases the effectiveness in addressing the underlying human needs *and* creates distance from other societal subsystems. Refocusing on game-based mental health interventions, they can be viewed as a combination of 2 domains: the entertainment game industry, which has developed specialized skills in digital art and animation, programming, project management, storytelling, game design, and media business, and mental health care, which focuses on psychiatric diagnoses and their etiology and treatment. To summarize, health care practices are not intended to craft digital entertainment and vice versa. The differences between DMHIs and entertainment games are illustrated in the Table 1.

Table 1. Differences between the paradigms of health care and entertainment are exemplified through digital mental health interventions (DMHIs) and digital entertainment games.

	DMHI	Digital entertainment games
Underlying paradigm	Health care	Entertainment
Paradigm code	Health	Leisure
Underlying need	Alleviating disorders and increasing well-being	Offering enjoyment, relaxation, and social connection
Users	Patients, clients	Consumers, players, fans
Goal	Introducing behavioral change and alleviating symptoms	Captivating and entertaining the player
The scientific base	Extensive research base	Growing research base
Categorized by	Therapeutic modality (eg, CBT[a])	Game genre (eg, FPS[b])
Evaluated by	Efficacy and safety	Game experience, business metrics, and reviews
Initiative to use	Often recommended by a health care professional	Chosen by the player from a wide variety of alternatives
Entry to market	High threshold: clinical evidence, regulations, and gatekeepers	Low threshold: global digital marketplaces
Availability	Growing number of interventions	High number of commercial games
Purchase	Insurance often pays for the service.	The customer pays for the service.
Business model	B2B[c]	B2C[d]

[a]CBT: cognitive behavior therapy.

[b]FPS: first-person shooter.

[c]B2B: business to business.

[d]B2C: business to consumer.

We are not aware whether the tension between health care and entertainment would have been previously framed in this way. However, the disparate goals of health care and entertainment have attracted prior attention. Yardley et al [38] discussed the need for digital interventions to promote "effective engagement" rather than merely pursuing an increase in user interaction. They highlighted the need to establish a causal connection between user interaction with the intervention and the intended behavior change. Exploring gamified information systems, Liu et al [39] described the phenomenon as "meaningful engagement": the intervention needs to reach its experiential outcomes—to be sufficiently enjoyable and feasible—to reach its instrumental outcomes of behavior and symptom changes. Furthermore, Siriaraya et al [40] separated "game value" from "therapeutic value," highlighting the difference between the 2 paradigms. These considerations emphasize how engagement and effectiveness are distinct, and we suggest that this relates to the 2 paradigms and their codes.

Differentiating Among Gamified Interventions, Serious Games, and Purpose-Shifted Entertainment Games

DMHIs with and DMHIs without game elements are actively developed, and the former particularly negotiates the underlying paradigms of health care and entertainment. We classified game-based interventions into the following 3 categories: gamified DMHIs, serious games, and purpose-shifted digital entertainment games. We refer to them collectively as gDMHIs, "game-based interventions" in short. As the intervention adapts more elements from entertainment games, on the one hand, its gameness [41] increases, and, on the other hand, its intentional therapeutic functionality transforms (Figure 1).

Figure 1. Three categories of game-based digital mental health interventions (gDMHIs) are positioned between health care and entertainment. DMHI: digital mental health intervention.

	Health care	gDMHI			Entertainment
Intervention	DMHI	Gamified DMHI	Serious game	Purpose-shifted digital entertainment game	Digital entertainment game
Description	DMHI without game elements	DMHI with game elements	A serious game with a therapeutic intention	A digital entertainment game used for therapeutic ends	A game with the primary purpose to entertain

At one end of the continuum, DMHIs pursue health benefits and use minimal game-based elements. At the other end, there are digital entertainment games that may have incidental health benefits to their primary aim of capturing the interest and attention of the player. The former can be described as functional software that serves a particular purpose, whereas the latter is built to create experiences that are valuable in their own right [42,43]. The design of digital entertainment games is a specialized domain differentiated from traditional, functional software development [44,45], which is also reflected in the concepts used. Functional software has users, and its evaluation focuses on usability and user experience, whereas games are evaluated based on their playability and game experience [46].

Between health care and entertainment lie 3 categories of gDMHI. When game design elements are incorporated into a DMHI, the intervention becomes gamified [47]. The 2 most common rationales for using gamification in health care are improving user engagement and the effectiveness of the intervention, and the most common game elements include levels, progress feedback, points, rewards, narration, and personalization [7]. The incorporated game elements should not be superficial and exogeneous to the designed intervention, but synergistic with the experience the intervention intends to create [48]. In addition, gamification is not limited to the features visible to the user but can include the use of game design principles and methods in design and development [47].

In contrast to gamified applications, serious games are full-fledged games that are used for purposes beyond entertainment [47,49], often in education, health care, and organizational development. Gamified applications and serious games are frequently differentiated in the research literature [50], but in practice, the line between the two is not easy to draw. To distinguish between gamified and full-fledged game interventions, Liu et al [39] suggested that gamification incorporates game elements on top of real-world systems without sacrificing their functionality, whereas serious games are separate from real-world systems. Thus, a gamified intervention may more closely resemble and augment functional applications while retaining the instrumental functions of the system, whereas a full-fledged game often includes a fictional world for the player to immerse in.

To further clarify, we differentiated game-based interventions from "serious games for health" serious games used within the health care system by clinicians and patients for therapeutic and educational purposes [51,52]. Not all game-based approaches within health care are interventions: only those that prevent, assess, and help manage disorders are interventions, in contrast to software with educational and information management aims [53].

Whereas gamified and serious game DMHIs are intentionally designed for therapeutic purposes, purpose-shifted games take an alternative approach. These are games designed for entertainment purposes but used for serious, therapeutic purposes, either with or without modifications [54]. The rationale for this approach lies in the finding that playing digital entertainment games may have a positive impact on well-being regardless of the design and use intention of the games [55,56]. Positive effects arise, for instance, from the users' connection with other people, which that alleviates loneliness and creates meaningful relationships; the games' cognitive demands, which train attention, perception, and executive functions; and the positive, eudaimonic experiences offered by the games [57,58].

The forte of the purpose-shifted approach is that commercially available video games are accessible, affordable, and of high quality compared with many designed gamified interventions and serious games. Consequently, this approach is quite popular. Recent reviews found that 14 of 27 interventions for depression [3] and 13 of 28 interventions for anxiety [2] used a purpose-shifted approach, and the rest of the interventions were designed. However, the approach also comes with a considerable downside: researchers have limited opportunities to continue intervention development because they do not control the intellectual property, code, art assets, or delivery of the game.

Differentiating among gamified games, serious games, and purpose-shifted entertainment games exhibits the variance in gDMHIs. Moreover, it contributes to understanding the developer's approach and position between the 2 underlying paradigms: is the intervention a functional application to which game elements are added, an entertainment game whose purpose is shifted, or a tailor-made serious game? Because game-based interventions draw from both health care and entertainment, there is a need to consider both perspectives in their development.

Bridging the Paradigms of Health Care and Entertainment

The TEME Framework

Overview

Interventions are intended for a particular audience who, by interacting with the interventions, hopefully, achieve positive changes that are explained by the interventions' mechanisms of action [10-13]. To contrast and discuss the paradigms of health care and entertainment, we focus on 4 interrelated themes that are necessary, but not sufficient, for the development of new products (Table 2). We acknowledge that other aspects are also necessary, including privacy [59,60] and integration with existing infrastructure [61]. However, we consciously focus on the 4, as they are illustrative of the differences between and strengths of the 2 paradigms and serve to solve the tension between them.

Table 2. The target audience, engagement, mechanisms of action, and effectiveness (TEME) framework for game-based intervention development.

Theme	Key question	Health care	Entertainment
Target audience	Who is the intervention engaging and effective for?	Health indication and user characteristics frame the target audience.	Differences in game preferences create various audiences.
Engagement	Does the user want to interact with the intervention?	Engagement is associated with effective mechanisms of action.	Subjective and objective engagement are measured.
Mechanisms of action	What explains the intervention effects?	The mechanisms of action are evidence based.	The mechanisms of action are synergistic with their game-based implementation.
Effectiveness	What does the intervention achieve?	The intervention helps achieve behavioral change and symptom reduction.	Interaction is satisfying and fulfills the players' psychological needs.

Target Audience: Who Is the Intervention Engaging and Effective for?

Intervention development begins with the target audience's needs [62]. In mental health, there are 2 main ways in which user needs are conceptualized: a diagnostic approach and transdiagnostic approach [63]. The former frames the need through diagnostic taxonomies, and the latter focuses on a particular symptom or health-related behavior. However, both approaches frame the intervention in terms of a health indication, and it is the health care paradigm that provides the initiative; goal; and, consequently, methods for evaluating the intervention's success.

Health indications, such as ADHD, schizophrenia, and depression, create the initial frame for the target audience. However, the actual target market is a subpopulation of this total addressable market influenced by several implicit factors. Users' age, gender, education, personality, and prior experiences with mental health services and the severity of their symptoms influence user engagement [64]. Knowing these background factors provides an opportunity to target audiences that favor digital interventions and to extend the intervention reach to new and underserved audiences through inclusive and participatory design [65]. Although our discussion emphasizes the end user, the intervention's target audience may also include other stakeholders, such as therapists in case of interventions that blend web-based and face-to-face therapies [66].

Besides the factors influencing DMHI use in general, some aspects influence user engagement with gDMHIs specifically. This reflects the considerable differences in users' game preferences [67]. Appreciating the divergence in player motivations goes back to Bartle [68], who noticed that the players of multiuser dungeons (an obsolete multiplayer game genre) engage with the games for divergent reasons and in different ways. On the basis of "a long, heated discussion," he identified the following 4 motivations to play: *achievers* play to pursue game-related goals, *explorers* seek to understand the fictional game world, *socializers* focus on role playing and interacting with others, and *killers* compete for dominance through conflict. Bartle's [68] insight was that players engage in an apparently similar activity for widely different reasons and use the affordances of the game to serve their preferences. Since his original work, player motivations have been explored further. A review of 12 player typologies found that there is surprising conceptual uniformity in the categorizations, concluding with 5 primary player motivations, adding immersion¸ which is concentration on the story, fantasy, and narrative, to Bartle's original 4 [69]. In addition to affecting *how* games are played, game preferences influence *which* games are played. Using survey data, Mandryk and Birk [70] classified players into 4 categories: those who appreciate single-player games, those who appreciate first-person shooter or action games, those who appreciate casual games, and those who appreciate most genres. Moreover, the researchers found that their categorization was not associated with depression, indicating that people with depression appreciate various genres. Thus, the game genre decision partly defines who finds the genre attractive and engaging.

We advocate an integrative approach to the target audience. The health indication provides a rationale for the intervention and limits the target audience. In addition to the factors influencing engagement with DMHIs, the chosen game genre influences who are drawn to the game-based intervention, continue to engage with it, and hence gain a positive impact from the interaction. Understanding the target audience allows developers to identify and cater to the variance in the users, their needs, play styles, and preferences and to remove frictions that prevent players from enjoying the intervention as much as they expect to.

Engagement: Does the User Want to Interact With the Intervention?

The user's motivation to interact with the gDMHI is to gain certain benefits and enjoy their time while doing so. According to concepts proposed by Siriaraya et al [40], the "therapeutic value" of the intervention is a function of its "game value": the more experientially pleasurable the intervention is, the more likely the player is to continue to interact with it. These 2 concepts are related through the behavioral change that the interaction invites. The capability, opportunity, motivation, and behavior (COM-B) system describes 3 antecedents for behavioral change [12]. To build the user's capabilities, opportunities, and motivation, the intervention can, for instance, educate, persuade, train, and model new behaviors, which we call the mechanisms of action. Behavioral change can lead to symptom change [13], although often after a significant delay of days and weeks, which should motivate attention to the player experience.

Mere interaction with the intervention, however, is not sufficient, which Yardley et al [38] highlighted through the concepts of microlevel and macrolevel engagement. For instance, an exergame delivers its effects when the user trains with it, exhibiting microlevel engagement. This may turn into macrolevel engagement with the broader goals of the intervention when the intervention teaches the user healthy exercise routines and encourages the transfer of new behavior outside the immediate interaction. Thus, unlike commercial entertainment games, whose success is often closely tied to microlevel engagement, gDMHIs are driven by 2-tier engagement, and a successful intervention becomes obsolete once the player has internalized the intended change, which is a considerable digression from the entertainment paradigm. Subjectively, microlevel engagement may be experienced as a reduced effort to interact with the intervention. Subjectively, microlevel engagement may be experienced as a reduced effort to interact with the intervention [71]. This is also what the player may expect from a game-based approach: when the intervention is introduced through the notions of "game" and "play," they allude to interactions that are more pleasurable than those with solutions more strongly associated with a functional approach.

To design for microlevel engagement, the concept needs a clear definition and metrics. Here, we turn to Perski et al [72], who provide a useful definition: "(1) the extent (eg, amount, frequency, duration, depth) of use and (2) a subjective experience characterized by attention, interest and affect." The 2 sides represent complementary aspects of engagement, objective and subjective aspects, which require different approaches in their evaluation [73,74]. The subjective criteria may be pursued through qualitative research, such as user interviews, think-aloud protocols, and focus groups that provide rich and detailed qualitative data on engagement [75], or swiftly through questionnaires [76]. Subjectively, high levels of engagement with gDMHIs may be experienced as immersion, where the player becomes unaware of the mediating technology, perceiving the interaction as unmediated [77]. The phenomenon is also known as presence, a sense of being "in the game." It has many similarities to the notion of flow, where the subject is absorbed in the task and becomes unaware of their surroundings [74,78,79]. This pleasurable mental state is the experiential value players seek from the game and manifests as a sense of "want to" rather than "have to" engage with the game [80].

To complement the evaluation of a subjective sense of engagement, game analytics can provide objective indicators of engagement. Among the strongest and most valuable tools in commercial entertainment game development, game analytics provides proof, also in business terms, that the target audience enjoys spending time with the game [81]. User analytics offers insights into microlevel engagement by measuring the time spent with the intervention, accompanied by metrics of retention, that is, players returning to the intervention.

Entertainment games are a medium focused on building engagement that is experienced as immersion. This provides the developers with a user-centered goal that can be evaluated both subjectively and objectively. The health care paradigm complements the approach by ensuring that evidence-based mechanisms of action are in place so that user interaction contributes to the expected health benefits.

Mechanisms of Action: What Explains the Intervention Effects?

Overview

Mechanisms of action explain how and why the intervention achieves the intended change in the user's behavior and symptoms [10]. They have also been called "mechanisms of change" [13], and "intervention functions" [12], and they include sharing knowledge, building motivation, changing beliefs, modeling new behaviors, and persuading change. In game-based interventions, these rationales are given a digital form through their game-based implementation. Next, we describe and contrast 3 common and distinct approaches to game-based interventions: adapting existing psychotherapies, offering cognitive training, and encouraging physical exercise (Table 3).

Table 3. Three approaches to game-based interventions exhibit the potential synergy between health care rationale and its game-based implementation.

Approach	Mechanisms of action	
	Health care: "what"	Entertainment: "how"
Adapting existing psychotherapies	Behavior change through an increase in mentalization capabilities	Narrative and story-driven implementations
Offering cognitive training	Training cognitive functions such as attention	High-paced action games
Encouraging physical exercise	Increased physical activity	Virtual reality, augmented reality, and fitness games

Adapting Existing Psychotherapies

Numerous existing psychotherapies have been adapted as gDMHIs, the most prominent of which is cognitive behavioral therapy [2,3]. There are numerous benefits to using an existing therapy to guide the development work: it provides a theoretical foundation, a rationale on how and why the intervention should work, credibility with stakeholders, and legitimacy for the work. Despite the differences between psychotherapies, their effects seem curiously similar [82]. It has been suggested that there are common factors that explain their effectiveness [83], although the research is ongoing [84]. Leiman [85] conceptualized that all psychotherapies seek to change the patient's position toward their challenges. When the client begins the therapy process, they are in an object position to their problem. Through therapy, they gain an understanding of their problem and capabilities to control it and, consequently, shift toward a subject position. Thus, the effectiveness of psychotherapy is based on the growth of mentalization capabilities and self-reflection, which then lead to behavioral changes.

Narratively rich game genres, such as role-playing and adventure games, may be particularly suited for adaptations of existing psychotherapies that invite an active reflection on one's thoughts, emotions, and behaviors. The interactions with game characters can be used to, for instance, simulate challenging social situations through role playing, model effective behaviors, and develop emotional regulation. An example of this approach is SPARX, a serious game for adolescents living with depression. The computerized CBT intervention consists of 7 modules, including psychoeducation, building hope, encouraging behavioral activation, and coping with negative emotions [86].

Offering Cognitive Training

Compared with psychotherapeutic approaches, the mechanisms of action of cognitive training games are considerably different. Their rationale lies in the finding that many mental disorders are associated with cognitive deficits [87]. For instance, depression is related to moderate deficits in memory, attention, and executive function, and these deficits may prevail partly even after depression is in remission [88]. Computerized interventions have been designed to address these deficits, and this approach has been found effective in addressing depressive symptoms [89].

Compared with reflective psychotherapeutic games that rely on player interaction with the narrative, characters, and story, the mechanisms of action in cognitive training games are more closely associated with the game mechanics. For instance, fast-paced first-person shooter games, real-time strategy games, and other action games may provide pathways for improving cognitive skills [90] and alleviating cognitive deficits associated with mental health challenges. Furthermore, the mechanisms of action may also be related to game preferences: reflective therapies may be preferred by those with a tendency for immersion and socialization, whereas cognitive training games appeal to achievement, exploration, and domination motives. Bearing in mind that fast-paced games are preferred by younger audiences [31], the interventions may be suited to addressing cognitive deficits associated with mood or neuropsychological disorders in the youth. An example of this approach is EndeavorRx, a gDMHI that seeks to alleviate pediatric ADHD [91].

Encouraging Physical Activity

To further contrast the mechanisms of action of reflective psychotherapeutic games and those of cognitive training games, the effectiveness of exergames is dependent on increasing physical activity. The rationale lies in the finding that physical exercise has significant and large antidepressant effects [92,93]. For instance, the augmented reality game Pokémon Go, which encourages finding, gathering, and collecting digital fantasy pets from various real-life locations, has been found to contribute to a greater number of daily steps and increased social interactions because the locations are frequented by like-minded players [94]. These interactions, in turn, may have positive effects on mood [95]. It appears that the interventions that encourage physical activity often use a purpose-shifted approach facilitated by the availability of exergames [2-4,96]. Currently, however, the quality of evidence on the effectiveness of exergames for mental disorders is low.

We highlight how development efforts need to find the synergy between the health research–based mechanisms of action and their game-based implementation. The 3 described mechanisms of action, built on existing psychotherapies, cognitive training, and physical exercise, exemplify how health care research can intertwine with the game genre implementation.

Effectiveness: What Does the Intervention Achieve?

The effectiveness of gDMHIs is indicated by behavioral and symptom changes [10,13]. Reaching a meaningful reduction in symptom scores indicates a clear benefit expected by clinicians and the players and payers of the intervention alike. To complement the symptom- or disorder-focused approach, the intervention may have other, equally meaningful benefits that occur in parallel or in addition to the symptom change. As the World Health Organization (WHO) [97] states in its constitution, "health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." In subjective terms, symptom alleviation may be related to improved quality of life [98]. To illuminate the complexity of the concept, a qualitative synthesis of the experiences of people with mental disorders found that good quality of life was associated with feelings of well-being, positive self-perception, control, autonomy, a sense of belonging, participation in meaningful activities, and a positive future view [99]. In other words, an improved quality of life is not perceived merely as the absence of symptoms.

Expanding from the symptom-based approach, the impact of gDMHIs may be considered through the self-determination theory [100]. It describes the following 3 universal human needs that contribute to intrinsic motivation, self-regulation, and well-being: competence, autonomy, and relatedness. Digital games have a unique possibility to contribute to the 3 needs by fostering a sense of competence by presenting the players with increasingly difficult puzzles as their skill increases, creating a sense of connection with other players enjoying similar activities, and supporting player autonomy by offering choices and various ways to play. As opposed to mediums that are more passively consumed, games are characterized by a sense of agency [101]: the player does not spectate the protagonist but becomes them, controls them, and sees the fiction through them. By answering to the players' needs, game-based interventions can have positive effects across the cognitive, social, and emotional spheres [56].

However, whether the interaction serves the underlying human needs depends on both the game design and the players' mindset. Games that serve the players' needs are associated with continued motivation to play [102,103] and affective well-being [55]. When the players use the game to fulfill their psychological needs, playing can be viewed as adaptive and healthy [104], whereas using the game as an avoidance behavior is associated with mental distress and problematic gaming [105]. Thus, creating designs that answer to the players' deeper psychological needs and encourage healthy playing styles is vital.

User interaction with the gDMHI produces a vast amount of data, including behavioral biomarkers [106], which may contribute toward understanding the psychological needs, mechanisms of action, and mental well-being beyond the disorders. Players' interaction with the game mechanics and puzzles provides indications of their motor and cognitive performances, which are particularly useful in cognitive training interventions. Players' affective states and changes in their social interactions may be derived from their text-based outputs and interactions with other players, which contributes to therapies that use reflective approaches. However, the use of behavioral biomarkers as outcome measurements is only growing. Recently, they have been used, for instance, in the assessment of social anxiety [107], mood disorders [108], and mild cognitive impairment [109].

To summarize, gDMHIs are expected to contribute to a significant reduction in mental health symptoms, which is preceded by player engagement and behavior change [13]. Thus, the overall effects of the intervention may extend beyond the symptom change that the digital medium affords to accurately measure. Leveraging in-game data provides corroboratory insights into why and to what extent the interventions are effective, including in terms of broader psychological needs. This contributes to understanding how the interaction impacts a user's behavior, which is, hopefully, generalized in the broader context of the user's life [110], exhibiting macrolevel engagement.

Translating the TEME Framework to Intervention Development

Overview

New product development is a gradual, evolving process [10,11]. It can be described in phases, bearing in mind that the research, design, and development efforts, particularly in a novel domain, are often characterized by exploration, iteration, looping back to earlier phases, and redesign based on feedback. Therefore, the development phases should be considered nonlinear.

We summarized gDMHI development into 4 phases (Table 4). The design begins with research into the target audience and their needs, which are performed through a high-level concept that outlines the intervention. The intervention, as well as the service concept more broadly, is advanced iteratively during development. The evaluation of the intervention likewise gradually grows more comprehensive, culminating in a randomized controlled trial (RCT) that is valued as a particularly strong proof in health care. Should the results prove favorable, the solution may be implemented, and its development may continue in live production.

Table 4. Throughout the game-based digital mental health intervention development phases, the emphasis shifts among the 4 themes: target audience, engagement, mechanisms of action, and effectiveness. The level of focus on the themes are represented as higher focus (HF) and lower focus (LF).

Theme	Concept design	Development	Evaluation	Production
Target audience: who is the intervention engaging and effective for?	HF	HF	LF	LF
Engagement: do users interact with the intervention?	LF	HF	HF	HF
Mechanisms of action: what explains the intervention effects?	HF	LF	LF	LF
Effectiveness: what does the intervention achieve?	LF	LF	HF	LF

Throughout the 4 phases, the focus of the development team fluctuates between the paradigms of health care and entertainment: designing an effective health care intervention and an engaging video game experience [111], pursuing instrumental and experiential outcomes [39], or, in other words, creating therapeutic value and game value [40]. The 2 complementary perspectives intertwine through the development process.

Concept Design: A Model for Addressing the Target Audience's Needs

The concept provides an overview of *what* the intervention is, which is intimately related to the following question: *who* is it for? Understanding the target audience and their contextual needs and preferences allows defining the characteristics of the intervention [10,11,112]. Interviews, questionnaires, focus groups, desk research, and ethnography can be used to create a rich understanding of the target audience's preferences, media used, and target audience's thoughts about and frictions with the existing solutions and services. However, the tools are secondary to the aim of shifting one's perspective through empathy, which is a cornerstone of design [111]. In fact, several development frameworks, models, and philosophies focus on users. They include participatory design [113]; service design [111]; persuasive design [114]; and user-centered design [115], which is also common in gDMHI design. A study exploring 20 development processes found that 50% of them adopted a user-centered approach in the concept phase, and the rest invited user participation in the development phase [116]. Accentuating the importance of users reflects the threats of overly focusing on the solution instead of the need it addresses, which may lead to users rejecting the intervention, and necessitating costly changes later in the development [4,117]. Starting from the target audience, as well as other necessary stakeholders, facilitates the definition of the intervention objectives, technology, and game genre [51].

It is a common misconception that user research would directly inform the design. Users can describe their experiences with existing solutions, but developers are responsible for integrating the understanding into a model that considers the mechanisms of action, technological possibilities, stakeholder dependencies, commercialization, and regulations. Often, the digital concept aims to challenge the dominant, nonscalable, one-to-one, and in-person model of mental health service delivery [118]. The concept can also include considerations of the business model: how the intervention is priced, purchased, and compensated [119]. In contrast to the entertainment industry, which is dominated by the direct-to-consumer model, where the player chooses, uses, and pays for the game, health care characteristically includes more complicated commercial models. Aitken and Nass [32] described 4 such commercial models: direct-to-consumer model, where the user pays for the service; device-like reimbursement model, where the cost of the intervention is covered by the medical benefit plan when the intervention is prescribed by a physician; drug-like reimbursement model, which relates the intervention to pharmacy benefit; and value-based contracting, where the intervention is provided for an organization and paid per the benefits achieved. Thus, the preliminary documented concept is a user-centered account of whom the team is designing for, a science-based account of how the intervention contributes to the user's health, and a description of the intended commercial model.

Development: Iterating the Design and Planning Its Implementation

During development, the team gradually turns the concept into an actual intervention. The phase is iterative: it oscillates between design and testing, which seeks to ensure that the team is progressing in the right direction [10,112,115]. During development, the team can make use of methods from entertainment, which allow the team to focus specifically on the intervention features, and methods from health care, which focus on establishing and implementing the intervention in the complex health care ecosystem.

The success of games is tied to the experience they create [46]. There are various perspectives on game experience [120]; however, in general, it is built of layers, as the user interacts alone or with other players with the game system, its look and feel, and the underlying systems. The interaction leads to an experience that the player may find immersive, motivating, and pleasurable. Entertainment game design has a wealth of methodologies that can be used to hone the game-user interaction [121-123], which acts as a focus point for the interdisciplinary efforts in visual and audio design, software development, and storytelling [44].

The business-to-consumer digital entertainment industry has established distribution platforms that allow developers to focus on game development. Health care, in contrast, currently lacks such global, or even national, distribution platforms. Therefore, it is important to design for feasibility and consider the implementation of the intervention early [11]. If the intervention is introduced into an organizational context, it needs to fit the existing practices, improve current processes, and integrate with the existing software solutions [124]. In fact, many interventions are expected not only to offer end user benefits but also to be easy to adopt and contribute to organizational efficiency. The Non-adoption and Abandonment of technologies, and the challenges to Scale-up, Spread, and Sustainability of such technologies (NASSS) framework structures the complex health care environment in which the intervention may be implemented [125]. It highlights the interrelations among the health condition, technology, value proposition, stakeholders adopting the solution, and their organizational and wider context over time. In conclusion, the development process gradually builds not only the digital intervention, in the narrow sense of the word, but also the related services and the operating models that sustain it.

Evaluation: Progressive and Comprehensive Intervention Evaluation

The evaluation of the intervention grows gradually more comprehensive. In development, the intervention is tested for its playability and game experience, ensuring that the game-based intervention is found sufficiently favorable by the players in the target audience [46] and is meaningful for other stakeholders. As the development progresses, there is increasing interest in evaluating the intervention's health-related effectiveness. A feasibility study, a higher-order concept than playtesting, focuses on the following question: can the intervention work? [126]. Feasibility studies allow for evaluating whether the intervention can attract the appropriate target audience, understanding how acceptable the participants consider the intervention and its procedures, and understanding how the intervention is to manage in practice and contribute to the development of data collection methodologies. However, a feasibility study provides only initial indications of the intervention's effectiveness. Pilot studies can create stronger, although inconclusive, evidence of intervention effectiveness [126]. Should the intervention pass the preliminary evaluations, an RCT can be conducted. It provides high-quality evidence on the effectiveness and safety of the intervention for regulators, clinical stakeholders, and the scientific community. However, because conducting an RCT is demanding, expensive, and slow, progressing to them without ensuring the overall feasibility of the intervention is not advised [112].

It is important to evaluate the intervention comprehensively beyond the summative results: formative evaluation can provide insights into how and why the intervention is or is not successful in its context [127]. Qualitative research can contribute to understanding the intervention's impact and player experience [128,129], and evaluating engagement creates insights into the intervention's feasibility, acceptability, attractiveness, and dose-response relationship. However, the evaluation of engagement is often lacking, and there is substantial heterogeneity in how it is reported [26,73]. One approach is reporting the following 6 factors: the number of users, their profiles, the number of modules in the intervention, the number of times they are accessed, the percentage of users receiving a therapeutic dose, and the achieved clinical change [26]. Economic evaluation is not to be overlooked either, as it often forms the rationale for adopting a digital approach. Economic evaluation can be performed to understand, for instance, the cost-effectiveness of the intervention and to guide strategic decision-making and investments [130].

We encourage a progressive and comprehensive evaluation of the intervention, that is, considering the subjective user experience and objective engagement alongside the clinical metrics. Complementing summative evaluation with formative and economic evaluations allows for an understanding of the intervention feasibility and whether the benefits justify the costs, which facilitates translating the research to complex real-world environments should the intervention prove both effective and engaging.

Production: Implementing the Intervention in Real Life

When the intervention works in controlled research settings, it may be implemented in more complex, real-life settings. Following the principle of path dependence, the decisions made in the earlier stages regarding, for instance, the health indication, mechanisms of action, game genre, and technical implementation continue to exercise their influence in the production phase. Building on the established foundation, the attention turns to marketing, service production, partnerships, and continuing development.

Implementing the intervention often encounters challenges: the research-to-practice gap [27]. Common barriers include user preference for face-to-face therapies, the perceived complexity of the digital intervention, limited research evidence regarding the intervention, low user engagement, the costs of the intervention, and practitioners' resistance. To overcome these challenges and achieve real-world impacts, developers should prepare for them using numerous models [124,125,131]. The Reach, Efficacy, Adoption, Implementation, and Maintenance (RE-AIM) model provides an overview of the components necessary for creating an impact on a population level: the intervention needs to reach a broad audience, be effective, be adopted in numerous settings, be implemented as intended, and be maintained over time [131]. Thus, besides the need for the intervention to be proven effective, the implementation of the intervention demands marketing and organizational support for dissemination. Another useful perspective is the consolidated framework for implementation research, which consists of 5 domains [124]. Intervention implementation is dependent on the intervention characteristics, relationship of the intervention with external stakeholders, organization's internal capabilities to produce the service, individuals within the organization delivering the intervention, and implementation processes. Outside the research setting, the development team needs to consider ways to deliver the intervention to users en masse, which demands changes in organizational structures and service management.

Should the intervention reach a sufficiently considerable population, the developers may begin to view the software as a continuous service. Here, methodologies already in use in game development may prove useful. In contrast to the earlier, linear development process that considered the launch of the game the conclusion to the development, the prevailing game as a service model focuses attention also on postlaunch development [132]. This approach, also called live operations, relies on using business metrics and user feedback to guide the continuous development efforts and add new content [133]. In the future, there is potential in considering gDMHIs as a continuous, evolving service rather than unaltered products [134]. However, it is still unclear to what degree the digital intervention may be developed while retaining the effects and evidence gathered in the previous stages, and there is little research on gDMHI live operations. This reflects the nascent industry that is still waiting for successful interventions to attract a large number of users to fund the continuous research and development of a live product.

Discussion

Summary

gDMHIs use elements of entertainment games to achieve health-related outcomes. We describe how these interventions draw from the health care and entertainment paradigms (Table 1) and categorize them in a continuum between the two (Figure 1). We then introduce 4 themes, the TEME framework (Table 2), to negotiate between the 2 paradigms and facilitate their interdisciplinary development from concept design to production (Table 4).

Contributions to the Development Research

Previous research has discussed the tension of interventions being both engaging and effective [38-40]. By contrast, the existing development frameworks have facilitated the development of behavioral interventions, digital interventions, and serious games for health [10-13]. We expand on the prior literature by elaborating, contrasting, and negotiating the differences between the paradigms of health care and entertainment. The paradigm of health care frames and measures user needs through diagnoses and behavior, has expansive research on mechanisms of action, and is unrelenting in its focus on proving effectiveness, yet it has a shorter history in crafting and implementing engaging experiences in the digital setting. Meanwhile, digital entertainment leads and pioneers in this field. It has expansive practices in iteratively creating immersive experiences in numerous game genres and has advanced development methodologies to measure and design for subjective and objective engagement. However, the entertainment paradigm lacks an understanding of the health indications, mechanisms of action, and health care ecosystem. Thus, the interdisciplinary gDMHI development requires broad competencies in both paradigms and their methods: the digital game–based medium and the health care context.

The TEME framework supports interdisciplinary collaboration by focusing on 4 themes necessary for development: understanding the target audience, ensuring that the intervention is found favorably by them, basing the intervention on proven mechanisms of action, and ensuring its effectiveness. When the 4 themes are reflected in development, developers can seek synergy between health care research and the game-based medium. Common approaches include adapting existing psychotherapies, offering cognitive training, and encouraging physical exercise. However, there are also other developments to be imagined and researched: perhaps the genre of peaceful and serene walking simulators [135] characterized by the ponderous, slow pace could be used to encourage mindfulness practice, or web-based communities could be used to offer peer support, a sense of belonging, and empowerment [136]. We encourage iterative intervention development and evaluation beyond symptom change, considering the behavioral, economic, and organizational impacts.

Earlier, gamification and serious games were considered 2 distinct lines of research [50]. Taking an integrative stance, we suggest that gamified interventions, serious games, and purpose-shifted digital entertainment games can also be viewed as a continuum between health care and entertainment. This distinction contributes a novel perspective to the classification of serious games and serious games in health [51,53,137], allowing an understanding of the developer's position between the 2 approaches.

Earlier, Fleming et al [115] called for a paradigm shift in the development of digital interventions. In particular, they suggested increasing efforts in user-centered design, creating engaging interventions, fostering collaboration, and conducting rapid testing and implementation. Building on these principles, we describe how the development of gDMHIs requires using the strengths of both digital entertainment and health care through an integrative, interdisciplinary framework.

Conclusion: Game-Based Elements Are More Than a Spoonful of Sugar

"In every job that must be done/There is an element of fun/You find the fun and snap!/The job's a game," said supernanny Mary Poppins when instructing unwilling children on how to get their chores done. With the mindset shift, the mislaid items find their place through the magic of motivation. Similarly, the effectiveness of a gDMHI depends on the design's ability to conjure motivation and identification with the change in the users. Engagement and effectiveness depend on the target audience, the underlying mechanisms of action, and their execution as a game. When successful, the game-based approach is more than adding a spoonful of sugar to sweeten an otherwise uninteresting task. Rather, it allows creating interventions that bridge the treatment, engagement, and implementation gaps: they allow expanding intervention reach, inspire effective engagement, and allow viable intervention production.

Acknowledgments

This research was funded by the Technology Industries of Finland Centennial Foundation and Jane and Aatos Erkko Foundation Future Makers funding program "New Game Technologies to Create Digital Medicine for Neural Disorders and Sustaining Brain Health" granted to JMP. The authors would like to thank Isaac Moshe and Otso Saariluoma for their comments on the early versions of the manuscript, as well as the peer reviewers for their valuable feedback.

Authors' Contributions

LL originated the concept of the paper and wrote the manuscript. JMP revised the manuscript and contributed to the approach and structure of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Design dynamics that evolve during a designer's prototyping process encapsulate important insights about the way the designer is using his or her knowledge, creativity, and reflective thinking. Nevertheless, the capturing of such dynamics is not always an easy task, as they are built through alternations between the self–first and self–third person views.

Objective: This study aimed at introducing a conceptual framework, namely 2D-ME, to provide an explainable domain that could express the dynamics across the design timeline during a prototyping process of serious games.

Methods: Within the 2D-ME framework, the Technological-Pedagogical-Content Knowledge (TPACK), its adaptation to the serious games (TPACK-Game), and the activity theory frameworks were combined to produce dynamic constructs that incorporate self–first and self–third person extension of the TPACK-Game to Games TPACK, rules, division of labor, and object. The dynamic interplay between such constructs was used as an adaptation engine within an optimization prototype process, so each sequential version of the latter could converge to the designer's initial idea of the serious game. Moreover, higher-order thinking is scaffolded with the internal Activity Interview Script proposed in this paper.

Results: An experimental case study of the application of the 2D-ME conceptual framework in the design of a light reflection game was showcased, revealing all the designer's dynamics, both from internal (via a diary) and external (via the prototype version) views. The findings of this case study exemplified the convergence of the prototyping process to an optimized output, by minimizing the mean square error between the conceptual (initial and updated) idea of the prototype, following explainable and tangible constructs within the 2D-ME framework.

Conclusions: The generic structure of the proposed 2D-ME framework allows its transferability to various levels of expertise in serious games mastering, and it is used both for the designer's process exploration and training of the novice ones.

Introduction

Background

Serious games are games that focus on learning while entertaining. As their design entails elements from both the game and learning design, it is a process of a rather complicated thread of decisions. Conceptualizations of this process contribute to serious game design modeling frameworks [1]. With regard to serious game designing, the work of Hunicke et al [2] proposed the Mechanics, Dynamics, and Aesthetics (MDA) framework. In particular, their work is fundamental in the area and realizes 3 distinct components that can be viewed from the user's and the designer's perspective. The Mechanics component describe specific options of actions that the user can perform while interacting with a game, and they can be described through verbs (eg, move). On the other hand, the Dynamics component refers to the combined player options toward a system of interactions at a higher level than the Mechanics component, that is, they can be considered the system-behavior of a game. However, the Mechanics component, being more specifically defined at a lower level of abstraction, is more reliable than the Dynamics component. Finally, direct and indirect interactions of the player with the game result in the Aesthetics component that refers to the emotional responses of the player (eg, fun), as they are provoked by the combination of the game Mechanics and Dynamics components, the latter bridging the Mechanics component with the Aesthetics component. Thus, a flow is realized during the game design, that is, an initial selection of the Mechanics component, then the Dynamics component, and finally the Aesthetics component. Although the work of Hunicke et al [2] was criticized as situational [3], it can serve as a direct framework to outline the serious game design. A detailed list of core mechanics was proposed by Järvinen [4] and a list of comprehensive Dynamics was proposed by Pendleton and Okolica [5].

Research in the area of serious game designing resulted in further frameworks that followed the work of Järvinen [4]. Moreover, Ávila-Pesántez at al [6] provided a systematic literature review regarding the methodologies, frameworks, and models applied to game designs in the period from 2008 to 2016, resulting in 11 approaches, whereas Viudes-Carbonell et al [7] provide a state of the art of 6 models in the area. However, the Learning Mechanics–Game Mechanics Framework [8] is worth mentioning, as it was based on the idea that learning occurs while interacting with the game, that is, Learning Mechanics can be mapped to the game's Dynamics component and relevant thinking skills according to the revised Bloom taxonomy [9]. Thus, the learning objectives are diffused in the serious game design [10] to entail the game's educational character. Following this approach, Pendleton and Okolica [5] proposed the Game Design Matrix structure, which reorientates the building block of the MDA framework [2] by first selecting the Dynamics component, according to the expected level of mastery in the Bloom taxonomy, so that the emphasis is initially given to the learning objectives that drive the learning outcome of the serious game. However, the design procedure is an iterative process and Hunicke et al [2] underline the importance of iterative analyses and refinement of the game design results.

In a more detailed approach, Viudes-Carbonell et al [7], following the MDA framework, consider the game design as iterative cycles of design, test, evaluation, and redesign and stress the idea that the iterations would eliminate the risk of failure while designing a serious game. In particular, they focus on the prototyping iterations and consider them as series of small steps toward the enhancement of the quality of the game outcome. Following this path, Fullerton et al [11] consider prototyping an important part of the game design. Prototyping may take place by various means, for example, by pencil and paper, computer, and other artifacts in many disciplines (eg, engineering), to break out a complex problem to subproblems and work on these separately. However, a game is rule based; thus, it is sensitive to changes and/or prediction of possible impacts owing to rule changes. In this perspective, prototyping may resolve unpredictability issues in game design [12]. Moreover, considering games as pieces of art when compared with average software [13], their designing is even unpredictable as the design space may dynamically evolve through the emergence of new ideas and creativity.

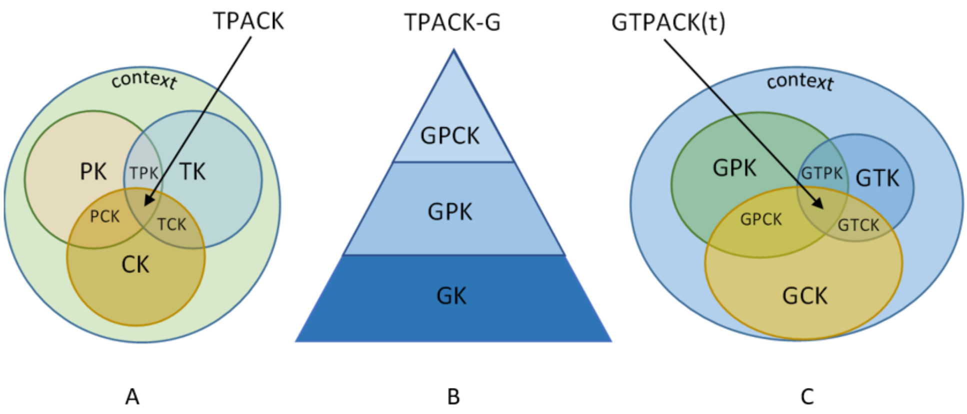
The aforementioned approaches provide the frameworks of designing and establish steps for the enactment of design ideas. However, they do not refer to the knowledge that is needed for the materialization of the game design. With regard to this direction, the frameworks described in subsequent sections have been considered.

Design Frameworks and Serious Games

The Technological-Pedagogical-Content Knowledge Framework

The Technological-Pedagogical-Content Knowledge (TPACK) was proposed as a framework to account for the knowledge needed by the teachers to use information and communications technology in their classrooms [14-16]. In particular, this framework extended the notion of Shulman [17] concerning the pedagogical content knowledge (PCK), by foreseeing the inclusion of knowledge related to technology. Figure 1A depicts the TPACK framework and manifests the interplay between forms of knowledge (content knowledge [CK], pedagogical knowledge [PK], technological knowledge [TK], PCK, technological PK [TPK], and technological CK [TCK]). More specifically, CK refers to the knowledge of the content of the lesson, for example, the concepts that are to be taught; PK refers to the pedagogical considerations as to how to teach the content; TK refers to the knowledge about the technological affordances and their use; TCK and TPK refer to the way the technology could support and materialize the delivery of content and pedagogy; and finally, PCK refers to the pedagogical way in which the content could be delivered to the learners. The contextualized synthesis of all these forms of knowledge constitutes the core TPACK framework. TPACK is usually presented as 3 overlapping equal cycles denoting 3 forms of knowledge (CK, PK, and TK) and their overlaps (TCK, TPK, PCK, and TPACK), all included in a circle that denotes the knowledge that is needed for the integration of technology in a relevant sociocultural context. TPACK has been widely used as a framework to reflect information and communications technology integration in the classroom even under education emergency conditions [18].

Figure 1. Schematic representation of the (A) Technological-Pedagogical-Content-Knowledge (TPACK), (B) Technological-Pedagogical-Content-Knowledge–Game (TPACK-G), and (C) Games Technological-Pedagogical-Content Knowledge (GTPACK; see the GTPACK subsection) frameworks. CK: content knowledge; GCK: game content knowledge; GK: game knowledge; GPCK: game pedagogical content knowledge; GPK: game pedagogical knowledge; GTCK; game technological content knowledge; GTK: game technological knowledge; GTPK: game technological pedagogical knowledge; PCK: pedagogical content knowledge; PK: pedagogical knowledge; t: dynamic; TCK: technological content knowledge; TK: technological knowledge; TPK: technological pedagogical knowledge.



The TPACK-Game Framework

TPACK serves as a theoretical reference framework of necessary knowledge for the technology integration in different contexts; for example, Foster et al [19] proposed TPACK as an aid for the teacher when selecting a game to realize its constraints and affordances for technology, pedagogy, and content. However, Willermark [20] commented on TPACK for its abstract reference to general technology that could be used in the classroom, that is, it lacks the specificity that might contribute to further specification of knowledge that is needed. In this regard, in the specific case of computer game integration in the classroom, Hsu et al [21] proposed TPACK-Game (TPACK-G; Figure 1B) to reflect the knowledge that the teachers need in this case. In particular, they define game knowledge (GK) as the knowledge about the general use of computer games, game PK (GPK) as the pedagogy related to the way a game is used in the classroom, and game PCK (GPCK) as the "knowledge of using games to implement teaching methods for any targeted content" [21]. On the basis of prior work on the developmental pathway of TK and TPK to TPACK, Hsu et al [21] proposed the GPCK as a pyramid, where GK constitutes the basis, followed by the GPK, and finally, at the top, the GPCK. Upon this modeling, they claim that for the development of specific GPCK, the GK and GPK are prerequisites, so a lack of the foundation knowledge of how to play a game, that is, familiarity with gaming environment (GK), leads to a lack of GPK and therefore GPCK [21]. Structural relationships were also detected between the TPACK-G attitudes toward games and actual teaching use [22].

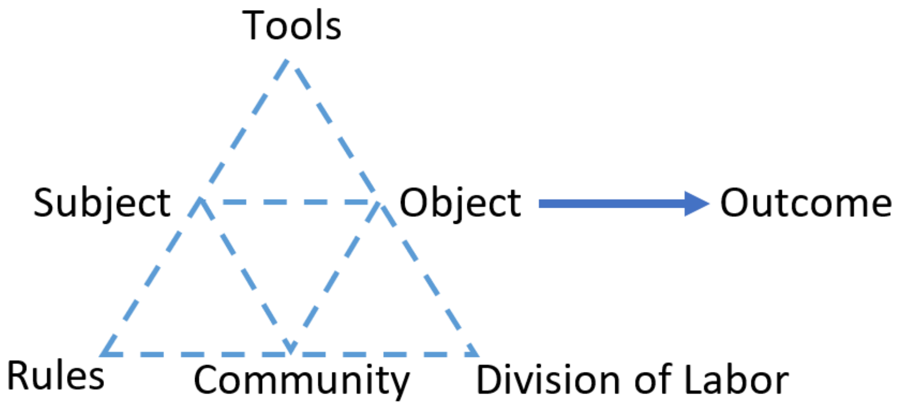
Both the TPACK and TPACK-G frameworks are proposed through a "stationary-like" approach, whereas a more dynamic one might reveal the evolution of types of knowledge over time while an activity takes place, for example, during the iterative approach toward the designer's activities while designing a serious game. The activity theory (AT) framework may provide a lens toward this direction, as explored in the subsequent section.

The AT Framework

Overview

The AT framework has its roots in the 1920s and provides a conceptual framework according to which, the human activity connects the individual world of the subject with the social one (Figure 2). Upon its initial formulation [23,24], the AT framework focused on the activities of the subject, for example, human being. For the subject to meet his/her needs, he/she performes activities by interacting with objects in the world by means of tools that mediate the interaction. Thus, the subject is involved in an activity motivated by an expected outcome (the "why" of the activity), pursues goals that direct the activity (the "what" of the activity), and performs operations (the "how" of the activity) [25]. However, the connection between subjects and activities is bidirectional as they mutually determine one another. Basic principles of AT have evolved through the works of Leontiev [23,24], namely [26] (1) object orientedness, which states that objects differentiate the activities that are directed to them upon motivation toward a need; (2) hierarchical structure of activity, which is a hierarchical system that shows the dynamic relationship among 3 levels of human activity. From a top-down perspective of the activity, at the top, the activity driven by the motive is considered. However, the activity in a lower level is performed through conscious actions that are directed to goals (possibly decomposed to subgoals) that are to be undertaken to fulfill the object. At an even lower level, actions are performed through unconscious operations that are orientated to conditions under which the goal is to be reached; (3) tool mediation, toward a purposeful activity; (4) development, as a context to analyze the activity, for example, from the research respective, this leads to the analysis of the dynamics of the object transformations over time; and (5) internalization externalization.

Figure 2. Schematic representation of the main constructs that form the activity theory framework.



Synergies of AT in Serious Games Prototyping

In the work of Carvalho et al [27], the AT framework was used for the analysis and design of serious games. In particular, they proposed the AT-based conceptual model of serious games, which contributes to the realization of the components of a game and their roles and to the recognition of the educational objectives. In addition, they foresee 3 activities: the gaming, the learning, and the instructional activity and their tensions to describe the contexts in which the game is used. Moreover, for each activity, they propose elements taxonomized into actions, tools, and goals per activity, upon which a game may be analyzed or designed. However, the AT-based model of serious games is restricted only at interactions between the triad, that is, subject, object, and tools. The works of Viudes-Carbonell et al [7] and Manker et al [28] use the AT approach to propose analyses of the prototyping procedure during the design of a serious game. In particular, Viudes-Carbonell et al [7] focus on the iterative character of the serious game design and present an early-stage methodology and a prototype for learning a case-concept. Moreover, Manker at al [28] also focus on the game prototypes and among other, on the role of the prototype to the internalization and externalization of the designer's ideas. The combination of the AT framework with the TPACK framework, namely TPACKtivity, has been proposed by Terpstra [29] as a lens to follow preservice teachers' (PTs') TPACK development through their activities, that is, realizing its dynamic character across the time.

Contradictions, Social and Relational Self-views Within AT

The traditional logic considers contradictions in a system as problems; dialectical logic, however, considers that learning and development are driven by them. Hence, within the AT framework (Figure 2), analysis of the trajectory of the object across time can contribute to the realization of the evolution of its current existence and the expected contradictions that may drive its further development [26]. Thus, a deep assumption is that the activity develops across the time mainly through contradictions that arise, that is, upon resolving 1 contradiction, another may arise. Continuous approach of the activity provides continuity in viewing the driving forces (triggers and resolutions of contradictions) that steer this activity further. Focusing on the subject of the activity system, initial ideas about the dichotomy of the context-free information processing of human functioning as opposed to society were further elaborated, extending the subject approach in the AT. In this direction, Stetsenko and Arievitch [30] proposed a framework to combine the social and relational view of the self. In their approach, the subjectivity that is developed outside and in the activity system of reference, may result from the role according to the social position of the human being (ie, serious game designer), which along with social interactions and collective practices coevolve. On the other hand, the self is considered as an active agentive role that an individual does not only acquire historical cultural norms and experiences but also develops them further through change and novelty. In this sense, the ever-expanding social practices entail human subjectivity, and both social and relational views of the self, coexist, or self-coexist among planes of the activity through the internalization and externalization processes.

The aforementioned design frameworks present either the design of a serious game through the lens of the AT framework or the combination of TPACK with the AT framework. However, they hardly focus on the subject of the activity (ie, the designer), and when they do so, a macrolevel is adopted, referring mostly to the procedures per se, for example, the connection of the subject's internal plane with the world's plane.

Study Aims

In this paper, we introduce the 2D-ME framework, an innovative conceptual framework that adopts a microlevel approach toward the serious game designer's inner world while he/she is prototyping. In particular, we dynamically followed the designer's first- and third-person views (2D-ME) during the prototyping activity under the lens of the AT framework and an extended version of TPACK in the game design area, namely Games TPACK (GTPACK). Under this aim, the following research questions were investigated:

1. Is 2D-ME a useful framework for describing the prototyping dynamics during the design of a serious game?
2. How do the internal (first person) and external (third person) views facilitate the optimization of the prototyping output during a serious game design?

Although we refer to the serious game designer, the 2D-ME framework could easily be transferred to the case of serious game developer (sometimes these 2 roles are undertaken by the same person). Moreover, as it offers new insights in the internal processes during prototyping, the 2D-ME framework could also be used as a research framework for analyzing the research aspects of dynamics during creative prototyping.

Despite the conceptual character of the proposed 2D-ME framework, its practical implementation can easily be realized via a series of steps:

1. Conceptualization of the initial idea target of the serious game
2. Identification of the AT constructs
3. Activation of a metacognitive process (eg, reporting in a diary via a self-interview script), which could facilitate the interplay between the roles of first- and third-person view during the prototyping
4. Enabling and capturing of the dynamics between the AT constructs
5. Adaptation of the AT dynamics for the convergence of prototype successive versions to the initial idea target of the serious game

Methods

The Proposed 2D-ME Conceptual Framework

Main Constructs and Dynamics

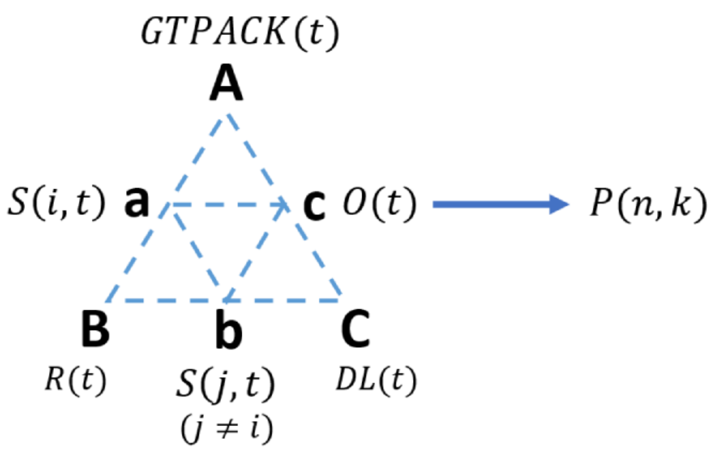
Stemming from the design frameworks presented so far, the proposed 2D-ME conceptual framework is described in this section. Figure 3 depicts the main constructs of the 2D-ME framework. As it is apparent from the comparison between the shapes of Figure 2 (AT) and Figure 3 (2D-ME), a connection of the 2D-ME framework with the TPACK, TPACK-G, and AT is noticeable. This is materialized by the inclusion within the 2D-ME framework of (1) the concept of triangles and interactions as in AT and (2) the combination of TPACK with the TPACK-G as a new entity in the AT triangle, namely GTPACK. However, all constructs of AT (Figure 2) are replaced with new ones (Figure 3), as follows:

- Instruments or mediating artifacts → *GTPACK(t); t=1,2,...*
- Subject → Subject *S(i,t), i* =first-person or third-person view; *t=1,2,...*
- Rules → Rules *R(t); t= 1,2,...*
- Community → Subject *S(j,t), j*=first-person or third-person view; *j≠i*
- Division of Labor → Division of Labor *DL(t)*
- Object → Object *O(t), t*= 1,2,...
- Outcome → prototype *versions P(n,k), n=1,2,...,N; k=1,2,..., M* (last version)

As it is apparent, the 2D-ME framework embeds within its structure a dynamic activity within its constructs that interact and (potentially) are modified across time (*t*). In particular, the prototype designer is considered as the subject *S*(*i*,*t*) and subject *S(j,t), j≠ i*, alternating across time (*t*) between the first-person and the third-person views. The *S*(*i*,*t*), motivated toward the materialization and optimization of the object *O*(*t*), that is, the game prototype *P(n,k), n = 1,2,...,N; k = 1,2,...,M*, at specific time instances *k*, uses their current *GTPAK* (*t*) to produce each prototype version *(P(:,1), P(:,2),...)* toward *P*(:,*M*), which is the final version of the outcome of the activity system. It should be noted that the *n* parameter expresses the different dimensions of prototype (see *The Object Outcome [Prototype]* section). Apparently, the first-person and the third-person view of the subject communicate upon rules *R*(t) and division of labor *DL*(t).

As it can be deduced from the aforementioned 2D-ME structure (Figure 3), the flexibility of the AT framework to project the activity at different levels of analysis is used here to shift from a macro- to a microscale approach. More specifically, at the macroscale approach, the prototyping procedure in the game design provides samples of the evolution of the game design across the time. From a main concept perspective, the 2D-ME framework adopts a microscale approach by following the inner iterative prototyping procedure that follows the game designer across the time. Upon this, an AT triangle is defined, in which the subject, that is, the designer of the serious game, is the focus of the approach. The 2D-ME framework foresees the designer to adopt 2 perspectives while prototyping, that is, the first-person and third-person views. In this way, 2D-ME follows the internalization and externalization actions within the game designer and provides a conceptualization of the prototype design before its externalization to the others (collaborators, users, etc). To further explain the main concept, a description of each entity of 2D-ME is presented in subsequent sections.

Figure 3. Schematic representation of the main constructs that form the 2D-ME framework. DL: division of labor; GTPACK(t): Games Technological-Pedagogical-Content Knowledge (dynamic); O: object; P: prototype; R: rules; S: subject.



The GTPACK

The GTPACK (Figure 1C) is considered in 2D-ME as a tool that extends the TPACK in the area of the necessary knowledge base for the serious game designing. In particular, the Game CK refers to the cognitive content of the game, that is, the subject matter of the discipline of reference. Game Technological Knowledge refers to the knowledge base relevant to the technology related to the games design and its use. Finally, Game PK reflects the knowledge of possible misconceptions, learning theories and how to apply them in games, metacognition, etc. On the basis of this perspective, in a game designing procedure, Game Technological CK might be triggered for the representation of the concept to be learned in the game environment, the GPCK might be triggered for the definition of the game dynamics, and the GTPK might be triggered for the selection of the game mechanics, whereas the GTPACK might be triggered for the whole game design and aesthetics. The GTPACK serves as a tool that mediates the activity of the subject upon the object toward the outcome. It should be noted that the GTPACK is not a stable framework across design time, as the designer might interact with resources (either human and/or material) that may alter its load and dynamics across the time.

The Subject

The 2D-ME framework proposes 2 points of view of the subject, the first-person and the third-person view, considering transitions from the internalization to externalization processes and vice versa, yet both defined within the same person. In particular, the first-person view considers the subjective version of the subject in the activity system that reflects his/her activity following rules of designing a serious game, that is, the social world. The third-person view considers the self-version of the subject that reflects his/her activity according to the object of the activity system that he/she acts upon as the designer. The third-person view is the agentive self who leads the activity as he/she are engaged with the social world. On the basis of this perspective, the first- and third-person views hold a GTPACK and they both coevolve with the activity, yet the third-person view is mainly reflective, to actively introduce possibilities; enhance them by prioritizing other actions; and possibly generate activities that stem from the reality, fantasy, and serendipity.

The Rules

In the AT framework, the rules primarily mediate how the subject acts in relation to the object, including the tools used and the ways they are used [31,32]. This could include specific and/or well-established patterns of behaviors that could be followed because of either cultural norms and/or other reasons (eg, professional and legal mandates). In 2D-ME, the rules refer to the ways of communication between the first- and the third-person views during the subject's communication. Apparently, this interpersonal communication follows some norms (rules) that facilitate the process by which the subject is engaged in unspoken internal dialogue among different and sometimes conflicting attitudes, thoughts, and feelings, all represented by the first- and third-person views. Clearly, these rules are subject dependent and can be imposed, sustained, redefined, modified, or dropped within a dynamic process that could add to the metacognitive skills of the subject.

The Division of Labor

The main responsibilities (what is being done by whom) that are involved toward the object define the division of labor in AT, also taking into consideration the horizontal division, that is, across tasks, and the vertical division, that is, across the power, positions, access to resources, and rewards [31,32]. In 2D-ME, the division of labor refers to the contribution of 2 subject's views, that is, the first- and third-person views, toward the object within the interpersonal communication. The concept of horizontal and vertical division can also be transferred at this inner level by considering the different aspects that could be triggered during the interpersonal communication. For example, the horizontal division could include a systematic definition of a sequence of interpersonal sessions across the prototyping process. Moreover, the vertical division could prioritize the first-person view in the access to and use of technological resources (eg, game developing software), leaving space for the third-person view for reviewing the aesthetics (eg, rewarding and/or corrective feedback on game sensation, fantasy, or challenges).

The Object Outcome (Prototype)

The object in AT can be approached by various views, that is, the object is seen as a thing to be acted upon, an objectified motive, or a desired outcome [33]. The object in 2D-ME is to materialize an idea toward optimizing the outcome, which is a prototype of the game. The prototypes could vary in purpose, as they can refer to a role, an implementation approach, a look, or a sense of feeling. These include interaction with the users (role), the construction of the game (implementation), and users' experience (look and feel) [21]. This multiplicity in roles results in multiple dimensions (denoted with the parameter n, with N being the total number of dimensions). The various versions of the prototype in 2D-ME (ie, $P(n,k)$, $n = 1,2,...,N; k = 1,2,...,M$) are tangible externalizations of the development transformations that the activities undergo between the constructs across the serious game design process.

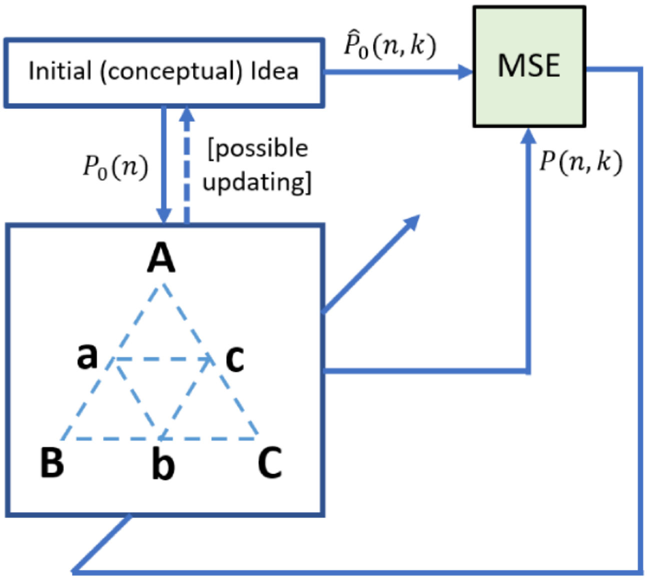
Prototyping Optimization

The proposed 2D-ME conceptual framework considers the prototyping process as an optimization process that converges to the optimal prototype ($P(N,M)$) by minimizing a cost function. This is clearly depicted in Figure 4, where the constructs triangle (Figure 3) is used as an adaptation engine. The cost function per k is the convex function of the mean square error (MSE) between the conceptual (initial and updated) idea of the prototype and its current version ($P(n,k)$) is presented as follows:

The adaptation engine provides the convergence, so the whole activity gradually reaches to the optimized outcome, that is, $P(N,M)$. However, the optimization convergence is not seen within an absolute perspective but rather from the designer's view and experience. This means that the current optimization process could stop at a point that the $P(N,M)$ will not express the full spectrum of the designer's skills and knowledge, but the process will reach at a point where the designer has already concluded for the validity of the final output and the sufficient use of their knowledge and experience, that is, their current level of GTPACK.

Furthermore, as it can be seen from Figure 4, the initial idea ($P_0(n)$; $n = 1,2,...,N$) acts as a trigger to the adaptation engine and, at the beginning of the process, it is considered as static. However, the processes within the adaptation engine (eg, the interpersonal communication), apart from the update of the version of $P(n,k)$, could potentially affect the initial idea, as well. In this vein, its transformation, that is, , is considered at the next stages of the design process. This transformation could alter specific dimensions of the prototype (eg, eliminate some and add new ones) and/or the characteristics of each dimension. Apparently, the frequency of the changes of the is anticipated to be low, considering the level of the designer, that is, how clear and solid is the initial idea in his or her mind. To this end, during the optimization process, some versions of the could be constant across k, for example, . This is, usually, anticipated as the prototype converses to its optimum version, because the designer has already a clear view of its intended and the constructed version.

Figure 4. Schematic representation of the prototyping optimization process in 2D-ME framework. The constructs triangle (Figure 3) is used as the adaptation engine toward the minimization of the difference of the conceptual (initial and updated) idea of the prototype <inline-graphic xlink:href="games_v11i1e41824_fig10.png" mimetype="image" xlink:type="simple"/> and its current version ($P(n,k)$), that is, gradually reaching to the optimization of the prototype (at $k=M$) across its intermediate versions (at $1 \le k \le M$) and across its dimensions. MSE: mean square error.



Capturing of Dynamics

From what it is presented so far, it is clear that 2D-ME entails dynamics among its constructs and in the prototyping optimization process. To capture such dynamics, some sampling tools should be used. Clearly, the interpersonal communication (between the self–first person and the self–third person) that is involved in 2D-ME sets the highest hurdle in the dynamics capturing process. One way to infer for the activation of such communication could be the use of a systematic approach that would include a subject's diary. The latter could be structured on specific contextual factors reflected in a set of statements. A characteristic example of such statements is included in the activity checklist [34,35], which is based on the AT. As the activity checklist provides a "contextual design space" [28], this could be adapted, accordingly, to include statements that could help the designer to describe in his/her diary the dynamics used between the 2D-ME constructs. In this way, the activity checklist itself can serve as a "valuable aide memoir and a tool for reflexivity" [36]. Nevertheless, the activity checklist contains many items (43 for design and 37 for evaluation) [35] that make its full use quite difficult in practice. As a remedy, adaptation of the activity checklist to the form of interview questions, limited in number, was proposed by Duignan et al [37]. Hence, this interview form of activity checklist could trigger reflection and self-talk and could assist in capturing specific dynamics at the various phases of the prototyping process. In this vein, internal questions related with the 2D-ME dynamics that could be self-answered and documented in the diary could be formed, as an internal Activity Interview Script (iAIS), tabulated in Textbox 1.

An additional source of understanding the dynamics is via the exploration of the alterations across the different versions of the prototype. Apparently, this is a lower quality sampling of the dynamics when compared with the aforementioned approach; it provides, however, a way of monitoring the dynamics, especially when exploring the differences across the dimensions (n) of the prototype versions across the design time. A process of deconvolution is then applied to identify the constructs that were more frequently used in a current version of the prototype. Projecting this construct activation across the whole prototyping process, the dynamics per construct can be revealed.

Textbox 1. The internal Activity Interview Script.

Question 1. Goals-related questions

- Question 1.1. What are the different roles that you identify in yourself and are involved in the prototyping?
- Question 1.2. How do you breakdown, in a step-by-step form, your prototyping process?
- Question 1.3. How this fine-graining process can vary?
- Question 1.4. How do you know that you have successfully completed each intermediate goal?
- Question 1.5. How could you evaluate the achievement of your higher-level goals?

Question 2. Contradictions-related questions

- Question 2.1. What contradictions can you identify between your different roles?
- Question 2.2. How do you resolve such contradictions?

Question 3. Tools, transition, internalization, externalization–related questions

- Question 3.1. How does Games Technological-Pedagogical-Content Knowledge support the transition between the first-person and third-person view?
- Question 3.2. How does Games Technological-Pedagogical-Content Knowledge affect the way you think and reason about the prototyping activity?
- Question 3.3. How difficult is to perform the different interpersonal roles?
- Question 3.4. How do you use representations of your work between the different interpersonal roles?
- Question 3.5. How do you internally handle the complexity of the prototyping process?

Question 4. Rules, division of labor–related questions

- Question 4.1. How do explicit or implicit rules, norms, and procedures affect your different interpersonal roles?
- Question 4.2. How do you organize the different interpersonal roles across the prototyping process?

Experimental Case Study Setup

An experimental case study was set up as a running example of the realization of 2D-ME in practice. In particular, the case refers to a PT as the designer of a serious game for kindergarten through grade 12 students. The motivation for the latter was drawn from the physics student's exercise textbook (page 63) for the fifth grade for primary school in Greece. In the latter, an exercise related to the light reflection on mirrors presents a situation in which a series of mirrors are fixed at different positions in a box. At the perimeter of the box there are 4 openings where specific objects (compass, scissor, and pencil) and a boy's eye are positioned. The student is asked to identify and draw the paths of the light reflections on mirrors so as the boy can see the 3 objects (see $P_o(n)$ in Figure 6). This exercise was presented to the PT as a stimulus for the design of a related serious game on light reflection. The PT was at his final semester of his studies at the Department of Primary Education, Democritus University of Thrace, Greece, and he already had attended 1 semester concerning serious game design using Scratch [38]. In particular, concerning his GTPACK, the PT had Game CK about the light mirror refection, which was the concept to be practiced by the serious game. Moreover, he had extended GPK because of his studies and good Game Technological Knowledge based on the familiarity with the game prototyping, design, and implementation in Scratch. Thus, his current GTPACK was considered adequate for this experimental study. It should be noted that the PT was already aware about the GTPACK framework.

The research design foresaw controlled experimental situation that took place at the Democritus University of Thrace computing laboratory within 1 month. The PT willingly participated in this experiment and was informed about the experimental process before embarking on it. More specifically, he was asked to express in a diary the conceptualization of his initial idea $P_0(n)$ of the serious game and then to proceed to his prototyping activity and optimization (Figures 4 and 5). Moreover, he was addressed with the aforementioned iAIS and was advised to document his relevant thoughts in the diary during the prototyping procedure. It was made clear to the PT that the use of the diary should be spontaneous and in no way should hamper his creative impetus. Furthermore, he was informed and consented that an observation documentation would be made by a researcher (first author, SH) to capture the explicit prototyping performance of the PT. At the end of the experiment, the PT consented to openly share the diary; a thematic analysis of the diary was manually conducted and combined with the data from the observations along with the outcome of the whole activity.

Figure 5. Schematic representation of the dynamics across the prototyping optimization for *k=1,2,...,5*. At the top, the Games Technological-Pedagogical-Content Knowledge (GTPACK) alteration across are displayed, where the dynamics affect its internal set (at *k=1,4*). The constructs dynamics are denoted with arrows, accompanied with the related internal Activity Interview Script (iAIS) questions (Textbox 1). The optimization process is depicted for each outputted prototype, whereas the estimated mean square error (MSE) is depicted at the bottom, showcasing its reduction as the game design evolves.

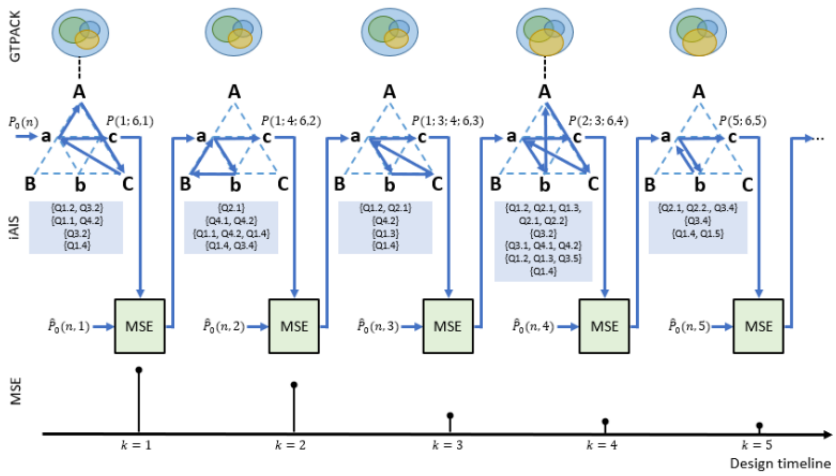


Figure 6. Illustration of the produced game prototype scenes, along with the addition of the Scratch programming code at each *k*, *k=1,2,...,5*. The initial idea, $P_0(n)$, that acts as the stimulus for the creation of the light reflection game is also depicted.

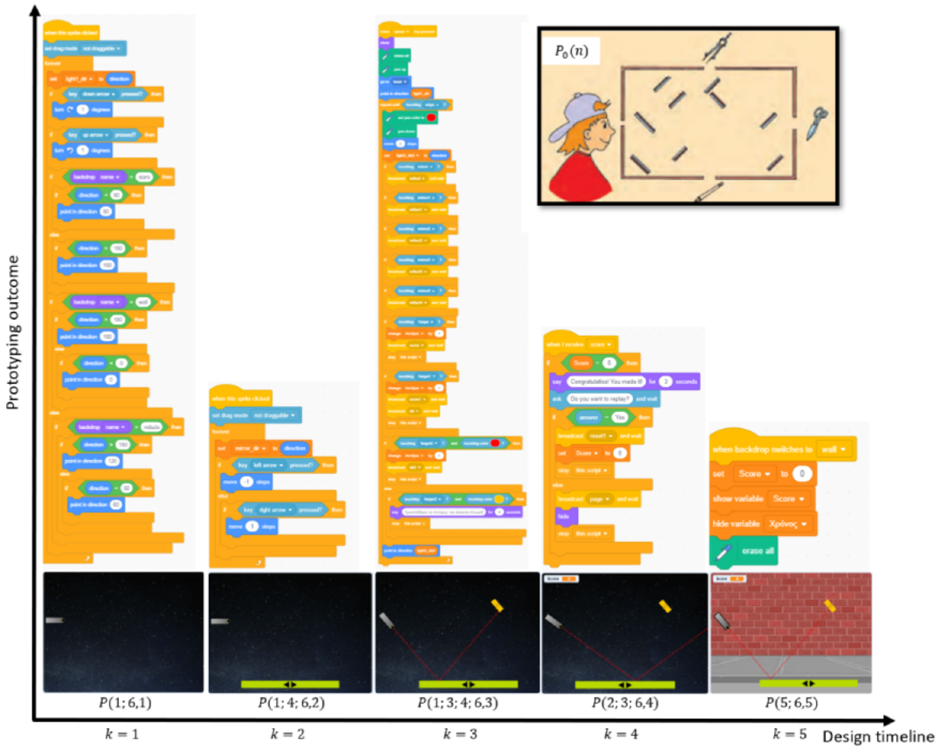

Results

Conceptualization of the Initial Idea

The PT formulated his/her initial idea $P_0(n)$ of the serious game, based upon his/her GTPACK. Textbox 2 shows what he wrote in the diary.

From the excerpts mentioned in Textbox 2, it can be inferred that the PT conceptualized his initial idea $P_0(n)$ of the serious game. He also defined the *N*=6 dimensions, where *n*=1 corresponds to the space (sprites: a source of the light ray, one mirror and one target), *n*=2 denotes the dynamics (hidden objective, player autonomy, limited actions, and feedback), *n*=3 refers to mechanics (move, rotate, aiming and shooting, and allocating), *n*=4 corresponds to the sprite costumes (a torch, a line, a top view of a mirror, and a top view of a brick), *n*=5 refers to the aesthetics, and *n*=6 is for the programing dimension.

Textbox 2. Initial idea formulation-Diary excerpt

I can extend the image in the school textbook where there is a source that produces the light ray and mirrors at stable positions to reflect it so as through successive reflections it can reach a specific point. The students are asked to hypothesize the reflections and then draw a line to depict the path of the light ray as it reflects in this labyrinth of mirrors. Thus, if the student realizes this path once, then there is no interest to resolve it. So, I need to extend this activity towards a more interactive and interesting situation through my serious game. Keeping the analogy with the textbook activity, where it is presupposed that the student already has been taught the light mirror reflection, my educational aim is to involve the students in a serious game, in order to further elaborate the light reflection concept in more dynamic situations than the textbook, eg, the student can try the mirror reflection towards different lines of the ray and not in a specific labyrinth. Thus, my objective is to move the cognitive effort from the applying level and beyond according to the Bloom's taxonomy. Moreover, I can use depictions from the textbook that the students are acquainted of, i.e., a torch as a source for the light ray, a line for the light ray, top view of a mirror and a top view of a brick as target.

I will elaborate on the well-known K-12 students' misconceptions about the light reflection, concerning the equality of the angles of the light ray as it lands on and reflects from the mirror surface. I will assume that the students had already been taught the light mirror reflection; thus, they have conquered the first two levels of the Bloom's taxonomy, so my serious game will not provide relevant information.

My objective is to move the cognitive effort concerning the aforementioned concept at the applying level of in the Bloom's taxonomy.

As a tool I will use Scratch.

I will follow the GDM design framework and I will choose dynamics and mechanics from those presented in the work of [5], combined with additional important elements, namely:

- *Space and Dynamics: The student should manage to apply the idea of the equal angles that are employed in the mirror reflection, but I do not want to show this; they must hypothesize the light line in a space arrangement that with include three sprites, ie, a source of the light ray, one mirror to reflect upon and one target where the reflected ray should hit, respectively. Thus, I choose the hidden objective dynamic. I also want the student to arrange in a way the game space, so I choose the player autonomy dynamic; yet, with limited actions so as not to be confused. Finally, I will provide feedback to his/her efforts, eg, a score counting the successive efforts toward the shooting the target with the reflected light ray.*
- *Mechanics: The torch will be at a stable position, but the student could rotate it. The mirror would be horizontally positioned in the bottom of the scene and could be moved in both directions on the x axis and the target will be at a stable position. Thus, I choose move, rotate, for the objects, aiming and shooting for the light ray, allocating for the hypothesized path of the light ray.*
- *Sprite costumes: I will use depictions from the textbook that the students are acquainted with, ie, a torch as a source for the light ray, a line for the light ray, top view of a mirror and a top view of a brick as target.*
- *Aesthetics: I think that the acquaintance of the students with the sprite costumes, the appealing scene, the explicit roles of the sprites and the challenge to target the brick will motivate the students to have fun and keep playing it toward higher scores. All these will contribute to the esthetics dimensions of my serious game, ie, its sensation (sense of pleasure), fantasy (make-believe), challenge (obstacle course), discovery (uncharted territory), and expression (self-discovery).*
- *Programming: I need to program all the needful with Scratch.*

Dynamics in Adaptation Engine and Prototype Optimization

Overview

During the activity, the PT followed iteration paths through which a series of enhancement of the prototypes that were developed in Scratch resulted in the final output (the game). Here, indicative versions of the prototype are presented to reflect the dynamics and realization of the adopted optimization procedure within the 2D-ME framework. In particular, we followed the $P(n,k)$, $n = 1,2,...,6$, $k = 1,2,...,5$, prototypes in the sequential order that they were developed, cumulatively constructing the serious game aspects. It should be noted that not all dimensions are simultaneously activated across the prototyping, because the PT placed the effort according to his temporal preferences and focus on specific dimensions.

Diary-Based Sampling

As a first means of dynamics acquisition, excerpts from the PT's diary were used for each version of the prototype. Figure 5 facilitates the presentation at multiple levels that are used during the application of the 2D-ME framework, showcasing the activity system that the PT was involved in, its dynamics across the triangles' vertices (Figures 3 and 5: {A,B,C},{a,b,c}), and the optimization procedure that took place. The corresponding activated dimensions (separated by semicolon) are described below; researcher SH's external view based on the iAIS is also noted within brackets and included in Figure 5:

- Initial idea: , Prototype: P (1;6,1)
  - a→A: "From the first person view, I will start by setting the main scene and creating the first sprite; however, my GTPACK is not adequate to achieve this" (Question 1.2). "I need to enhance my GTK on how to program the reflection of the light ray on a moving mirror" (Question 3.2).
  - A→C: "I need to incorporate multiple roles within myself to activate a reflective path for my design decisions" (Question 1.1 and Question 4.2).
  - C→a: "From the first person view, I now feel more confident to start materializing my $P_0(n)$ idea" (Question 3.2).
  - a→c: "From the first person view, I managed to write the Scratch code for the main scene and the first sprite and produce the first version of my object, ie, $P(1;6,1)$" (Question 1.4).

- Initial idea: , Prototype: P (1; 4; 6, 2)
  - a→b: "From the first person view, I will next put the mirror in the scene" (Question 1.2). "From the third person view, I realized that I need to revise my initial idea for the size and the way the mirror should look like, to avoid trivial game options" (Question 2.1).
  - b→B: "The third person view helps me to identify design pitfalls and use one rule, i.e., to be on the shoes of the user, in order to better understand the game" (Question 4.1 and Question 4.2).
  - B→a: "From the first person view, I keep as a rule to really play the prototype, in order to feel the pitfall that I conceived as such from the third person view" (Question 1.1 and Question 4.2). "I also follow the rule to distinguish between what remains the same and what should be changed towards optimization" (Question 1.4).
  - a→c: "From the first person view, I understand that the third person view scaffolds my thoughts for the next step towards the implementation of my initial idea and I managed to write the Scratch code for the mirror, selecting the analogous size and view, producing the second version of my object, i.e., *P(1; 4; 6,2)*" (Question 1.4 and Question 3.4).

- Initial idea: , Prototype: P (1; 3; 4; 6,3)
  - a→b: "From the first person view, I will next put the brick and the light ray in the scene and adopt the sprite costumes of a line and top view of a brick, respectively" (Question 1.2). "From the third person view, I realized that I need to revise my initial idea for the fixed angle of the light source to avoid trivial game options" (Question 2.1).
  - b→C: "I realized that I need to have a more organized sequence of reflections; hence, I have decided to adopt more frequent alternation between the first and third person view during my design process" (Question 4.2).
  - C→a: "From the first person view, I now feel more excited to put more degrees of freedom to the torch" (Question 1.3).
  - a→c: "From the 1st person view, I managed to write the Scratch code for the addition of the brick, the light ray and the rotation of the torch, producing the third version of my object, i.e., *P(1; 3; 4; 6,3)*" (Question 1.4).

- Initial idea: , Prototype: P (2; 3; 6,4)
  - a→b: "From the first person view, I will next include the feedback to the student via a score display; however, I feel that something is missing..." (Question 1.2 and Question 2.1). "From the third person view, I had the idea of inserting randomness in the game. I find myself a bit strange when I have ideas that I do not know how to implement. It is a contradiction to my general attitude to proceed safely. However, when I follow them, I believe that new possibilities are revealed." (Question 1.3, Question 2.1, and Question 2.2).
  - b→A: "I feel that I need to expand my GTPK towards the motivational and engaging role of the surprises in the game through randomness and its relevant programming" (Question 3.2).
  - A→C: "I can use my enhanced GTPACK and identify better the involvement of my different roles in myself for the technology- and aesthetics-related aspects of the prototyping" (Question 3.1, Question 4.1, and Question 4.2).
  - C→a: "From the first person view, I broke down the move mechanic across my prototyping procedure, in order to realize which objects it should refer to, and materialize the decided randomness" (Question 1.2, Question 1.3, and Question 3.5).
  - a→c: "From the first person view, I managed to write the Scratch code for the addition of the score and incorporate movement of the sprites, producing the fourth version of my object, i.e., *P(2; 3; 6,4)*" (Question 1.4).

- Initial idea: , Prototype: P (5; 6,5)
  - a→b: "From the first person view, I feel that, most probably, I have reached the point of satisfaction with the structure of the game so far; but I am not 100% sure..." (Question 2.1). "From the third person view, I visualized a more interesting approach, focusing on the game aesthetics, that incorporated the sense of depth in the main scene" (Question 2.2 and Question 3.4).
  - b→a: "From the 1st person view, I understood that this reflection provides me with many options to increase the sensation and fantasy of the game, using different 3D scene backgrounds" (Question 3.4).
  - a→c: "From the first person view, I managed to write the Scratch code for the addition of a 3D background in the scene, producing the fifth version of my object, i.e., *P(5; 6,5)*" (Question 1.4). "I believe that, at this point, I have achieved my first higher goal to construct a good prototype of these functionalities and aesthetics of the game, converging to the initial idea conceptualized in the form of $P_0(n)$" (Question 1.4 and Question 1.5).

It should be noted that in the excerpt of the optimization process presented earlier, the initial idea was kept constant across k, as the level of the game designing was of low complexity, trying to conceive and materialize the basic environment and functionalities of the game. As the game advanced, updates of the $P_0(n)$ took place, for example, through the insertion of >1 mirrors spreading randomly in the scene space and introduction of various game levels with different degrees of difficulty (eg, random distribution of nonreflecting obstacles and time limitation per level). Moreover, the GTPACK of the PT was enriched during the prototyping process, showcasing the internal dynamics that are developed across the design time at the GTPACK level, depicted as expanded overlapping spaces in Figure 5 (top). The estimation of the MSE (Figure 5, bottom) was based on the comparison (equation 1) between the current and the $P(n,k)$ across the n dimensions. As the dimension of programing (n=6) is not included in the , this was excluded from the MSE calculation, involving the dimensions of n=1,2,...,5 in equation 1. As at each k, not all dimensions are involved in $P(n,k)$, the highest drop in the MSE is expected when many dimensions of $P(n,k)$ are activated, as it can be seen at k=3 (P(1; 3; 4; 6,3)).

Prototype-Based Sampling

At a second sampling of the dynamics, with lower resolution, the materialization of the prototypes per optimization version were also analyzed. Figure 6 depicts the sequence of the produced prototypes for k=1,2,...,5, reflecting the specific dimensions that were examined at each k, visualized at the scene level and the corresponding Scratch code; the stimulus from the exercise textbook used as $P_0(n)$ is also presented. From Figure 6, at k=1, there is a very simple output at the scene level (one sprite); however, there is more extended structure at the programing level. This reflects the activation of the GTPACK as a means for extending the gaming programing background. At k=2, the work at the programing level is simplified and the scene is extended with the inclusion of the second sprite. The complexity of the programing is increased at k=3, because there is the addition of the third sprite and the light ray. This shows higher convergence to the initial idea, revealing that the PT follows an optimization process. In addition, at k=4, the experimentation with the light ray and the rotation of the sources (already seen at k=3), along with the addition of the user feedback (score) reveal an activation of the GTPACK (to enhance the game programing skills) and of the third-person view (also seen in Figure 5). In this way, the PT sees his prototype from the eyes of the user and tries to accommodate the issues of trivial solutions and lack of feedback, thus increasing the game options and esthetics. The interpersonal interaction about esthetics continues at k=5, in which the scene becomes 3D, providing more immersive impression to the user. Here, it seems that the dynamics between first- and third-person views are the ones that dominate (also seen in Figure 5), as the enhancement of the external (user's) view of the game is the focus at this stage of prototyping.

Discussion

Principal Findings

The proposed 2D-ME conceptual framework surfaces the roles of the first- and third-person views that challenge the designer to realize aspects of his/her self in this iterative procedure. Being more reflective, the designer may realize that the self may be both a subject influenced by the society norms, for example, in the aforementioned case, the programing rules, but also a driving self that may influence the society through the output of their game design. These roles were reflected in the case study presented, which served as a showcase of the 2D-ME framework to reveal the dynamics within the iterative process of the prototype optimization, seen both from the designer's space (diary) and the game design outcome (prototype). This may contribute to more knowledgeable game designers, as it provokes reflection in a fine-grained way of thinking at different levels. It should be noted that the case study presented did not entail the hierarchy of the AT framework and was kept mostly at the activity system level, focusing on the optimization procedure.

In the case study presented, the user is a PT, who had already acquired a basic knowledge of the GTPACK framework because he works in the education sector. Nevertheless, there is no requirement for someone to have any specific level of prior knowledge to use the 2D-ME framework; simply, someone who undertakes a prototype design process (in the specific case of game design) will most probably have a basic level of the TPACK in the field. Even if he/she is not an expert, during the prototyping process, he/she will interact with the knowledge base and would acquire extra knowledge in the area. This is schematically shown in both Figure 1C and Figure 5 (GTPACK), where the context of the GTPACK is not split in equal sections but there are different levels of knowledge within it (Figure 3, c), which are dynamically expanded during the interaction with the knowledge base (Figure 5; increased GTPACK for k=3→4). In addition, the knowledge of the iAIS is not provided as a constrain but as a guide to help the user formulate the internal reflection on the activities during the prototyping; someone could follow their own pathway of metacognitive process stimulation. However, we believe that the proposed iAIS targets all the reflective aspects that could be helpful to serve as a tool of memoir and reflexivity during prototyping.

Apart from focusing on the monitoring of the internal dynamics during the prototype optimization process, 2D-ME can also be used as a means of structure for the designer's skills development in the reflection and creativity. Diary writing itself requires the designer to rethink events and processes, along with thoughts, contradictions, decisions, outcomes, which have all taken place at the various stages of the prototyping process, and "relive" it, as many times they want, even after its end. This strategy promotes their critical thinking and reasoning skills, that is, their higher-order thinking skills [39]. In addition, the stimulus from the iAIS (Textbox 1) sets an organized pathway of reflection steps that span across the triangle constructs involved in the 2D-ME framework. In this way, the activity dynamics are scaffolded by the iAIS stimulus and gradually become more imprinted in the game designer's reflection strategy and higher-order thinking. When the narrative information of the diary is transformed into dynamics within the 2D-ME framework (Figure 5), a more externalized representation is achieved that could be visible, apart from the designer themselves, to others, as well. This can provide information for some characteristics of the designer's personal way of thinking and creating, increasing their explainability, especially when they are not tangible at the prototype level and/or cannot be easily inferred from the final output (eg, the $P(n,M)$). In this way, the 2D-ME framework could provide more objectified basis for the analysis and comprehension of the expert designer's process, from idea conception to the final output, which can be used for teaching the novice designers, help them to better understand their internal processes, and improve their designing skills and outcomes.

In the case study that was presented here, the prototyping process was optimized by taking into consideration the relation between 2 adjacent versions of the prototype, that is, for the creation of $P(n,k)$, $P(n,k–1)$, $(k>1)$ was considered as input to the AT triangle (Figure 5). Nevertheless, additional views could also be adopted, and a higher (>1) order of memory could be used, for example, for the creation of $P(n,k)$, $\{P(n,k – 3), P(n,k – 2), P(n,k – 1)\}, (k >3)$ can be used as a sequence of inputs. Moreover, this sequence could also vary across the whole process, both in the number of the previous versions used and in their continuity, for example, $\{P(n,k – 3), P(n,k –1)\}, (k >3)$. This depends on the scale of the focus that is used at each k, providing the opportunity to the designer to shift from the micro- to the macroscale of the prototyping process [40,41]. This influence of previous prototype versions within the creation of the new one materializes the convolution of the dynamics adopted in the past with the dynamics shaped in the current version, in an effort to create a new, more enhanced prototype. This blending of dynamics in a macrostructural approach showcases the causalities that are created across the prototyping process that, in a way, contribute to the personal characteristics of the designer's style. For example, sequential use of the prototyping versions (eg, as in Figures 5 and 6) could reveal steadier design style, in which each step is cumulatively constructed from the previous one. A more discontinued use of past prototyping versions could express more diffusion of the design ideas at various time instances of $k – l$ $(l = 1,2,…| k – l >0)$, revealing a distributed way of materializing the design ideas, in which different parts of them gradually are synthesized and construct a more integrated prototype version at the kth time instance.

The adopted bilateral sampling of the dynamics in the 2D-ME framework, that is, via the analysis of the diary notes and the prototype versions, provides both the internal and external views of the prototyping dynamics and outcome, respectively. Additional means of dynamics sampling could also be foreseen by incorporating other sources of relevant information, such as biosignals. In fact, the biological-signal data from multiple biological-signal sources, for example, electroencephalography, electrocardiography, electromyography, electrooculography, and electrodermal activity, can be combined with artificial intelligence or machine learning or deep learning to provide additional queues of the developer's state (eg, stress, relaxation, or hyper or hypoactivity) during the design of the game and the creation of a series of prototypes [42-44]. In this way, the projection of the creative thinking onto the physiological signals and testing of the same protocol to game users could reveal the transferability of the designer's intentions to the gamers via the similarity of the related acquired signals. This could be used as a measure to optimize the game design and create a dynamic cocreation process [45-48], which could adapt to the specific characteristics of the designer and the target group of the serious game users [49-53].

Limitations and Further Research

The proposed 2D-ME conceptual framework provides new insights into the internal dynamics of the game designer's prototyping process. Clearly, the presentation here of 1 case study with 5 prototype versions cannot express the whole range and magnitude of such dynamics. However, it serves as a good example of the potentialities the 2D-ME framework could provide, both to the game designers and educators and researchers. In addition, the adoption of MSE (equation 1), as a cost function for the optimization process (Figure 4), could also be further explored, as alternative and a combination of metrics could be involved. The selection of such cost functions should consider the acceptable variation that relates with the context of a particular applied game design problem and should clearly express, as much as possible, the gains from its minimization under the game design problem's particular circumstances [54]. Extensive experimental application of the 2D-ME framework (eg, in educational settings of game design) could further validate its efficiency to monitor the dynamics evolved within the game design prototyping process, not only under the controlled settings, as presented here, but also at more naturalistic environments, for example, at designers' workplaces or laboratories.

The 2D-ME conceptual framework attempts to explain the self–first and self–third person views of prototyping dynamics in serious games design. Nevertheless, as it combines the TPACK and AT frameworks in a dynamic way, it shows many potentialities to be extended further to various design problems, additionally to the area of game design. In this regard, in our future plans, we foresee 2D-ME to be applied in the areas of arts, where the game design is replaced by art design. In many areas of art, such as painting, sculpture, literature, architecture, cinema, music, and theater, the design dynamics is the driving force for the creativity and the development of the artwork through prototyping. Clearly, the 2D-ME framework can easily embrace and explain such dynamics. Furthermore, sharing of the prototype version at specific k time instances to an external group (eg, experts, colleagues, mentors, and educators) could provide an additional level of external input to the internal world of the designer, extending the role of the community. In this vein, the current 2D-ME framework can be extended to the 2D-ME-ALL one, embracing external inputs and dynamics during the prototyping process—thus, enhancing the social and collaborative aspects in the use of the AT objects and extending to runaway ones with even broad societal ramifications [55]. Clearly, during the development of the prototype versions, externalization and projection from the "inner" to the "outer" world is possible and, under a cocreation perspective, wishful, to arrive at an optimized version. Moreover, this externalization does not have to be for the whole prototype but could be associated with specific parts (processes) of the prototyping, where external feedback is needed, upon the personal decision of the designer. In addition, it could happen during 1 or many iterations, providing a dynamic interplay between the inner and outer worlds. Approaching this as interconnected AT systems (constellations) [56] mainly shifts the locus of attention to the multitude of such internal activities, as externalized via their relationships, rather than the interplay between the self–first and self–third person views within the game designer's mind. In this sense, the selection of the scale is important, and the inclusion of interconnected AT systems could explain a concept of collective contribution (ie, transition from the person to the group and, further, to society). Apparently, this can happen in the case of complementary contributions by different experts participating in the game prototyping, for example, directors, graphic designers, composers, light experts, and character creators. It also can be expanded to an interdisciplinary context in which the experts come from distant backgrounds (eg, health and technology). However, even in such cases, the 2D-ME framework could be adopted by each expert to describe the steps that they undertook to arrive at their final contribution to the game design. Finally, there are some creative processes that are performed alone by nature, for example, music composition and painting. In such cases, it is important to focus on the internal dynamics that take place in the artist, as, in this way, we can identify personal traits and idioms that finally characterize the personal artistic style. In this kind of cases, the constellation of AT systems could, probably, be adopted if we want to model the audience interaction with the artistic outcome, especially in cases where there is an interactive part in it, for example, music installations or interactive spaces (eg, Xenakis polytopes). These views and extensions of 2D-ME, along with the addition of biosignals' input by incorporating artificial intelligence, machine learning, or deep learning tools, set the forthcoming research goals; work has already embarked toward such endeavor.

Conclusions

A new conceptual framework, namely 2D-ME, that provides insights upon the dynamics that evolve during a serious game designer's prototyping process has been presented here. Combining information from both the games space, TPACK, and AT, the 2D-ME framework provides explainable representation of, somehow, intangible processes; most of them not easily identifiable in the externalization of the prototyping process, that is, the prototype itself. Using dynamic constructs, the 2D-ME framework incorporates the alternations from first-person to third-person views and vice versa, stimulated by an organized way of internal self-interview (iAIS), providing dynamics monitoring that drive the prototype optimization process. A paradigm of the practical implementation of the 2D-ME framework in the case of a game design on light reflection exemplifies its potentialities and efficiency to capture the fine-grained dynamics involved during the production of the prototype version across the design timeline. Owing to its generic structure, the 2D-ME framework has high transferability to other areas of designing, for example, arts, and could be used both as a means of exploration of the expert designer's creative process and training of the novice ones, providing explainable representations of the underlined higher-order thinking.

Acknowledgments

The authors would like to thank the preservice teacher for his participation in the experimental case study and data sharing. This work was supported by the Khalifa University of Science and Technology, Abu Dhabi, UAE, under award number CIRA-2020-031.

Abstract

Background: The question of how video games can shape aggressive behaviors has been a focus for many researchers. Previous research has focused on how violent video game content leads to postgame aggressive behaviors. However, video games not only convey violence or prosocial content to players but also require cognitive effort from individuals. Since human cognitive resources are limited, consuming more cognitive resources in a game leads to less cognitive resources to suppress aggressive impulses. Therefore, the depletion of cognitive resources from playing video games may also lead to changes in postgame aggressive behaviors.

Objective: This study aimed to examine the relationship between cognitive resources consumed in video games and postgame aggressive behaviors.

Methods: A total of 60 participants (age: mean 20.22; range 18-24 y) were randomly assigned to either the high-load group or the low-load group. Participants from both groups played a video game centered around college life. In the low-load group, participants followed the gameplay instructions to complete it. In the high-load group, participants were given an extra digital memory task to complete while playing the game. Participants in both groups played the video game for about 25 minutes. A maze selection task was then conducted to measure the participants' helping and hurting behaviors.

Results: The independent samples 2-tailed *t* tests showed that the high-load group had significantly higher hurting scores (mean 3.13, SD 2.47) than the low-load group (mean 1.90, SD 2.12; t_{58}=−2.07, *P*=.04; Cohen *d*=−0.535), whereas helping behaviors were not significantly affected (t_{58}=1.52, *P*=.13; Cohen *d*=0.393).

Conclusions: As more cognitive resources are consumed in a video game, more hurting behaviors are exhibited after the game. This finding proposes an alternative route by which video games impact aggressive behaviors, adding to previous theories and raising concerns about the popularity of cognitive training games.

KEYWORDS

video games; hurting; helping; cognitive resources; aggressive behaviors

Introduction

Video games have become popular as a form of entertainment [1]. The General Aggression Model [2] and the General Learning Model [3] suggest that violent content in video games influences aggressive cognition [4,5] and negative emotions [6,7], leading to aggressive behaviors [8,9]. However, individuals passively receive content delivered by the game and actively invest cognitive resources while playing video games, potentially affecting social behaviors in the short term.

Two possible explanations were initially used to study honest behaviors [10,11], which help us understand the relationship between cognitive resource consumption and social behavior. The "Will" hypothesis [12] suggests that individuals have a natural tendency to engage in negative behaviors (eg, cheating) and therefore need to expend cognitive resources to overcome the impulse to engage in negative behaviors. The "Grace" hypothesis [13] assumes that individuals are naturally inclined to engage in positive behaviors (eg, honesty) and that individuals need to expend cognitive resources to overcome the original impulse so that they can behave negatively to gain benefits (eg, cheating).

Both aggressive (eg, hurting) and prosocial (eg, helping) behaviors are regulated by human cognitive processes [2,3] and are closely linked to cognitive load. According to social learning theory [14], both aggressive and prosocial behaviors are acquired by observing and imitating others. This position suggests that cognitive elements such as attention [15], executive function

[16], and working memory [17] impact aggressive and prosocial behaviors and are hindered by cognitive load. Therefore, these 2 hypotheses (the "Will" and "Grace" hypotheses) concerning honest behavior based on decreased cognitive resources may be equally beneficial in elucidating both hurting and helping behaviors.

Based on the aforementioned reasoning, the "Will" hypothesis suggests that when individuals use excessive cognitive resources while gaming, they may lack sufficient cognitive resources to control the impulse and therefore may display more hurting behaviors. Conversely, the "Grace" hypothesis posits that if cognitive effort is extended in the video game, the individual may lack sufficient cognitive resources to restrain the initial impulse and subsequently display more helping and less hurting behaviors. At present, it remains unclear as to which outcome transpires from expending cognitive resources in gaming.

This study examines the relationship between cognitive resource consumption in video games and postgame aggressive behaviors. If the "Will" hypothesis is met, consuming more cognitive resources during video gaming will lead individuals to show more aggressive behaviors after the game. If the "Grace" hypothesis is met, consuming more cognitive resources during gaming will lead individuals to show less postgame aggressive behaviors.

Methods

Participants

Participants were recruited through a college social media platform (ie, WeChat groups for college students). The participants were screened based on the following criteria: (1) no history of mental disorders, (2) normal or corrected-to-normal vision, and (3) no prior experience with the task used in this study. A total of 63 participants were recruited, and 3 of them did not show up, resulting in a final sample of 60 college students.

An a priori power analysis using G*Power (version 3.1.9.7; Heinrich-Heine-Universität Düsseldorf) was conducted to estimate the sample size. Based on data from Yin et al [18] (n=40), which compared 2 independent groups on the same task, the minimum effect size in that study was 0.77. With a significance level of α=.05, Cohen *d*=0.77, and power=.80, the minimum sample size needed with this effect size was 56 for the independent samples 2-tailed *t* tests used in this study. Therefore, the obtained sample size of 60 was more than adequate to test the hypothesis.

The 60 participants were randomly assigned to the high-load group (n=30, 50%; 11/30, 37% female; age: mean 20.47, range 18-24 y) and the low-load group (n=30, 50%; 12/30, 40% female; age: mean 19.97, range 18-24 y). Informed consent was obtained from each participant before the experiment.

Measures

Video Games

The study used a video game adapted from the one used by Yin et al [18], where participants played the role of a first-year college student facing diverse situations based on college life. The content that the participants encountered in the scenarios was neutral (ie, not including hurting or helping behavior, to avoid in-game hurting or helping content from affecting postgame maze choices) and related to daily life at college, such as choosing which clubs to join, what they chose to wear out, and what sports they were involved in after class. In the low-load group, participants followed the game instructions to complete it. In the high-load group, participants had an additional digital memory task while playing the game. They had to memorize a 4-digit "password" and enter it after completing 5 situations. Subsequently, they received a new password and had to enter it after 5 further situations. In 60 situations, they were given the "password" 12 times, and throughout the game, they had to keep a 4-digit number in their memory. In the high-load group, participants could not take notes while trying to remember the password. Thus, they had to memorize it internally and update the numbers after every 5 situations. They were told to prioritize remembering the password correctly and follow the game instructions to finish it, thus requiring more cognitive effort and resources than the low-load group. On average, the participants completed the game in approximately 25 minutes.

Maze Selection Task

The maze selection task used in the study was modified from the Tangram Task, which is commonly used in psychological research on video games [8,19,20]. Notably, the results of the Tangram Task have been found to correlate significantly with aggression and prosocial behaviors measured through scales and laboratory tasks [21]. In some countries, students may be unfamiliar with tangrams, so Yin et al [18] suggested using mazes instead to measure helping and hurting behaviors.

In the maze selection task, participants were required to choose 11 mazes for the next participant (who is fictional) from 30 given mazes. The fictional participant would walk the maze using paper and pencil, and if they could walk at least 10 mazes in 10 minutes, the fictional participant would be paid an additional ¥30 (US $4.12). There were 10 mazes based on 5 × 5 cells (small and easy), 10 based on 10 × 10 cells (medium), and 10 based on 20 × 20 cells (large and challenging). Participants could help the following participant by selecting easier mazes or hurt them by selecting difficult mazes. The helping score was the total number of easy mazes chosen, and the hurting score was the total number of difficult mazes chosen. Notably, higher scores indicated more helping or hurting behaviors.

Analyses

Only 1 of the 30 participants in the high-load group misremembered the "password" in 1 response, whereas a total of 360 responses (30 participants in the high-load group × 12 responses per participant) were recorded during the experiment. The incorrect response accounted for 0.3% (1/360) of the total responses in the high-load group. Therefore, it was concluded that having only 1 incorrect response was acceptable and that the participants in the high-load group retained their memory for the 4-digit number throughout the experiment. The analysis of the data then included all 30 participants in the high-load group, including the 1 who incorrectly remembered once.

After completing the data collection, we conducted independent samples 2-tailed *t* tests using the helping and hurting scores from the maze selection task as dependent variables and groups (high-load and low-load groups) as independent variables. In the pretests for equality of variances, the samples passed the Levene test for homogeneity of variances (helping scores: $F_{1,58}$=0.03, *P*=.87; hurting scores: $F_{1,58}$=0.52, *P*=.48). Therefore, the Student *t* test was used to calculate the statistical probability (*P* value), and Cohen *d* was used to indicate the effect size.

Ethical Considerations

The study was approved by the Research Ethics Committee of South China Normal University (#SCNU-2021-275). Written informed consent was obtained from each participant. Our data underwent deidentification processes. Participants received ¥30 (US $4.12) as compensation.

Results

Descriptive statistics for the helping and hurting scores from the maze selection task are shown in Table 1. The independent samples 2-tailed *t* tests showed a significant difference between the 2 groups in hurting scores (t_{58}=−2.07, *P*=.04; Cohen *d*=−0.535) but not helping scores (t_{58}=1.52, *P*=.13; Cohen *d*=0.393). The high-load group had significantly higher hurting scores (mean 3.13, SD 2.47) than the low-load group (mean 1.90, SD 2.12; *P*=.04).

Table . Descriptive statistics for the helping and hurting scores from the maze selection task. The helping score was the total number of easy mazes (based on a 5 × 5 cell) participants chose in the maze selection task, and the hurting score was the total number of difficult mazes (based on a 20 × 20 cell) they chose, with higher scores indicating more helping or hurting behaviors.

Score	High-load group, mean (SD)	Low-load group, mean (SD)
Helping	2.07 (2.41)	2.97 (2.17)
Hurting	3.13 (2.47)	1.90 (2.12)

Discussion

Principal Findings

The main finding of this study is that investing more cognitive resources in video gaming led to significantly more postgame hurting behaviors (*P*=.04), whereas helping behaviors were not significantly affected (*P*=.13). Consistent with the "Will" hypothesis [12], individuals in this study may be more inclined to exhibit aggressive behaviors, and inhibiting aggressive behaviors requires a drain on cognitive resources. When cognitive resources are consumed during play, individuals may not have sufficient cognitive resources to inhibit aggressive behaviors and therefore tend to exhibit more aggressive behaviors after gaming.

Comparison to Prior Work

Over the past 2 decades, research on the influence of video games on aggressive behavior has relied heavily on the General Aggression Model [2], suggesting that the violent content in video games is a key factor in causing individuals to exhibit more aggressive behavior. The results of this study complement this model by suggesting another possible cause of more aggressive behavior, namely, the consumption of excessive cognitive resources in games. In actual play, these 2 processes may alter aggressive behaviors simultaneously. The violent content of the game shapes individuals' aggressive scripts and schemas [2]. In contrast, a large amount of cognitive input in the game leaves individuals without sufficient cognitive resources to suppress their impulses to hurt.

This result also raises concerns about cognitive training in video games. In recent years, the use of video games for cognitive training has become increasingly popular [22]. Video games are easy to access and fun, and participants are more willing to participate regularly in video game–based cognitive training [23,24]. Numerous studies have shown that video game training improves individuals' visual attention [25,26] and executive functions [27-29]. However, the results of this study suggest that excessive cognitive resources spent on games may harm individuals' social behaviors. Therefore, further research is urgently needed to assess how cognitive training games affect individuals' aggressive behaviors.

It is important to state that this study provides evidence solely for the potential effect of cognitive load in gameplay on postgame hurting behaviors, and one must not infer directly from this outcome that cognitively training games inevitably result in long-lasting aggression. In most laboratory studies of video games [4,15,18-20], measures of social behavior are typically completed within 20-30 minutes after the game. Changes in social behavior observed under such conditions are generally transient and can be recovered after a period of time. This is also true in high-load games, where participants may feel cognitively exhausted for a short period of time after the game and are more likely to display aggression, but not irreversibly.

However, models of aggression and learning have been proposed specifically for this scenario. Anderson et al [2] note that while the temporary nature of the postgame effect is acknowledged, prolonged and repeated exposure to this state through extended gameplay can permanently alter an individual's levels of aggression or prosocial tendencies. Therefore, although the laboratory findings indicate a short-term aftereffect of playing video games, it still warrants careful consideration and attention.

In addition to the duration of aftereffects and long-term effects, several factors were not tested in a single experiment. For example, it is unclear whether all highly cognitively demanding games induce aggression or only certain types of games. It is also uncertain whether the effect of cognitive load differs from the effect of violent game content and whether these effects interact. Further research is needed to investigate these aspects.

Limitations

This study has certain shortcomings. First, it has been suggested that some cognitive factors such as attentional bias to different information also influence social behaviors [15], and it is still unknown whether these factors interact with the cognitive resources consumed in video games. The interaction of these factors with the consumption of cognitive resources during gameplay could be further tested, which would help to deepen our understanding of the mechanisms by which cognitive resources influence postgame social behaviors.

Second, only 1 task, the maze selection task, was used to measure helping and hurting behaviors, and multiple tasks measuring aggression and prosocial behaviors are needed to test this effect. The maze selection task is founded on a localized adjustment of the Tangram Task, which has undergone extensive use in numerous studies. Furthermore, the modified task has obtained validation through research that establishes its efficacy in measuring helping and hurting behaviors. Therefore, we believed that the results in this study are reliable. However, if multiple tasks measuring aggression and prosocial behaviors were used, it is possible to compare whether different types of social behaviors can all be affected by the in-game consumption of cognitive resources.

Third, the manipulation of cognitive resources in the game was achieved by increasing the working memory load. Therefore, it remains to be tested whether the same results can be obtained by depleting cognitive resources in other ways (eg, inhibition or switching ability). Investigating different manipulation of cognitive resources in future studies will aid in determining whether different types of cognitive depletion affect postgame social behaviors equally.

Conclusion

This study highlights the negative impact of excessive cognitive resources spent on video games, potentially related to increased postgame aggressive behavior due to insufficient cognitive resources for inhibiting aggressive impulses. This finding proposes an alternative route by which video games impact aggressive behaviors, adding to previous theories and raising concerns about the popularity of cognitive training games.

Abstract

Background: Chinese gamers use computer and mobile phone games widely. Consequently, concerns regarding the development of internet gaming disorder (IGD) in adolescents have been raised. However, only a few studies have focused on the influence of gaming devices on IGD.

Objective: This study aims to compare sociodemographic information, gaming use characteristics, personality traits, and gaming motivations between computer game users (CGUs) and mobile phone game users (MGUs), as well as identifying IGD predictors.

Methods: This was a cross-sectional study. A total of 3593 internet game players took part in an online survey, which included sociodemographic information, gaming patterns, gaming motivations, the Chinese version of the Video Game Dependency Scale, and the Chinese Big Five Personality Inventory brief version. The population was divided into 2 groups for comparison by mobile phone or computer use, and the IGD population was also compared within the 2 groups.

Results: There were significant differences between the 2 gaming device groups in the time (t_{2994}=7.75, *P*<.001) and money (t_{2994}=5.11, *P*<.001) spent on gaming and in internet game addiction scores (t_{2994}=3.68, *P*<.001). Individuals using different gaming devices had different game motivations and personality traits and preferred different genres of games. Results showed that IGD predictors were different for the 2 groups, for example, strategy (odds ratio [OR] 4.452, 95% CI 1.938-10.227; *P*<.001) and action shooter (OR 3.725, 95% CI 1.465-9.474; *P*=.01) games increased the risk for MGUs.

Conclusions: Gaming devices should be considered during early identification, such as long daily gaming time, much money spent on gaming, neuroticism, and conscientiousness. In addition, more research should be conducted on new gaming devices and IGD treatment.

KEYWORDS

internet gaming disorder; gaming device; gaming motivation; personality traits; gaming use characteristics

Introduction

Over the past few decades, internet games have been firmly integrated into people's daily routines, especially among children and adolescents. According to the China Internet Network Information Center (CNNIC) latest report, by the end of December 2021, the number of internet users in China had reached 1.032 billion, and over 517.93 million netizens play games, accounting for 52.4% of the total number of internet users [1]. It is considered that video game activities improve basic attentional functions [2]. However, its inappropriate use has been considered a serious public health issue. Playing games for long periods can increase the incidence of dry-eye disease, obesity, and mental health problems [3,4]. Previous studies have found a positive association between digital device use and poor sleep quality and psychological distress, such as depression or internet gaming disorder (IGD) [5-8].

The American Psychiatric Association [9] first included IGD in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) in 2013 as a disease that needs further exploration, and in 2019, the World Health Organization (WHO) officially included it as a psychiatric disorder in the *International Classification of Diseases 11th Revision* (ICD-11) [10]. The reported prevalence of IGD varies due to differences in the measurement and sampling methods. Thus, the worldwide prevalence of gaming disorder is 3.05% [11]. In China, the prevalence of problematic gaming among adolescents is 5%-17% [6]. Furthermore, many studies have investigated the risk factors for IGD, but few studies have considered the influence of gaming devices; today, a large proportion of gamers use mobile phones, which allows them to play games limitlessly, which may increase the IGD risk.

Steam, the largest digital platform for gaming on a personal computer (PC), announced that 20,313,451 users registered on it during the coronavirus pandemic [12]. The same year, according to Google, mobile phone gamers across 10 countries increased their duration and frequency of gaming by two-thirds [13]. According to a 2020 survey, 62.5% of underage internet users in China regularly play online games. Among them, 28.9% play computer games and 56.4% play mobile phone games [14]. Owing to advances in technology, people's entertainment has been gradually replaced by computers and video games, and many scenarios that would not happen in the real world are implemented in the virtual world, making digital games more attractive to people [15]. Games have become an increasingly popular pastime, especially during the coronavirus pandemic [16]. In today's developed visual media, in addition to computers, mobile phones are another popular terminal for internet games. Different devices can meet different needs [17]. Computer games often feature high-quality sound and visual effects and usually require more time to play; therefore, they have the potential to provide immersion, fulfillment, and competitiveness. In addition, mobile phone games are not only easier to access than computer games but they also increase feelings of social connection and reduce feelings of isolation and negative emotions. One study found that texting games are easily associated with social networking service applications [18]. In addition, recent advances in smartphone gaming platforms have made it easier to access a wide variety of game genres [17]. Furthermore, recently, the number of mobile phone game users (MGUs) has increased dramatically, and the mobile phone gaming market has flourished, leading to a gradual shift in the traditional gaming model from desktop PC– to mobile device–based gaming models [19]. Therefore, this study aims to explore the differences between computer game users (CGUs) and MGUs to gain a deeper understanding of IGD.

In addition, exploring internet gaming use characteristics is important to better understand IGD. Internet gaming characteristics can be used as IGD predictors, including weekday/weekend game time and money spent on games, which can provide information for clinical diagnosis and treatment [20,21]. The influence of the game genre on IGD is worth mentioning. Analysis of variance reveals that internet gaming addiction varies according to the game genre [22]. A noteworthy finding was that IGD might be more prevalent in users of specific genres, especially real-time strategy and first-person shooter games [23]. Gaming motivation is another important factor for predicting IGD. Escapism motivation has demonstrated a significantly strong association with IGD [24]. Other types of motivation may also be used to predict disease [25]. Thus, the theory, assessment, and treatment of IGD can be improved by examining the association between specific types of motivation [26].

Previous studies have indicated that personality traits may also play a necessary role in the development of IGD [27]. Personality traits are characterized by high stability, reflecting thoughts, attitudes, emotions, and behavioral patterns. Despite some controversy, the 5-factor model has become a widely accepted framework of personality traits, which includes 5 dimensions: conscientiousness, extraversion, agreeableness, neuroticism, and openness [28]. Personality traits can affect an individual's experience of games, causing players to show different degrees of pathological game use disorder [29]. Gamers with IGD show high levels of neuroticism [30]. Individuals high in neuroticism tended to experience negative emotions. The act of playing games, especially in immersive environments, provides gamers with alternative virtual reality to relieve negative moods [5]. In addition, gamers with low conscientiousness have a higher risk of developing IGD because they are less persistent in pursuing goals and focusing on responsibilities in their daily lives [31]. Individuals with IGD tend to overplay games, which can affect their relationships, work, or education. Conscientious people are less likely to allow important aspects of their lives to be negatively affected by games [32]. However, results for other personality traits have been inconsistent.

Although previous studies have reported features associated with IGD, most have focused on computer games. Given that each gaming device has unique interface characteristics, we hypothesize that there are some differences in the psychometric properties and development of IGD between CGUs and MGUs. This study aims to compare internet gaming use characteristics and personality traits between different gaming devices and to explore potential specific predictors for IGD according to different gaming devices (mobile phone or computer).

Methods

Study Design and Subjects

This was a cross-sectional study that collected the internet addiction scores, game time, money, game type, game motivation, and personality traits of different gaming device users through an online survey. Differences in these indicators across users of gaming devices or gaming addicts were compared to infer the characteristics of these different populations playing games and the association between devices and gaming addiction.

This study was conducted between October and November 2019 in China. We issued online questionnaires through WeChat (a cross-platform instant messaging tool), based on a network survey. For better understanding, we used the Chinese version of the scale and the Chinese questionnaire. Participants could fill in the questionnaire anonymously by scanning the quick response (QR) code of the survey program Questionnaire Star (a free online questionnaire, survey, and voting tool). On the first page of the questionnaire, we briefly introduced the purpose of this study and some matters that needed attention when filling in the questionnaire. We also demonstrated the voluntary nature, anonymity, and confidentiality of the survey. Individuals could choose the "accept" or "reject" options. Participants could choose "reject" to exit the survey page, and those who chose "accept" would skip to the next page and continue to complete the questionnaire.

The participants were recruited online through WeChat, Weibo, or other social apps. In this study, the inclusion criteria were (1) aged 15-25 years, (2) played online games in the past 12 months, and (3) understood the questionnaire content and agreed to participate. The survey initially recruited 4012 participants. Those who had never played online games or only played offline games were excluded (n=103, 2.6%). Individuals who had severe physical or mental disorders (n=87, 2.2%) were also excluded. To be specific, the following individuals were excluded: (1) current or previous history of psychiatric disorders, including but not limited to schizophrenia, bipolar disorder, or depression, and (2) current or history of medical disorder, including but not limited to neurological and endocrinological disorders. Diagnoses of schizophrenia, affective disorders, and other disorders were obtained by experienced clinicians through the DSM-5 interview [9]. For example, if a subject presented with cognitive, affective, and behavioral disturbances and severe dissonance in clear consciousness (eg, paradoxical thinking or commentary hallucinations), schizophrenia was likely to be diagnosed; if a subject presented with significant and persistent high or low mood, depressive disorder or bipolar disorder was likely to be diagnosed. Other psychiatric disorders were also diagnosed according to the criteria in the DSM-5. In addition, we recommended that these excluded individuals seek professional medical advice. Questionnaires that lacked authenticity were deleted (eg, multiple replies from the same IP address; n=55, 1.4%). In addition, we removed responses in which the gaming device was neither a computer nor a mobile phone (eg, Nintendo Switch, Sony PlayStation, or virtual reality headsets) and individuals who played computer and mobile phone games evenly (n=174, 4.3%). Finally, a total of 3593 (89.6%) internet game users were included.

Ethical Considerations

The study protocol was approved by the Institutional Review Board. All participants were fully informed about the purpose of this investigation and signed an online informed consent form. The study was conducted in accordance with the Declaration of Helsinki, and it was approved by the Research Ethics Committee of Second Xiangya Hospital of Central South University (protocol code 2020004, date March 1, 2020).

Procedures and Measures

Self-administered questionnaires were used to collect sociodemographic information, gaming use characteristics, IGD, and personality traits. Before starting the study, the questionnaire was tested with a small sample of adolescents to improve readability and intelligibility, and it was finalized after the preliminary study.

Sociodemographic data included gender, age, education level, marital status (married or unmarried), and structure of the family (either a sibling or an only child).

In terms of gaming use characteristics, participants were asked which gaming device they used most often (mobile phone, computer, or others).Three groups were divided by reports from the responders based on the gaming time spent on either a computer or a mobile phone: (1) computer game: individuals who played only computer games or played more computer games than mobile phone games; (2) mobile phone game: individuals who played only mobile phone games or played more mobile phone games than computer games; (3) others: individuals who played computer and mobile phone games evenly or the gaming device was neither a computer nor a mobile phone. Participants were also asked about their motivation for playing games, the game genre (role-playing games [RPGs], strategy games, action shooter games, and brain and skill games), and the time (hours/day) and money (yuan/month) spent on gaming in the past 12 months. Specifically, gaming motivation included sensation seeking, escaping reality, coping with negative emotions, passing time, and making friends.

IGD was assessed using the Chinese version of the Video Game Dependency Scale (VGD-S). The scale is a revision of the English version developed by Rehbein et al [33,34] and covers the description of IGD in the DSM-5, published by the American Psychiatric Association (Cronbach α=.92). The scale developed by Rehbein et al [34] is a 4-point Likert-type scale (strongly disagree to strongly agree) consisting of 18 items, with 2 items for each criterion. Participants were asked to choose an experience during the past 12 months from the list of 18 descriptive items. At least 1 of the 2 items must be answered with "strongly agree" to meet the diagnostic criterion. Participants who met 5 or more of the 9 criteria were placed in the IGD group (Cronbach α=.90).

We used the brief version of the Chinese Big Five Personality Inventory to measure personality traits [35-37]. The scale consists of 8 items for each subtype, and there are 40 items in total. In addition, it is scored on a 6-point Likert scale ranging from 1 (strongly disagree) to 6 (strongly agree) and demonstrates high construct validity and reliability (Cronbach α=.85).

Statistical Analysis

First, to reduce bias and confounding variables, we used propensity score matching (PSM) to match CGUs and MGUs based on demographic information. Chi-square tests and *t*-tests(two tails) were used to compare demographic information, IGD scores, internet gaming use characteristics, and personality traits between CGUs and MGUs. Logistic regression analysis was performed to identify IGD predictors in different game device groups. A 2-sided statistical significance level was set at $P<.05$. SPSS Statistics version 26.0 (IBM Corp) was used in this study.

Results

Sociodemographic Data

A total of 3593 subjects were included in the analysis. Of these participants, 1511 (42.1%) were CGUs and 2032 (57.9%) were MGUs. Considering the huge number of differences, PSM was used to match the age, gender, education, marital status, and family structure (only child in the family or not). Next, we acquired 1:1-matched samples, and 1498 (99.1%) CGUs and 1498 (73.7%) MGUs were included. The mean age for each group was 19-20 years (CGU: mean 19.6, SD 1.7 years; MGU: mean 19.6, SD 1.7 years), and most of them were male (CGU: 1259/1498, 84.0%; MGU: 1270/1498, 84.8%). Almost all subjects were unmarried (CGU: 1447/1498, 96.6%; MGU: 1456/1498, 97.2%), and over half of them were an only child (CGU: 886/1498, 59.1%; MGU: 839/1498, 56.0%), which did not present a significant difference. The results of the χ^2 test indicated a significant difference regarding the education level (χ^2_1=38.3, $P<.001$) of the 2 device-specific groups: the percentage of people who earned a bachelor's degree or higher was greater in the CGU group (886/1498, 59.1%) than in the MGU group (717/1498, 47.9%); see Table 1.

Table 1. Sociodemographic data of the 2 different gaming device groups.

Characteristics	MGUs[a] (n=1498)	CGUs[b] (n=1498)
Age (years), mean (SD); *t* (*df*)/χ2 (*df*)=0.16 (2994), *P*=.87	19.58 (1.67)	19.59 (1.70)

[a]MGU: mobile phone game user.

[b]CGU: computer game user.

Comparisons of Gaming Pattern IGD Score and Game Genre Between CGUs and MGUs

Participants with IGD and the overall population were compared separately between the 2 groups (Table 2). For the overall population in the CGU group, the mean IGD score was 2.95 (SD 2.67) and the mean time and money spent were 2.21 (SD 1.56) hours/day and 111.31 (SD 189.80) yuan/month (mean US $15.95, SD US $27.20), respectively, while in the MGU group, the mean IGD score was 2.60 (SD 2.57) and the mean time and money spent were 1.95 (SD 1.26) hours/day and 63.00 (SD 149.05) yuan/month (mean US $9.03, SD US$21.36), respectively. IGD scores (t_{2994}=3.68, $P<.001$), time (t_{2994}=7.75, $P<.001$), and money (t_{2994}=5.11, $P<.001$) in the MGU group were all significantly lower than those in the CGU group. The 2 most popular game genres in the CGU group were strategy (1048/1498, 70.0%) and action shooter (205/1498, 13.7%), whereas in the MGU group, the 2 most popular game genres were strategy (981/1498, 65.5%) and RPGs (200/1498, 13.4%). For subjects with IGD in the CGU group, the mean IGD score was 6.86 (SD 1.48) and the mean time and money spent were 3.08 (SD 2.00) hours/day and 228.34 (SD 238.15) yuan/month (mean US $32.73, SD US $34.13), respectively. In the MGU group, the mean IGD score was 6.74 (SD 1.46) and the mean time and money spent were 2.75 (SD 1.63) hours/day and 160.78 (SD 261.41) yuan/month (mean US $23.04, SD US $37.47), respectively. The time (t_{681}=2.37, P=.02) and money (t_{681}=3.53, $P<.001$) spent in the MGU group were significantly lower than those in the CGU group. In addition, the 2 most popular game genres in both groups were strategy (CGU: 246/369, 6.7%; MGU: 222/314, 70.7%) and RPGs (CGU: 69/369, 18.7%; MGU: 47/314 15.0%).

Table 2. Within-group comparisons of IGD[a] scores, gaming patterns, personality traits, gaming motivations, and game genres.

Characteristics	MGUs[b]		CGUs[c]		Total statistics		IGD statistics

[a]IGD: internet gaming disorder.

[b]MGU: mobile phone game user.

[c]CGU: computer game user.

[d]RPG: role-playing game.

Comparisons of Personality Traits and Gaming Motivations Between CGUs and MGUs

Table 2 outlines the significant differences between device-specific groups regarding gaming motivations and personality traits. For the overall population in both groups, CGU participants presented higher openness than MGU participants (t_{2994}=3.98, *P*<.001), and for subjects with IGD, CGU participants presented lower agreeableness than MGU participants (t_{681}=−2.76, *P*=.006). Referring to gaming motivations, including sensation seeking, escaping reality, coping with negative emotions, passing time, and making friends, the two most important game motivations were passing time (CGU: 854/1498, 57.0%; MGU:1008/1498, 67.3%) and coping with negative emotions (CGU: 711/1498, 47.5%; MGU: 673/1498, 44.9%) in the two groups among the overall population. For the subjects with IGD, the most two important motivations in the CGU group were coping with negative emotions (212/369, 57.5%) and seeking sensations (211/369, 57.2%), while in the MGU group, those were passing time (193/314, 61.5%) and coping with negative emotions (181/314, 57.6%).

Identifying IGD Predictors by Game Device Group

After controlling for sociodemographic factors, multivariate logistic regression was conducted to identify IGD predictors in the different game device groups (see Table 3). In the CGU group, a higher daily gaming time (odds ratio [OR] 1.301, 95% CI 1.182-1.432; *P*<.001), more money spent monthly on gaming (OR 1.002, 95% CI 1.001-1.003; *P*<.001), higher neuroticism (OR 1.060, 95% CI 1.038-1.083; *P*<.001), and lower conscientiousness (OR 0.922, 95% CI 0.894-0.951; *P*<.001) were associated with IGD, in addition to motivation for sensation seeking (OR 2.387, 95% CI 1.781-3.200; *P*<.001), escaping reality (OR 3.407, 95% CI 2.347-4.945; *P*<.001), and coping with negative emotions (OR 1.456, 95% CI 1.085-1.955; *P*=.01). In the MGU group, a higher daily gaming time (OR 1.377, 95% CI 1.226-1.547; *P*<.001), more money spent monthly on gaming (OR 1.004, 95% CI 1.003-1.006; *P*<.001), higher neuroticism (OR 1.087, 95% CI 1.063-1.112; *P*<.001), and lower conscientiousness (OR 0.928, 95% CI 0.898-0.960; *P*<.001) were associated with IGD, in addition to motivation for sensation seeking (OR 2.244, 95% CI 1.651-3.050; *P*<.001), escaping reality (OR 2.271, 95% CI 1.496-3.447; *P*<.001), and coping with negative emotions (OR 1.493, 95% CI 1.099-2.029; *P*=.01). Compared to brain and skill games, strategy (OR 4.452, 95% CI 1.938-10.227; *P*<.001) and action shooter games (OR 3.725, 95% CI 1.465-9.474; *P*=.01) increased the risk for the occurrence of IGD in this group, which was different from the CGU group.

Table 3. After adjusting for sociodemographic data[a], binary logistic regression analyses of factors predicting IGD[b] in device-specific groups.

Characteristics	CGUs[c]		MGUs[d]	
	OR[e] (95% CI)	*P* value	OR (95% CI)	*P* value
Gaming patterns				
Gaming time	1.301 (1.182-1.432)	<.001	1.377 (1.226-1.547)	<.001
Money spent	1.002 (1.001-1.003)	<.001	1.004 (1.003-1.006)	<.001
Gaming motivations				
Sensation seeking	2.387 (1.781-3.200)	<.001	2.244 (1.651-3.050)	<.001
Escaping reality	3.407 (2.347-4.945)	<.001	2.271 (1.496-3.447)	<.001
Coping with negative emotions	1.456 (1.085-1.955)	.01	1.493 (1.099-2.029)	.01
Passing time	1.113 (0.832-1.490)	.47	0.906 (0.656-1.251)	.55
Making friends	1.026 (0.742-1.419)	.88	0.891 (0.614-1.294)	.54
Personality traits				
Neuroticism	1.060 (1.038-1.083)	<.001	1.087 (1.063-1.112)	<.001
Conscientiousness	0.922 (0.894-0.951)	<.001	0.928 (0.898-0.960)	<.001
Openness	0.983 (0.958-1.009)	.19	1.003 (0.971-1.031)	.98
Agreeableness	0.990 (0.910-1.021)	.53	0.991 (0.959-1.025)	.60
Extraversion	1.003 (0.980-1.027)	.78	1.001 (0.973-1.031)	.92
Game genres				
Brain and skill	N/A[f]	N/A	N/A	N/A
Strategy	1.486 (0.612-3.607)	.38	4.452 (1.938-10.227)	<.001
Action shooter	1.500 (0.577-3.901)	.40	3.725 (1.465-9.474)	.01
RPGs[g]	1.557 (0.583-4.159)	.38	2.434 (0.963-6.150)	.06

[a]Sociodemographic data included gender, age, education, marital status, and family structure (only child or note).

[b]IGD: internet gaming disorder.

[c]CGU: computer game user.

[d]MGU: mobile phone game user.

[e]OR=odds ratio.

[f]N/A: not applicable.

[g]RPG: role-playing game.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to compare internet gaming usage characteristics and personality traits among people using different gaming devices. The main research findings are as follows: First, the game time, money spent, and IGD scores in the CGU group were higher than those in the MGU group. Second, subjects in different groups preferred different game genres and had different game motivations and personality traits; for example, subjects in the CGU group preformed lower openness than those in the MGU group. Third, the time and money spent on games, neuroticism, conscientiousness, motivation to seek sensations, escaping reality, and coping with negative feelings were associated with the occurrence and development of IGD in both groups in multivariate logistic regression; for MGUs, comparing the brain and skill, strategy, and action shooter games may bring more risks for IGD.

Several researchers have reported that time and money are dominant factors for IGD, and our study found that these 2 factors take effect in each group [20,33,38,39]. In this way, it seems that some developers of highly profitable games become whipping boys. However, in fact, most developers are just enthusiasts who want to create the most enjoyable gaming experience for their players, while game publishers are more concerned about monetization and drive developers in this way, due to which the game comes with paid content to attract players to invest as much time and money in the game as possible. Moreover, to maximize profits, the classical gaming operation pattern usually does not have fixed endpoints, which can easily cause gaming addiction [40]. The playing time, game currency input, and addiction value of the CGU group were higher than those of the MGU group. Some possible explanations are that mobile phones are currently more adapted to some medium-quality or online games with social attributes, while some computer games have higher quality, more immersive experiences, and higher prices, and high-quality games cause greater addiction problems. However, furthermore, as technology advances, the technological differences between mobile phones or other mobile devices and computers will become increasingly smaller. We can assume that mobile phone game addiction may replace computer game addiction as a larger social health issue within a few years because mobile devices are more accessible and often free to play.

The game genre plays an important role in the development of IGD, and it is important to explore its impact on IGD [41]. Our study showed that the 2 groups had different gaming preferences. For the addicted population, both groups preferred strategy and adventure games, and for MGUs, the strategy and action shooter games may bring more risks. Previous research has found that strategy games and action shooter games are popular among teenagers with high IGD risks [42]. Action shooter games have been reported to be associated with high impulsivity, disinhibition, and inattention [42]. Therefore, teenagers' liking strategies or action shooter games need the necessary acquaintances and encouragement to engage in healthy behaviors.

Although many studies have reported the relationship between RPGs and addiction, this study did not find meaningful differences, possibly due to the heterogeneity of the subjects. The reason for the different game preferences between the 2 groups may be that the number of popular games varies on different devices, particularly when the Chinese government tightens restrictions on game distribution, which requires further research.

Certain personality traits can make individuals more prone to addiction. This study found that neuroticism and conscientiousness were both identifying factors for IGD in each group, which is consistent with previous findings [33,43,44]. Highly neurotic individuals are more likely to feel stimuli from the external environment. Online gaming is often one of the choices to gain a sense of security [31]. In addition, it is difficult for those with low levels of conscientiousness to assume appropriate responsibilities or obligations, and the online world offers an environment of less oversight and responsibility, which is tempting for them [33]. Because the 2 personality traits are significantly associated with several addiction disorders, parents and educators should not only value highly neurotic and conscientious adolescents but also help them overcome personality disorders [45,46].

We also found that the openness of the MGU group was higher than that of the CGU group. This means that people in the MGU group preferred to maintain their own gaming habits and did not easily change their game types and modes. In the IGD subgroup, the agreeableness of the CGU group was lower than that of the MGU group. Agreeableness is an assessment of the degree to which an individual likes to appear with others, and it reflects their attitude toward others. Low agreeableness can display a hostile, cynical, and ruthless attitude [47]. The finding indicates that computer game players prefer to enjoy the game alone and may encounter more social problems.

Motivations to seek sensations, escape reality, and cope with negative feelings were seen as factors strongly related to game addiction in our research, which is consistent with previous research findings [24]. In the total population, 34.5% of MGU subjects and 41.4% of CGU subjects played games because of sensation seeking, while in the IGD population, the number of people was >50%. People get pleasure from completing objectives, and developers have designed many large and small objectives in their games (eg, beating an opponent or just checking in online). Some of these in-game objectives are easy to complete, while others seem hardcore (especially those in competitive online games that require expert skills, coping, and long-term patience). These different difficulty levels allow all types of people to find their own goals in the game and earn pleasure by completing them. Some research has found that dealing with negative emotions, such as fear of failure, by imitating game characters against the real world under performance can be seen as a negative reinforcement for gaming disorder [48].

The CGU group was more motivated to look for sensations, possibly because computer games are more immersive. Players interact more with the digital world and have more fun after completing their objectives. There were >40% MGUs and CGUs whose gaming motivation was discomfort, similar to seeking sensations, among the IGD population; the 2 groups also exceeded 50%. As mentioned before, the online world offers an environment with less oversight and accountability, where players can vent their emotions unscrupulously and take less responsibility; in addition, it is noteworthy that negative emotions are often associated with high neuroticism and low conscientiousness. More than half of the participants played games to pass the time; however, interestingly, passing time did not become an IGD predictor, suggesting that most players use games in a healthy way and as a form of entertainment, and only a minority will develop IGD.

In addition, some users play games to make friends or escape reality. Some games, such as RPGs, provide a complete set of worldview settings in which people can temporarily escape from reality and meet the psychological needs of making friends [49]. This study found that people in the CGU group had a stronger motivation to make friends than those in the MGU group, reflecting that computer game players are more enthusiastic about making friends. Some studies have found that fixed social needs aggravate the progression of internet addiction [50,51]. Therefore, for computer game players, they should not only be encouraged to engage in more offline social interactions to meet their needs but also be helped in social skills.

Limitations

This study had several limitations. First, because this was a cross-sectional study with a nonrepresentative sample, causality and generalizability were limited. Therefore, longitudinal research and recruiting more representative samples are necessary. Second, the research data were self-reported and came from an online survey, which may be biased in terms of the reliability and applicability of the conclusion; thus, comments about the game usage of participants' relatives or acquaintances and offline assessment of IGD by clinicians can be included to obtain more accurate and realistic results in subsequent research. Third, considering the restrictions on game introduction in the Chinese Mainland, the study did not include people using new devices, such as PlayStation, Switch, or virtual reality headsets, and research on new devices can be designed for further study. Fourth, currently, there is no internationally recognized scale for evaluating game addiction; therefore, the results of this study should be based on preliminary results. Fifth, the study did not consider confounding factors, such as smoking, alcohol consumption, household income, and social status, which play important roles in gaming addiction and motivation. These data can be obtained in follow-up studies.

Conclusion

In summary, our study showed that there are significant differences between CGUs and MGUs in gaming usage patterns, game genres, motivations, personality traits, and internet game addiction scores. Furthermore, we found that time and money spent on games, neuroticism, conscientiousness, motivation to seek sensations, escaping reality, and coping with negative feelings are associated with the occurrence and development of IGD. Given the difference between CGUs and MGUs, there are 2 important implications for clinical research on gaming addiction disorders. More attention should be paid to high-quality computer games because of their high picture quality, immersive experience, and potential adverse consequences. The other is that useful regulation for computer game players with impaired social functioning or poor personality traits ought to be implemented. However, targeted measures need to be adopted to help people with IGD, and further studies may consider longitudinal research, including new game devices, to determine the causal relationship between addiction and various devices and other factors and accompany the innovation of game devices.

Acknowledgments

The authors would like to thank all the study participants. This work was supported by the National Natural Science Foundation of China (no. 81971249), the National Key R&D Program of China (no. 2020YFC2005300), and the Natural Science Foundation of Hunan Province (no. 2020JJ4782).

Abstract

Background: Mixed reality (MR) and its potential applications have gained increasing interest within the medical community over the recent years. The ability to integrate virtual objects into a real-world environment within a single video-see-through display is a topic that sparks imagination. Given these characteristics, MR could facilitate preoperative and preinterventional planning, provide intraoperative and intrainterventional guidance, and aid in education and training, thereby improving the skills and merits of surgeons and residents alike.

Objective: In this narrative review, we provide a broad overview of the different applications of MR within the entire spectrum of surgical and interventional practice and elucidate on potential future directions.

Methods: A targeted literature search within the PubMed, Embase, and Cochrane databases was performed regarding the application of MR within surgical and interventional practice. Studies were included if they met the criteria for technological readiness level 5, and as such, had to be validated in a relevant environment.

Results: A total of 57 studies were included and divided into studies regarding preoperative and interventional planning, intraoperative and interventional guidance, as well as training and education.

Conclusions: The overall experience with MR is positive. The main benefits of MR seem to be related to improved efficiency. Limitations primarily seem to be related to constraints associated with head-mounted display. Future directions should be aimed at improving head-mounted display technology as well as incorporation of MR within surgical microscopes, robots, and design of trials to prove superiority.

(JMIR Serious Games 2023;11:e41297) doi:10.2196/41297

KEYWORDS

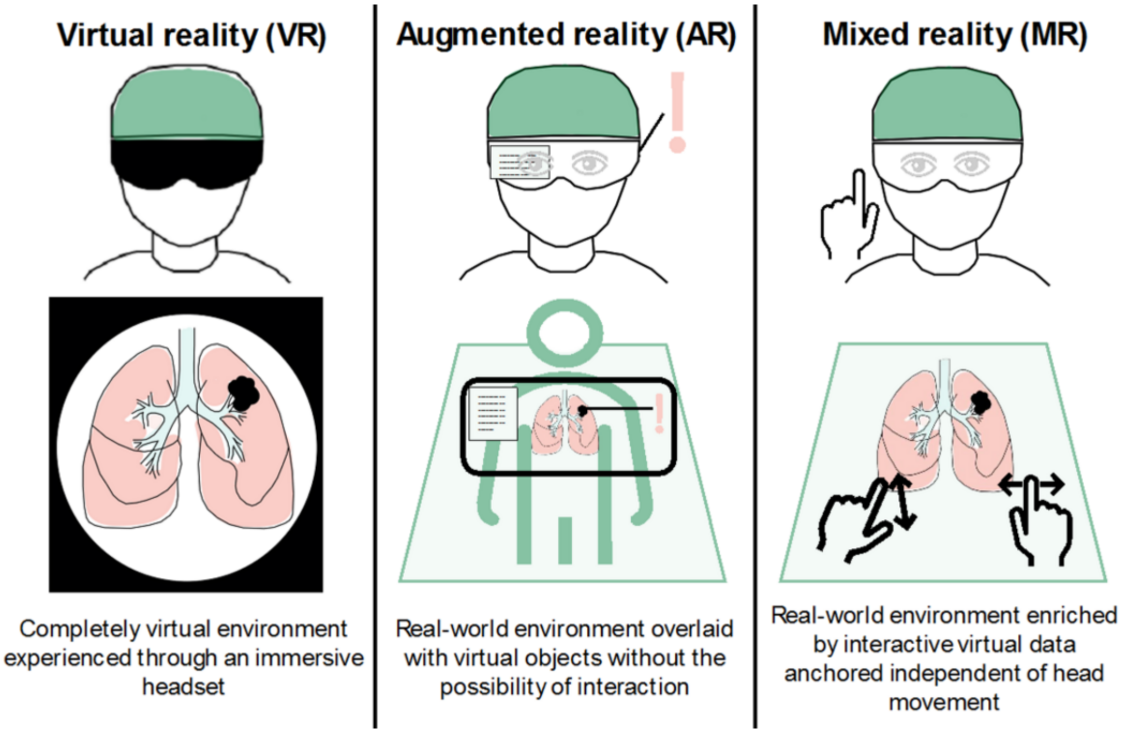
mixed reality; extended reality; surgery; intervention; education

Introduction

Over the recent years, mixed reality (MR) has gained interest within the medical community [1,2]. According to the landmark paper by Milgram et al [3], MR can best be viewed as a real-world environment enriched by virtual data presented within a single display, allowing for interaction through various means. Currently, MR is primarily experienced through head-mounted displays (HMDs) that allow virtual objects to be overlaid onto the real world using optical and video-see-through display techniques [4]. MR should be distinguished from virtual reality, referring to a completely virtual environment experienced through an immersive headset and augmented reality, which refers to virtual objects being overlaid onto a real-world environment without the possibility of interaction. More specifically, augmented reality merely projects visual data onto the real world, whereas MR anchors the visual data into the real world independent of the user's movement and allows for real-time interaction (Figure 1).

Theoretically, MR can offer many advantages for application during medical procedures or interventions by allowing the integration of relevant patient-specific data within real-time, real-world observations in a single display. It provides the ability to create interactive interfaces that facilitate procedural planning and intra-procedural navigation and can support training and education. The goal of this narrative review is to provide a qualitative overview of the different applications of MR across surgical and interventional medicine, identify its advantages and disadvantages, and reflect on its potential for future applications.

Figure 1. Graphical depiction of the differences between virtual, augmented, and mixed reality.

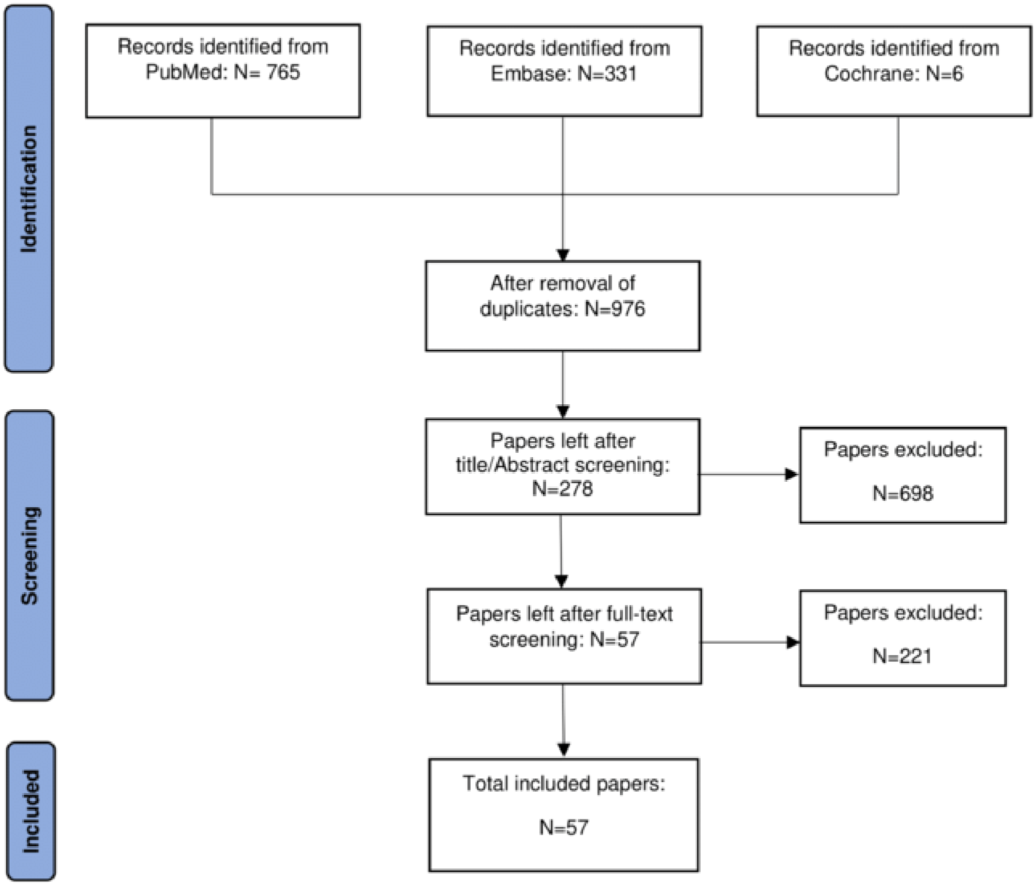


Methods

A targeted literature search within the PubMed, Embase, and Cochrane databases was performed on April 2, 2022, regarding the application of MR within surgical and interventional practice. Keywords in our title and abstract search included all commercially available devices for MR (Multimedia Appendix 1). Papers were screened for relevance and originality by 3 independent researchers (MTV, MW, and LMDH). Studies were included if they met the criteria for technological readiness level 5 or higher, and as such, had to be validated in a relevant environment. In short, technology readiness level is a method developed by NASA (National Aeronautics and Space Administration) in 1974 and adopted by the European Union and is used to assess technological maturation according to 9 levels, with 9 indicating the most mature level.

Papers were excluded if they involved augmented or virtual reality, for which the ability of interaction was used to differentiate between augmented reality and MR. Non-English literature and abstracts or conference proceedings were also excluded. Reference lists of all papers were screened for additional relevant literature. The flowchart of the search is shown in Figure 2. We categorized results into "preoperative and interventional planning," "intraoperative and interventional guidance," and "surgical and interventional training and education."

Figure 2. Flowchart of the conducted search on mixed reality in surgical and interventional practice.



Results

Preoperative and Interventional Planning

Within cardiovascular surgery and interventional cardiology, MR has been evaluated primarily for congenital defects that benefit from improved visualization of structural anomalies. Two studies involving congenital cardiac surgery reported a significant reduction in time required for surgical planning and intraoperative preparation when planning was done using MR instead of two-dimensional imaging [5,6]. Additionally, no intraoperative modifications to predefined surgical plans were reported in the MR group, whereas this was noted in 17.6% of cases in a 2D control group. This difference was attributed to improved spatial representation and visualization of relevant anatomy, improved depth perception, and a satisfactory correspondence to intraoperative findings in the MR group. Additionally, faster intraoperative recognition of structures was reported, presumed to be the result of improved processing of pathological structures and surgical steps by repeated visual representation beforehand [5,6]. Moreover, workload associated with mental transformation of images was reduced due to the more realistic surface features compared to 3D-printed heart models [5]. A reported future step for MR within preoperative planning of cardiac surgery would be the accurate visualization of coronary arteries and intracardiac structures and incorporating simulated movement and blood flow dynamics into the hologram.

Within orthopedic surgery, Lu et al [7] describe a collection of cases in which MR primarily improved preoperative doctor-patient communication and patients' understanding of complex pathology.

In otolaryngology and maxillofacial surgery, studies have demonstrated improved understanding of tumor-related anatomy and planning of surgical approach when MR was used instead of conventional radiological imaging [8,9]. Mitani et al [8] found that MR facilitated recognition of dissection lines in parotid tumor surgery, where consideration of detailed maxillary anatomy is of critical importance.

Within oncological surgery, MR has been applied for preoperative planning of minimally invasive electroporation and microwave ablation for advanced gastrointestinal tumors of hepatic origin. It improved remote and hospital-based analysis of patient-specific anatomy and optimized surgical approach [10]. MR-guided surgical planning for liver resection refined understanding of hepatic vascular anatomy and tumor location, improving accuracy of resection while preserving a larger residual liver volume [11].

In urology, MR-guided preoperative planning for laparoscopic nephron-sparing resection of complex renal tumors resulted in reduced operating time and a lower conversion rate to total nephrectomy when compared to conventional 2D computed tomographic (CT)–guided planning [12,13]. The reduced operating time presumably resulted from the ability to perform a more comprehensive analysis of the renal tumor before surgery, allowing significantly more patients in the MR group to be scheduled for laparoscopic partial nephrectomy instead of total nephrectomy (82% vs 46%; *P*<.001). This suggests that MR improves assessment of surgical risks and allows for modification of surgical strategy as needed, presumably by facilitating a more intuitive, stereoscopic, and comprehensive anatomical study. They also reported significantly increased patient satisfaction when MR was used during preoperative counseling [13].

In studies addressing preoperative planning, no limitations specifically related to the use of HMD are reported.

Intraoperative and Interventional Guidance

In neurosurgery, the efficacy of MR was reported in multiple studies that demonstrated adequate technical feasibility and safety for intracranial tumor surgery, epilepsy surgery, and spinal surgery [14-20]. Benefits mentioned include the following: (1) the ability to display holographic images of (tumor-related) anatomy onto a patient; (2) enhanced ergonomics; (3) improved preservation of attention and focus of the surgical team; (4) an intuitive workflow supported by voice commands and hand gestures; (5) cost efficiency of MR with HMD compared to conventional systems for neuronavigation; and (6) the possibility to share the surgeon's real-time perspective with other team members and residents during surgery [14-16,18]. Overall, the reported accuracy of lesion localization was satisfactory in both intracranial and spinal procedures [16,17,20,21]. Furthermore, MR guidance demonstrated improved efficacy during transforaminal percutaneous endoscopic lumbar discectomy and external ventricular drain placement compared to conventional methods of neuronavigation, resulting in a significantly reduced operating time and exposure to radiation, increased accuracy, and a reduction of attempts required for correct drain positioning, with comparable postoperative outcome [22-24]. Interestingly, this effect was particularly strong in novice residents, practically eliminating the learning curve associated with external ventricular drain placement by performing as well as experienced surgeons while guided by MR [24]. In addition, MR-based neuronavigation for surgical treatment of hypertensive intracerebral hemorrhage has deemed feasible [25].

Several feasibility studies and case reports within interventional cardiology and cardiovascular surgery have been published that highlight positive experiences with MR during implantation of a vena cava filter [26,27] and percutaneous interventions on noncongenital pulmonary artery stenosis [28], resulting in lower doses of contrast medium and radiation exposure. This could be of particular importance in patients with reduced kidney function. A desired future development that is mentioned is the development of dynamic heart models that incorporate movement of the heart and related structures during the cardiac and respiratory cycles [29,30].

Within orthopedic surgery, MR has mostly been used in spinal procedures, such as lumbar pedicle screw implantation, operational treatment of lumbar intervertebral disc herniation, and percutaneous kyphoplasty [31-33]. Several comparative studies report reduced bleeding and radiation exposure, shorter operating times, improved accuracy of screw placement, higher success rates, and improved pain and functionality scores when MR was compared to traditional x-ray guidance [31-33]. These results were attributed to improved anatomical understanding, resulting in smaller surgical trauma and a clearer incision site [32]. Reported disadvantages to MR include higher requirements for preoperative CT imaging, which might restrict its use to more specialized centers [31-33]. General acceptance of MR using HMD was reported as good in a study that investigated surgeon experience [34]. The devices were rated as comfortable to wear and image quality and accuracy were deemed satisfactory. Learnability of voice commands and hand gestures was well rated, although surrounding noise or lack of command understanding limited practical functionality. The potential added value for MR guidance was rated highest for surgical correction of deformities, followed by osteotomy revision and tumor surgery, especially within spinal and pelvic surgery. Greatest benefit was expected in terms of increased intraoperative accuracy, improved surgical outcome, and reduced exposure to radiation. These results demonstrate that MR can establish a sufficient support base for its application among orthopedic surgeons.

In otolaryngology and maxillofacial surgery, evidence suggests that MR enables easier extracapsular dissection of parotid tumors, which is related to lower complication rates, improved preservation of glandular tissue, and decreased incidence of saliva fistulas [9]. Tian et al [35] reported satisfactory use of intraoperative MR in cochlear implant surgery due to improved positioning of the implant. In temporal bone surgery, MR enables the surgeon to distinguish vital anatomical structures, resulting in improved surgical confidence [36]. Another reported advantage of MR is the undisrupted visual-motor axis during surgery by allowing the surgeon to preserve focus on the patient by eliminating the need for an external monitor for guidance, improving ergonomics. This was highlighted by Tang et al [37] during mandibulectomy for maxillofacial tumor resection, in which deviation from the intended surgical plane was reduced by alleviating the need to look at a monitor. They also reported improved efficiency and safety of the procedure.

Within oncological surgery, one study reported a reduction in operating time by a third and improved perceived surgical precision during minimally invasive resection of gastrointestinal tumors [10]. Moreover, MR enabled better identification of dissection lines and understanding of vascular anatomy in hepatic surgery, facilitating segmental resection [38,39]. This was highlighted in a study [11] that demonstrated MR-guided hepatectomy for hepatocellular carcinoma resulted in shorter operating time, fewer intraoperative bleeding, and a reduction in portal vein occlusion time due to an improved understanding of spatial anatomy. Furthermore, these patients had better recovery of liver function and fewer postoperative complications compared to traditional hepatectomy [11]. Percutaneous indocyanine green injection for guidance during laparoscopic anatomic liver resections was also improved when guided by MR [40]. Other feasibility studies highlight satisfactory outcomes and improved intraoperative lesion localization in breast cancer surgery [41], pediatric nephron-sparing Wilms tumor surgery [42], and robot-assisted transanal total mesorectal excision [43]. In laparoscopic cholecystectomy, MR guidance is feasible, but it was not preferred over traditional 2D methods in one study. Especially more experienced surgeons responded neutrally or negatively toward the implementation MR for laparoscopic cholecystectomy due to increased operating time and no significant improvements in outcome [44]. Lastly, in an extensive survey-based study [45], the reported overall experience with MR using HMD was good, with an important advantage being the ability to superimpose (visual) information on the patient's body. They concluded that MR using HMD improved the overall speed and comfort of a surgical procedure by providing intraoperative support and additional guidance to the surgical team [45]. A reported disadvantage of concern to MR is the inability to integrate the real-time movement of abdominal organs and the effects of soft-tissue deformation into the hologram, limiting translation of preoperatively acquired images to the real-time surgical site [38]. This is especially problematic during minimally invasive procedures and requires the development of complex prediction models to overcome these problems.

Evidence from comparative studies supports the use of MR within urology [12,13]. In laparoscopic nephron-sparing surgery for complex renal tumors, MR resulted in reduced operating time, warm ischemic time associated with renal artery clamping, reduced estimated blood loss, and a lower conversion rate to total nephrectomy when compared to a conventional approach with 2D CT guidance. Other factors such as inhospital stay, postoperative serum creatinine, and complication rate were similar among groups. The authors attributed the observed benefits to improved intraoperative identification of relevant anatomical structures, such as a tumor's feeding arteries, thereby preventing clamping of the main renal artery [12,13].

Within interventional radiology, Deib et al [46] conducted a feasibility study into MR-guided percutaneous spine procedures. They concluded that MR using HMD was noninferior to guidance by traditional monitors and might prove especially valuable during procedures that are conducted in spatially limited environments, as key anatomic landmarks could be reliably projected onto the procedural site, which limits disruption of the visual-motor axis.

MR might also be beneficial in plastic and reconstructive surgery due to the ability to project holographic visualizations of anatomical structures onto the patient to guide reconstruction. An example of this was a study [47] into auricular reconstruction, in which an image of the contralateral auricle was projected onto the ipsilateral surgical site. After appropriate positioning was ensured, MR resulted in improved perceived reconstructive results compared to a conventional approach with transparent film guidance [47]. Application of MR during vascular flap transfers and reconstructions that require identification and preservation of target perforator vessels, such as deep inferior epigastric perforator flap reconstruction of breast tissue, resulted in improved localization of the target perforating vessels when compared to Doppler-ultrasound [48]. An encountered problem, however, was related to adequate depth perception of the target vessels, which was limited using MR [49].

Within pulmonary surgery, MR can be used to visualize the location of small pulmonary nodules in patients scheduled for resection by video-assisted thoracoscopic surgery based on images acquired by preoperative CT. Using HMD, one study [50] reported that 94% of nodules were accurately localized, compared to 30% by manual palpation. This is especially relevant, as failure to localize a target nodule might lead to unplanned lobectomy or sampling error. Another study [51] reported the ability to integrate simulated lung deflation into the hologram, which improved surgical instrument placement and allowed for easier identification of nonpalpable lesions, which are notoriously difficult to localize once the lung is deflated [50,51].

Although the above demonstrates the feasibility of MR using HMD, some limitations specifically related to the use of HMD are reported. A recent meta-analysis proposed that using HMD during intracranial tumor surgery might provide additional challenges regarding depth perception, possibly increasing inaccuracy in surgery with small target lesions [52]. These issues restrict HMD use during intracranial procedures that require navigation on submillimeter level and are performed with a microscope. A solution could be the integration of preoperatively acquired holograms into the visuals obtained through the surgical microscope instead of HMD [15]. A reported drawback in cardiovascular surgery is the lack of integration with other often used head-worn devices, such as surgical loupes and headlamps [29]. Other reported limitations related to HMD are as follows: (1) holographic drifts while walking around the hologram [14]; (2) delayed image tracking with fast head movement [37,53]; (3) the perceived parallax effect [45]; (4) holograms being affected by surgical light [37,53]; and blind spots caused by obstruction of the surgical field by the hologram [14,54]. The latter, however, seems manageable with adjustable hologram opacity [14]. Another technological limitation is the relatively short battery life of the HMD, which poses difficulties for long surgeries [37,45,53]. Ergonomic disadvantages were related to perceived added strain on the musculoskeletal system of head and neck, eye strain, and visual discomfort [45,54].

Surgical and Interventional Training and Education

Due to its inherent qualities, MR could benefit surgical and interventional training and education. Condino et al [55] developed a multimodal MR-based surgical simulator for hip arthroplasty. Authors reported that this improved perception of spatial relationships between real and virtual objects. Such a simulator could be of relevance, since hip arthroplasty accounts for a multitude of reported adverse events in orthopedics, and risk of complications during the procedure is strongly related to surgeon experience.

Within otolaryngology and maxillofacial surgery, MR facilitated surgical training of maxillary carcinoma resection, and its overall usefulness was rated 4.5 on a 5-point scale in a survey study among otolaryngologists. This was attributed to improved understanding of the surgical procedure [8]. Additionally, MR can provide a training method for transcanal endoscopic ear surgery and cochlear implantation [36].

The possibility to establish a bidirectional audiovisual connection between the observer wearing an HMD and other participants at a remote site offers unique opportunities for training and education, as it allows medical students and residents to participate in (surgical) ward rounds and procedures remotely from a first-person perspective, providing teaching that was otherwise inaccessible to students [56]. This was recently supported in a study regarding introduction of an HMD within grand surgical rounds [57]. Moreover, it allows for telementoring through data sharing and communication with other surgical team members or surgical residents [45]. Telementoring by off-site experts using HMD has already been demonstrated in neurovascular procedures and cancer surgery [58,59].

Furthermore, evidence suggests a benefit to patient education as well, as an increase in comprehension and a decrease in anxiety was experienced by patients after being subjected to MR-based counseling [60], while simultaneously providing a potential method of intervention to improve patients' understanding of their own disease and adherence to treatment, and hence, facilitate knowledge transfer between health care professionals and individual patients [61].

In studies addressing surgical and interventional training and education, no limitations specifically related to the use of HMD are reported.

Discussion

The introduction of MR seems to have impacted the role of technology within surgical and interventional practice. The increasing number of studies on MR-based modalities using HMD has accelerated this development. It is likely that this number will continue to grow in the following years, mirroring the technological developments that succeed each other in rapid pace. Based on our findings, we can hypothesize that MR-based strategies for preoperative planning and intraprocedural guidance have certain benefits including, but not limited to the following: (1) challenging procedures with high anatomical complexity; (2) procedures that are performed infrequently or are otherwise highly specialized and of low volume, such as rare congenital cardiac defects; (3) procedures that involve an extensive learning curve; (4) procedures that rely on extensive preoperative imaging for intraprocedural guidance; and (5) general education and skill training purposes. Additionally, an increasing number of studies are emerging that highlight the feasibility and potential superiority of MR for more common procedures. In this regard, it is important to note that the benefits of this technology, although complex in nature, do not have to be limited to complex, uncommon procedures but can also further improve safety and efficacy of more simple and routine procedures by improving workflow.

An often reported benefit of MR is related to improved efficiency, which could be the result of improved planning and execution. The immersive, high-quality holographic models of patient-specific anatomy that are compatible with the newest HMD facilitate interaction and allow for improved understanding of complex spatial relationships between relevant anatomical structures, improved spatial orientation, and identification of target pathologies, thereby enabling better visualization and preparation beforehand. As modern medicine is moving toward personalized precision treatment, these patient-specific holograms and qualities of MR could further enhance individually customized surgical plans, including decision-making regarding surgical approach. During a procedure, the ability to project a reconstructed holographic image onto a patient allows for better identification of important patient-specific anatomical landmarks, prevents disruption of the visual-motor axis, and intuitively improves the accuracy of most interventions, resulting in improved surgical performance and reduced operating time. As many procedures that rely on real-time imaging and monitoring for guidance are radiation-based, improved efficiency can result in a significant reduction in total radiation exposure to both patient and physician. This is further illustrated by an experimental model that was developed for real-time radiation exposure dose visualization [62]. Patients and health professionals regularly exposed to radiation could benefit from such a model by creating awareness and ultimately avoiding unnecessary radiation, although validation in a relevant environment is still needed. Furthermore, by decreasing the need for contrast fluids, patients with reduced renal function could benefit as well. Data sharing options could result in better cooperation between team members and improve telementoring and remote counseling by facilitating transfer of knowledge between experienced physicians and resident doctors, thereby improving skill and merit in the inexperienced colleague. Besides, MR seems to possess added value for medical education, skill training, and patient counseling, as suggested by multiple reports that support improved efficiency and engagement as well as increased surgical confidence and skill level when MR-based technologies are used. Ultimately, this could result in more skilled surgeons in the operating room, decreasing the complication risk associated with human inexperience.

Although the overall experience with MR is rated positively in most studies, drawbacks of this technology seem primarily related to HMD and include ergonomic and visual concerns through the added strain of an HMD on head and neck musculature as well as visual fatigue. The experienced field of view might be limited, and occurrence of the parallax effect has been described, which refers to the phenomenon when content in the background moves at a different speed compared to content that is positioned on the foreground [45]. For certain areas that involve dynamic organs, the static nature of holograms based on preoperatively acquired imaging is perceived as an important hurdle for satisfactory and accurate intraoperative guidance, as well as problems related to soft-tissue deformity and disturbed depth perception. These problems hinder the application of MR during intra-abdominal and cardiovascular procedures and warrant the development and integration of prediction models for soft-tissue deformation and dynamic movement of organs into the displayed holograms. In that regard, the development of technology that allows the integration of simulated lung deflation into holograms for pulmonary surgery seems promising [51]. Other reported minor disadvantages are related to battery life, delayed image tracking with swift head movements, and the need for additional training to tolerate eye strain and visual discomfort caused by the hologram. However, these disadvantages do not seem to impact the generally reported positive experience of MR technology, and we expect most of these problems to be solved with ongoing technological development or integration within other emerging technological supportive tools for surgery, such as the surgical robot and surgical microscopes, which seem less susceptible to most reported HMD-related drawbacks of current MR technology. In this regard, it seems of utmost importance that we do not blind ourselves for the potential applications of MR beyond HMD to further accelerate the advancement of this technology.

Since the introduction of HMD for MR, they have evolved from heavy, obstructive, and wired devices to become lighter, see-through, and wireless. Especially the emergence of the Hololens (Microsoft) has offered a more immersive experience compared to previous generations of HMD and has accelerated both innovation and interest in the usefulness of this technology. As a result, almost all studies use Hololens as the designated HMD, whereas the use of other commercially available HMD within health care is limited. Given the value of competition for technological advancement, a more heterogeneous field of HMD suppliers besides Microsoft would be desirable to improve and accelerate development of this technology. Future developments should include the integration of MR within images acquired through surgical microscopes, in robotic surgery, and in the construction of holograms based on real-time data with prediction models that reflect the dynamic nature of organs as opposed to holograms based on preoperatively acquired static imaging. This seems a prerequisite next step for the maturation and adoption of MR technology in current clinical practice and can be designated as the next frontier to overcome for this technology. Besides, focus should be aimed at designing clinical studies to validate the superiority of MR-guided procedures compared to conventional ones. This warrants specific outcome parameters that assess outcome on both the surgical (for example NASA task load index) and patient side (composite end points), which obviate the need for an extensive sample size to prove superiority and make clinical trials more executable.

Limitations to this narrative review are related to the qualitative nature of the paper, which limits its level of evidence. Therefore, the paper should primarily be viewed as a general summary of the topic and a document that could be used to guide future research. The results of our search might also be troubled by the lack of a clear and universally applied definition of MR. As we have noticed, the terms augmented reality and MR seem to be used interchangeably in the literature. We hypothesize that this finding is primarily related to the novelty of the technique, and we expect that, as development progresses, they will become more established in clinical practice.

In conclusion, the implementation of MR seems to possess certain benefits, primarily related to efficiency and accuracy by facilitating preoperative planning and intraoperative guidance, especially in complex, low-volume cases that involve complex anatomy. However, this does not preclude its use in more common, less complex procedures. Besides, it may also benefit surgical training and education of younger residents and peers. Areas of improvement seem to be primarily related to issues involving the use of HMD, which warrant attention to applications beyond HMD in future developments.

Acknowledgments

MTV and MW were responsible for the search, screening, and writing of the manuscript. TPCVD, JPR, and NPVdK provided advice and reviewed the manuscript. LMDH contributed to the search and reviewed the manuscript. All authors approved the final version before submission.

We would like to thank Floor Patist for her contribution to Figure 1.

Conflicts of Interest

TPCVD is the founder and current Chief Medical Officer of Augmedit B.V., Naarden, The Netherlands.

Abstract

Background: User involvement is widely accepted as key for designing effective applied games for health. This especially holds true for children and young people as target audiences, whose abilities, needs, and preferences can diverge substantially from those of adult designers and players. Nevertheless, there is little shared knowledge about how concretely children and young people have been involved in the design of applied games, let alone consensus guidance on how to do so effectively.

Objective: The aim of this scoping review was to describe which user involvement methods have been used in the design of applied games with children and young people, how these methods were implemented, and in what roles children and young people were involved as well as what factors affected their involvement.

Methods: We conducted a systematic literature search and selection across the ACM Digital Library, IEEE Xplore, Scopus, and Web of Science databases using State of the Art through Systematic Review software for screening, selection, and data extraction. We then conducted a qualitative content analysis on the extracted data using NVivo.

Results: We retrieved 1085 records, of which 47 (4.33%) met the eligibility criteria. The chief involvement methods were participatory design (20/47, 43%) and co-design (16/47, 37%), spanning a wide range of 45 concrete activities with paper prototyping, group discussions, and playtesting being the most frequent. In only half of the studies (24/47, 51%), children and young people participated as true design partners. Our qualitative content analysis suggested 5 factors that affect their successful involvement: comprehension, cohesion, confidence, accessibility, and time constraints.

Conclusions: Co-design, participatory design, and similar high-level labels that are currently used in the field gloss over very uneven degrees of participation in design and a wide variety of implementations that greatly affect actual user involvement. This field would benefit from more careful consideration and documentation of the reason of user involvement. Future research should explore concrete activities and configurations that can address the common challenges of involving children and young people, such as comprehension, cohesion, confidence, and accessibility.

Introduction

Applied Games

Applied games, or serious games, describe (usually digital) games designed to drive desired cognitive, behavior, or other changes in players and the wider community [1-4]. In recent years, applied games have seen increasing interest in areas, such as *well-being* [5], *mental health* [6], *and education* [7,8].

Applied games markedly differ from entertainment games in that they need to fit the capacities, needs, preferences, and contexts of often highly idiosyncratic target end-user audiences; find game mechanics and content that are both appealing or "fun" to the target audience; and deliver the "active ingredients" producing the desired changes, be it learning content, persuasive messages, or medical treatment regimes [4,9]. This is particularly true for applied games targeting children and young people (CYP), whose general and gaming capacities, preferences, and contexts not only drastically differ from those of adult designers and players but also from each other, depending, for example, on their developmental stage [3,10].

As in general design and development, one major successful strategy for sensitizing applied game designers to the specifics of target end users is to directly involve end users (and other relevant stakeholders) in the design, implementation, and evaluation of the game in question [11-13]. Involving users in the design process has been shown to improve use and treatment engagement [13,14], usability [15], and system adoption and adherence across stakeholders [16-18]. On the side of developers, it promises improved understanding of user needs, reduced development costs and time, and improved design quality [19]. Consequently, there are growing calls for regularly using user involvement methods in the design of applied games for health [10,11,20].

User Involvement

However, "user involvement" describes a wide and messy field. Different research and practice communities have developed parallel traditions with confusing differences and overlaps in name, underlying values, and details of implementation, for example, human-centered design [15,21] in computing and human-computer interaction (HCI); participatory design [22,23], co-design [21], or coproduction [24] in design; patient and public involvement in health [25,26]; or action research, participatory research and science, or citizen science across the (social) sciences [15,25,27-29]. Despite regularly involving end users in the form of playtesting, applied game design still has no strong tradition of granting users more agency and input, particularly in the early stages of the design process [30,31]. In addition, recent analyses have shown that digital mental health intervention projects vary greatly in how they approach user involvement and often fail to document how user involvement methods are implemented in detail [10,20]. Bergin et al [16] observed in their recent review that few studies similarly reported any user experience of the involvement processes used—there is no even consensus on how the user experience of study participation should be captured. As a result, there is presently little empirical data on how differences in the detailed implementation of user involvement would affect end-user engagement and the overall efficacy of involvement. Consequently, we do not have evidence-based guidance on how to best involve end users and other stakeholders in the design of applied games [32], for example, for mental health [1,16,33] or education [8,34].

This lack of evidence and guidance is particularly pertinent for user involvement of CYP, and we neither know what roles, activities, or tools help engage and maintain their participation [17,29] nor what implementation factors would affect their involvement or actual adoption, adherence to, and efficacy of developed interventions (an exception was found in a study by Shah et al [35]).

Research Questions

Thus, before we can begin to articulate potential best practice guidelines for the implementation of user involvement in designing applied games with CYP, we need basic stocktaking of actual existing practice and evidence. To this end, this scoping review aimed to describe *how user involvement has been implemented in designing games for CYP and what factors (if any) likely affect effective CYP involvement*. We articulated this aim in 4 research questions (RQs):

- RQ1: What user involvement methods are used for what purpose?
- RQ2: In what roles are CYP being involved?
- RQ3: How are user involvement methods implemented in detail?
- RQ4: What factors affect effective CYP involvement?

Methods

Study Design

For our scoping review, we combined a systematic literature review [36] with inductive qualitative content analysis [37]. We report our method following the revised 2020 PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [36]. We did not preregister this scoping review because of the descriptive and exploratory nature. All study materials can be found in the Open Science Framework repository (Multimedia Appendix 1).

Eligibility Criteria

As noted, our review focuses on *user involvement methods* in the design of *applied games* with *CYP*. With "user involvement methods," we capture any approach that involves end users in the design of a game, such as participatory design, co-design, play-centric design, or user-centered design. With "applied games," we mean any attempt to create or use game-based software for a nonentertainment change. "CYP" was interpreted verbatim from the records that captured a variety of age ranges, for example, 2 to 4 years or 16 to 25 years.

Unfortunately, there are no well-established standard terms or controlled vocabularies for our search focus; for example, applied games are commonly called "serious game," "game-based," "game for X," or "gamified X." Following similar reviews [10,11,38], we developed a core search string that combined a range of synonymous keywords for each aspect, such as *CYP*, *games*, *applied contexts*, and *user involvement methods* (Textbox 1).

We analyzed papers published in the last 10 years (January 1, 2010, to December 7, 2021), and as the field of applied games is quite new, we did not expect a great number of texts before this date. We implicitly focused on selecting papers that had a specified “applied context” (Textbox 1) in which, for example, games were developed with young people for “mental health” or “education.” Furthermore, we focused on the last 10 years of records owing to the development and changes in technologies and methodologies. Capturing recent (within 10 years) studies provides an up-to-date overview of the state of the literature.

We included full length papers that reported on the design of game-based software targeting CYP and explicitly featured and reflected on user involvement methods. As we are interested in understanding the factors affecting user involvement, we excluded papers that did not reflect or evaluate the user involvement methods they used. We did not exclude papers based on application contexts—we wanted to avoid unnecessary focus on a specific domain, such as health-related literature, because insights may already have been made in educational gaming or entertainment game design but ignored by us because of a narrow focus on health-related literature. We excluded short or work-in-progress papers, because they did not provide enough space for detailed reflection and reporting on the methods used. We did not investigate gray literature because of the difficulty of creating a reliable and reproducible search strategy for such a dispersed and unstructured collection of materials with no core databases. See Textbox 2 for the full inclusion and exclusion criteria.

Textbox 1. Full list of used synonymous key terms for constructing search strings, in which a search string combines all terms, that is, children and young people (CYP) synonyms AND games synonyms AND applied context synonyms AND user involvement method.

CYP

- Young people
- Young adults
- Students
- Kid
- Child
- Adolescent

Games

- Game
- Video game
- Computer game
- Gamified
- Game based

Applied contexts

- Mental health
- Mental disorders
- Anxiety or depression
- Therapy
- Cognitive behavioural therapy
- Human computer interaction (HCI)
- Education
- Learning
- Behaviour change

User involvement method

- Co-creation
- Co-design
- Co-production
- Participatory design
- Patient centred design
- Patient partner involvement
- User-centred design
- Person-centred
- Collaborative
- Iterative design
- Cooperative

Textbox 2. Inclusion and exclusion criteria.

Inclusion criteria

- Article features user involvement methods
- Article reports on the design of game-based software
- Game-based software targets audience of children or young people
- User involvement methods are evaluated or reflected on
- Full paper

Exclusion criteria

- No user involvement method
- No reflection or evaluation of user involvement method
- Not related to game-based software
- Not published in English
- Not a full or original paper (eg, work in progress, conference summary, or workshop)
- No children and young people involved
- Not retrievable

Information Sources and Search Strategy

We searched 4 databases: the ACM Digital Library, IEEE Xplore, Scopus, and Web of Science. These databases mirror the interdisciplinary structure of research on applied games: the Association for Computing Machinery Digital Library and IEEE Xplore, which cover computing and HCI conferences and journals in which the bulk of technical games research is published, while Web of Science and Scopus capture disciplines such as medical research, psychology, and education.

Before starting our search, we iterated on variations of search strings implementing our target keywords (Textbox 1) for each database, because each database afforded different search strings tools. The final search strings are presented in Multimedia Appendix 2. We conducted the first full search on May 7, 2021, and the last search on July 5, 2021.

The studies retrieved from the databases were managed using State of the Art through Systematic Review (StART; version 3.3, Beta 03; Laboratório de Pesquisa em Engenharia de Software). StART identified additional studies through snowballing, which were added to the selection for screening. In addition, 14 studies were manually added.

Selection Process

We first removed duplicate records using StART, which identified duplicates across databases. Additional duplicates were then manually removed from the selection. The first author then manually screened titles, keywords, and abstracts against the eligibility criteria; sourced full texts of the eligible studies; and then manually assessed full texts for eligibility. Finally, records that were reported in the same study were merged.

Data Items and Collection Process

All relevant information was extracted in StART, which was then exported (xlsx format) into the qualitative data analysis software NVivo (version 12; QSR International) for open coding across the extracted information. For each eligible study, the first author extracted standard metadata (title, authors, abstract, and year) in addition to a range of descriptive data.

To describe our sample and study characteristics, the first author coded papers by the following parameters:

1. Discipline: disciplines were coded first verbatim by the title and self-description of the publication venue and then inductively aggregated; for example, a paper published in ACM HCI was coded as “human-computer interaction,” as it describes itself as “The ACM CHI Conference on Human Factors in Computing Systems is the premier international conference of Human-Computer Interaction (HCI).”
2. Date of publication: extracted from paper metadata
3. The country where the study was conducted: extracted verbatim from the Methods section
4. The number of CYP involved: extracted from the Methods section of the paper
5. The age and age range of CYP involved: extracted from the Methods section of the paper
6. The kind and number of participant groups involved: participant groups (eg, children, parents, and clinicians) were first extracted verbatim from the method sections, and then the number of different groups was counted.

To describe user involvement methods and roles, the first author coded papers for the following factors:

1. The self-labeled user involvement methods used: extracted verbatim from how the authors labeled their study in the title or Methods section; this resulted in multiple labels for some studies in which terms were used interchangeably.
2. The authors’ stated aims of user involvement: first extracted verbatim from the “goal” or “aim” statements of each paper, then inductively coded into higher-level categories, such as “determine features and functionality” or “explore methodology”; 1 paper could entail multiple aims.

3. In what capacity were CYP involved: first extracted as verbatim labels given to their roles in the paper (Multimedia Appendix 2); where roles were not explicitly labeled in the paper, we noted them as "not stated." On the basis of the full paper description of children's involvement, we inductively mapped each study on the Druin [39] 4-fold typology of children's roles in the development of new technologies.

Finally, to describe *how user involvement was implemented and how to identify emerging factors affecting it*, we imported the extracted data fields and full-text PDF documents into NVivo for inductive qualitative content analysis [37]**.** The first author inductively coded the method, discussion, and conclusion sections of papers for related emerging themes in the first and second focused coding cycle [40]. Descriptively, (10) *study structure*, (11) *activities*, and (12) *media and tools* have emerged as high-level categories. Of these, the activities were clear and distinct enough that we could conduct a follow-up frequency count. In terms of (13) *factors affecting user involvement*, 4 themes emerged.

Bias and Certainty Assessment

Because the aim of our study was narrative description, not establishing summary effects, no bias or certainty assessments were performed.

Synthesis of Results

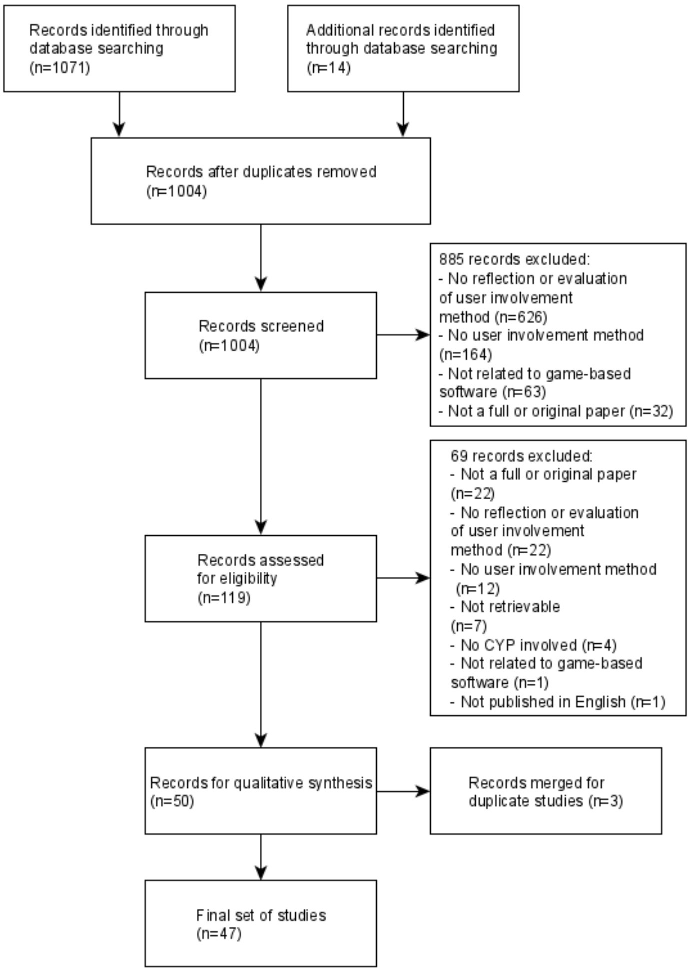
For descriptive summary reporting, we calculated the frequencies for (1), (2), (4), (5), (6), (7), and (11). Emerging themes and observations were synthesized through standard inductive qualitative content analysis.

Results

Study Selection

Our search returned 1085 records. Title and abstract screening removed 81 duplicate records and further excluded 885 records, of which 164 (18.5%) did not clearly incorporate user involvement methods, 626 (70.7%) lacked explicit reflection of user involvement methods, 63 (7.1%) were not related to game-based software, and 32 (3.6%) were not full papers. At the full-text stage, of the remaining 13.4% (119/885) of records, we excluded a further 69 (58%), of which 22 (32%) were not full papers, 12 (17%) lacked user involvement methods, 22 (32%) lacked a detailed reflection of them, 4 (6%) had no CYP involvement, and 1 (1%) was not related to games; we could not obtain access for 7 (10%) records, and 1 (1%) was not published in English. Of the 50 remaining papers, we merged 3 (6%) paper pairs that reported the same study, resulting in 47 final studies in the analysis. Figure 1 presents the PRISMA flow diagram.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. CYP: children and young people.



Study Characteristics

Table 1 presents the characteristics of the included studies; 47% (22/47) of the studies were from computer science and HCI, 19% (9/47) were from education, 17% (8/47) were from serious games or games design, 11% (5/47) were from health, and 6% (3/47) were from psychology. There was no clear upward or downward trend in the publications over time. In total, 85% (40/47) of studies were conducted in the Global North, led by European countries (15/47, 32%), then the United Kingdom (13/47, 28%), Australia and New Zealand (7/47, 15 %) and the United States (4/47, 9%), followed by Brazil (3/47, 6%) in the Global South.

The sample size of CYP involved ranged from 2 to 109, with an average of 23 (SD 24.8) and a median of 13. Table 2 shows the frequency of sample sizes with 26% (12/47) studies involving 6 to 10 participants, 23% (11/47) involving 11 to 25 participants, 19% (9/47) involving 26 to 50 participants, 17% (8/47) involving 1 to 5 participants, and 15% (7/47) involving >51 participants. This is likely because (1) most studies focused on interventions for intersectional groups, such as children with learning difficulties, in which sampling can be challenging; and (2) user involvement methods often value “thick data” with small-sample qualitative methods and a struggle to scale to large participant numbers. Nevertheless, many studies have reported “small sample sizes” as a limitation.

Table 1. Characteristics of studies.

Study	What method or methods were labeled or framed?	Participant groups, n	Groups involved	Discipline	How long was the study?	Median age (years)	Young people, n

[a]CYP: children and young people.
[b]HCI: human-computer interaction.
[c]N/A: not available.

Table 2. Sample size variance (n=47).

Sample size groups	Frequency, n (%)
1-5	8 (17)
6-10	12 (26)
11-25	11 (23)
26-50	9 (19)
>51	7 (15)

The youngest age sampled across all studies was 3 years, and the oldest was 25 years as a part of a "young people" sample spanning ages 16 to 25 years [52]. The median age sampled was 11.5 years. Most studies (30/47, 64%) sampled an age range from 0 to 3 years (where 0 would be a precise age in years and 3 would be an age range of, eg, 6 to 9 years; Table 3).

Although our review focused on studies involving children, we were also interested in the participant groups that were involved. The plurality of studies (23/47, 49%) involved 3 different participant groups. The predominant groups were CYP (n=47, 100%) owing to inclusion criteria specifying CYP involvement. Studies also label CYP as patients, learners, or target audiences.

Subject-matter experts (39/47, 83%), such as health professionals (11/47, 23%), teachers (18/47, 38%), and other experts (10/47, 21%), were cumulatively the second-most frequent participating group (Table 4). Other experts encompassed were from areas such as film, photography, art, and music. The researchers conducting or facilitating the study were the next most frequently involved group (36/47, 77%) in the design process. Researchers included those carrying out the study and references to scientists who were also involved in the study. Some studies also used designers and developers (17/47, 36%), which included game design companies, masters' students in HCI, game designers, graphic designers, and artists, to help with the development of games or interactive technologies. Support groups (5/47, 11%) included learning assistants, pastoral care coordinators, and special education coordinators who helped support CYP participation.

Study length varied greatly, and in 17% (8/47) of studies, the study length could not be determined from the sampled records. The most frequent duration was 2-3 months (10/47, 21%), followed by studies conducted in ≤1 day (8/47, 17%). Studies conducted in ≤1 day were often short workshops or sessions of 1- to 2-hour activities. Studies conducted over 1 to 7 days (5/47, 11%) were the next most frequent. This was followed by studies that took either 4-6 months (4/47, 9%) or 10-12 months (4/47, 9%). Studies conducted between 2 and 4 weeks (3/47, 6%) and 10-12 months (4/47, 6%) were less frequent, and the lowest frequency was 7 to 9 months (2/47, 4%). A consideration to take into account is that it is not clear whether some studies are reporting the length of the whole study, including recruitment, procedure, and analysis, or whether they are reporting the duration of participants involvement in the study.

Table 3. Age variance (n=47).

Age range variance (years)	Frequency of studies, n (%)
0	7 (14)
1	5 (11)
2	10 (21)
3	8 (17)
4	6 (13)
5	2 (4)
6	3 (6)
7	3 (6)
8	0 (0)
9	3 (6)

Table 4. Stakeholder groups involved (n=47).

Stakeholder group	Frequency in studies, n (%)
Children and young people	47 (100)
Researchers	36 (77)
Teachers	18 (38)
Designers and developers	17 (36)
Health professionals	11 (23)
Other experts	10 (21)
Carers and family members	9 (19)
Support groups	5 (11)

User Involvement Methods Used

Self-labeled User Involvement Method

The overwhelming majority of studies self-labeled their user involvement method as "participatory design" (20/47, 43%) or "co-design" (16/47, 34%; Table 5). However, different studies have used and understood these terms differently with no stable consensus. Some considered participatory design as the overall research area and co-design as the method [56,60,77,82]. Others positioned the 2 as separate methods [62,66], while others used terms interchangeably [75,85]. The most common definition of "participatory design" was to "involve end users in the design process" [45,48,68,72,86], which some interpreted strongly because end users fully and equally participated throughout the whole design and development process [68,70], while others read it weakly as "invit[ing] users to contribute ideas" [71]. There was further less consensus and clarity regarding the meaning and use of "co-design."

Table 5. Frequency of self-labeled user involvement methods (n=47).

User involvement method labeled	Frequency in studies, n (%)
Participatory design	20 (43)
Co-design	16 (34)
Cocreation or cocreativity	3 (6)
Design-based research	2 (4)
User-centered design	2 (4)
Realist evaluation	1 (2)
Iterative design	1 (2)
Participatory action research	1 (2)
Person-centered approach	1 (2)

Stated Goals of User Involvement

Several studies have expressed >1 goal of involving users (Table 6). The most frequently stated aim was to design a game, either a prototype or a finished system (22/47, 47% of studies); 38% (18/47) of studies aimed to gather feedback on features and functionality; 26% (12/47) of studies were "meta"-studies aimed at examining involvement, that is, understanding the impact and form of CYP involvement overall; and a further 21% (10/47) of "meta"-studies explored a particular user involvement method or technique. For example, Benton and Johnson [48] explored the use of the participatory design approach to meet the needs of young people with autism spectrum disorder. A further 19% (9/47) of studies aimed to develop skills, meaning that the process served as a learning outcome, such as developing CYP design skills. Overall, 17% (8/47) of studies aimed to understand CYP needs and preferences around gaming, and a further 15% (7/47) of studies aimed to understand CYP's perception and concerns around the context or technology of the study. Overall, 6% (3/47) of studies focused on improving the user experience of existing products or prototypes, and finally, 4% (2/47) of studies explicitly aimed to create guidelines on how to conduct co-design with CYP (other studies did produce recommendations or guidelines but did not state this as the intended goal behind user involvement [47,62,64,73,82]).

In summary, the included studies stated a wide range of reasons for involving users, with the overwhelming majority focusing on directly informing design and development, from formative research on user needs, preferences, concerns, and contexts (15 studies) to feedback on features and functionality (18 studies), directly making a game (20 studies), or improving user experience (3 studies). Against this stand comparatively fewer "meta"-studies in user involvement and supporting methods themselves (22 studies) and the aim to skill up CYP (9 studies).

Table 6. Frequency of user involvement goals (n=47).

Goals of studies	Frequency, n (%)
Design a game with participants	22 (47)
Feedback on features and functionality	18 (38)
Examine involvement	12 (26)
Explore methodology	10 (21)
Develop skills	9 (19)
Understand children and young people needs and preferences	8 (17)
Understand perceptions and concerns	7 (15)
Improved user experience	3 (6)
Create guidelines	2 (4)

Involvement Roles of CYP

The dominant verbatim labels used for CYP involvement roles were "informant" (26/47, 62% of studies) and "co-designer" (20/47, 42%), followed by "playtester/tester" (4/47, 9%), "validation" (4/47, 9%), "co-creator" (4/47, 9%), "end user" (2/47, 4%), and "co-researcher" (1/47, 2%). Overall, 11% (5/47) of studies did not indicate a particular role of involvement (note that a single study could identify multiple roles for CYP; hence, percentage added up to >100%).

Similar to self-labeled methods, these role labels can cover a wide variety of actual degrees and types of involvement. In addition, we coded all studies using the Druin [39] influential taxonomy of 4 possible roles children can play in the design of new technology, in which each successive role can be seen to be more agentic than and encompass the previous ones: ([[[[user]tester]informant]design partner]). Each role also differs in the CYP-adult interaction (from indirect observational input to feedback, dialogue, and elaboration on adult ideas), forms of technology materializations engaged with (from ideas to prototypes to existing products), and goals of inquiry (from developing theory about use to assessing technology effects to improving design and usability):

1. *CYP as users* describes studies in which adults observe CYP using technology to assess technology effects and build use theory.
2. *CYP as testers* describes studies where CYP act as usability (or play-) testers, usually of prototypes, which can help assess effects, build theory, and improve designs; here, CYP can provide direct feedback on designs.
3. *CYP as informants* describes studies in which CYP can be involved in the full spectrum of human- or user-centered design methods, from formative research, such as interviews, contextual inquiries, and the like, to testing and validating prototypes at the evaluative end; here, CYP can engage in dialogue with adults and elaborate on their ideas and concepts.
4. *CYP as design partners* describes studies where CYP are equal stakeholders to adults; throughout the design process, they may engage in all the previously described activities, but in addition, CYP may engage in user research and design activities, such as data collection, brainstorming, or prototyping themselves, directly and jointly with adults.

We coded each included study according to these roles by examining how CYP had been involved in the procedure of the user involvement method and mapping this to the Druin [39] taxonomy (Table 7). According to this classification, in 51% (24/47) of the studies, CYP were involved as design partners; 70% (33/47) of studies involved CYP as informants; and testers and users were involved in 11% (5/47) of studies each. In 2 studies, CYP were only involved as users, and 1 study involved them only as testers. Finally, it is worth noting that 2 studies explicitly adopted Druin [39] taxonomy and ensured the involvement of CYP in each of the 4 roles [43,75].

Table 7. Role of children across studies.

Role	Total number of occurrences	Studies
User	5	[43,58,66,72,75]
Tester	5	[28,43,53,62,75]
Informant	33	[41-43,45,46,48-50,52,53,55-57,59,60,63,64,66-70,74-84]
Design partner	24	[22,43,44,46,47,49,51,54,55,59-63,65,68,69,71,73,75,79-81]

How User Involvement Is Implemented in Detail

Inductive coding of the studies' method descriptions yielded 3 high-level categories of how user involvement was implemented in detail: structure and sessions, activities, and media and tools. *Session structure* describes recurring stages and an overarching facilitation organization. *Activities* captures the specific tasks conducted with stakeholders, while *media and tools* describe the range of media and existing games used in activities.

Session Structure

In total, 8 studies involved an initial *onboarding or sensitizing stage* to create familiarity with the project topic and team, communicate its goal, and help in understanding the upcoming process [22,50,54,68,74,75,78,81]. This was suggested to build trust between participants, foster user engagement, and make an effective co-design process more likely [22,81]. In 2 studies, onboarding consisted of exploring an existing solution to familiarize oneself with the technology and underlying concepts of the research area [48,81]. In another study, the sensitization steps involved introducing users to the topic through challenges and competitions, which also helped build trust with facilitators [22].

Ten studies [41,42,44,47,48,59,63,64,82,85] described an *ideation or brainstorming stage* to help frame user needs and provide users with a starting place. Notably, brainstorming could be used to generate game ideas [42] or to understand existing user practices and areas of technology-based support [44]. This was often supported by starting exemplars and paper templates [41,47,59,63,64], such as empty scenario storyboards or empty mobile phone screens, or a homework task and prepared video-seeding material for ideas [50]. Two repeatedly mentioned challenges and considerations for this phase are the common "groupthink" converging of participant groups on a first or loudly voiced idea blocking further ideation [47,48] and CYP capabilities to actually conduct ideation [47]—although some noted that CYP tends to bring a beneficial high degree of gaming literacy [82].

In total, 17 studies [45,47,49,51,52,55,56,58,62,63,65,70,71,74,75,77,79] reported the *prototyping stage*. These prototyping stages included sessions in which CYP were involved in the design and development of game ideas [52,58,75], game characters or narrative [49,62,71], and generated alternative ideas to an existing idea [63,77]. Prototyping was seen to afford a sense of ownership in the resulting designs for CYP [62], often challenging researchers' assumptions on end users, and often leading to in-depth reflection from participants [55,70,71]. Reflection was 2-fold, in which studies designed sessions of reflection, and reflection surfaced unexpectedly. For example, 2 studies designed reflection meetings to iterate and improve future design sessions [45,74], whereas another study found that the design process led to participants reflecting on their game-play experiences compared with other participants [55]. One study deliberately scheduled reflection meetings after prototyping as the basis for future iterations [74]. Two challenges observed in this phase were the limitations of the prototyping tools used and what CYP wanted to portray, in which the limitations of paper prototyping were challenging for CYP to articulate the actions they expected from a digital prototype [51].

An *evaluation stage* was rarely mentioned across studies, where the design process was discussed with participants on its engagement, effectiveness, and efficacy as a user involvement method. Outside the reflection meetings, 4 studies scheduled an evaluation stage to gather feedback on the user involvement process [45,47,80,81]. These studies discussed how to make the interaction during the design process more engaging [45], how they found the process as a whole [80], how they could be more involved [47], and how they could cooperate with others [81]. Notably, only 7 studies evaluated the prototypes developed at the end of the study [43,45,47,52,53,80,81].

Activities

Our coding resulted in 45 different activities, of which 19 (42%) were only shown in a single study (omitted in Table 8). Paper prototyping was the most frequently conducted activity, mentioned in 20 studies with labels, such as "paper play activity" [44] or "sketchbook prototyping" [52]. We coded this separately from low-fidelity prototyping (used in a further 7 studies); even though the boundaries between the 2 are not clear-cut, some low-fidelity prototyping would involve paper storyboards and sketches. Regardless, both were reported as affording a positive experience to end users [58,68,80], for example, by giving every participant some hands-on experience [45]. Hands-on experience affected both agencies, in which hands-on experience was a method to assess games with users and understand outcomes [65,66], and learning, in which hands-on experience served as a method of learning technology or understanding the context [28,45,59]. The prepared templates were repeatedly mentioned to facilitate prototyping [63,86]. Paper prototyping was reported to be inclusive [45], low cost [51,65], and using only easily accessible materials [51]. Observed challenges in prototyping included struggling to represent the intended playful interaction with digital technology [51], and that was less suited to older teens because of the hypothetical or "blue-sky" situations when they are at a developmental point of building their own opinions distinct from others [49].

Mapping between activities and design stages was difficult because activities were used across different design stages and in cases that were not transparent when and why activities were used. For example, (focus) group discussions, the second-most prevalent activity (19 studies), were used as icebreakers [45,56], to generate ideas [46,50,63] and reflect on the end product [22,55,57,61]. In another instance, the fourth-most prevalent activity interviews (used in 17 studies) were used equally formatively to discover and define the problem space [41,59,82] and evaluate prototypes or concepts [24,52,53,81]. Presumably because our study sample overall leaned toward "earlier" sensitizing, ideation, and prototyping stages, most activities were used in these stages; only *feedback sessions*, some instances of *game-play evaluation*, and 1 *timeline activity* [68] (asking CYP players to chart their game-play likes and dislikes and experiences of challenge) occurred during an evaluation phase.

The included studies entailed little explicit reflection or evidence of the effectiveness of the conducted activities, with a few exceptions. For example, Nouwen et al [68] outlined which particular activities generated particular user insights and related design impacts. Pavarini et al [70] organized feedback sessions in which CYP could suggest features and processes for better future user involvement. However, even these observations remain unvalidated and can disagree with one another. Thus, although several studies recommended "free play" to provide CYP creative freedom of expression [55,68,86], Nouwen et al [68] found that this had little design impact because the media created during free play were unsuitable for the design brief. Further details of methods and activities can be found in Multimedia Appendix 3.

Table 8. Frequency of activities across studies that were used in more than one study (n=47).

Activities	Description	Frequency, n (%)
Existing games (demonstration or play)	Participants are given existing games, game prototypes, or materials to play or interact with	18 (38)
Group discussion or focus group discussion	Participants work together and talk about ideas, concepts, or solutions	19 (40)
Paper prototyping	Participants use mainly paper to design ideas and solutions	20 (43)
Interviews (with end users)	Researchers interview end users (CYP[a]) for their thoughts, preferences or feedback on a prototype, context, or problem area	17 (36)
Playtesting	Participants are given a prototype game and asked to play it (feedback is optional sometimes)	14 (30)
Storyboarding	Participants are given panels, comic strips, and slides and asked to generate how they would use the game, a scenario, or a solution	11 (23)
Surveys or Questionnaires	Both qualitative and quantitative surveys. Includes tools such as Likert scales and researchers directly asking CYP to give an answer on a scale	12 (26)
Brainstorming	Participants work together to generate ideas through group discussions, activities, or in some cases, individually	9 (19)
Role-play (or simulation)	Participants take on the role of others, for example, CYP acting as doctors, to bridge the challenges different stakeholders undergo	9 (19)
Feedback Session	Participants are shown a prototype and asked to give feedback	7 (15)
Introductory media (presentation, movie, etc)	A presentation, movie, talk, or activity is used to help onboard young people on what the goal of the workshop or activity is	6 (13)
Low-fidelity prototyping	Prototyping with models, figures, blocks, and early development digital games	6 (13)
Free play	Participants are given a game or demo and no goals are set; they can interact how they choose	5 (11)
Sticky notes	Tasks involving sticky notes or post its, usually a group-driven task	5 (11)
Scenario-based tasks	Participants are given a scenario in relation to the applied content with which to design a solution	4 (9)
Blank template task	Participants are given a template, for example, the wireframe of a phone screen, and use these to design solutions	3 (6)
Game idea or feature evaluation	Specifically when participants evaluate a component or proposed idea of a game	3 (6)
Logbooks (or taskbook or diaries)	Participants complete a workbook or taskbook after activities; also includes participants keeping a log of their behavior	3 (6)
Storytelling	Users create and share stories or concepts	3 (6)
Timeline (narrative design)	Creating a journey, or series, of steps in which a procedure, process, or story occurs over time or between different users	3 (6)
Game design workshops	Workshop that encompassed ideation and then evaluation and reflection of those ideas on how they can be improved	2 (4)
Icebreakers	Informal discussions and activities for participants to get to know each other	2 (4)
Map task	Using real world maps to choose a setting for their game idea and generate ideas [41,66]	2 (4)
Peer interviews	Interviews conducted by CYP to other CYP to gather data and help understand the context area	2 (4)
Question and answer	An activity were users presented predetermined answers (eg, cards) to questions proposed by researchers	2 (4)
Sensitization session	“Packages” or information circulated before user involvement sessions to understand CYP experience with context and games	2 (4)

[a]CYP: children and young people.

Media and Tools

Following the study by Brandt et al [87], participatory design tools and media can be classified into whether they support the practices of *making*, *telling*, and *enacting*. Bossavit and Parsons [50] observed that 2D mapping (making tool) and videos (telling tool) were useful for understanding concepts, while playing games (enacting) supported idea generation.

The choice of the media or tools used was a point of contention. Some suggested that CYP struggled to express themselves speaking while at the same time preferred speaking to writing [45,47]. In comparison, visual approaches and working with visual aids proved more engaging and effective, especially in younger age groups, potentially owing to their less-developed reading and writing abilities [49,50,62,66]. An exception to the method of media was seen in the studies by Metatla et al [67] and Regal et al [75] with visually impaired children, in which educational robot toys and physical building blocks were used to facilitate creativity through touch and sound. Overall, it seems that preferences for spoken, written, or visual media are related to the age of participants [45,49,62]. Therefore, this suggests that the choice of media and tools used should be determined by understanding participant preferences before the activities take place.

In total, 18 studies used existing games as activities. Existing games varied between existing prototypes developed before the study and existing commercial games [71,76,88]. Existing games were used not only as a tool for narrowing the scope of the research and "managing the expectations" of young participants but also as an icebreaker activity [76,88]. Existing prototypes were sometimes used as a starting point for prototyping or were introduced to users for feedback [45,47,76]. That said, several studies found that concepts and features proposed by CYP were usually informed by the commercial games they were familiar with [50,60,82,85].

Factors Affecting User Involvement

Overview

In this section, we report 5 prominent themes that studies have repeatedly covered as affecting user involvement: *comprehension*, *cohesion*, *confidence*, *accessibility*, and *time constraints*. We intentionally did not tie these themes to one particular conception or standard of "good" involvement. Rather, we took the study authors' own conceptions at face value: if a study articulated something as problematic or positive, we took it as such, also to reflect the variety of goals studies articulated for user involvement.

Comprehension

This theme captured that CYP *regularly struggled to understand the design process and context they participated in*. CYP repeatedly reported that they did not fully comprehend or remember the benefits or outcomes of the project and how it would impact their daily life [44] nor the aim or purpose of the task assigned to them [72,77,81]. A usability evaluation of one involvement method similarly revealed that tasks were either hard to identify and understand or hard to perform [77]. This problem could be even more common, as Waddington et al [83] observed that CYP did not mention when they struggled with an activity or prototype in their study, so long as they could engage with it; they therefore found it often necessary to gather additional external stakeholder feedback, because CYP did not complain. According to Porcino et al [72], some of these comprehension issues could arise from the lack of a clearly stated objective, insufficient time for a task or technology to become familiar with it, or facilitators not familiar with a given technology or method.

Relatedly, *how well-informed CYP were about a subject matter* impacted the efficacy and efficiency of user involvement: participants who were familiar with a given context proved to be more productive and gave much more concise feedback than unfamiliar ones [53]. Similarly, studies have found it difficult to define problems and identify designs in areas where participants were ill-informed about [54,81]. This should not be considered a one-way street. For example, Durl et al [22] found that involving vulnerable adolescents in a co-design study on alcohol abuse not only resulted in better design results but also made the adolescent participants more informed about alcohol abuse.

A final challenge to comprehension was *lacking familiarity with used technologies and methods*: this could be the use of basic technology like microphones [74] or the fact that participatory methods differ strongly from what CYP may be used to do in adult-guided activities in school. CYP expected asymmetry in power with adults dictating the direction of the study but experienced more symmetry in power and decision-making because of their suggestions being acknowledged [81]. This challenge could be addressed with additional introductory training and warm-up activities, which consume additional money and time [60].

Cohesion

Most studies involved ≥3 different groups of stakeholders. Therefore, it was unsurprising that many studies reflected on *different groups working together effectively as a united team* as a major factor of effective user involvement, which we here will call *cohesion*.

First, several studies reported *struggling to achieve agreement on a concept, solution, or decision*, likely because of the control each stakeholder group was given [42,74,76]. Control in terms of decision-making and contributing to the design process could be caused by expecting CYP to come to a natural agreement without clear constraints or guidance from adults. Two studies in particular presented open questions to young people and then presents "no right answer," which could be the cause of friction between young people [74,76]. Common approaches to this issue were discussion (for understanding different points of view) and voting mechanisms (for integrating disagreeing points of view into a decision) [76]. A connected challenge was ensuring that different end-user groups contributed more or less equally to decisions and end results [42,50,64,65]. Several authors observed that cohesion required *trust* between participants, although no particular approach has been suggested to build trust [42,76].

Another key factor for cohesion was a *cooperative and collaborative mindset and atmosphere*. Seven studies noted that these allowed CYP to express their views, support each other, and share ideas [22,28,42,55,59,80,81]. In contrast, a competitive dynamic was found to result in less-open idea sharing [76]. The study by Triantafyllakos et al [80] was one of the only studies to reference incentives, in which they used competition and challenges among participants to generate more ideas.

Breakdown in *communication* could lead to frustration and disappointment [76]. So, how can we afford to function in communication? One study found that a "natural" flow of communication among CYP in which each would have a chance to speak required dedicated facilitation [74], whereas another found that CYP compared with adults were much more direct and unfiltered in criticism, suggesting adult stakeholders should capitalize on this and not be guarded or protective of their ideas [47]. Using existing examples of games [45], as well as explicit tools and conceptual frameworks [55], was found to facilitate discussion.

Confidence and Empowerment

Confidence describes CYP's beliefs in their ability to effectively participate in user involvement, akin to the psychological construct of self-efficacy [89], and influences their participation in several ways [43,68].

CYP would participate more deeply if they felt more confident, which was largely seen as grounded in their past experience; for example, CYP's past experience with film production or game-making [81], using existing technology CYP are familiar with [44,85], immediate past experience of progress in particular workshop activities [68], or simply longer participation over time [47] would all increase CYP confidence, with positive effects.

However, studies differed in their view of whether CYP are generally confident to voice their opinions [43,83]. Two studies found that CYP had no apparent issue voicing their views directly [47,53], whereas others suggested to use behaviorally "honest signals," such as eye tracking, because CYP aged 5 to 12 years may say what adults like to hear [43,76] or observed parental interference as an obstacle to CYP sharing unfiltered feedback around sensitive topics like sexual health [62]. Flexibly adjusting group sizes and session lengths to fit CYP needs was found to make them more comfortable overall and share their views more openly [86].

Empowerment was also discussed in studies where young people were given control to make decisions or choices, facilitated by participating in activities, ownership of end products, and the innate challenge of designing a game, all contributed to a sense of empowerment [45,61,81]. While giving CYP power to make decisions over the end product increased a sense of empowerment [77,86], multiple and repetitive user involvement activities were reported to diminish it over time [64]. In addition, there were concerns about the misuse of empowerment as a method of manipulating participants to support the findings desired and empowerment tokenism, where the control over things lacks importance and others make important decisions [61]. Treating CYP as true design partners in game design was found to make it easier for adult participants to connect with CYP's concerns and, in turn, foster creativity [28].

Accessibility

Accessibility describes whether the CYP felt the involvement process was accessible to them and included them in the design. Accessibility was mentioned as a concern, especially in studies that targeted an end-user CYP population with specific needs that forced shaping user involvement around them [64,74,79,83]. Tailoring involvement tools for CYP's varying abilities [50] and engaging experts associated with CYP's disabilities (such as carers or teachers) [67] were 2 proposed strategies for improving accessibility. One game-specific accessibility issue mentioned was the development of game mechanics that would be accessible to all players, including those with disabilities, but remains challenging for all end-user groups [74,83].

Time Constraints

Time constraints have emerged as a major consideration in structuring user involvement. Co-designing games is time-consuming [65], to the point where de Jans et al [54] suggested that the months required for adults and CYP learning how to collaborate does not fit industry game development timelines. Several studies found that practical time constraints resulted in insufficient discussion of all ideas [74], insufficient preparation, and insufficient time for producing deliverables [76]. Three studies reported breaking the design process into separate phases across different days or sessions to maintain interest, attention, and energy as another important time-related constraint 51,75,76

Discussion

Principal Findings

Out of a total of 47 studies, 36 (77%) of our sample were self-labeled participatory design or co-design (Table 5). In line with previous reviews in related fields, such as co-design in health [90] or CYP involvement in child-computer interaction [91], these 2 broad labels gloss over a wide variety of actual involvement roles, aims, and activities. Most studies sampled (35/47, 74%) involved CYP as "mere" informants and about half (24/47, 51%) as true design partners (Table 7). These numbers appear to indicate deeper user involvement for CYP than in recent systematic review of general serious game development processes by Maheu-Cadotte et al [92] (who found only 1 in 21 processes involved participants as co-designers). However, because their inclusion criteria did not limit eligible studies to those with explicit user involvement, this is an unequal comparison.

The stated aims for user involvement ranged from instrumental ones of making a game or identifying features and functionality to meta-methodological interests, upskilling, and many others. We counted 45 different activities, with prototyping, interviewing, playtesting, and playing existing games being the most common. Studies commonly reported "early" onboarding, ideation, and prototyping phases; we found little mention of "later" development or production stages [64,78,82]. Furthermore, no records linked or referenced openly shared user-created design materials outside of screenshots and workshop photographs. Studies used a wide variety of tools and media, with some consensus that these should be tailored to the (developmental) preferences and abilities of the involved CYP. The reviewed studies did not discuss users' accreditation or rewards for their contributions, outside of 1 example, which suggests uncertainty on how to motivate or reward CYP for their participation.

Our qualitative coding of method reflection produced five factors that are likely to affect successful CYP involvement:

1. Comprehension: the better the CYP know and understand the context and subject matter and design process and used methods, tools, and technologies, the better their engagement and results seem to be.
2. Cohesion: engaging and effective CYP involvement depends on different stakeholder groups working collaboratively as one team, with reaching an agreement as a common challenge and facilitating a comparative noncompetitive mindset as an important success factor.
3. Confidence: the more confident the CYP were in their ability to participate, license to participate, and agency granted to them, the deeper they seemed to engage.
4. Accessibility: both age and disabilities or special needs put extra demand on making user involvement accessible to all participating CYP.
5. Time and space: affording creative time and space can help further the discussion of ideas and maintain interest throughout participation.

Reflection

Perhaps the strongest overarching observation when conducting this systematic review was how differently studies understood and used relevant terms such as "co-design" (2 studies could label their activity "co-design" and "focus group" yet do drastically different things); how differently and unevenly studies reported methods; how differently studies implemented these methods; and in how little detail studies actually documented their involvement methods, despite the fact that our review systematically sampled studies that explicitly reported and reflected on their user involvement. For instance, although we tried to map activities onto "where" in a standard design process, following the example in Vandekerckhove et al [20], we were not able to do so because of the low to absent detail of reporting. This is sadly in line with prior findings on co-design methods: studies rarely report sufficient detail to reproduce them, and there is no standard reporting format [90]. This lack of consensus terminology and reproducible method documentation standards hinders replication. This makes systematic assessment and integration of evidence difficult. In addition, it impedes actual know-how flows beyond tacit and in-person sharing between the members of a research group and project.

Unless we have clear, reliable, and reproducible standards for identifying and reporting types or degrees of user roles and identifying and reporting involvement methods, it is difficult to generate a meaningful systematic body of evidence on which roles or methods work better or worse for which groups of participants, contexts, or aims. This may be one reason why only 4 of the sampled studies reported any qualitative empirical evaluation of what worked and what did not with their involvement methods, even though 46% (22/47) of studies stated meta-methodological aims, such as assessing end-user involvement or involvement methods. Consequently, most reflections and derived recommendations on how to conduct user involvement remain speculative. Thus, we cannot conclude with much certainty anything about, for example, which user roles might work "better." Although there is a normative preference for the "deepest" possible involvement in much of participatory design, several studies in our review suggested that CYP struggled to act as meaningful co-designers in applied game design [76] and were more able to express themselves as play testers than when sketching their own concepts [63]. This may be partially because of the fact that applied game design requires both domain and game design expertise, which CYP likely does not bring, which may be bridged by more careful onboarding activities or involving multiple stakeholder groups with complementary expertise [60]. Although the involvement of young people has been reported to be essential to realize game prototypes, whether CYP has expertise, or even the availability to consistently collaborate, is a challenge for future research [93]. The important point here remains that we are at present not able to answer such questions or advise on "what works best" because of poor reporting.

Limitations

Our sample is obviously limited by its English-only focus and 10-year date range. The literature before 2010 would potentially paint a distinctively different picture, which would lead to divergent conclusions in this review. Study selection and coding were all performed by the primary author alone, meaning that we could not quantify the likely reliability and reproducibility of these steps, for example, intercoder reliability. The overall poor quality of method reporting in the sampled studies and the lack of existing controlled vocabularies or taxonomies of involvement methods means that our coding involved substantial degrees of judgment and construction in categorizing different kinds of involvement activities or classifying studies by user role. This does not impact verbatim extractions of self-labeling or similar, and we believe our overall assessment of the sheer diversity of reported practices is not touched by this.

Future Research

The first obvious direction for future work is to provide a robust shared basis for reporting and assessing user involvement in applied game development (with or without CYP); we need better consensus methods for defining, labeling, and identifying user involvement roles and methods and better guidance and standards on reporting user involvement in sufficient detail for later analysis or replication. Second, on this basis, we can start to analyze and empirically evaluate what kinds of session structures, methods, roles, media, and tools are more engaging in CYP and more effective for different involvement aims. Third, our review suggests that comprehension, cohesion, confidence, accessibility, and time constraints are likely to impact CYP involvement. Here, methodological research can explore whether and how much these factors matter, and then again, which structures, methods, roles, media and tools, and specific implementations thereof are better suited to support them.

Conclusions

This scoping review aimed to explore how CYP have been involved in the design of applied games. We found that a small range of labels (co-design and participatory design) hid a wide variety of actual involvement methods, aims, structures, roles, and implementations. Comprehension, confidence, cohesion, accessibility, and time constraints emerged as 5 likely nonexhaustive factors affecting effective and engaging CYP involvement. However, the reviewed literature documented its user involvement practices inconsistently and in little detail, and its recommendations for future practices are largely not grounded in robust empirical evaluations of (alternative) involvement approaches. Future work is needed to advance more robust and reproducible documentation of user involvement to enable knowledge sharing, as well as more systematic research on "what works" in user involvement of CYP in applied game design.

Abstract

Background: Games and game components have become a major trend in the realm of digital health research and practice as they are assumed to foster behavior change and thereby improve patient-reported and clinical outcomes for patients with type 2 diabetes.

Objective: The aim of this systematic review was to summarize and evaluate the current evidence on the effectiveness of digital health interventions containing game components on behavioral, patient-reported, and clinical outcomes for patients with type 2 diabetes.

Methods: An electronic search was conducted in MEDLINE and PsycINFO in April 2020; updated in April 2022; and supplemented by additional searches via Google Scholar, Web of Science (which was used for forward citation tracking), and within the references of the included records. Articles were identified using predefined inclusion and exclusion criteria. In total, 2 reviewers independently conducted title, abstract, and full-text screening and then individually performed a critical appraisal of all the included studies using the Cochrane risk-of-bias tool version 2. A consensus was reached through discussion.

Results: Of 2325 potentially relevant titles (duplicates excluded), 10 (0.43%) randomized controlled trials were included in this review. Quality assessment revealed a high risk of bias for all randomized controlled trials except for 10% (1/10), with performance bias due to the lack of blinding being the major source of bias. There is evidence suggesting that digital health interventions containing game components can substantially improve motivation for physical activity (1/1, 100% of the studies dealing with PA motivation), exercise intensity (3/5, 60%), dietary behavior (4/4, 100%), health literacy (1/3, 33%), mental quality of life (2/2, 100%), glycated hemoglobin level (2/6, 33%), BMI (1/3, 33%), fasting plasma glucose level (1/2, 50%), waist circumference (1/1, 100%), and aerobic capacity (1/1, 100%).

Conclusions: Published studies indicated that digital health interventions containing game components might improve health behavior patterns, quality of life, and clinical outcomes in patients with type 2 diabetes. However, the intervention types and outcomes studied were heterogeneous, and study quality was mostly low, which translates to ambiguous results. Future research should focus on sound methodology and reporting as well as on identifying game components that contribute to significant positive effects.

Introduction

Background

According to the 2021 and most recent Diabetes Atlas provided by the International Diabetes Federation, diabetes affects 537 million people worldwide, which equals a share of almost 7% of the world's total population [1]. Compared with the data provided in the 2019 Atlas, this is an increase in diabetes prevalence of almost 16% within 2 years [1]. The vast majority of people diagnosed with diabetes (95%) live with type 2 diabetes [2,3].

Apart from genetic predispositions and a higher probability of having a diabetes diagnosis at an older age, several risk factors of type 2 diabetes are lifestyle-related, such as physical inactivity; malnutrition; and, correspondingly, overweight and obesity [4]. Therefore, several clinical practice guidelines on the treatment of type 2 diabetes focus not only on pharmacological interventions but also on a comprehensive self-management regimen that includes theory-based behavior change [4-7]. Measures for the latter warranted by the so-called Diabetes Self-Management and Education (DSME) regimen defined by the American Diabetes Association (ADA) include education on symptoms, etiology of and coping with diabetes, the adoption of a healthy (ie, high fiber- and fruit- and vegetable-based) diet, and the uptake of regular physical activity (PA) as a means to achieve weight loss [4,6]. Apart from the education component, continuous monitoring of blood glucose values, food intake, and frequency and intensity of PA is a requirement of DSME [6].

The potential of digital health applications, such as telemedicine, for supporting patients regarding DSME is well documented for patients with a more recent diabetes diagnosis, especially for applications that enable continuous glucose self-monitoring or health care provider feedback on the values recorded [8].

Recently, interest has spiked in digital health applications containing game components as they are expected to offer aid in behavior change [9], which, for many patients, is a necessary precondition for successful DSME [10]. Game components such as scoring systems, trophies, and leaderboards have been shown to be effective in increasing the motivation for uptake of healthy behaviors in a number of chronic conditions [11] as well as a measure of health promotion. However, the methodological quality of the evidence is still moderate to low [12]. Educational games often rely on storytelling elements such as coherent narratives and episodes, which generate a so-called transportation effect where players immerse themselves completely in the narrative world, which loosens reluctance toward behaviors perceived as laborious or unpleasant, such as PA [13,14]. Exergames stimulate PA by challenging the players' abilities and rewarding success [15].

A moderating role of the regulatory mode can be assumed in the relationship between gaming and behavior change. According to theory, either individuals can assess the situation they are in and then develop the most adequate strategy to reach a behavioral aim (assessment) or they can just initiate the behavior for which they strive (locomotion). Locomotion is associated with higher intrinsic motivation, whereas assessment is associated with anticipating failure and, therefore, procrastination [16].

In 2016, a meta-analysis including both types of game-based interventions (educational games and exergames) for patients with diabetes (type 1 and 2) showed no effect on blood glucose values (glycated hemoglobin [HbA_{1c}]) but showed an effect on quality of life, balance, and muscle strength [17]. Theng et al [18] found that videogames were useful tools for diabetes education independent of diabetes type. However, the analyses are outdated (both searches were conducted in 2014) given the substantial increase in the availability of gamified health interventions, as evidenced by a recent overview of gamified interventions used in the context of diabetes [19], half of which were launched after 2016. The median survival time of reviews is 5.5 years before they are outdated [20]. In addition, patient populations and the measures taken to deal with type 1 and type 2 diabetes differ greatly [7], and so do the effective components of digital health applications [8]. Therefore, targeted game-based interventions are necessary as well. Furthermore, given the complex requirements of DSME, focusing the analysis solely on clinical outcomes and neglecting behavioral outcomes as well as patient-reported outcomes (PROs), as did Martos-Cabrera et al [21] and Kaihara et al [22], is limited in perspective.

Objectives

Therefore, the questions to be answered were as follows: (1) *Do digital game-based interventions have an effect on the health behavior of patients with type 2 diabetes?* and (2) *Do digital game-based interventions have an effect on clinical outcomes and PROs in patients with type 2 diabetes?*

Methods

The protocol for this systematic review was published beforehand in PROSPERO (CRD42020209706) and followed during the conduct of the review. Reporting of the results adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [23].

Study Inclusion and Exclusion

The inclusion and exclusion criteria were defined according to the population, intervention, control, outcome, and study design scheme (Textboxes 1 and 2). For this purpose, digital health interventions containing game components were defined as the intervention group, whereas usual care or the use of digital health interventions without a game component were defined as the control group.

Textbox 1. Study inclusion criteria.

Population

- Participants with type 2 diabetes (no age restriction)

Intervention

- Use of digital health applications containing game components identified in previous reviews [12,17] (such as virtual reality, serious gaming, or exergaming)

Comparison

- Use of digital health applications without game components or standard or usual care

Outcome

- Primary outcomes:
  - Behavioral outcomes such as physical activity or dietary behavior
- Secondary outcomes:
  - Patient-reported outcomes such as self-efficacy, patient empowerment, and quality of life
  - Clinical parameters such as glycated hemoglobin (blood sugar value), BMI, and systolic blood pressure or diastolic blood pressure

Study design

- Randomized controlled trials
- Nonrandomized studies (only when n>10)

Textbox 2. Study exclusion criteria.

Population

- Participants without diabetes or with type 1 or gestational diabetes

Intervention

- No treatment or intervention

Comparison

- No treatment or intervention

Outcome

- Neither behavioral outcomes nor patient-reported outcomes or clinical parameters studied

Study design

- Cross-sectional studies, qualitative studies, reviews, and meta-analyses

Only studies published in English or German were included.

Database Search

An electronic database search was conducted in MEDLINE (via PubMed) and PsycINFO to cover both medical and psychological research. The initial search was conducted in April 2020 and updated in April 2022 with no restrictions on start time. The search string (Multimedia Appendix 1) included terms covering type 2 diabetes (population), including Medical Subject Heading terms and synonyms for *game* and *gaming* (intervention) as well as game components, and was piloted in previous research [24]. Population and intervention terms were linked with the operator *AND*. No restrictions were imposed on the outcome category of the search string to avoid accidentally excluding relevant effects of gamified interventions.

Additional searches were conducted within the references of the included studies (backward citation tracking) as well as on Google Scholar and Web of Science, where publications citing the included studies were checked (forward citation tracking) in July 2022.

Screening and Data Extraction

The screening of relevant records was a 2-step process. First, 2 independent reviewers screened the titles and abstracts of all records found by the database and hand searches. If deemed relevant by at least one reviewer, the full text was assessed for eligibility by both reviewers as well. The reference manager EndNote (Clarivate Analytics) was used for both screening and duplicate removal.

Data were extracted according to the population, intervention, control, outcome, and study design scheme, aiming at allowing for a comparison of the effects of different gamified intervention types on the aforementioned outcome domains. In addition, the following information was extracted from each study: (1) bibliographic information, (2) population characteristics, (3) the allocation of the study participants to the intervention and control group or control groups, (4) treatment or interventions applied to the control group (as a means to account for plausible confounding factors), (5) inclusion and exclusion criteria of each applicable study (as a means to account for plausible confounding factors), and (6) outcome measures (to inform quality assessment).

The data extraction sheet was piloted by 2 researchers on 2 of the included studies, which were randomly selected, and subsequently slightly adjusted by including the category “outcome measures.” Data extraction was performed using a Microsoft Excel (Microsoft Corp) spreadsheet.

For a visual representation, HbA_{1c} values at baseline and after intervention completion were extracted in percentage or mmol/mol depending on the data available in the included studies, along with the SD. Δ HbA_{1c} was computed, and statistical significance was extracted from the included studies. The threshold for statistically significant effects was set at $P<.05$. No assumptions were made if information was missing; this was labeled as “not reported” instead. All study results were tabulated. Apart from the tabulation and visualization of HbA_{1c} results, the presentation of the results is narrative.

Quality Assessment

The randomized controlled trials (RCTs) found were assessed for study quality by applying the Cochrane risk-of-bias tool version 2 (RoB 2) [25], whereas cohort studies, if included, were assessed using the corresponding Critical Appraisal Skills Programme (CASP) cohort study checklist [26]. Case-control studies were assessed using the corresponding checklist also provided by the CASP [27]. The RoB 2 covers bias within an outcome resulting from the randomization process (selection bias); blinding of participants, assessors, and analysts; deviations from intervention delivery (performance bias); changes in participants’ adherence to the intervention (attrition bias); modalities of outcome measurement; or selective reporting (reporting bias). RoB 2 assessment was performed for each relevant study outcome according to our inclusion criteria. According to the RoB 2 manual, the overall risk of bias within a study was deemed high if 1 study outcome had a high risk of bias. Both records by Höchsmann et al [28,29] were treated as 1 study with several outcomes. CASP checklists for nonrandomized studies cover the same categories except for randomization and blinding while also putting an emphasis on practical implications of the study results. In contrast to the RoB 2, CASP checklists were applied to the entire study instead of to selected outcomes. The RoB 2 deems studies to be at a low risk of bias when a low risk of bias is detected for all relevant domains. Some concerns regarding the risk of bias within an outcome can be assumed when some concerns are raised for at least one domain. A high risk of bias can be assumed when multiple domains raise some concerns or a high risk of bias is detected for at least one domain [25]. With the CASP, overall risk of bias is assessed by answering the following question: “Do you believe the results?”

Quality assessment was performed for the effect of both assignment to the intervention (ie, the intention-to-treat effect) and adherence to the intervention (ie, the per-protocol effect).

All steps of the review—screening of titles and abstracts and full texts, data extraction, and quality assessment—were performed by at least 2 researchers independently (LO, LH, or PT in the first search period and LH and TH in the second search period) to minimize bias. Differences in inclusion, extraction, and quality assessment were resolved through discussion with a third person not involved in the screening process (SD).

Diversions From the Protocol

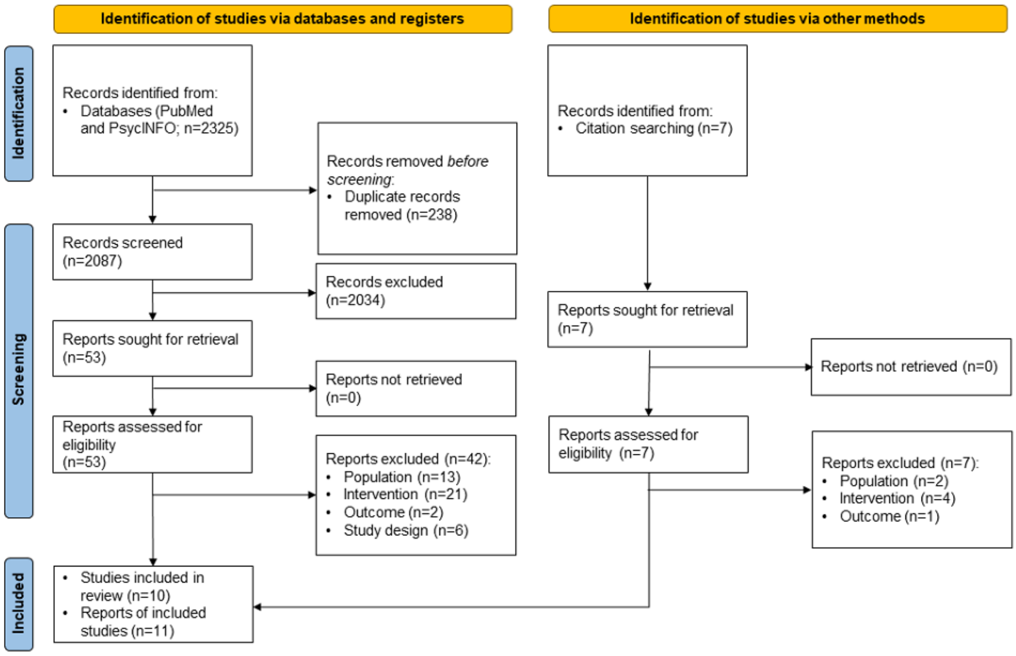
Contrary to the protocol registered with PROSPERO, research question 2 was adapted so that it clearly addressed PROs. Furthermore, we refrained from performing a search in key journals as these were all listed in MEDLINE.

Results

Results of the Search Process

Both database searches (2020 and 2022) taken together yielded 2325 results. A total of 7 additional potentially relevant publications were identified via additional searches, but excluded after full text assessment. In total, 2087 publications remained after duplicates were removed, 2034 (97.5%) of which were removed after title and abstract screening. The full texts of the remaining 53 publications were assessed for eligibility. This process led to the exclusion of 25% (13/53) of the studies as they addressed a population outside this review’s scope, such as patients with type 1 or prediabetes [30-42]. Another 40% (21/53) of the studies were excluded as the interventions studied did not have a game component [43-63]. A total of 15% (8/53) of the studies were excluded as they used 1-armed designs or did not study any of the prespecified outcomes but solely patient experiences, such as satisfaction with the application [64-71]. A complete list of the excluded studies with reasons for exclusion can be found in Multimedia Appendix 2 [30-71]. Finally, 10 studies were included in the qualitative data analysis [28,29,72-80]. Höchsmann et al [28,29] reported results from the same study in 2 records. The process of study selection is depicted in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram depicting study inclusion.



Descriptive Statistics of the Populations Studied

All the included studies (10/10, 100%) were RCTs. However, Kempf and Martin [78] and Brinkmann et al [72] applied a crossover design in which participants in the control group received the intervention later during the study period. The study samples ranged from 8 participants [72] to 465 participants [76]. The lowest mean age was 44 (SD 7.9) years [79] and the highest mean age was 68 (SD 5.8) years [73]. Brinkmann et al [72] only reported the age span of the study participants, which was 67 to 75 years. Overall, 533 female participants and 1061 male participants were included. The intervention duration ranged from 30 minutes (exergame) [72] to 36 weeks (self-management app with quiz component) [74]. In total, 30% (3/10) of the RCTs performed follow-up analyses after the intervention period, with follow-up times ranging from 7 days [72] to 48 weeks [77]. A complete overview of the population characteristics of the included RCTs can be found in Table 1.

Table 1. Study and population characteristics of the included randomized controlled trials.

Study, year, title, journal, and country	Study design	Study duration	Follow-up time	Population characteristics				
				Sample size, n	Age (years)	Sex	Inclusion criteria	Exclusion criteria
Brinkmann et al [72], 2017, "Effects of Cycling and Exergaming on Neurotrophic Factors in Elderly Type 2 Diabetic Men—A Preliminary Investigation"/Experimental and Clinical Endocrinology & DiabetesExp Clin Endocrinol Diabetes, Germany	Individually randomized crossover trial	30 min once	None	8	Ranging from 67 to 75	8 male participants	• Not reported	• Nonsmoking • Absence of diabetic retinopathy, neuropathy, nephropathy, or cardiovascular complications
Dugas et al [73], 2018, "Individual Differences in Regulatory Mode Moderate the Effectiveness of a Pilot mHealth trial for Diabetes Management among older Veterans"/PLOS ONE[a], United States	Individually randomized controlled trial	13 weeks	None	27	Mean 67.8 (SD 6.1)	Not reported	• Veteran patients with type 2 diabetes • Affiliated with a Veterans Affairs medical center • Aged >60 years • Poorly controlled diabetes (HbA_{1c}[b] >7.9%)	• Blindness • Deafness • Serious mental illness • Homelessness
Glasgow et al [74], 2010, "Outcomes of Minimal and Moderate Support Versions of an Internet-Based Diabetes Self-Management Support Program"/Journal of General Internal Medicine, United States	Individually randomized controlled trial	16 weeks	None	463	Mean 58.4 (SD 9.2)	233 male and 230 female participants	• Aged 25 to 75 years • Type 2 diabetes diagnosis • BMI >25 kg/m^2 • At least one or more risk factor for CVD[c] • Telephone access • Internet access at least twice a week	• None

Study, year, title, journal, and country	Study design	Study duration	Follow-up time	Population characteristics				
				Sample size, n	Age (years)	Sex	Inclusion criteria	Exclusion criteria
Grewal et al [75], 2015, "Sensor-Based Interactive Balance Training with Visual Joint Movement Feedback for Improving Postural Stability in Diabetics with Peripheral Neuropathy: A Randomized Controlled Trial"/Gerontology, United States	Individually randomized controlled trial	45 min twice a week for 4 weeks	None	39	Mean 63.7 (SD 8.2)	20 male and 19 female participants	• Ability to walk on one's own for 20 meters • Type 2 diabetes • Peripheral neuropathy	• Diagnosis of cognitive, vestibular, or central neurological dysfunction • Diagnosis of musculoskeletal abnormality • Active foot ulcers • Charcot joints • History of balance disorder
Höchsmann et al [28,29], 2019, "Effectiveness of a Behavior Change Technique–Based Smartphone Game to Improve Intrinsic Motivation and Physical Activity Adherence in Patients With Type 2 Diabetes: Randomized Controlled Trial"/JMIR Serious Games and "Novel Smartphone Game Improves Physical Activity Behavior in Type 2 Diabetes"/American Journal of Preventive Medicine, Switzerland	Individually randomized controlled trial	24 weeks	None	36	Mean 57 (SD 5.5)	19 male and 17 female participants	• Physically inactive (<150 min of moderate-intensity PA[d] per week) • BMI >25 kg/m² • Type 2 diabetes • Non–insulin-dependent • Aged 45 to 70 years • Having used a smartphone regularly for 1 year before the study	• Health risks counterindicating PA • Impaired mobility • Acute infections • Injuries
Kempf and Martin [78], 2013, "Autonomous Exercise Game Use Improves Metabolic Control and Quality of Life in Type 2 Diabetes Patients—a Randomized Controlled Trial"/BMC Endocrine Disorders, Germany	Crossover individually randomized controlled trial	30 min per day for 12 weeks	None	220	Mean 62 (SD 11; [intervention group]) and 60 (SD 9; [control group])	119 female and 101 male participants	• Type 2 diabetes • Diagnosis>5 years ago • Aged 50 to 75 years • BMI >27 kg/m² • Included in disease management program for diabetes	• Regular PA • Pharmacological therapy (except metformin and DPP-4[e] inhibitors)
Kerfoot et al [76], 2017, "A Team-Based Online Game Improves Blood Glucose Control in Veterans With Type 2 Diabetes: A Randomized Controlled Trial"/Diabetes Care, United States	Individually randomized controlled trial	24 weeks	48 weeks	465	Mean 59.5 (SD 9.9)	28 female and 428 male participants	• Type 2 diabetes • Inadequate glucose control • Taking oral diabetes medication • Insulin- and non–insulin-dependent	• Not reported

[b]HbA_{1c}: glycated hemoglobin (blood sugar value).

[c]CVD: cardiovascular disease.

[d]PA: physical activity.

[e]DPP-4: dipeptidyl peptidase 4

Results of the Quality Assessment

Applying the RoB 2, a high risk of bias was detected in 90% (9/10) of the included RCTs [28,73-80]. A total of 10% (1/10) of the studies had a low risk of bias [72]. For 40% (4/10) of the RCTs, multiple reasons for a high risk of bias were detected [73,74,79,80], whereas for 30% (3/10) of the studies, only 1 reason was found [75,77,78]. The allocation sequence was random in all but 10% (1/10) of the cases [79]. Major sources of bias were the blinding of study participants and personnel to the allocation to either the intervention or the control group [73,74,76,77,79,80] and, to a smaller degree, inadequate (ie, nonreliable or nonvalidated) measures for outcome assessment [28,73-75,79,80], both of which translate to detection bias. Most of the included RCTs (7/10, 70%) conducted per-protocol analyses [28,29,72,73,75,77,78,80], whereas another study did not specify the type of analysis [79]. As such, the effect estimate was potentially biased by dropouts in all but 20% (2/10) [74,76] of the included RCTs (attrition bias). Glasgow et al [74] and Kerfoot et al [76] performed an intention-to-treat analysis, whereas the remaining authors all performed per-protocol analyses except for Koohmareh et al [79], for whom the type of analysis could not be discerned. Bias because of selective reporting was detected by comparing the outcomes described in the Methods sections and those reported in the Results sections [75,76]. The results of the quality assessment can be found in Figure 2.

Figure 2. Results of the quality assessment applying the Cochrane risk-of-bias tool version 2 [28,29,72,-80].

Game Types and Components Analyzed in the Included RCTs

Of the 10 included RCTs, 4 (40%) focused on an exergame [28,29,72,75,78], one (25%) of which reported first behavioral and then clinical results of the same exergame intervention studied with the same population [28,29]. A total of 20% (2/10) of the studies reported on the effects of game components within digital self-management applications for diabetes [73,80]. In 40% (4/10) of the RCTs, the authors analyzed quiz games with DSME content [74,76,77,79]. The digital intervention studied by Brinkmann et al [72] combined an exergame with a game for cognitive problem-solving.

Within the exergames, virtual reality components such as virtual race tracks were used [72,75,78]. Scoring systems awarding trophies to winners or when individualized scores were achieved were used in 60% (6/10) of the interventions [28,29,73,74,76,79,80]. Storytelling features were part of 20% (2/10) of the interventions studied [28,79], and 10% (1/10) of the interventions applied a team-based approach to the game [78].

Among the 4 RCTs in which the authors reported on the matter [72,75,78,79], intervention intensity varied between 30 minutes once (equal to intervention duration) [72], 15 minutes per day for 6 weeks [79], 30 minutes per day for 12 weeks [78] and 45 minutes twice a week for 4 weeks [75].

A complete overview of the intervention types and game components studied in the included RCTs can be found in Table 2.

Table 2. Intervention characteristics of the included randomized controlled trials.

Study, year	Intervention group	Control group	Intervention	
			Duration	Intensity
Brinkmann et al [72], 2017	• Exergaming: interactive video games using Wii Fit Plus combining physical activity and cognitive challenges (n=8) aiming to improve neurotrophic factors	• Cycling on stationary bicycle (n=8)	30 minutes	30 minutes
Dugas et al [73], 2018	• Using self-management app with game elements (point reward system for achieving target values in clinical and behavioral outcomes) aiming to improve diabetes outcomes in 4 randomized conditions: • App use only (n=5) • App use including provider communication features (n=5) • App use including team engagement features (n=6) • App use including team engagement and provider communication features (n=6)	• Usual care (n=5)	13 weeks	Not reported
Glasgow et al [74], 2010	• Self-management website allowing for goal setting in medication adherence, nutrition, and exercise, including quiz component (n=169) • Augmented with (1) follow-up calls with a member of the study staff to ask questions about the study and receive help in handling the website and (2) group meeting with other study participants (n=162)	• Enhanced usual care (automated feedback on health risks based on patient-provided disease-relevant parameters; recommendation of preventive behaviors; n=132)	16 weeks	Not reported
Grewal et al [75], 2015	• Virtual obstacle-crossing task with audio and video feedback on a virtual reality interface • Ankle-reaching task with virtual representation and feedback onscreen (n=16)	• Usual care (n=18)	4 weeks	45 minutes twice a week
Höchsmann et al [28,29], 2019	• Smartphone game "Mission: Schweinehund" based on self-determination theory and including behavioral or motivational elements as well as a storyline where users restore a garden with resources gained through individualized in-game workouts tracked via phone sensors (n=18)	• 1-time lifestyle counseling and structured exercise plan (n=18)	24 weeks	Not reported
Kempf and Martin [78], 2013	• Wii Fit Plus including balance board (n=120)	• Routine care (n=100)	12 weeks	>30 minutes per day for 12 weeks
Kerfoot et al [76], 2017	• Team-based mobile DSME[a] quiz with scoring system plus booklet on civic issues (n=227)	• Team-based mobile quiz on civic issues plus DSME booklet (n=229)	24 weeks	Not reported
Koohmareh et al [79], 2020	• Amoo mobile game—glycemic index and calorie training game (n=30)	• Educational content similar to the game through a brochure (n=30)	6 weeks	15 minutes per day for 6 weeks
Maharaj et al [80], 2021	• mySugr—self-monitoring and self-management app with nudging and game component (point reward system for certain behaviors; n=44)	• Glucose Buddy—self-monitoring and self-management app (n=45)	2 weeks	Not reported
Turnin et al [77], 2021	• DSME software including quiz components (n=135)	• Usual care (n=128)	48 weeks	Not reported

[a]DSME: Diabetes Self-Management and Education.

Effects of Gamified Health Interventions on Health Behavior

Exercise intensity and adherence were studied in 50% (5/10) of the included studies [28,29,73-75,78]. A total of 40% (4/10) of the studies reported on nutritional behavior [73,74,79,80], and 20% (2/10) of the studies reported on medication adherence [73,74].

Positive effects on behavioral PA outcomes were reported in several of the included RCTs (4/10, 40%). A total of 50% (2/4) of the exergames studied led to an increased intensity of PA (measured as step count, caloric expenditure, and self-report) in the study participants [28,29,78], and so did the quiz component nested within the DSME website studied by Glasgow et al [74]. However, the latter was only effective when the website was supplemented with follow-up calls by study staff as a supportive measure in handling the website and group meetings with other study participants [74]. Only Höchsmann et al [28] reported on PA adherence and found no substantial effect of their exergame on PA adherence, where PA exercises were nested within a coherent narrative. However, the intervention statistically significantly increased intrinsic motivation for PA ($P<.001$), whereas intrinsic motivation decreased in the control group (1-time lifestyle counseling and structured exercise plan) during the study period. Between-group effects were significant. The authors also found a significant positive relationship between time spent doing the in-game exercises and PA motivation (P=.01) [28].

Dugas et al [73] found no overall intervention effect of any of the intervention arms studied on adherence as a whole (quantified using an in-app rating system; Table 3), but they found a statistically significant interaction effect (in regression analysis) of time spent using the self-management app with game elements and assessment (P=.01). They also found a statistically significant interaction effect of time and locomotion on weekly exercise adherence ($P<.05$) [73].

In 40% (4/10) of the RCTs, the authors found significant positive effects on *nutrition behavior*. Glasgow et al [74] reported a significant decrease in fat intake in the intervention group compared with that in the control group (P value for intergroup differences=.006). Koohmareh et al [79] found that participants using their educational game on glycemic index and calorie intake paid significantly more attention to the glycemic levels and calorie count of their food (P value for intergroup differences=.001). Maharaj et al [80] showed that participants using the mySugr app with the reward system could significantly reduce their high-fat food consumption, whereas no significant changes were found in the control group using a self-management app without a game component (P value for intergroup differences=.052). Interaction effects of time and assessment as well as of time and locomotion were found by Dugas et al [73] for nutrition adherence (quantified using an in-app rating system) as well. The authors also found a significant positive effect of locomotion on nutritional adherence ($P<.05$) but none of assessment (P value not reported) [73].

Glasgow et al [74] found no significant effect of the intervention on medication adherence or on eating habits other than fat intake (P value for intergroup differences=.006). Dugas et al [73] found an interaction effect of time spent using the intervention and assessment on medication adherence (P=.04).

A total of 40% (2/5) of the exergames studied had no effect on PA intensity [75,78]. Overall, positive effects of digital health interventions with game components could be found on motivation for and intensity of PA as well as on eating habits.

Table 3. Results of the included randomized controlled trials according to all relevant outcomes and overall study quality.

Study, year	Outcome (outcome measure)	Results		Study quality according to RoB 2[a]
		Statistically significant	Nonsignificant	

Brinkmann et al [72], 2017	• BDNF[b], VEGF[c], and IGF-1[d] (all measured using an enzyme-linked immunosorbent assay)
	• Heart rate
	• Lactate values
		• Clinical parameters:
		  • Significantly better lactate values in intervention group (*P*=.04)
			• Clinical parameters:
			  • Insignificant lower heart rate in intervention group (*P*>.05)
			  • Insignificant increase in BDNF in intervention group (*P* value not reported)
			  • Insignificant increase in VEGF in intervention group (*P* value not reported)
			  • Insignificant increase in IGF-1 in intervention group (*P* value not reported)
				• High

Dugas et al [73], 2018	• HbA_{1c}[e]
	• Regulatory mode (locomotion and assessment scales developed by Kruglanski et al [81])
	• Adherence to healthy behaviors (glucose, medication, and nutrition tracking entered manually into app; PA[f] tracked via Fitbit or manually; and recorded app use, all quantified using in-app point rating system)
		• Behavioral outcomes:
		  • Significant positive causal relationship between locomotion and weekly adherence score (*P*<.05)
		  • Significant positive causal effect of interaction between time and assessment during intervention time on adherence (*P*=.01)
		  • Significant positive causal effect of interaction between time and locomotion for app use, including provider communication features, on adherence (*P*=.04)
		• Clinical parameters:
		  • Significant positive causal effect of app use, including provider communication features, on HbA_{1c} (*P*<.01)
		  • Significant positive causal effect of interaction between time and adherence on HbA_{1c} (*P*<.01)
			• Behavioral outcomes:
			  • No treatment effect of any intervention arm on total adherence (*P* value not reported)
			• Clinical parameters:
			  • No significant between-group differences in HbA_{1c} during intervention time (*P* value not reported)
				• Low

Study, year	Outcome (outcome measure)	Results		Study quality according to RoB 2[a]
		Statistically significant	Nonsignificant	

Glasgow et al [74], 2010	• Health literacy (brief questionnaire by Chew et al)
	• Dietary behavior ("Starting the Conversation Scale" by Ammerman et al)
	• Adherence to medication for diabetes, blood pressure, and cholesterol (medication-taking items of the Hill-Bone Compliance Scale)
	• Fat intake (National Cancer Institute Percent Energy from Fat Screener)
	• Total weekly caloric expenditure (Community Healthy Activities Model Program for Seniors Questionnaire)
	• HbA_{1c}
	• BMI[g]
	• Lipid ratio
	• Mean arterial pressure
		• Behavioral outcomes:
		  • Significant improvement in eating habits in intervention group but not in control group (*P* value for intergroup differences ≤.001)
		  • Significant decrease in fat intake in intervention group but not in control group (*P* value for intergroup differences=.006)
		  • Significant increase in PA in intervention group but not in control group (*P* value for intergroup differences=.04)
			• Behavioral outcomes:
			  • No significant improvement in medication adherence in intervention group vs control group (*P* value for intergroup differences=.29)
			  • No significant differences in eating habits (*P* value for intergroup differences=.08), fat intake (*P* value for intergroup differences *P*=.46), PA (*P* value for intergroup differences=.63), and medication adherence (*P* value for intergroup differences=.86) between intervention groups
			• PROs[h]:
			  • No interaction effect of health literacy on any of the outcomes measured (P not reported)
			• Clinical parameters:
			  • No significant improvement of HbA_{1c} (*P* value for intergroup differences=.42), BMI (*P* value for intergroup differences=.19), lipid ratio (*P* value for intergroup differences=.90), and mean arterial pressure (*P* value for intergroup differences=.83) in any study arm
				• Low

Grewal et al [75], 2015	• Postural stability (FES-I[i] and postural stability)
	• Diabetes peripheral neuropathy (VPT[j])
	• Daily PA (time spent sitting, standing, and walking and total step count) measured via shirt-worn sensor
	• Quality of life (SF-12[k])
		• PROs:
		  • Significant improvement in mental health component of SF-12 in intervention group but not in control group (*P* value for intergroup differences=.04)
		• Clinical outcomes:
		  • Significant reduction in average center of mass sway area (in degrees) in intervention group but not in the control group (*P* value for intergroup differences=.009)
		  • Significant reduction in medial-lateral center of mass sway area in intervention group but not in the control group (*P* value for intergroup differences=.008)
		  • Significant reduction of hip and ankle sway in the intervention group but not in the control group (*P* value for intergroup differences=.008)
		  • Significant reduction of ankle sway degree in intervention group but not in control group (with and without blindfold; *P* value for intergroup differences=.02)
				• Low

Study, year	Outcome (outcome measure)	Results		Study quality according to RoB 2[a]
		Statistically significant	Nonsignificant	

			• Behavioral outcomes:
			  • No significant differences in time spent sitting (*P*=.62), standing (*P*=.36), or walking (*P*=.08) in intervention and control group
			• PROs:
			  • No significant differences in physical component of SF-12 in intervention and control group (*P* value for intergroup differences=.64)
			  • No significant differences in FES-I in intervention and control group (*P* value for intergroup differences=.31)
			• Clinical outcomes:
			  • No significant reduction in anterior-posterior center of mass sway area in intervention or control group (*P* value for intergroup differences=.38)
			  • No significant reduction in average center of mass sway area in intervention or control group when blindfolded (*P* value for intergroup differences=.18)
			• No effects on VPT reported	

Höchsmann et al [28,29], 2019	• Intrinsic PA motivation (12-item version of the Intrinsic Motivation Inventory)
	• PA adherence (step count, stride cadence, completed vs canceled in-game workouts, and duration and patterns of game use)
	• HbA_{1c}
	• Aerobic capacity (cardiorespiratory fitness [maximum oxygen uptake and first ventilatory threshold])
	• Daily PA (step count via accelerometer wristband)
	• Total cholesterol
	• LDL-C[l]
	• HDL-C[m]
	• Triglycerides
	• Resting heart rate
	• SBP[n]
	• DBP[o]
			• Behavioral outcomes:
			  • Nonsignificant increase in intrinsic PA motivation after intervention on the subscale for value/usefulness (*P*>.05) but significant between-group differences (*P*<.05)
			• Only descriptive reporting of PA adherence
			• Clinical parameters:
			  • No changes in resting heart rate (*P*=10), SBP (*P*=.38), and DBP (*P*=.18) in any of the study groups
			  • No changes in skeletal muscle mass in any of the study groups (*P*=.71)
			  • No changes in total cholesterol (*P*=.55), HDL-C (*P*=.46), LDL-C (*P*=.74), and triglycerides (*P*=.95) in any of the study groups
				• Low [28]
				• Moderate [29]

Study, year	Outcome (outcome measure)	Results		Study quality according to RoB 2[a]
		Statistically significant	Nonsignificant	

		• Behavioral outcomes:
		  • Significant increase in intrinsic PA motivation in the intervention group (*P*<.001) and nonsignificant decline in the control group (*P*>.05)
		  • Significant between-group differences in intrinsic PA motivation after intervention (*P*<.05)
		  • Significant between-group differences in intrinsic PA motivation after intervention on the subscales for interest or enjoyment (*P*<.05) and perceived competence (*P*<.05) (significant increase in intervention group (*P*<.001)
		  • Significant increase in intrinsic PA motivation after intervention on the subscale for perceived choice in the intervention group (*P*<.05) but no between-group differences (*P*>.05)
		  • Significant relationship between in-game exercise (measured in minutes) and changes in intrinsic PA motivation (total score) (*P*=.01)
		  • Daily PA increase in the intervention and control group with a significant difference between groups (*P*<.001)
		• Only descriptive reporting of PA adherence
		• Clinical parameters:
		  • Significantly higher increase in step count in intervention group than in control group (*P*<.001)
		  • No changes in HbA_{1c} in the intervention group but increase in the control group (significant between-group differences) (*P*=.02)
		  • Significant increase in aerobic capacity in the intervention group and decrease in the control group (significant between-group differences) (*P*<.001)
		  • Significantly higher decrease in body fat mass in intervention than in control group (*P*=.045)		

Kempf and Martin [78], 2013			• Clinical parameters: • No significant differences in DBP, SBP, total cholesterol, HDL-C, LDL-C, triglycerides, metformin or DPP-4[t] inhibitor treatment, or physical well-being in any of the study groups (*P* value not reported)	• Low

Study, year	Outcome (outcome measure)	Results		Study quality according to RoB 2[a]

[t]DPP-4: dipeptidyl peptidase 4.

[u]PPR: patient-pill ratio.

[v]Amoo: diabetes test designed by Koohmareh et al [79].

[w]SDSCA: Summary of Diabetes Self-Care Activities.

Effects of Gamified Health Interventions on PROs

In the included RCTs, data were provided on health literacy in general [74,79,80], quality of life [75,78], diabetes-related impairment [76,78], and subjective well-being [78].

Concerning *health literacy*, Koohmareh et al [79] found a significant positive effect of their educational game on knowledge concerning a diet adequate for patients with diabetes (measured on a self-developed scale; *P*=.001). Maharaj et al [80] found no significant median differences in illness beliefs (measured using the Brief Illness Perception Questionnaire) between the gamified mySugr and the self-management app without any game components (*P* value for intergroup differences=.05). Glasgow et al [74] used health literacy as a moderating variable in a multivariate analysis of covariance to measure the effects of their self-management website with quiz elements but found no interaction effects (*P* value not reported).

In the domain of *quality of life*, Grewal et al [75] found a significant improvement in mental well-being because of the virtual balance training they studied (*P* value for intergroup differences=.04) but no effect of said intervention on physical well-being (*P* value for intergroup differences=.64; both measured using the Short Form 12 Health Survey). The same effect was demonstrated by Kempf and Martin [78], who studied Wii Fit Plus games, using both the Short Form 12 Health Survey and a German depression scale. *Subjective well-being*, measured using the 5-item World Health Organization Well-Being Index scale, improved significantly in the study by Kempf and Martin [78] as well (*P* value for intergroup differences=.004).

Grewal et al [75] and Kempf and Martin [78] studied the effects of gamified interventions on *diabetes-related impairment* both using the Problem Areas in Diabetes Scale. Although the latter found a positive effect of the Wii Fit Plus games (*P* value for intergroup differences=.03) [78], the former found no effect of virtual balance training (*P* value not reported) [75]. In terms of impairment, Grewal et al [75] found no effect of the virtual balance training on fear of falling (*P* value for intergroup differences=.31).

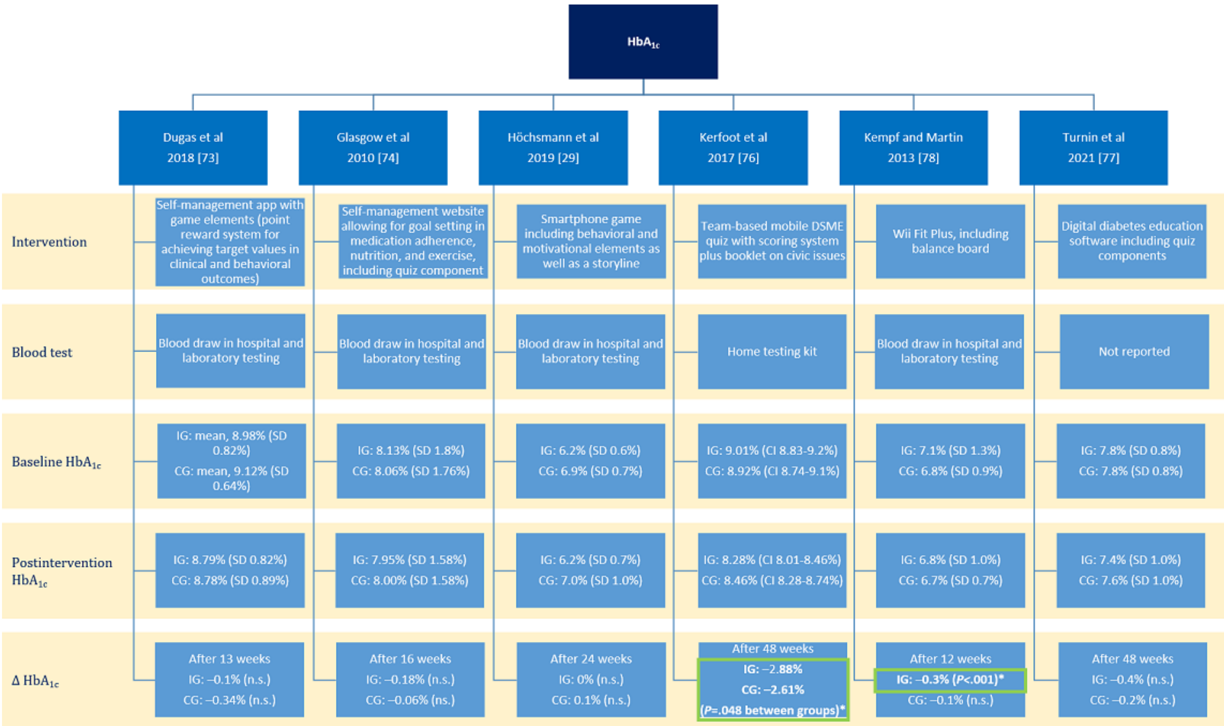
Overall, sparse positive effects of digital health interventions with game components could be found on health literacy and diabetes-related impairment, whereas substantial evidence was found for the improvement of subjective mental well-being.

Effects of Gamified Health Interventions on Clinical Outcomes

The clinical outcome studied most often in the included RCTs was HbA_{1c} [29,73,74,76-78]. Furthermore, 30% (3/10) of the included studies analyzed changes in BMI [74,77,78], whereas Höchsmann et al [28], Glasgow et al [74], and Kempf and Martin [78] also analyzed lipid outcomes and blood pressure values. Fasting plasma glucose (FPG) was studied twice [78,79], and so was the heart rate of the participants [28,72]. Brinkmann et al [72] studied cognitive parameters in conjunction with lactate values, and Grewal et al [75] analyzed postural stability.

The effects of the gamified interventions on HbA_{1c} levels studied in 60% (6/10) of the RCTs are depicted in Figure 3, where asterisks mark significant changes in HbA_{1c}. Only Kerfoot et al [76] (*P* value for intergroup differences=.048) and Kempf and Martin [78] (*P* value for intergroup differences<.001) found significant positive effects of a mobile, team-based DSME quiz and Wii Fit Plus games, respectively, on HbA_{1c} levels in terms of a reduction in the intervention group and significant between-group effects. Dugas et al [73] found a significant effect of time spent using the self-management app with an award system on HbA_{1c} levels in a regression analysis (*P*<.01), as well as an interaction effect of total adherence score (additive score of exercise, nutrition, and medication adherence; *P*<.01).

Figure 3. Effects of the interventions studied on glycated hemoglobin (HbA_{1c}) levels. *Significant. Δ HbA_{1c}: difference in HbA_{1c} between pre- and postintervention measurement; CG: control group; DSME: Diabetes Self-Management and Education; IG: intervention group; n.s.: not significant [29,73,74,76-78].



Kempf and Martin [78] also found significant positive effects of the intervention on *BMI* (*P* value for intergroup differences=.008); however, Glasgow et al [74] (*P* value for intergroup differences=.20) and Turnin et al [77] (*P* value for intergroup differences=.08), also studying DSME software with quiz components, did not. Significant effects on *FPG* after using the same software were also reported by Kempf and Martin [78] (*P* value for intergroup differences=.008) but not by Koohmareh et al [79] (*P* value for intergroup differences=.63), who studied the same intervention type. Significant effects were not found on lipid outcomes and blood pressure values [29,74,78] or on cognitive outcomes and lactate values [72]. Grewal et al [75] found their exergame, including a virtual obstacle course, to have a positive effect on postural stability when compared with usual care (*P* value for intergroup differences=.009).

Turnin et al [77] found a significant reduction in *waist circumference* in the intervention group when compared with the control group both before and after adjusting for confounding factors such as baseline HbA_{1c} levels, age, sex, or obesity (*P* value for intergroup differences=.04). The authors also reported an increased effect on waist circumference in those with a higher frequency of use (*P*=.008).

No significant effects were found on *heart rate* [29,72], *blood pressure* (systolic or diastolic) [29,78], or *lipid values* (ie, on total cholesterol, triglycerides, low-density lipoprotein cholesterol, or high-density lipoprotein cholesterol) [29,78] in any of the RCTs that reported on these values.

Brinkmann et al [72] studied the vascular endothelial growth factor as an indicator of *diabetes retinopathy* but found no effect of the Wii Fit exergame they studied (*P* value not reported). Furthermore, they found no effect of the intervention on insulin-like growth factor–1 as a proxy for *poorly adjusted diabetes* (*P* value not reported).

Brinkmann et al [72] found improved lactate values in the intervention group (*P*=.04) but not in the control group (*P* value not reported), which used a stationary bicycle, thus indicating higher *fitness* levels owing to the exergame. Improved fitness because of an exergame was also demonstrated by Höchsmann et al [29] using aerobic capacity as an indicator (*P*<.001). Grewal et al [75] found improved postural stability to be an effect of the virtual balance training they studied (*P*=.009).

As Brinkmann et al [72] aimed to also improve *cognitive functioning* of the study participants by adding cognitive challenges to the exergame, they studied the brain-derived neurotrophic factor as an indicator of learning and memory capacity and found no significant effect of the intervention (*P* value not reported).

Overall, sparse positive effects of digital health interventions with game components could be found on clinical outcomes, with fitness-related outcomes improving the most.

A complete overview of the effects found in the included RCTs can be found in Table 3. If not stated otherwise, differences in outcomes are reported between the intervention and control group(s) before and after the study in Table 3.

Discussion

Principal Findings

Despite heterogeneity in the effects of the gamified applications studied in this review on behavioral, clinical, and patient-reported outcomes, certain patterns emerged. Exergames had the tendency to improve fitness-related and, to a smaller extent, clinical values (as shown in 4/10, 40% of the RCTs [73,76-78]), whereas educational games affected disease-related knowledge and especially nutrition behavior (as shown in 4/10, 40% of the RCTs [73,74,79,80]). In addition, exergames had a potential to improve outcomes related to self-reported well-being such as quality of life and diabetes-related impairment (as shown in 2/10, 20% of the RCTs [75,78]).

Comparison With Prior Work

The results confirm those of a meta-analysis by DeSmet et al [82], who showed significant positive effects of serious games on health behavior independent of any diagnosis and its theory-based determinants and significant but much smaller effects on various clinical outcomes. As for nutrition behavior, which improved according to 40% (4/10) of the RCTs included in this review solely because of self-management applications with quiz elements, Ledoux et al [83] found similar effects of a serious game for young patients with type 1 diabetes.

Somewhat surprisingly, self-efficacy was not among the outcomes studied in the included RCTs despite existing evidence that both exergames and serious games can increase the feeling of being able to actively affect one’s health outcomes [65,84]. A precondition derived from behavior change theories is the option for goal setting by the intervention participants themselves as opposed to behavioral goals predefined by the intervention developers [85]. This precondition was met by all the gamified interventions studied in this review that used a reward or scoring system as these game components allow for the autonomous setting of target values that the users aim to achieve and, thus, generate intrinsic motivation [12].

A coherent narrative as an instrument of storytelling was used in only 20% (2/10) of the included interventions; however, it aided in producing positive effects on behavioral, knowledge-related [28,79], and clinical outcomes [29]. As such, the results confirm observations made for narrative health communication messages when delivered in a digital manner [86].

Physical fitness because of an increase in PA owing to interventions with game components is an especially promising result as PA is one of the primary target behaviors of diabetes self-management. The same is true for dietary behavior [6]. As such, these results underline once more the potential of digital interventions for DSME, acknowledged also by the ADA and the European Association for the Study of Diabetes in a joint statement [87].

The relatively high mean age of the study participants is surprising insofar as the traditional target group for digital health applications of all sorts is usually younger people [88]. Christensen et al [17], in sensitivity analyses, also found a positive effect of game-based interventions only for people aged <18 years. Especially regarding exergaming, the positive effects for older people because of high engagement have already been proven elsewhere [89]. Given the fact that most of the gamified interventions studied in this review (7/10, 70%) were designed for mobile devices, the high penetration of such devices in all age groups might play an important role in overcoming the digital health divide because of age [90]. Therefore, the results need to be considered in light of demographic changes and a rise in the demand for health care, especially for chronic diseases [91].

With intervention duration varying widely (Table 2), statements on its relevance have to be made with caution. However, the results show that effects on clinical outcomes can be achieved via digital health interventions with game components after at least 12 months [76,78], which corresponds to the concept of DSME as a continuous, long-term intervention [4,6]. However, even 36 weeks of intervention duration did not guarantee significant effects on BMI and HbA_{1c} [74], hinting at a washout in intervention fidelity common in digital health applications [92].

The fact that generally positive effects of digital health interventions of any kind are biased because of low overall study quality also mirrors findings of recent evidence syntheses [22,93]. The methodological issues concerning the quality of obtainable evidence raised in the joint statement by the ADA and the European Association for the Study of Diabetes [87] persist in this review even though all the included studies (10/10, 100%) were RCTs or had adaptive RCT designs. The issue of blinding of study participants and personnel to the allocation is common in digital health trials as the fact that one did not receive a gamified health application is easily uncovered [8]. Therefore, the study conducted by Maharaj et al [80] is a positive example of comparing 2 digital health applications whereby one is augmented with game components. The issue of missing outcome data because of dropouts, well known to researchers in multiple fields, is also common in digital health research [94] and is linked to the issue of intervention fidelity. The reasons as to why trial participants may lose interest in the use of digital health applications can be numerous [92]. Therefore, participatory design is an important precondition for gamified applications as well [95]. Nonvalidated outcome measures, another major source of bias in the included RCTs, point to the need to develop core outcome sets for digital health applications with or without game components.

Strengths and Limitations

Robust and reproducible systematic review methods were used to identify the best available evidence, and the results were reported according to the PRISMA checklist (Multimedia Appendix 3 [23]). Owing to the fact that all steps taken in this review were performed by 2 researchers independently and checked by a third researcher, it is highly unlikely that relevant records were overlooked or incorrectly discarded as irrelevant. The same is true for information in the included records relevant to the quality assessment.

The focus on research published in German or English is a limitation. Owing to the diverse intervention types (with intervention durations varying widely) and outcomes studied in the rather large number of included RCTs (compared, eg, with the meta-analysis by Christensen et al [17]), a meta-analysis especially of clinical outcomes was not deemed feasible. Rather, the broad realm of outcomes studied allows for a holistic overview of the potential effects of digital health interventions with game components.

Some of the included RCTs (3/10, 30%) had a considerable loss to follow-up, which would have required intention-to-treat analyses. However, most studies (7/10, 70%) conducted per-protocol analyses instead. Furthermore, the reasons for dropout were not always reported.

Little to no follow-up time after the intervention period limits the comparability of the gamified interventions studied in the included RCTs with other digital or analog behavior change interventions that have demonstrated sustainable effects over time [96]. However, according to both theory and evidence, sustainable and long-lasting behavior change over a time span of at least 6 months is necessary to achieve improved health outcomes and still not easily achieved [85]. Owing to limited reporting of intervention intensity, no discernible patterns regarding effectiveness could be found. Moreover, effective components of gamified health interventions regarding both clinical outcomes and behavior change have not been identified yet [97].

Conclusions

This systematic review provided a thorough analysis of the effectiveness of digital health interventions with game components for the self-management of type 2 diabetes. The included RCTs analyzing exergames showed positive effects on fitness-related outcomes and, albeit only in 1 case, also on HbA_{1c}. Educational games improved dietary habits and subjective mental health and well-being. However, the evidence base was ambiguous and further limited because of the considerable risk of bias in the study designs of most of the included RCTs (9/10, 90%). Nevertheless, the results imply that digital health interventions with game components can help improve PA, dietary habits, and well-being. Therefore, these applications, when developed based on theory and evaluated rigorously, can help achieve the behavioral goals mentioned in several guidelines for DSME. Given the mostly low quality of the included RCTs, the presented evidence allows for nothing more than the suggestion of digital health interventions with game components as a supplement to traditional DSME, which corresponds to the statement by Fleming et al [87]. The main results of this review are summarized in Textbox 3.

Textbox 3. Main results of the review.

- The variety of game components used in digital health interventions for type 2 diabetes ranges from quiz components over storytelling elements to full-scale exergames.
- Digital health interventions containing game components might improve the health behavior patterns, quality of life, and clinical outcomes of patients with type 2 diabetes.
- The methodological quality was low in most of the included randomized controlled trials.

Further research should compare digital health interventions that contain game components with those that do not rather than comparing the former with usual care and, as such, risking bias because of high dropout rates. Furthermore, longer follow-up assessments are crucial to detect whether the effects of gamified interventions are sustainable. Adaptive study designs such as microrandomization, where individuals are randomized to several intervention components or treatments for the study duration [98], could be used to determine which game components have an effect on which outcome domain (behavioral, PROs, or clinical). Larger sample sizes would allow for more detailed subgroup analyses [99] to determine which user groups, in addition to those defined by age, profit the most from digital health interventions containing game components. Finally, but importantly, a comparison of the effects of digital health interventions with game components for patients with type 1 and 2 diabetes is bound to provide further insights.

Acknowledgments

The work for this review was partly funded by the county of Saxony, Germany.

Authors' Contributions

LO and LH devised the study design and conducted the literature search, study selection process, quality assessment, and data extraction together with TH. SD and PT were involved in the consensus process during study selection, data extraction, and quality assessment. PT, OS, and MS analyzed the extracted data and derived points for discussion and implications. LH drafted the manuscript, which was critically revised for important intellectual content and approved by all the authors.

Conflicts of Interest

Unrelated to this study, OS served as a consultant for Novartis. Unrelated to this study, JS reports institutional grants for investigator-initiated research from the German Federal Joint Committee, Federal Ministry of Health, Federal Ministry of Education and Research, European Union, Federal State of Saxony, Novartis, Sanofi, Allergologisk Laboratorium København (ALK), and Pfizer. He also participated in advisory board meetings as a paid consultant for Sanofi, Lilly, and ALK. JS serves the German Ministry of Health as a member of the Sachverständigenrat Gesundheit und Pflege (expert advisory board on health and care).

Abstract

Background: Conventional exercises (CEs) can provide health benefits for older adults, but the long-term exercise adherence rate is low. As an emerging, stimulating, and self-motivating strategy, exergames (EGs) are defined as combinations of exercises and games that users carry out through physical actions. They can promote exercise, but the health effects of EGs versus CEs on the physical function and mental health (cognitive function, depression, and quality of life) of older adults remain controversial.

Objective: The aim of the study is to compare the health benefits of EGs versus those of CEs for the physical function and mental health of older adults.

Methods: A comprehensive search was conducted from the earliest available date to February 2023 in the following 6 databases: PubMed, Web of Science, Embase, Cochrane, CINAHL, and PsycINFO. All English-language randomized controlled trials comparing the effects of EGs versus those of CEs on the physical function and mental health of older adults, with nearly same physical activity between the 2 interventions, were included. Risk of bias was independently evaluated by 2 authors using the Cochrane risk of bias in randomized trials tool. Two authors independently extracted data. We followed the *Cochrane Handbook of Systematic Reviews of Interventions* to process and analyze the data for meta-analysis. Standardized mean differences (SMDs) and 95% CIs were used for continuous data, and random models were used for analyses.

Results: We included 12 studies consisting of 919 participants in total. Of these, 10 studies were eventually included in the meta-analysis. The results showed that EGs versus CEs exhibited no significant differences in physical (P=.13; τ^2=0.31; χ^2_6=26.6; I^2=77%; SMD=0.37; 95% CI –0.11 to 0.86) or cognitive function (P=.63; τ^2=0.01; χ^2_3=3.1; I^2=4%; SMD=0.09; 95% CI –0.27 to 0.44) effects.

Conclusions: Our findings indicate no significant difference between EGs and CEs in improving the physical function and cognitive function of older adults. Future studies are required to compare the effects of EGs versus those of CEs on cognitive function according to cognitive status, quantify the “dose-effect” relationship between EGs and health benefits, and evaluate the effects of different types and devices of EGs with regard to the health benefits of older adults.

Introduction

Background

With fertility rates declining and life expectancies rising, the global population is aging [1]. The number of adults older than 65 years has tripled over the past 50 years and, by 2050, older adults will make up a quarter of the global population [2-4]. Aging can lead to degenerative changes in the physical and cognitive function of older adults, resulting in impaired daily life functions and reducing the independence of older adults, thereby affecting their mental health and increasing the burden of health care [5]. Physical dysfunction is increasingly common at end of life [6], and the global pooled incidence rate of older adult frailty in communities is 43.4 per 1000 person-years [7]. Mental health problems are also common among older adults in China, and it is reported that 21,129 out of 88,417 older adults (23.6%) have these problems [8].

The physical and mental decline of older adults may eventually have serious social and economic consequences for an aging society [9]. For physical decline, frail older people (97/177, 54.5%) needs more health care services than nonfrail older people (30/987, 2.2%) [10,11], and the median hospitalization cost of frail patients is more than twice that of healthy patients (US $44,408 vs US $18,660) [12]. Furthermore, frail people also require continuous care at 5.82-fold the rate of healthy people after discharge [13]. Regarding mental health, studies predict that worldwide care costs for dementia, which is associated with cognitive decline, will increase to US $2 trillion by 2030 [14]. At the same time, the global economic burden of mental disorders in 2010 was similar to that of cardiovascular diseases, higher than that of cancer, and is expected to more than double by 2030 (US $2.5 trillion vs US $6.1 trillion) [15]. Thus, measures must be taken to promote healthy aging. A proven effective strategy is regular physical exercise [16].

Exercise is defined as "planned, organized and repetitive physical activity" [17]. Several studies have shown that conventional exercises (CEs), such as aerobic, resistance, and combined exercise, can improve the physical function and mental health of older adults [18-23]. However, older adults may not exercise due to lack of access to sports venues (eg, the COVID-19 pandemic), inconvenience, or lack of motivation [24]. In addition, the long-term exercise adherence rate for CEs among older adults seems to be low [25,26]. Therefore, an increasing number of studies have considered possible alternatives to CEs.

Exergames (EGs) are a combination of exercise and gaming that allows people to physically interact with a web-based game scene on a screen [27]. It requires the player's physical performance, as the technology used in the game system tracks the player's movements to control those in the game, thus immersing the player [28]. For example, in a Kinect-based EG [29], the game uses infrared light and cameras in the Kinect system to capture and track the player's movements and creates a full-body 3D web-based map, which is rendered by the screen in front of the player. Participants stand in front of the screen, imitate the actions of digital characters on the screen, and adjust their movements in real time based on instant visual and auditory feedback. It can be implemented in community centers, retirement institutions, long-term care facilities, assisted living, nursing homes, burn centers, hospitals, and homes [30,31].

EGs are an interesting strategy for active aging and good mental health [32]. They have been proven to be acceptable, feasible, safe, enjoyable, stimulating, and self-motivating tools [30,33-35]. EGs can be carried out at home, alone, or in groups, which may make it easier for older adults to participate in exercise [35]. In terms of physical function and mental health, in some studies, it is found that the EGs are better than CEs [36-38]; some have reported that EGs are as effective as CEs [39,40]; yet others have concluded that the effects of CEs are better [41]. In short, there is controversy regarding the effects of EGs and CEs on the physical function and mental health of older adults.

Research Gap and Aim

While 2 systematic reviews have compared the impacts of EGs and CEs on older adults, the results were inconclusive [42,43]. One compared balance and prevention of falls for EGs versus CEs in healthy older adults, and 20 randomized controlled trials (RCTs) were included [42]. EGs were found to have greater improvements in posture control and dynamic balance than CEs [42]. The other review compared the impact of EGs versus CEs on the cognitive function of older adults; it included 13 studies for systematic review and 11 studies for meta-analysis [43]. The results showed no statistical difference between the EGs and CEs in cognitive function [43]. However, these systematic reviews (1) did not distinguish sedentary video games from EGs; (2) searched only PubMed, Web of Science, and Cochrane databases; (3) included non-RCTs and quasi-experiments; (4) did not consider inconsistencies in exercise content between EGs and CEs; and (5) failed to distinguish the effects of EGs alone from the effects of EGs combined with other interventions, such as CEs.

Therefore, a systematic review should be conducted examining all the evidence, using quantitative analysis to compare the impacts of EGs versus CEs on older adults. Our study aims to compare the health benefits of EG versus CE programs for older adults' physical function and mental health (cognitive function, depression, and quality of life [QOL]). The comprehensive research results may provide a basis for the choice of rehabilitation strategy for the healthy aging of older adults.

Methods

The PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analysis) was used to report this review [44].

Search Strategy

PubMed, Web of Science, Embase, Cochrane, CINAHL, and PsycINFO were searched using subject headings and keywords from their inception up to February 2023. We limited the publication language to English. Search strategies are shown in Multimedia Appendix 1. The references of all included studies were reviewed for further relevant research. If more information about relevant research was needed, we contacted the first author.

Criteria for This Review

Types of Studies

Published peer-reviewed reports of RCTs were included. We considered trials in which randomization was implied with at least 2 intervention arms (ie, EGs and CEs). Quasi-randomized studies were excluded. Abstracts, systematic reviews, case reports, and registered trial reports were also excluded.

Participants

Studies focused on older adults, where all participants aged 60 years or older, were included. Studies with a hybrid sample (ie, younger and older adults) and older adults with hemiplegia or other paralysis were excluded.

Types of Interventions

Activities carried out under sitting conditions and controlled by handheld devices (ie, sedentary video games) were excluded. There must be a group where the only intervention is EGs not combined with any other intervention, such as CEs or cognitive training.

Studies comparing EGs with CEs (eg, aerobic and endurance training, resistance or strength training, multicomponent training, balance training, high-intensity interval training, Tai Chi, yoga, dance, Otago, physical therapy exercises, ball exercise, and treadmill) were included. The CEs performed precisely the same physical activity as the EGs but did not involve web-based feedback.

Types of Outcomes

Primary Outcomes

Physical function is defined as the ability to perform and complete objectively measured performance-based tasks that assess cardiovascular fitness, muscle strength, flexibility, mobility, and balance [45]. Physical function was measured by the gait speed test, Berg balance test, sit-to-stand test, or 30-second chair stand test.

Secondary Outcomes

Cognitive function is defined as a broad set of thinking abilities that can be measured using performance-based tasks [23]. Cognitive function was measured by the Montreal Cognitive Assessment (MoCA) or Mini-Mental Status Exam (MMSE). If a study used both MoCA and MMSE to measure cognitive function, we extracted only the data measured by MoCA because a previous study has shown that MoCA is a better cognitive function measurement method and can detect cognitive heterogeneity well [46].

Depression was measured by the Geriatric Depression Scale. QOL was measured by SF-36 (36 health survey questionnaire).

Screening Process and Data Extraction

Screening Process

Two reviewers (XC and LW) independently conducted literature screening, first screening titles and abstracts to determine whether the research met the inclusion criteria.

Then the full text was obtained to determine whether the study was eligible for inclusion. If 2 reviewers had disagreements, a third reviewer was to be consulted to decide whether to include it. If disagreements could not be resolved through discussion, we would attempt to contact the corresponding author of the study for clarification.

Data Extraction

Two authors extracted data independently. The extracted data included first author, age, sample size (female %), population type, dosage of intervention, types of intervention, types of control, outcome, device, and results for the review objectives. We extracted data presented in figure and graph form when 2 review authors independently obtained the same results. Disagreements were resolved by a third reviewer. If data were missing, we would contact authors.

Quality Assessment

Methodological quality was assessed independently by 2 authors using the Cochrane risk-of-bias tool [47], which includes the following seven contents items: (1) random sequence generation, (2) allocation concealment, (3) blinding of participants and personnel, (4) incomplete outcome data, (5) selective reporting, and (6) other bias.

Statistical Analysis

We followed the *Cochrane Handbook of Systematic Reviews of Interventions* to process and analyze data for meta-analysis [47]. The results of EGs and CEs were compared after the intervention. All results are continuous variables. Meta-analysis was performed using Review Manager 5.4 software (Cochrane). Standard mean difference and 95% CIs were used for continuous data. Subgroup analyses based on gender distribution were performed. The results were regarded as statistically significant when $P<.05$ [47]. The heterogeneity test was quantified using the I^2 statistic and the chi-square P value. The I^2 statistic was considered low, moderate, or large at 25%, 50%, or 75%, respectively [48]. A chi-square P value of .05 or less suggests heterogeneous meta-analyzed studies [47]. The random model was selected because the included studies from different populations were heterogeneous. Publication bias was assessed by examining funnel plots.

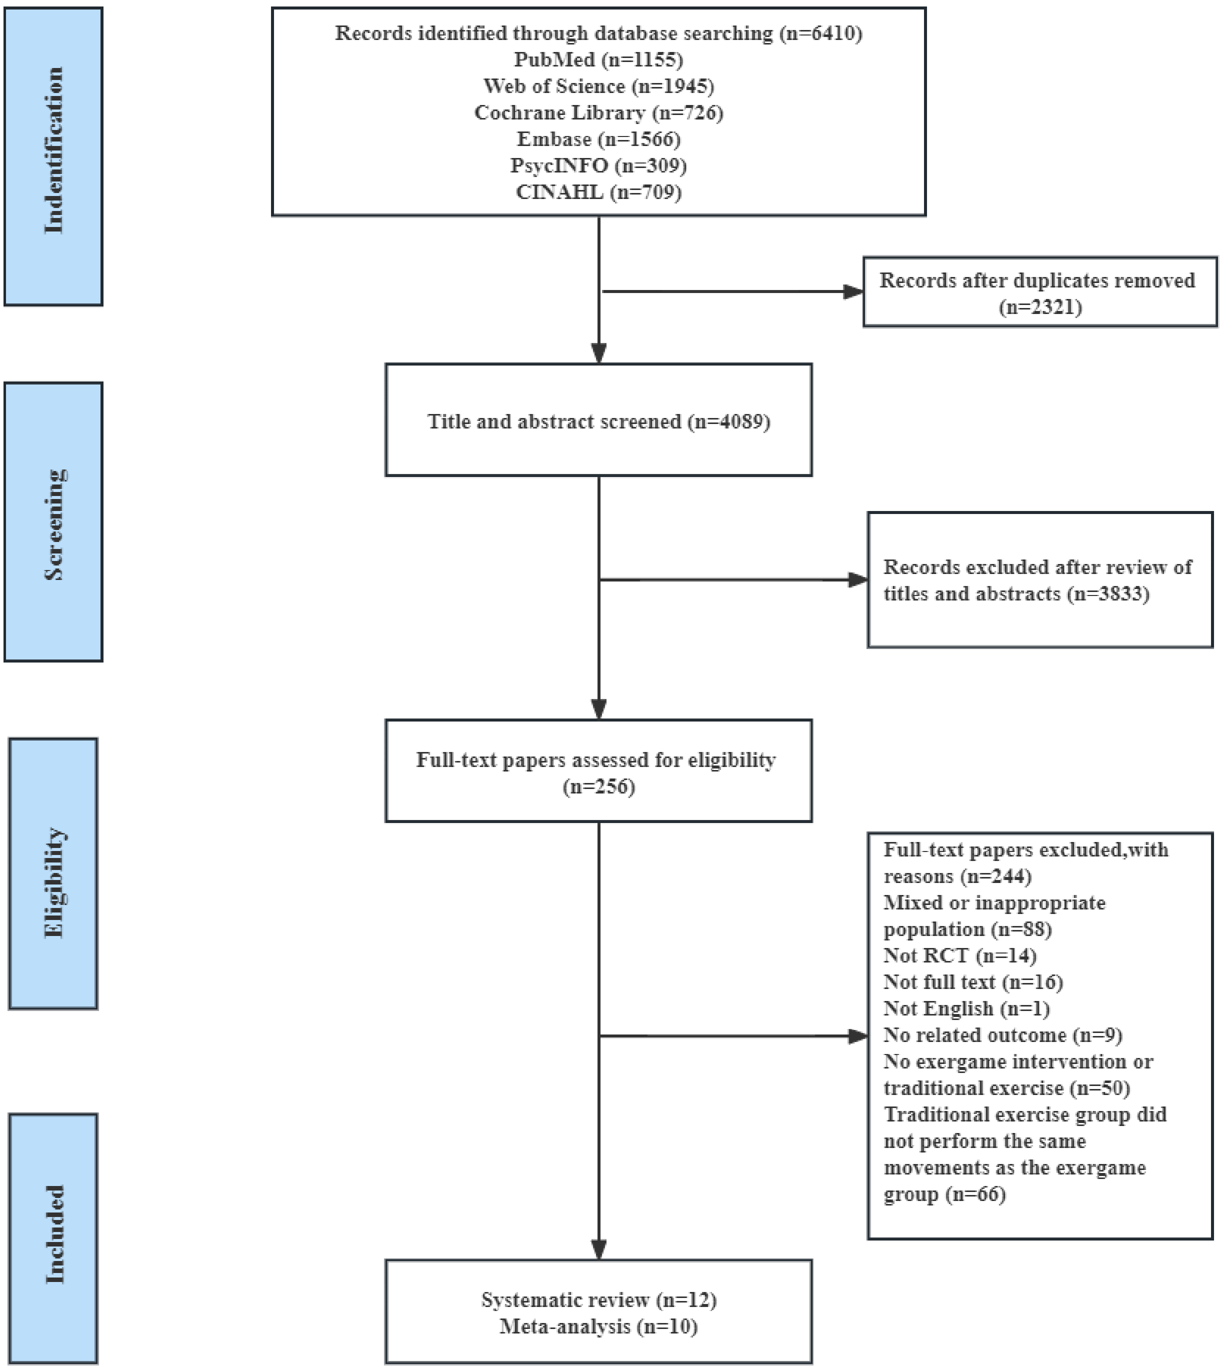
Results

Selected Studies

In total, 6410 potentially relevant studies were identified through database searching. After deduplication, the titles and abstracts of 4089 records were screened by checking the inclusion criteria; 256 studies were further screened by viewing the full texts for eligibility; 12 papers were included for the systematic review, and 10 papers were included for meta-analysis. Figure 1 shows the PRISMA flow diagram for paper selection.

Five studies focused on community-dwelling older adults [38,49-52], 3 studies recruited older adults from care facilities [29,40,53], 1 study was conducted in hospital and home [54], 1 study recruited older adults in a clinical physical rehabilitation unit [55], and 2 studies did not report the research setting [56,57]. Multimedia Appendix 2 [29,38,40,49-57] presents the characteristics of the included studies.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analysis) flowchart of the study selection process. RCT: randomized controlled trial.



Characteristics of Participants and Interventions

The 12 included studies had a total sample size of 919 participants, with individual studies ranging from 18 to 282 participants. One study only recruited women [56], 1 study had an equal proportion of female and male participants [55], 6 studies recruited more female participants [29,40,49,52,53,56], and 5 studies recruited more male participants [38,50,51,54,57]. In total, 6 studies focused on older adults with Parkinson disease [38,50,51,54,55,57], 1 on older adults with mild cognitive impairment [49], and 1 on frailty [29]; 4 investigated older adults without special conditions [40,52,53,56].

A 2-arm design was used in 11 studies, including an intervention arm and a control arm [29,38,40,50-57]; 1 study used a 3-arm design, including 2 intervention arms and a control arm [49]. The intervention duration ranged from 5 to 12 weeks, and the most widely used duration was 6 weeks. The frequency was 2 or 3 times per week, and the length of each session was 30 to 90 minutes. The older people in 2 studies only participated in a single session of exercise training [52,53]. In total, 4 studies used Nintendo Wii for the intervention [53,54,56,57], 5 studies used Kinect for the intervention [29,38,49-51], 1 study used Tymo for the intervention [55], 1 study used GRAIL for the intervention [52], and 1 study did not report the intervention device [40].

Among the control group exercises, 1 study consisted of squats, postural displacements, dance, and sports (volleyball and boxing) [53]; 1 included resistance exercise, aerobic exercise, Tai Chi, and balance exercises [29]; 1 included global exercises and balance exercises [57]; 1 used Tai Chi [49]; 1 included task-oriented exercise, walking, stretching, balance training, flexibility exercises, and coordination exercises [55]; 1 included passive range of motion for lower extremities, active free exercises, stretching exercises, strength training, resisted exercise, and balance training [54]; 2 included strength exercises and core training [40,56]; and 4 studies used treadmill training in the control group [38,50-52].

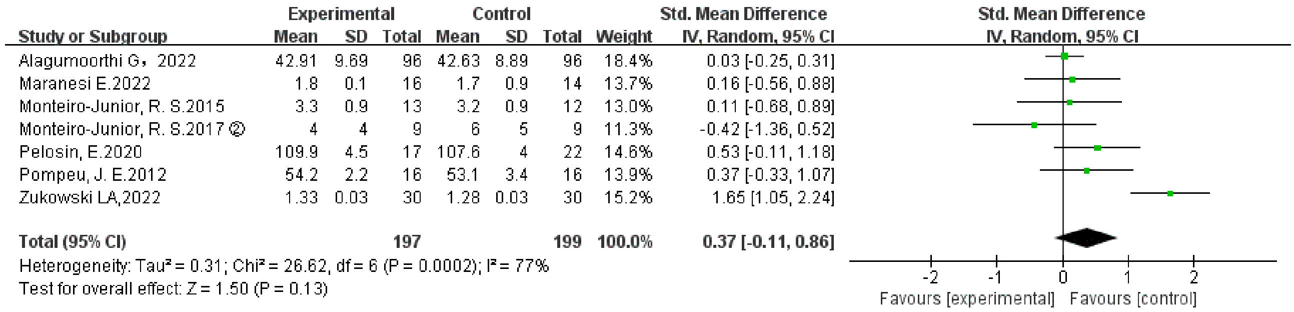
Meta-Analysis Results

Due to the lack of original data, we did not perform a meta-analysis of 2 papers [38,50].

Primary Outcome

Seven studies reported physical function according to the 30-second chair stand test, gait assessment (GaitRite, CIR Systems, United States), the sit-to-stand test, or the Berg balance test [40,51,52,54-57]. There was no significant difference between EGs and CEs (*P*=.13; τ^2=0.31; χ^2_6=26.6; I^2=77%; standardized mean difference [SMD]=0.37; 95% CI –0.11 to 0.86), more details in Figure 2.

Figure 2. Meta-analysis of the effect of exergames versus conventional exercises on physical function [51-57].

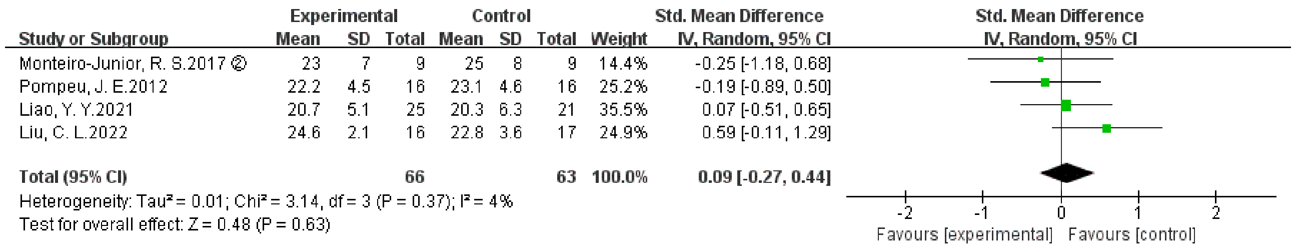


Secondary Outcome

Cognitive Function

Four studies reported cognitive function according to the MoCA or MMSE [29,40,49,57]. No significant difference was observed between EGs and CEs in MoCA or MMSE (*P*=.63; τ^2=0.01; χ^2_3=3.1; I^2=4%; SMD=0.09; 95% CI –0.27 to 0.44), more details in Figure 3.

Figure 3. Meta-analysis of the effect of exergames versus conventional exercises on cognitive function [29,49,53,57].



Depression

A single study reported depression and found no significant difference between EGs and CEs [40].

Quality of Life

Only 1 study reported QOL [38]. The results show that the SF-36 scores of the EG group improved more than those of the CE group.

Subgroup Analysis

To further compare the effects of EGs versus CEs on physical and cognitive functions in different gender distributions, the results of subgroup analysis are shown in Figures 4 and 5. No significant difference was observed in physical function between EGs and CEs when the percentage of females <50% (P=.23; τ^2=0.02; χ^2_2=2.4; I^2=18%; SMD=0.18; 95% CI –0.12 to 0.49) and when the percentage of females ≥50% (P=.40; τ^2=0.79; χ^2_3=19.5; I^2=85%; SMD=0.41; 95% CI –0.54 to 1.36). No significant difference was observed in cognitive function between EGs and CEs when the percentage of females <50% (P=.59) and when the percentage of females ≥50% (P=.42; τ^2=0.02; χ^2_2=2.3; I^2=13%; SMD=0.18; 95% CI –0.26 to 0.62).

Figure 4. Subgroup analysis of the effects of exergames versus conventional exercises on physical function [51-57].

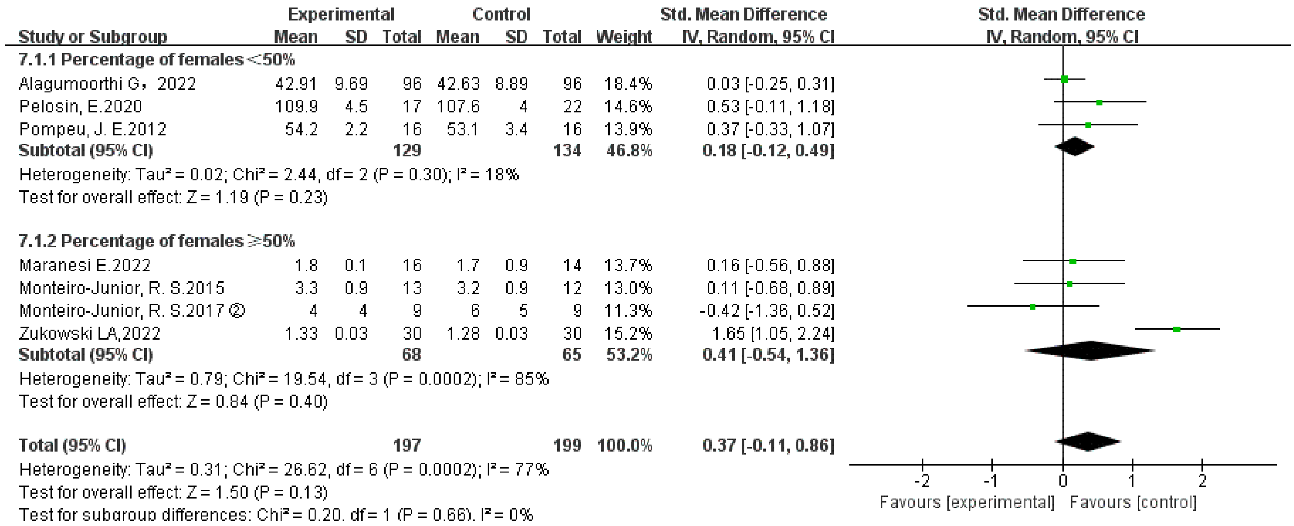


Figure 5. Subgroup analysis of the effects of exergames versus conventional exercises on cognitive function [29,49,53,57].

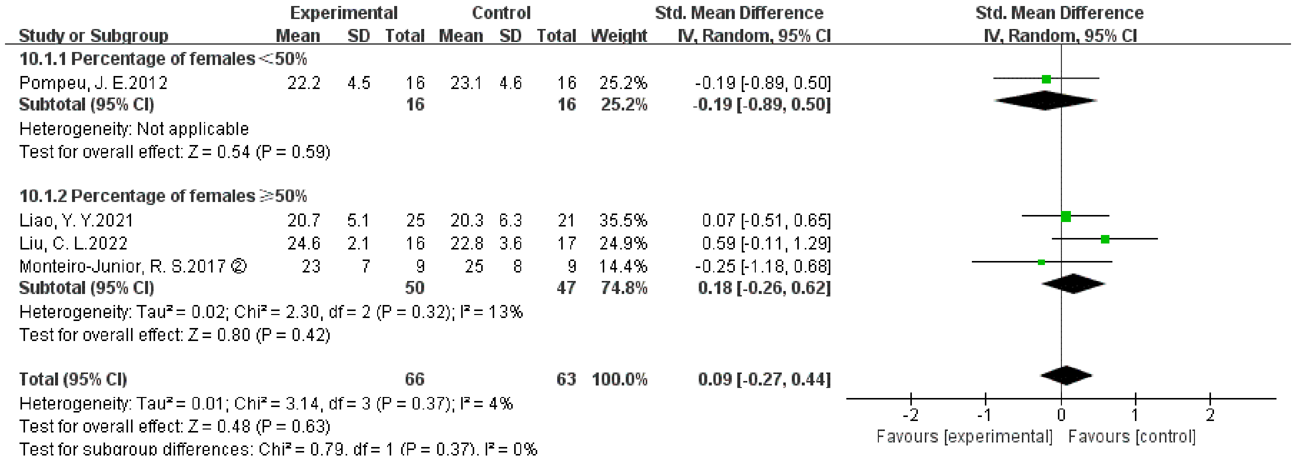
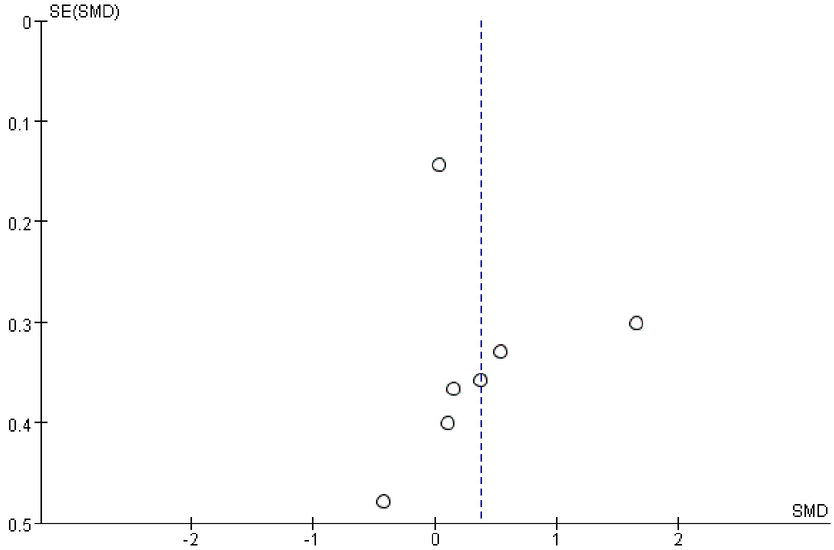


Publication Bias

The funnel plot did not show a clear funnel shape in physical function (Figure 6). The reason may be that some small studies with negative results may not favor the EG intervention.

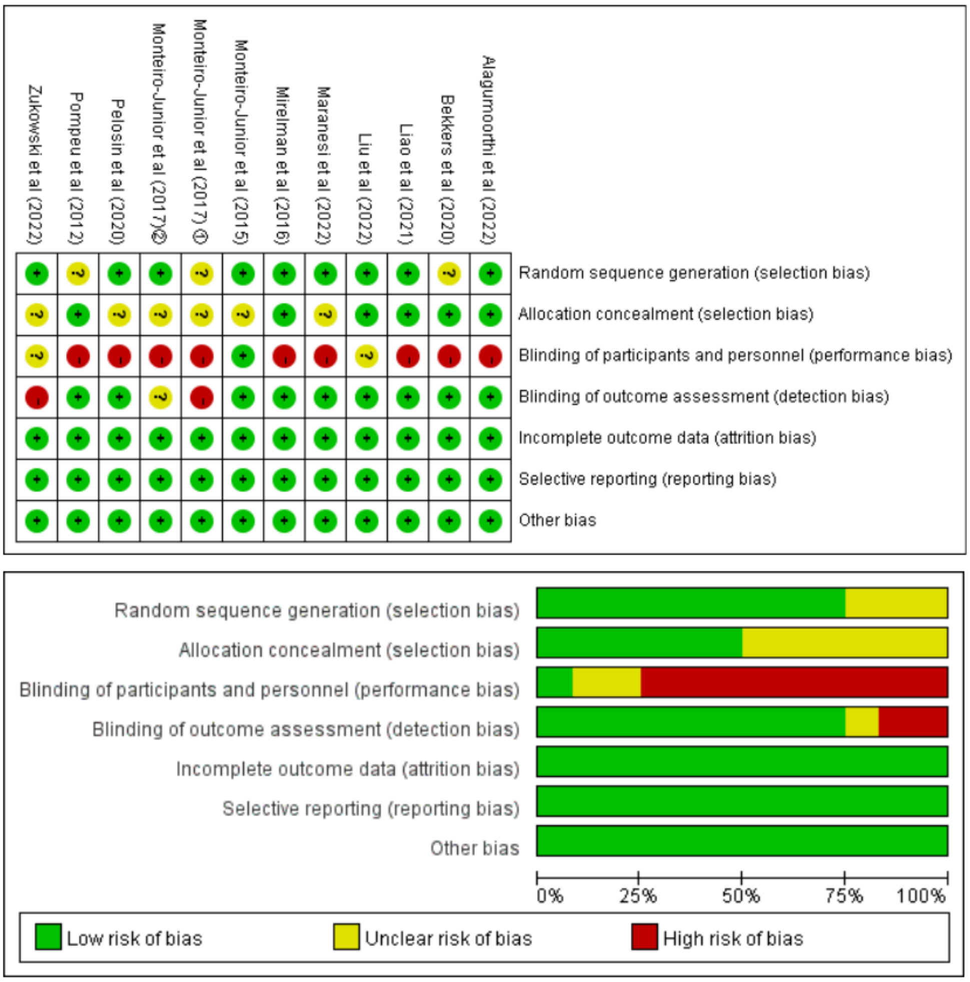
Figure 6. Funnel plot for publication bias assessment. SMD: standardized mean difference.



Quality Assessment

Figure 7 shows the results of the methodological quality assessment. The quality of the included studies was found to be acceptable. Regarding the risk-of-bias assessment [47], we found that 9 studies showed a high risk of performance bias [29,38,40,50,51,53,57], while 2 studies had unclear bias risk [49,56]. In total, 11 studies used a single-blind protocol [29,38,40,49-55,57], and 1 used a double-blind protocol [56]. Due to the EGs and CEs, it was not possible to blind patients or study personnel to the group allocation. High risk studies may overestimate the effect of EGs compared to CEs.

Figure 7. Analysis of the risk of bias in accordance with the Cochrane risk-of-bias tool [29,38,40,49-57].



Discussion

Principal Findings

By ensuring that EG and CE groups in the reviewed studies performed the same physical activity, this study is the first to compare the health benefits of EGs and CEs for older adults. We observed that EGs show potential as a novel approach for enhancing physical and cognitive function in older adults. The results of the meta-analysis show no significant difference in physical function or cognitive function between EGs and CEs after intervention. This means that EGs may replace CEs in these aspects. Our findings provide evidence of the beneficial effects of EGs, which may offer a promising strategy for promoting healthy aging in older adults. Given that EGs are an innovative, fun, and relatively safe form of exercise [58], this review presents timely evidence that suggests EGs could be a valuable tool for health professionals, such as physical therapists and occupational therapists.

The results show no significant difference in cognitive function between EGs and CEs. This supports the findings of previous studies [49,59,60]. One RCT with older individuals with dementia showed no significant difference in executive function, episodic memory, or working memory between EGs and aerobic training groups [60]. The other RCT suggested that the Kinect adventures training group and conventional physical therapy group had no significant difference in cognitive function after intervention, and both had positive effects on cognitive function in older adults [59]. In addition, EGs are inexpensive [61], safe [30,62], and easy to use [63], and healthy older adults living in the community can use them without supervision [64,65]. Therefore, the application of EGs in the cognitive rehabilitation of older adults should be promoted, especially for those with mild cognitive impairment or dementia.

However, our findings are inconsistent with a previously published systematic review and meta-analysis that compared the effects of EGs versus CEs on cognitive skills [43]. Based on that study, EGs seem to be more effective than conventional physical training for global cognitive performance. A possible reason is the potential ceiling effect [66]. The previous systematic review and meta-analysis included more patients with mild cognitive impairment or dementia, while our study included more older adults with normal cognitive function. Therefore, even before the intervention, the cognitive function of older adults in our study was quite good, which may make the improvement of cognitive function following EGs and CEs not obvious, resulting in a small difference in the improvement of cognitive function between the 2 groups. Thus, it is suggested that subsequent studies compare the effects of EGs and CEs on cognitive function according to the classification of the cognitive status of older adults.

Furthermore, EGs and CEs showed no significant difference in physical function. This is in accordance with previous findings [67,68]. This may be related to the impact of EGs on heart rate and energy expenditure similar to CEs [69]. Due to a lack of studies, we cannot analyze the impact of potential moderators (intervention time, intensity, and type of EG) on physical function. First, a subgroup analysis of the relationship between intervention time and effect shows that a weekly intervention affects physical function [42]. In that regard, there was no consensus on the duration of weekly interventions in the studies we included. Second, the intensity of EGs must be at least moderate to achieve the effect [69], while the included studies rarely measured the intensity of EGs. Finally, the types and devices of EGs will also affect the intervention effect. It is suggested that future studies explore the impact of different types and devices of EGs on the physical function of older adults. Subsequent studies should quantify the "dose-effect" relationship between EGs and health benefits in older adults, derive optimal intervention doses for EGs (eg, program period, weekly intervention duration, frequency, and intensity), and determine how different types and devices of EGs affect physical function in older adults.

Since gender distribution was very different among the studies, we performed subgroup analysis based on gender but found no difference in physical or cognitive function between groups at different distributions.

Only 1 study compared EGs versus CEs for depression, and only 1 paper compared the effects of EGs and CEs on QOL. The number of such studies is too small to conduct a meta-analysis. Therefore, future research needs to focus more on older adults' mental health and further explore and compare the effects of EGs versus CEs on depression and QOL.

According to the literature review, in addition to physical function and mental health, the included studies also compared adherence, motivation, cost-effectiveness, fall rates, accessibility, enjoyment, and attractiveness. One study showed no significant difference in adherence between EGs and CEs [38]; one study showed that the adherence of EGs was significantly higher than that of CEs [56]; and another study showed that EGs can improve the motivation and adherence of older adults in the long-term rehabilitation process [57]. One study found that EGs increased participants' motivation to do more repetitive movements with minimal or no instruction [54]; another study showed that the presence of motivating stimuli and the novelty aspect of EGs can be particularly important in patients with Parkinson disease who have reduced motivation [57]. One study reported that the extra cost of EGs is minimal compared to CEs (the costs of the computer, screen, safety harness, and platform are relatively low for medium-income countries) [38]. Three studies showed that the fall rate of older adults in the EG group was significantly lower than that in the CE group after the training [38,50,54]. Two studies reported that the advantages of accessibility, enjoyment, and attractiveness of EGs for older adults can further enhance the training effect of CEs [29,49]. However, the number of studies was small enough that a meta-analysis could not be done. We recommend that future research compares these outcomes between EGs and CEs because this information would be invaluable to establishing the added value of EGs versus CEs.

It is worth noting that while EGs may replace CEs in improving physical and cognitive function, it should be considered that not everyone is interested in EGs and not all EGs are suitable for older adults. A recent systematic review and qualitative meta-synthesis conducted by our group explored older adults' experiences of implementing exergaming programs [70]. We found that a small number of older adults were not interested in EGs, which may be due to age- or health-related factors (eg, vision, hearing, motor skills, or cognitive impairment). At the same time, most older adults have no experience with EGs and worry about whether they can understand and play such games correctly. In addition, people in East Asian countries (such as China, Japan, and South Korea) are more likely to feel embarrassed when using EGs because they feel uncomfortable being observed or judged by others. Finally, most existing EGs are not fully suitable for older adults due to a lack of flexibility and adaptability. However, most of these obstacles can be overcome, for example, by designing older people–friendly EGs for different target groups and giving older adults enough time to train and familiarize themselves with EGs.

This paper has limitations. Since we only included English-language studies, information deviations may occur. As exergaming is a fairly new field, there are few papers on this topic, and the number of studies included (and the total sample size) was not very large; thus, the results should be interpreted with caution. The overall methodological quality of the included studies ranged from medium to excellent, so our findings need to be interpreted with caution. Due to the heterogeneity of intervention types, intervention settings, intervention objects, and measurement tools for some outcome indicators, we were unable to conduct a comprehensive meta-analysis. The existence of publication bias resulted in heterogeneity (eg, differences in the intervention protocol) among the included studies, which reduced the quality of evidence. Finally, it must be acknowledged that the conclusions of this systematic review and meta-analysis may have been influenced by the professional backgrounds of the authors.

Conclusions

Our findings suggest that EGs are a novel and effective strategy for improving physical and cognitive function in older adults. There is no significant difference between EGs and CEs in improving the physical function and cognitive function of older adults, and EGs may replace CEs in these aspects. Our results confirm the effectiveness of EGs in rehabilitation programs for older adults and indicate that EGs may be a novel and feasible alternative to CEs. Future studies should compare the effects of EGs and CEs on cognitive function according to classification of the cognitive status of older adults. Subsequent studies should also quantify the "dose-effect" relationship between EGs and health benefits in older adults, derive optimal intervention doses for EGs, and explore the effects of different types and devices of EGs on physical function in older adults. More high-quality studies with more accurate outcome indicators are needed to further explore and compare the health benefits of EGs versus CEs.

Abstract

Background: Nursing professional skills training has undergone significant transformation due to the exponential growth of computer and medical technology. The innovative use of virtual reality (VR) in nursing education has emerged as a cutting-edge technical support technique that has gained attention as a highly effective method for improving nurse training quality.

Objective: This study aims to review the current status of VR technology in nursing professional skills training, research hotspots, and emerging trends in the last 15 years.

Methods: The Web of Science Core Collection database was used to search for literature on VR technology in nursing professional skills training covering the period from 2006 to 2022. Biblioshiny (K-Synth Srl) was used to import and convert the records to Bibliometrix (K-Synth Srl) for analysis, and R (R Core Team) was used for descriptive bibliometric analysis. VOSviewer (Leiden University) was used to cluster co-occurring keywords, and Scimago Graphica (version 1.0.16; Scimago Lab) was used to generate a geographical visualization of published countries and regions.

Results: A total of 1073 papers were analyzed, indicating a surge in research on the application of VR in nursing professional skills training in recent years, as evidenced by a positive trend in annual publication of relevant literature. The majority of studies were from the United States (n=340) and Canada (n=107), and Margaret Verkuyl was the most prolific author, leading the way with 9 publications. Furthermore, “Computerized Virtual Patients in Health Professions Education: a Systematic Review and Meta-Analysis” was the most frequently cited reference. Keywords such as *education*, *simulation*, *skills*, *students*, and *care* were most commonly used by researchers.

Conclusions: The bibliometric analysis provides a comprehensive overview of the use of VR in nursing professional skills training, indicating that VR-based training is an effective means of improving the skills and competencies of nursing students and professionals alike. The COVID-19 pandemic has reinforced the importance of developing VR-based distance education, despite challenges such as integrating virtual and real-world training and mitigating safety risks.

Introduction

Background

Nursing work holds a crucial position in health care. Nursing students, serving as a valuable pool of talent for the clinical nursing team, are essential figures in the advancement of nursing practice. They play a pivotal role in promoting the growth and development of the nursing profession and are a crucial component of the health care workforce [1]. Nursing educators face a significant challenge in cultivating the necessary expertise and skills among nursing students to provide effective patient care [2]. Considering the low efficiency of traditional nursing professional skills training methods, it can be challenging to motivate nursing students to engage with enthusiasm [3]. To ensure that nursing students possess sufficient expertise and are qualified to work in hospitals, many nursing educators use a variety of teaching strategies, including using VR, to enhance the quality of nursing professional skills training.

A virtual reality (VR) system can be defined as a highly interactive 3D digital media environment that generates a simulated reality and creates an immersive experience through the user's senses of vision, hearing, and touch. Essentially, it provides users with the feeling of being present in a separate virtual environment. The characteristics of VR systems can be summarized into 3 pivotal elements: immersion, interactivity, and sensory perception [4]. VR technology has been extensively applied in nursing theory teaching, nursing skills training, and clinical nursing teaching, both domestically and internationally. Yang and Huang [5] found that traditional nursing skills teaching fails to replicate the actual clinical environment. Students often lack the opportunity to gain genuine sensory experience of nursing operations and may learn various nursing procedures in a conventional and generic manner. This may hinder their ability to effectively transition into clinical work in the early stages of their career. Chu et al [6] showed that a VR-based immersive experiential learning model could be implemented for teaching and that situational learning was achieved through virtual laboratory and simulation training. Gao and Yao [7] provided a new idea for a method to teach endoscopic retrograde cholangiopancreatography to nurses by combining a VR endoscopic simulation system with microteaching. Jung and Park [8] built a head-mounted VR platform to enable students to observe the process of intravenous catheter implantation by modeling the angiography room. These examples provide a compelling argument for the potential of VR technology in enhancing the professional skills of nurses and nursing students.

Research Problem and Aim

The concept of "bibliometrics" was proposed by Pritchard in 1969, and it is defined as "the application of mathematical and statistical methods to books and other knowledge dissemination media" [9]. Bibliometrics offers a highly efficient tool for analyzing the progress of scientific research. It enables quantification of information on a specific research topic derived from online scientific citation databases, such as details on authors working in a field, publication numbers, and the distribution of research institutions [10]. Bibliometrics is a powerful tool that can assist in identifying significant literature in a research field and provide valuable data, such as keywords, institutions, country linkages, and distribution characteristics, in the form of a knowledge map. By quantifying the current state and future trends of the research topic, bibliometrics serves as an essential aid in comprehending the development of a particular field [11]. Generally, the greater the number of references included in a bibliometric method, the better we can comprehend the landscape of a research field [12]. A scoping review conducted by Yang and Huang [5] outlines the applications of VR technology in nursing professional skills training. There has been limited research on the scientific output of this field using bibliometric and visualization analyses. As a result, it is critical to comprehend the research status and hot spots of this field to aid in the advancement of nursing professional skills for nurses and nursing students. This study strives to offer a comprehensive analysis of the research field using the Web of Science (WOS) Core Collection as a basis and to serve as a valuable reference for future research.

Methods

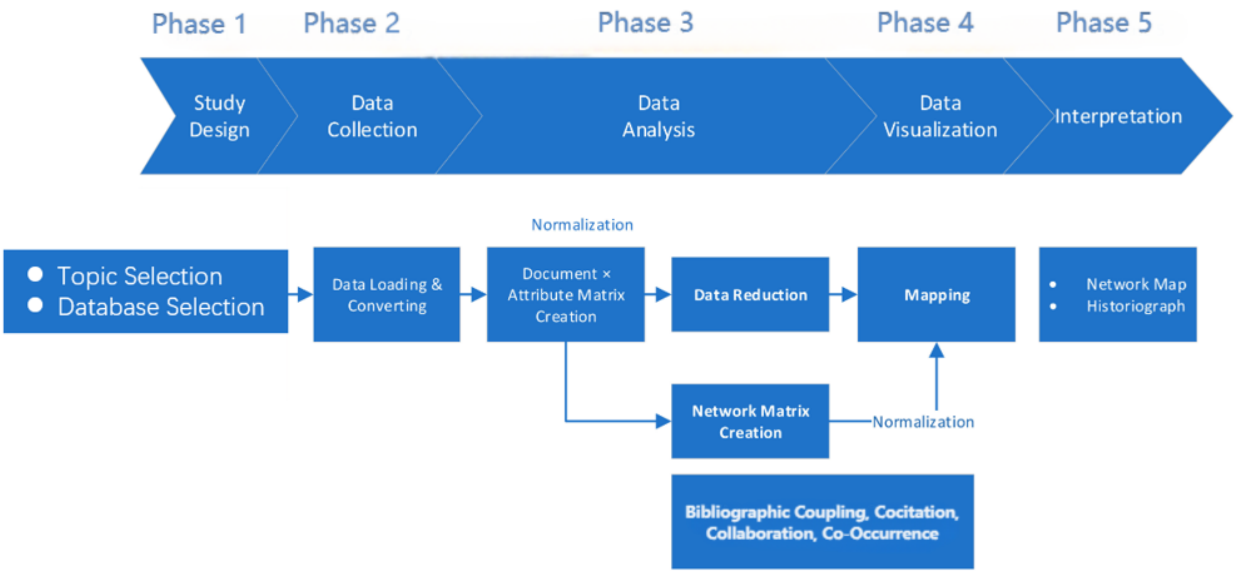
Data Sources and Search Strategy

For this study, articles and reviews that were published in English between 2001 and 2021 were included, using the WOS Core Collection database as the primary data source: (1) the retrieval expression was constructed using a formula that used a Boolean logic operator: TS=(virtual reality OR VR OR virtual medicine OR augment reality OR mixed reality OR virtual simulation) AND TS =(nursing* OR nursing practice OR nursing training OR academic training OR serious game), and the scope of literature was restricted to only articles and reviews; (2) the English language was selected; (3) there were 1073 documents retrieved in the search of WOS (as updated on 11 November 2022); and (4) all records were exported to plain text files, including the full record and cited references.

Bibliometric Analysis

A description of the bibliometric analysis method can be found in Aria and Cuccurullo [13]. Five rigorous steps, namely study design, data collection, data analysis, data visualization, and interpretation, were included in the analysis [14]. The complete methodology is schematically illustrated in Figure 1. The initial stage was the study design phase; nursing professional skills training was selected as the study topic. The research data resource chosen was the WOS Core Collection database, from which literature retrieval returned 1242 documents during the data collection phase. The review followed the structured approach outlined by Kable et al [15] for researching and evaluating literature. In this study, 2 reviewers (CH and LW) conducted an independent screening of the search results, with cross-checking used to resolve any disagreements. Training in document retrieval and screening was received by all researchers based on the textbook *Medical Literature Information Retrieval* [13]. A document-type filter was applied to the WOS, and articles and data papers were included, resulting in a sample of 1073 papers published between 2006 and 2022. All records were imported to Biblioshiny (K-Synth Srl) and converted to Bibliometrix (K-Synth Srl) for subsequent analysis. In the third stage, R (R Core Team) was used for descriptive bibliometric analysis and to develop a matrix of all documents. Biblioshiny, the Tidyverse package ggplot2 (Hadley Wickham), and VOSviewer (Leiden University) were used in the fourth stage to create a keyword cluster map. Scimago Graphica (version 1.0.16; Scimago Lab) was used to generate geographic visualization maps of the countries or regions. To identify influential sources, the Bradford law was used to unveil the journal distribution. The Methods section presents an interpretation of the data analysis and visualization outcomes.

Figure 1. Diagram illustrating the methodology of the bibliometric analysis, adapted with consent from the work of Aria and Cuccurullo [13] and Secinaro et al [14].



Ethical Considerations

An ethical approval application was not filed for this paper. The Chinese Hospital Association has stated that an ethics review is unnecessary for secondary analyses of published data.

Results

Descriptive Bibliometric Analysis

Each period's publication count is a reflection of the research field's development trends. Figure 2 presents the scientific output over the course of the study. There were 3 periods based on the number of publications: 2006 to 2013, 2014 to 2019, and 2019 to 2022. As seen in Figure 2, no relevant papers were released before 2006. From 2006 to 2013, the number of published articles increased annually, but at a relatively sluggish pace. The quantity of publications in 2019 (n=76) surpassed 75 for the first time. The number of articles published between 2019 and 2021 increased significantly, indicating that more scholars were focusing on the potential of VR in the nursing professional skills training field. Table 1 provides essential details on the 1073 research papers published in the WOS Core Collection database from 2006 to 2022. The annual average number of published research papers was 61.29, with each paper having an average citation count of 11.52. These papers had 4369 authors, with 59 of them being single-author papers. The average number of authors for each research paper was 2 (2.33). The collaboration index, which is the total number of authors of multi-authored papers divided by the total number of multi-authored papers, was 2.38. These papers also produced a total of 2388 author keywords.

The WOS Research Areas

One or more subject categories (SCs) are linked to each publication indexed in the WOS. In this study, the number of research areas covered by VR-based nursing professional skills training education literature increased from 2 in 2006 to 22 in 2022 (Figure 3). Figure 4 displays the annual changes in productivity in the top 10 areas of VR-based nursing professional skills training education, which illustrates changes in the focus areas of VR-based nursing professional skills training education. The most popular research area was nursing, followed by education and educational research and health care sciences and services. With the increasing maturity of VR technology and stable production of VR equipment, the explosive growth in publications in the field of nursing professional skills training can be attributed to the use of various teaching strategies, including VR, by many nursing educators to enhance the quality of education.

Figure 3. The count of Web of Science research areas included in the literature of VR-based nursing professional skills training.

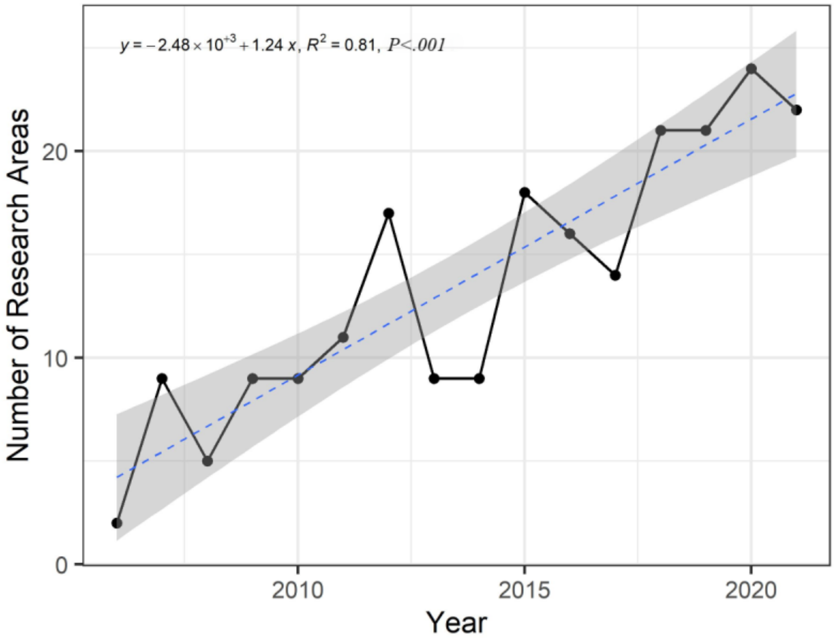

Figure 4. Yearly variations in the productivity of the top 10 Web of Science research areas in specific fields.

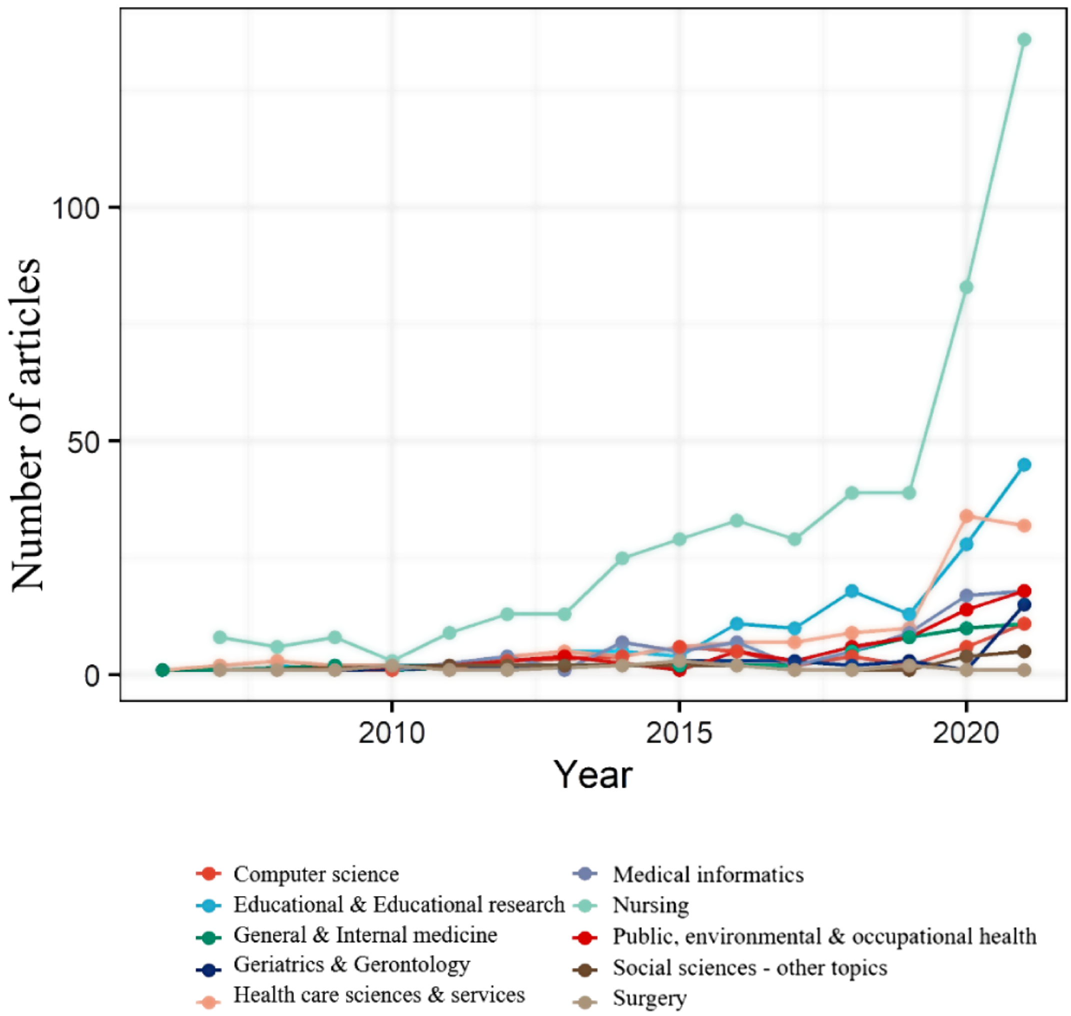

Research Countries and Institutions

Table 2 highlights that the United States has contributed the highest number of publications (340/1042, 32.63%) in the domain of VR-based nursing professional skills training, followed by Canada (107/1042, 10.27%), China (89/1042, 8.54%), Australia (71/1042, 6.81%), and the United Kingdom (51/1042, 4.89%). Of the total number of articles, 64.65% (658/1042) were published in these 5 countries. To generate a geographic visualization map (Figure 5), countries with more than 5 publications were analyzed using Scimago Graphica. The lines on the map indicate the degree of cooperation between different countries, with the thickness of the lines reflecting the extent of cooperation. It is evident from the map that the United States, Canada, Australia, China, and other countries have actively collaborated with other countries. Additionally, several scholars from Europe have shown interest in VR-based nursing professional skills training education and have conducted joint research projects to a certain extent. Table 3 highlights that while the United States has the highest number of publications, Canada's top 10 institutions rank higher in total citations, suggesting that both countries have robust support and funding for VR-based nursing professional skills training research.

Table 2. Countries with the highest total citation count for virtual reality–based nursing professional skills training research, ranked by the top 10.

Ranking	Country	Articles, n	Citations, n
1	United States	340	4215
2	Canada	107	1186

Most Influential Source Journals

Table 4 shows that *Clinical Simulation in Nursing* was the most cited journal with 1401 of 30,766 total citations (4.55%), while the *Journal of Medical Internet Research*, with an impact factor of 7.077, was the most impactful among the top 10 academic journals. Half of the journals in the table were ranked in the top quartile position. We also analyzed the distribution of research papers among leading sources and found that the top 5 journals accounted for 304 of 1042 (29.17%) of the total number of papers. The top 5 journals with the highest numbers of papers published were *Clinical Simulation in Nursing* (n=125), *Nurse Education Today* (n=93), *Journal of Nurse Education* (n=32), *Journal of Medical Internet Research* (n=27), and *Nurse Education in Practice* (n=27), with *Clinical Simulation in Nursing* having the most local citations (Table 4). According to the Bradford law, the source journals of VR-based nursing professional skills training papers were widely scattered, and the top 10 most influential journals were selected based on the number of local citations. Journals that were identified as core source journals in the field of VR-based nursing professional skills training according to the Bradford law are marked in Figure 6. These included *Clinical Simulation in Nursing*, *Nurse Education Today*, *Journal of Nurse Education*, *Journal of Medical Internet Research*, *Nurse Education in Practice*, *CIN-Computers Informatics Nursing*, and *Journal of Advanced Nursing*. These journals played a crucial role in the development of VR-based nursing professional skills training during the study period.

Table 4. Ranking of the top 10 journals in VR-based nursing professional skills training based on the number of local citations.

Journal	Local citations, n	Documents, n	Impact factor[b]	Rank (quartile)
Clinical Simulation in Nursing [a]	1401	125	2.856	Q1
Nurse Education Today [a]	1397	93	3.906	Q1
Journal of Nursing Education [a]	526	32	2.381	Q2
Journal of Medical Internet Research [a]	470	27	7.077	Q1
Nurse Education In Practice [a]	440	27	3.43	Q1
CIN-Computers Informatics Nursing [a]	421	25	2.146	Q3
Journal of Advanced Nursing [a]	407	19	3.057	Q1
Nurse Educator	385	18	2.791	Q1
JMIR Serious Games	382	18	3.364	Q2
Nursing Education Perspectives	343	17	0.59	Q3

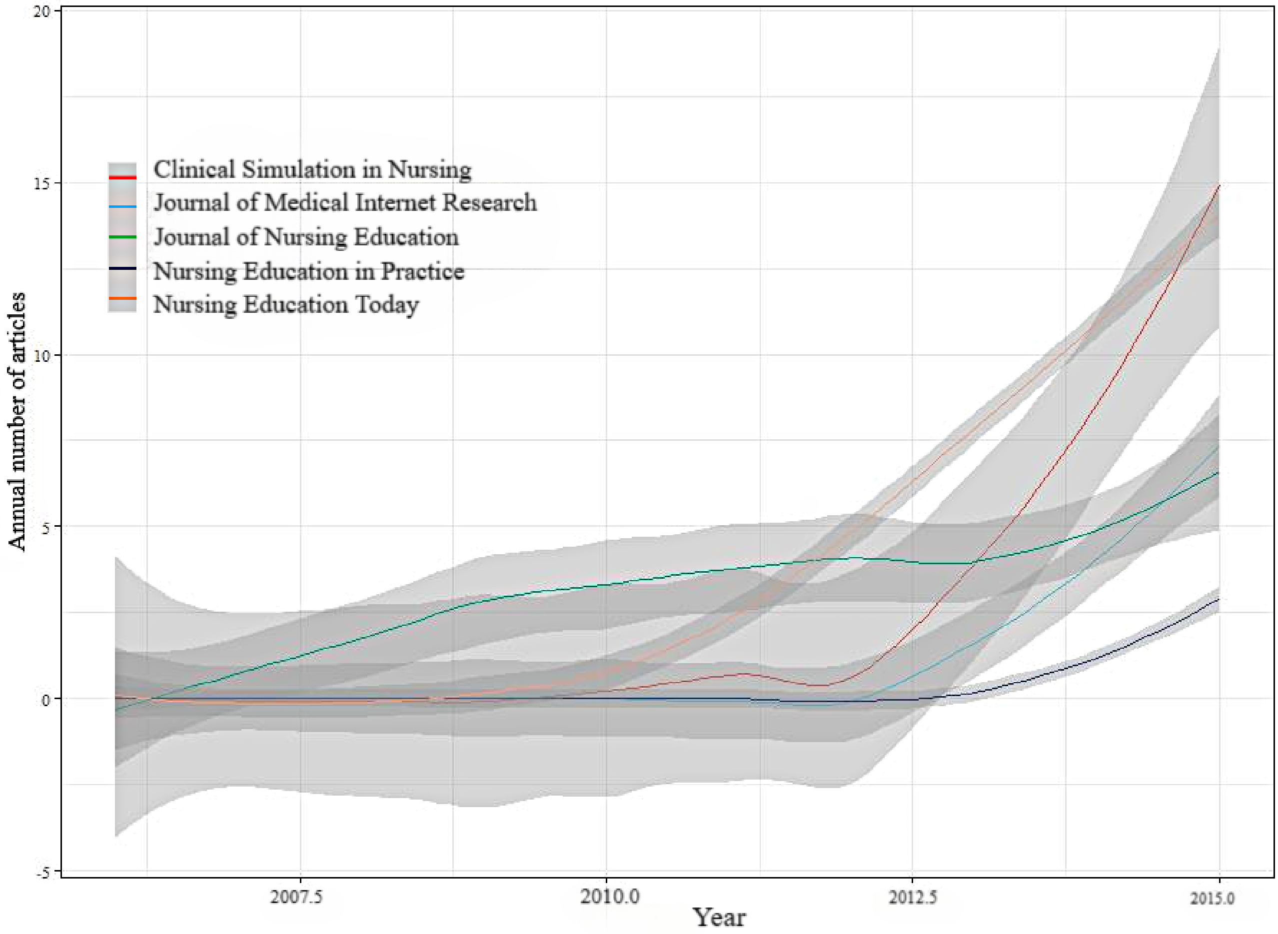
[b]Impact factor in 2021.

Figure 6. Temporal analysis of the publication sources of virtual reality–based nursing professional skills training.



Most Influential Authors

The H index is a widely accepted measure of scientific performance based on the number of citations received by a scientist's published papers [16]. Table 5 shows the top 10 authors with the largest H index: Margaret Verkuyl (H index 9), Shujuan Liao (H index 7), Daria Romaniuk (H index 7), Hilde Eide (H index 6), Sharon L Farra (H index 6), Michelle Hughes (H index 6), Paula Mastrilli (H index 6), Michelle Aebersold (H index 5), Lynda Atack (H index 5), and Luciana Mara Monti Fonseca (H index 5). The researcher with the highest number of citations, indicating significant influence, was Margaret Verkuyl. She is also the author with the highest density of collaboration (Figure 7). The top 10 most influential researchers included researchers from Canada (n=5), China (n=1), Norway (n=1), Brazil (n=1), and the United States (n=2). The 1073 papers involved 4369 authors. In total, 59 authors published 65 documents as sole authors, with an average of 4.92 co-authors per document and a collaboration index of 0.23. Each author contributed an average of 0.246 documents to the field, and on average, each document had 1.1 authors and 4.92 coauthors. These findings suggest that VR-based nursing professional skills training research is often a collaborative effort involving multiple authors.

Table 5. Authors ranked by the H index, with the top 10 being the most influential.

Author	H Index	G Index	Times cited[a], n	Scientific productions, n	First year published	Country
Margaret Verkuyl	9	16	268	21	2016	Canada
Shujuan Liao	7	13	250	13	2014	China
Daria Romaniuk	7	9	183	9	2016	Canada
Hilde Eide	6	10	124	10	2011	Norway
Sharon L Farra	6	7	114	7	2013	United States
Michelle Hughes	6	9	147	9	2017	Canada
Paula Mastrilli	6	10	165	10	2016	Canada
Michelle Aebersold	5	5	126	5	2015	United States
Lynda Atack	5	7	137	7	2016	Canada
Luciana Mara Monti Fonseca	5	8	68	8	2014	Brazil

Most Influential Papers

This section provides a list of the most influential papers (based on the number of citations) published between 2006 and 2022. Cocitations within a group of authors suggest that certain documents may include concept symbols. It is noteworthy that Tables 6 and 7 show a difference between the local citation score (LCS), which reflects the number of citations within the field, and the global citation score (GCS), which represents the total number of citations in WOS. The paper with greatest influence according to LCS was "Clinical Virtual Simulation in Nursing Education: Randomized Controlled Trial" (n=49). The paper with greatest influence according to GCS was "Computerized Virtual Patients in Health Professions Education: a Systematic Review and Meta-Analysis" (n=273). The papers in question may encompass theories that form the foundation of the field, early works that lay groundwork, and methodological principles [17].

Table 6. Top 10 papers ranked by the local citation score.

Paper	Year	Journal	Local citation score	Global citation score
Padilha et al [18]	2019	*J Med Internet Res*	49	108
Foronda et al [19]	2020	*Simul Healthc*	49	87
Cobbett and Snelgrove-Clarke [20]	2016	*Nurs Educ Today*	43	62
Cant and Cooper [21]	2014	*Nurs Educ Today*	39	94
Butt et al [22]	2018	*Clin Simul Nurs*	35	74
Cook et al [23]	2010	*Acad Med*	33	273
Padilha et al [24]	2018	*Clin Simul Nurs*	27	48
Duff et al [25]	2016	*Clin Simul Nurs*	26	50
Verkuyl et al [26]	2017	*Clin Simul Nurs*	26	50
Kidd et al [27]	2012	*J Psychosoc Nurs Men*	26	60

Table 7. Top 10 papers ranked by the global citation score.

Paper	Year	Journal	Local citation score	Global citation score
Cook et al [23]	2010	*Acad Med*	33	273
Cook et al [28]	2013	*Acad Med*	3	193
Zendejas et al [29]	2013	*J Gen Intern Med*	1	173
Foronda et al [30]	2016	*Nurse Educ Pract*	3	166
Gentry et al [31]	2019	*J Med Internet Res*	22	135
Kipping et al [32]	2012	*Burns*	6	130
Triola et al [33]	2006	*J Gen Intern Med*	13	123
Padilha et al [18]	2019	*J Med Internet Res*	49	108
Robert et al [34]	2014	*Front Aging Neurosci*	1	107
Manera et al [35]	2015	*Front Aging Neurosci*	3	106

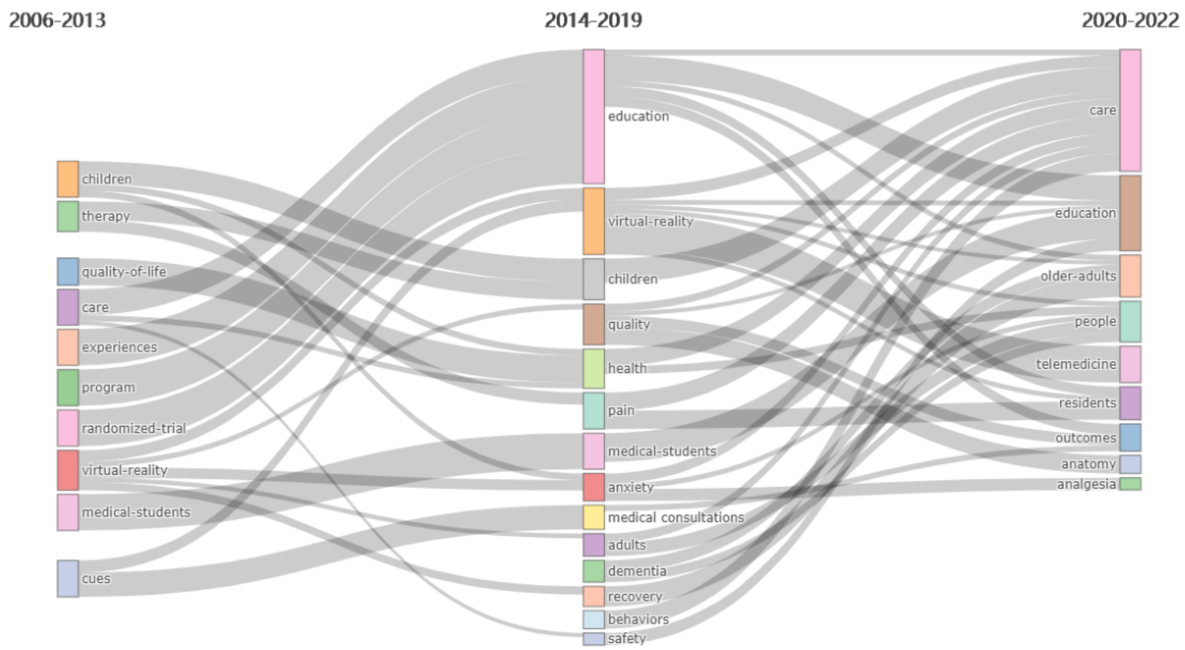
Distribution of Keywords

By conducting data cleaning to eliminate coding errors that could arise from different articles using varying keywords to introduce the same concept, we identified 2388 author keywords in 1073 published papers on VR-based nursing professional skills training between 2006 and 2022. The keyword analysis enables summary of the study's topics in the field and exploration of hotspots. For instance, *nursing* and *nurses* were recorded as *Nurses* to prevent discrepancies. *Education* had the highest frequency of 178 among the keywords, with other high-frequency keywords being *Simulation* (n=148), *Skills* (n=95), *Students* (n=84), *Care* (n=77), *Impact* (n=64), *Knowledge* (n=64), *Nurses* (n=62), *Virtual-reality* (n=58), and *Technology* (n=47), as shown in Table 8. Additionally, Multimedia Appendix 1 shows a keyword cluster map created using VOSview, while Figure 8 depicts the thematic evolution of the keywords.

Table 8. Top 10 keywords related to the application of virtual reality in nursing professional skills training.

Ranking	Keyword	Frequency	Centrality
1	*Education*	178	0.06
2	*Simulation*	148	0.05
3	*Skills*	95	0.04
4	*Students*	84	0.03
5	*Care*	77	0.05
6	*Impact*	64	0.06
7	*Knowledge*	64	0.05
8	*Nurses*	62	0.02
9	*Virtual-reality*	58	0.03
10	*Technology*	47	0.05

Figure 8. Map showing thematic evolution of keywords.



Discussion

General Information

Based on the annual number of publications, the publication years can be divided into 3 phases: 2006 to 2013, 2014 to 2019, and 2019 to 2022. The first phase, spanning from 2006 to 2013, saw an increase in the number of articles, albeit at a relatively slow growth rate. The second phase, from 2014 to 2019, was marked by significant advancements in VR device and software technology. This was exemplified by the launches of Project Glass by Google in 2012 and the first generation of the Oculus Rift VR headset by Oculus. These improvements resulted in an increase in the availability and quality of VR components [17]. In the period between 2014 and 2021, there was a noticeable increase in interest among scholars in computer science, as evidenced by periods 2 and 3. In the most recent phase, from 2019 to 2021, the number of publications exceeded 75 for the first time, with 76 articles published. This trend indicates an expanding interest among scholars in exploring the potential of VR technology in the field of nursing professional skills training.

Contributions to VR-based nursing professional skills training came from various countries worldwide, including the United States, Canada, China, Australia, the United Kingdom, Brazil, Korea, Spain, Singapore, and Turkey, with some taking a more prominent role. Notably, China is one of the few Asian countries to contribute to this field, indicating a lack of research emphasis on this topic among Asian scholars. In contrast, Canadian institutions and scholars have demonstrated continued interest in research in this area. A bibliometric analysis of VR and nursing professional skills training revealed Canada to have the highest contribution among all countries [23].

The frequency of cocitation can serve as a reflection of a journal's quality and influence. Among the ten journals with the highest cocitation frequency, half were found to be ranked in the top quartile. This suggests significant impact and recognition in the international community, indicating that the application of VR in nursing professional skills training has gained worldwide attention.

Following the analysis of cocited papers, it was found that "Clinical Virtual Simulation in Nursing Education: Randomized Controlled Trial" (n=49) was the most influential paper in terms of LCS. This study may contain foundational theories, pioneering early work, and methodological principles in the field. Similarly, "Computerized Virtual Patients in Health Professions Education: a Systematic Review and Meta-Analysis" (n=273) was deemed the most influential paper in terms of GCS. These works demonstrate how innovative research can impact an academic discipline for years to come and continue to inform contemporary research in the field.

Research Hot Spots and Frontiers

By using a combination of high-frequency keyword statistics, visualization analysis, and including relevant literature, this study indicates that an overwhelming majority of both domestic and international researchers have concentrated their efforts on exploring the application of VR technology in nursing education with a particular emphasis on nursing professional skills training.

Owing to variations in technological advancement, each country and region has conducted research to its own specifications with regards to the use of VR in nursing education. As an illustration, the VR nursing skills training system can provide a significant contribution to ensuring the proficiency of nursing students by enabling them to learn essential operational skills without the need for physical attendance, thereby providing them with the opportunity to review training materials anywhere at any time [23]. International research in this field commonly uses desktop VR system software to enhance students' clinical thinking skills. This type of software emphasizes immersive patient scenarios presented on the computer screen in which students are "placed" in a simulated clinical setting to observe and address the patient's discomfort and pain. The aim is to develop students' proficiency in making informed clinical decisions based on complex patient conditions [36]. The VR system can be improved in a short time according to teaching and learning needs, quickly meeting the skills training and teaching needs of various courses and improving the training effect. In order to give full play to the maximum benefit of the virtual system, it is suggested that schools and hospitals with suitable conditions choose VR technology to carry out skills training for students and promote their early adaptation to clinical practice.

In the field of nursing education, there are notable technical issues that exist with the application of VR technology at present. Caylor et al [37] pointed out that VR systems are faced with the problem of unclear navigation mechanisms within the operation interface. Poor experiences among nursing students during simulation learning are attributed to the confusing nature of the navigation interface within VR software platforms. Wilson et al [38] suggested that in future research on VR technology more attention be given to creating a simulation system with high fidelity, increasing the complexity of the cases presented within VR and reproducing challenging clinical case scenarios to enhance subjects' diagnostic reasoning abilities. Moreover, the development level and quality of VR software must be improved. This improvement is necessary due to the lack of understanding among VR technicians of the medical care field, which leads to failures to accurately reflect the key points and difficulties that teachers aim to emphasize. Additionally, it is vital to combine the advantages of VR teaching with existing nursing practices to ensure that VR technology is used effectively in nursing education [39]. To maximize the potential of VR technology in nursing education, researchers must consider providing a more comprehensive VR technology intervention, emphasizing multidisciplinary cooperation, and enhancing the familiarity of software technology developers with the nursing field. Additionally, teachers' proficiency in the operation of the virtual teaching process must be improved. To better explore the efficacy of VR technology in nursing education, it is crucial to enhance the VR teaching environment to improve nursing students' ability to apply the skills learned in virtual settings to clinical practice.

Applications and Development Trends in Research

Over the last 15 years, VR technology has been extensively implemented in nursing professional skills training. As mobile computing and sophisticated software programs continue to develop, highly immersive VR systems have become increasingly affordable and accessible [40]. Popular VR systems currently used in nursing professional skills training include Kinect from the United States, Nintendo Wii from Japan, HTC Vive from Taiwan, China, and Samsung Gear VR from South Korea. By integrating these VR systems into nursing education, we aim to facilitate the development of students' initiative and promote self-directed learning abilities, ultimately enhancing their clinical practice acumen.

As COVID-19 continues to impact the world, students' access to skills training may be limited. However, VR technology offers a viable solution to this problem. VR-based nursing skills training immerses students in a simulated environment, offering an opportunity to develop critical skills despite the pandemic. According to research, the use of a VR immersive experiential learning model for teaching fosters situational teaching through virtual laboratory and simulation training [6]. Furthermore, Gao and Yao [7] combined use of a VR endoscopic simulation system with the microteaching method to provide a new idea for teaching nurses endoscopic retrograde cholangiopancreatography. Jung and Park [8] developed a head-mounted VR platform for observing the process of intravenous catheter implantation in a highly realistic sensory scenario. This platform enabled students to view the entire arterial and venous system of the body, strengthening their theoretical and practical operation skills. Zhang et al [41] developed a highly realistic scenario simulation system for improving teachers' teaching ability and cultivating students' initiative, enthusiasm, and autonomous learning ability.

To establish VR technology as a reliable tool for improving nursing professional skills training, researchers must integrate knowledge from various fields, including nursing, computer science, neuroscience, psychology, social cognition, multisensory perception, and multimedia development. This requires an interdisciplinary approach that takes into account the needs of all stakeholders, including students, teachers, nurses, and software developers [42]. Thus, research on VR-based nursing professional skills training must involve a broad range of individuals to create effective teaching strategies that meet the unique needs of every student. High-quality research is necessary to explore the full potential of VR technology across various disciplines.

Strengths and Limitations

This is the first bibliometric analysis of VR-based professional skills training in nursing, providing a comprehensive understanding of the current state of VR in nursing education. Through analyzing keywords, countries or regions, institutions, authors, journals, and references, we have gained valuable insight into the research landscape. In the future, longitudinal in-depth studies on current hot topics or large, multicenter, high-quality randomized controlled studies guided by research trends can further enhance this field. At present, research in this field is predominantly limited due to technology and cost. To promote growth, policy and financial support should be provided to encourage researchers to learn from foreign advanced experience and enhance VR technology. Nursing staff must participate in program design from a nursing education perspective to create more suitable VR equipment and procedures. By vigorously developing the application of VR in the field of nursing education, we can better prepare our students for clinical practice.

However, it is important to note that this study used only one database (WOS), which may have excluded high-quality papers in the field. Additionally, the current word segmentation algorithm used in bibliometrics lacks necessary intelligence, leading to inaccurate extraction of some keywords. Thus, future bibliometric studies must strive to enhance the semantic understanding of citation data to facilitate accurate word segmentation and intelligent extraction of bibliometric knowledge. To ensure a more comprehensive and precise theoretical basis, future research should expand the database and source high-quality papers both domestically and internationally. This will better promote the advancement of nursing education and practice to new levels.

Conclusions

To review the application of VR technology in nursing professional skills training, this study used the WOS database, R, Scimago Graphica, and VOSview to provide a scientific and intuitive analysis. Bibliometric analysis indicates that research on VR-based professional skills training in nursing has experienced rapid development over the past 15 years. This is evident from the rising number of publications in core journals and increased collaboration between authors and countries or regions. Although this paper demonstrates an exponential growth trend in VR-based nursing professional skills training and positive feedback in the field's advancement, further investigation is required to understand the feedback mechanism.

Abstract

Background: As the gaming industry grows around the world, playing pervasive games is becoming an important mode of entertainment. A pervasive game is one in which the game experience extends into the actual world or where the fictive world of the game merges with the physical world. How pervasive games can adapt to the ever-changing nature of technology and design in current society requires a comprehensive review.

Objective: In this systematic review, we aimed to measure and analyze 4 dimensions of pervasive games through development, technology, experience, and evaluation. Moreover, we also aimed to discover and interpret their relationship with game, interaction, experience, and service design.

Methods: We first chose 3 well-known databases, Web of Science, Scopus, and EBSCO, and searched from 2013 to April 2022. A strictly thorough Boolean search for research keywords such as "pervasive game," "design," and "interactive" resulted in 394 relevant articles. These articles were identified, screened, and checked for eligibility to find valid and useful articles, which were then categorized and analyzed using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) method.

Results: The systematic selection was finally left with 40 valid and valuable articles. After categorization and analysis, all articles were classified according to 4 main themes, which were design and development (11/40, 28%), interaction and technology (15/40, 38%), users and experience (9/40, 23%), and evaluation and service (5/40, 13%). These 4 main areas can be subdivided into several smaller areas.

Conclusions: In the 4 areas of game design, interaction design, experience design, and service design, many scholars have studied pervasive games and made contributions. Although the development and technology of pervasive games have evolved with the times, there is still a need to strengthen emerging design concepts within pervasive games.

KEYWORDS

interactive; pervasive game; systematic review; design; mobile phone

Introduction

Background

During the global COVID-19 pandemic, people from all walks of life played video games to find joy, connection, and a sense of belonging. A game is a source of entertainment and comfort for millions of people in all countries, and it transcends age, race, gender, platform, and political party. In 2021, according to the Entertainment Software Association survey, 90% of gamers agreed that video games bring joy and strongly agreed that they can inspire (79%), provide mental stimulation (87%), and relieve stress (87%) [1]. Sensor Tower released its *Mobile Gaming 2022* report, which provides insight into how challenges affect different regions and game genres and which markets continue to grow in the face of these challenges. The biggest game opportunity is in China, as can be interpreted from the data. China currently leads the mobile game industry in terms of revenue and downloads and is expected to maintain its dominant position in the coming years [2]. Multiplayer online battle arena has proven to be one of the most challenging but rewarding game genres in the mobile game market, bringing a series of huge successes and painful failures. The latest high-profile multiplayer online battle arena to be released on cell phones is *Pokémon Unite*, developed by Pokémon Company in partnership with Tencent's TiMi Studio. *Pokémon GO* was downloaded more than 15 million times in the first 2 days of its release, making it the biggest release ever. By the end of the first week, the game had reached approximately 30 million downloads in 7 days [3].

Pervasive games are a very important subfield among the many game classifications. As early as 2009, Montola et al [4] wrote in their book that pervasive games were defined as having *one or more salient features that expand the contractual magic circle of play spatially, temporally, or socially.* Initially, pervasive games were relatively simple to play. Game players with other players and nonplayer characters communicate via phone, email, or MSN Messenger [4]. However, now, pervasive games are a whole new game style that extends game experiences into the actual world, weaving into the fabric of players' real-life settings [5]. According to some researchers, a pervasive game is when the player's experience is extended to the actual world, achievable because of the device's sensors [6]. These games are a relatively new type of entertainment that takes the game experience out of the device and into the actual environment, merging virtual and physical realities [7].

Pervasive games use mobile devices' data collection, geotagging, e-commerce, internet cookies, and social media capabilities [8]. Pervasive games rose to popularity with the release of Niantic's *Pokémon GO* in 2016. Two games now dominate the pervasive games market: *Pokémon GO* and *Ingress* [9]. Ingress has a rather simple core loop and low polish, but its dynamics seem to be tailored to enforce team socializing and collaboration [10]. After the successor to *Ingress*, *Pokémon GO* offers a more complicated primary gameplay loop. The mechanics of *Pokémon GO*'s main gameplay loop are more intertwined than those of *Ingress*; nonetheless, the game focuses significantly more on the individual's experiences in the Pokémon world and far less on social connections and collaboration [11].

Objectives

On the basis of the abovementioned background retrospect, it can be seen that further research on pervasive games is necessary. As design continues to evolve, many new concepts are being added. There is a need to add more current design factors in the game design industry. For example, interaction design, experience design, service design, and branding design are popular design concepts that constantly influence game design. In addition, the existing systematic review articles fail to provide detailed information on the review process. This includes keyword identification, article screening, and article eligibility. Moreover, because of this situation, prospective researchers could not reconstruct the survey, authorize interpretation, or assess the breadth of the data. Furthermore, this study is important because it provides researchers with an understanding of peer literature reviews and helps researchers better understand pervasive game design issues that may require academic attention. The current systematic analysis was conducted to answer the primary research question: Does the pervasive game embody other conceptions of thinking in the design field? The survey's primary focus was on perceptions of pervasive game design, including perceptions of design thinking in interaction design, experience design, service design, and branding design.

The *Methods* section describes the procedure used to answer the research topic of this study. The *Results* section conducts a systematic review and synthesis of the scientific literature to identify, select, and analyze the research needed on pervasive game design within design thinking situations. Finally, the *Discussion* section discusses the steps that must be followed, emphasizing the importance of aspiring academics understanding the issues.

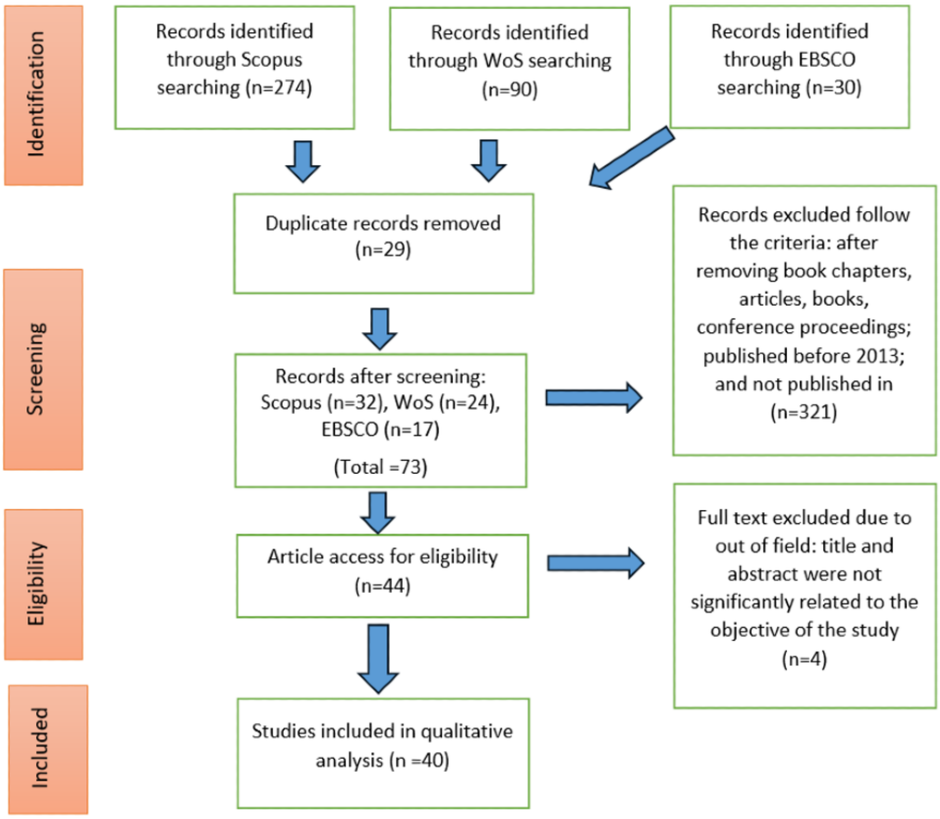
Methods

Overview

Several studies related to system evaluation have been conducted globally. However, only a few studies have focused on the design thinking connotations of pervasive games in the context of design thinking [4-8]. This section describes the need for a systematic analysis of the design thinking connotations of pervasive games. In contrast, the following section presents the methodology used to find the research answers formulated by this study. This literature analysis is divided into four sections: (1) design and development, (2) interaction and technology, (3) user and experience, and (4) evaluation and service. Furthermore, this section systematically reviews and synthesizes the scientific literature to distinguish, screen, and analyze important pervasive game research. Finally, reflecting on potential scholars suggests what actions should be taken to address the issues raised. The prerecording systematic reviews and meta-analysis (PRISMA [Preferred Reporting Items for Systematic Reviews and Meta-Analyses]) approach was used in this analysis, a documented standard for conducting a systematic literature review. In general, publication rules are required to aid writers in assessing and reviewing the quality and rigor of a review with relevant and necessary details. PRISMA also emphasizes the randomized study evaluation survey, an important feature in systematic analysis reports for various study types [12] (Figure 1).

In terms of instruments, the resilient character of 3 electronic databases, Scopus, Web of Science, and EBSCO, was used to evaluate this research methodology. This review's electronic database search included articles relevant to education, information technology, and social science. However, similar to Scopus, no database is perfect and detailed [13]. They mainly cover various fields, such as business and industry, economics, information technology, humanities, social sciences, communication and dissemination, education, arts, literature, medicine, and general science. This section also provides an overview of the 4 major subsections: identification, screening, eligibility, and data abstraction.

Figure 1. Flow diagram of the proposed search study. WoS: Web of Science.



Identification

The systematic review process can be divided into 3 main phases, each of which is responsible for selecting several appropriate papers for this report. The first step is the identification of keywords, followed by a search for related and analogous terms using resources such as the thesaurus, dictionaries, encyclopedias, and earlier research. Consequently, after determining all pertinent keywords, search strings for the databases Scopus, Web of Science, and EBSCO (Textbox 1) were formulated. This review successfully retrieved 394 papers from 3 databases during the first step of conducting a systematic review.

Textbox 1. Search strings.

Scopus

- TITLE-ABS-KEY ("pervasive gam*" AND design* AND (interaction OR interactive)) AND (LIMIT-TO (PUBYEAR, 2022) OR LIMIT-TO (PUBYEAR, 2021) OR LIMIT-TO (PUBYEAR, 2020) OR LIMIT-TO (PUBYEAR, 2019) OR LIMIT-TO (PUBYEAR, 2018) OR LIMIT-TO (PUBYEAR, 2017) OR LIMIT-TO (PUBYEAR, 2016) OR LIMIT-TO (PUBYEAR, 2015) OR LIMIT-TO (PUBYEAR, 2014) OR LIMIT-TO (PUBYEAR, 2013)) AND (LIMIT-TO (PUBSTAGE, "final")) AND (LIMIT-TO (DOCTYPE, "ar")) AND (LIMIT-TO (SRCTYPE, "j"))

Web of Science

- ALL= ("pervasive gam*" AND design* AND (interaction OR interactive)) and Articles (Document Types) and 2022 or 2021 or 2020 or 2019 or 2018 or 2017 or 2016 or 2015 or 2014 or 2013 (Publication Years)

EBSCO

- ALL= ("pervasive gam*" AND design* AND (interaction OR interactive)) and Articles (Document Types) and 2022 or 2021 or 2020 or 2019 or 2018 or 2017 or 2016 or 2015 or 2014 or 2013 (Publication Years)

Screening

During the preliminary screening, duplicate papers were eliminated from consideration. In the first phase, we decided not to include 29 articles. In the second phase, we used several inclusion and exclusion criteria developed to screen 73 articles. The first criterion was the literature, which consisted of research articles, as this is the most important source of useful information. Publications in the form of systematic reviews, reviews, meta-analyses, meta-syntheses, book series, books, chapters, and conference proceedings were excluded in the current investigation. In addition, the review focused solely on papers written in English. It is essential to remember that the plan was to select publications across 10 years, from 2013 to 2022. Thus, 321 publications were disregarded because they did not meet certain criteria.

Eligibility

A total of 44 articles were prepared for the third step, which is referred to as eligibility. At this stage, the titles of all the articles and the primary content they contained were subjected to a comprehensive review to verify that the inclusion requirements had been reviewed and that the articles were suitable additions to this study following the research goals. Consequently, 4 reports were excluded because they did not consist of pure scientific articles based on empirical evidence. Finally, 40 articles were included in the final analysis (Textbox 2).

Textbox 2. Selection criteria.

Inclusion criteria

- Language: English
- Timeline: 2013-2022
- Literature type: journal (only research articles)

Exclusion criteria

- Language: non-English
- Timeline: <2013
- Literature type: journal (book chapter and conference proceeding)

Data Abstraction and Analysis

An integrative analysis, which is one of the examination techniques used to analyze and synthesize different research designs, was conducted in this study. This technique was used to integrate qualitative, quantitative, and mixed methods. The primary focus of the specialists' research was on the formulation of pertinent topics and subtopics. The data collection phase was the initial step in developing the theme. We thoroughly combed through a collection of 40 papers, searching for statements or information that responded to questions raised by this study. The second step involved the expert and us analyzing the situation regarding pervasive games within design thinking, determining meaningful groups to form. The 4 primary themes that emerged from the design and development, interaction and technology, user and experience, and evaluation and service need to be overcome. We reviewed every developed theme from this point onward, including any themes, concepts, or ideas that have any connection. We established themes based on the findings of the study within the framework of this research. In this instance, a log was kept during the data analysis to document any analyses, opinions, puzzles, or other ideas pertinent to data interpretation.

We also compared the findings to resolve any inconsistencies that may have occurred while developing the theme. It is important to note that we discussed with academics any inconsistencies that may have occurred within the themes and tried to resolve the inconsistencies. In conclusion, the developed themes underwent minor adjustments to ensure coherence. Two specialists carried out the examinations: one specialized in the games industry and the other specialized in the game academic areas. This was performed to ensure that the problems were valid. By establishing domain validity, the expert review phase helped ensure that each subtheme was clear, important, and adequate. Adjustments were made at our discretion based on comments and feedback from industry professionals.

Results

Overview

By extending the game experience into the physical domain, pervasive games represent a new era of entertainment and interaction. Pervasive game design is one of the many issues that must be reconsidered. As the development of pervasive games becomes more and more successful, the need to incorporate new design concepts becomes increasingly urgent. There were 40 articles extracted and analyzed based on a searching technique. All articles were classified according to 4 main themes: design and development (11/40, 28%), interaction and technology (15/40, 38%), users and experience (9/40, 23%), and evaluation and service (5/40, 13%; Table 1).

[a]VISOLE: Virtual Interactive Student-Oriented Learning Environment.

Design and Development

Development Mode

Pervasive games are a completely new game form that extends game experiences into the physical world by incorporating information and communication technologies into the fabric of players' real-world environments. This emerging game mindset makes it difficult for developers to explore technologies and methods for providing a high-quality interactive experience for users and designing novel and compelling forms of content [36].

Model-driven development and domain-specific modeling have succeeded in many open or in-house information system scenarios. However, its application to games is rare and immature. Guo et al [35] illustrated solutions by describing a pervasive game case's technical and procedural development, incorporating model-driven development into the game development process. Furthermore, Guo et al [27] proposed a lightweight domain analysis that can be incorporated into the pervasive game development process. The domain analysis process is based on a game ontology that provides game design and domain analysis. They introduced the ontology, demonstrated its application in the domain analysis procedure, and evaluated and discussed the quality of the ontology using a user acceptance survey. The test results indicated that most potential users found the ontology useful and simple to use.

Development Tool

When developing pervasive games, programmers must deal with high turnover, cheating, and heterogeneity of devices and platforms. LAGARTO is an authoring tool for constructing location-based mobile games with augmented reality (AR) capabilities. These games are a subclass of pervasive games in which the game's progression depends on the location of the players. Maia et al [31] gleaned requirements for designing the LAGARTO software architecture from a literature review and focus group meetings. The tool consists of a web-based application for creating and managing games and a mobile app for tracking players. Their primary objective is to develop software that enables nonprogrammers to design, construct, and run location-based mobile games. The development of pervasive games is slowing down because of the multiple challenges that these games present to their creators, such as the vast array of interaction paradigms and the complexity of developing applications where so many innovative technologies converge. Bonillo et al [22] introduced JUGUEMOS, a toolkit designed to assist developers in creating pervasive games for interactive spaces. The toolkit addresses 3 difficulties that arise during the development of pervasive games: integrating heterogeneous devices, managing multiple displays, and facilitating game coding. They conducted case studies exploring the toolkit's expressivity, its ability to support collaborative multidisciplinary experiences, and its potential to support interactive experiences outside our interactive space. With the addition of pervasive or narrative components, however, the complexity of construction and support increases, necessitating a tool to manage the information appropriately and dynamically. Space and the pervasiveness of social interaction collaborate to achieve objectives by exchanging data between multiple pervasive games to improve the game experience. Arango-López et al [15] described a platform (*Geolympus*) that enables the creation of game experiences based on the player's location.

Development Direction

In recent years, games' design and development incorporating web-based elements into real environments have expanded. Such games include pervasive games, which seek to enrich the game world by combining these 2 realities to immerse the player more deeply in the story. The implementation of pervasive games has increased player engagement and motivation. New technologies have enabled advancements in the design and development of video games. Pervasive games have not been an exception, and combining traditional game elements with real-world elements and scenarios has made it possible to enhance motivation and user experience. However, previous research has demonstrated the need for a procedure to guide the design and development of pervasive games. In light of this, Arango-López et al [14] developed GeoPGD, a methodology that integrates the design of geolocated narrative as the core of the game experience. This methodology guides designers and developers through the various stages of creating pervasive games and provides tools for defining narrative elements, locations, and user-pervasive game interactions. Furthermore, Pløhn et al [39] described the Dynamic Pervasive Storytelling (DPS) approach and the design of the pervasive game *Nuclear Mayhem*, which was created to support a course in web game development at Nord-Trndelag University College in Norway. *Nuclear Mayhem* runs alongside the course for 9 weeks and requires specific elements to become part of the players' everyday lives, reminding them of the game they are playing. The game DPS as a model aims to increase the universality of the game and support the player's ongoing level of awareness in the game by incorporating real-world events. DPS uses real-world events as a building block to create the entire game story before the game begins by incorporating current events into its design and increasing the universality of the experience and in-game awareness as the game unfolds. This paper concludes that DPS is a promising approach to developing game narratives because it increases the universality of the game and promotes in-game awareness.

Mobile culture has given rise to many context-based products such as location- and hashtag-based apps. This poses new challenges for designers. Design methodologies that recognize context and allow it to influence design concepts are required. Kristiansen [48] focused on a design problem where live design practices can enhance the early design process: designing a pervasive game. Pervasive games are computer games that use cities as playgrounds and cell phones with GPS capabilities. Some contextual design approaches already exist, but the authors propose an approach that requires designers to conceptualize and implement ideas in the field, that is, at the game's location. The challenge is to develop a creative approach that includes on-site design work and generates game concepts for pervasive games. The proposed design approach, called *site storming*, was based on games involving individual scenario exploration of the site and various types of game cards, followed by a collective evaluation of the ideas generated. A series of evaluations showed that designers enjoyed using this method, stimulated idea generation, and live design influenced their design concepts.

The pervasive game aims to take computer games out of the PC and into the "real world" of cities, streets, and parks. This real-world physicality makes for an enjoyable player experience but presents a unique challenge for designing and coordinating such games. Neustaedter et al [49] explored how location-based games can be designed to overcome this scalability challenge—using Geocaching to determine how it has maintained user engagement and growth over the past decade. The findings show that Geocaching benefits from direct player creation of simple and complex game content. Geocaching also simplifies game choreography by allowing players to monitor game content, other players, and even nonplayers. Recently, developments in virtual reality technology have allowed users to consume immersive content from the comfort of their living rooms. Alternate reality promises to enhance this experience by incorporating physical environments into the simulation. Smart substitute reality (SSR) is a novel approach that combines the passive haptics of substitute reality with the active capabilities of a smart home environment. SSR is intended to serve as the basis for serious games. Eckstein et al [23] discussed the concept of SSR while implementing a prototype in our Smart Lab. They created multiple web-based environments with varying degrees of mismatch to the real world and added selected objects to induce additional tactile and thermal stimuli to enhance immersion.

Interaction and Technology

Outdoor Location

With the rise of pervasive computing, location-aware pervasive games are increasing rapidly. Chen et al [46] presented the design and implementation of *Your Way Your Missions*. This location-aware pervasive game uses the player's route to combat the inefficiencies of location- and radius-based information adaptation. *Your Way Your Missions* provides the player with a Google Maps–based tool to predefine the route and relies on self-reporting to obtain the player's planned route. Such a design returns the task to the player based on the task's location attributes and the player's intended route. The results show that the route predefinition and self-reporting approach is an effective way to obtain the player's planned route. This adaptation of information based on the player's planned route can help them locate the task at any time and location. Leone [24] also described this location-based outdoor interaction in his article. He described this small community's view of the connection between the real world and the video game world using physical and digital support. The paper highlights 3 games produced through participatory processes and argues for the role of urban and popular games as tools to promote citizenship. Other scholars have also suggested that using augmented or web-based field trips and pervasive educational games can potentially transfer learning content to the real world outside the classroom. Lemcke et al [37] presented the pervasive educational game *RouteMe*, which contextualizes the rather abstract topic of routing in ad hoc networks. The game was designed for college-level courses as a motivational supplement to these courses to enhance the learning experience. Students take on the role of routing nodes or applications with routing requirements. In 3 successive levels of difficulty, they are introduced to game concepts, learn basic routing mechanics, and become aware of the general limitations and capabilities of routing nodes.

With the increasing popularity of personal communication devices, the demand for location- and environment-based mobile services is growing exponentially. The mobile game as a service is no exception. Unfortunately, unlike other services, location- and context-based games strictly require near-field communication to create teams and arenas with nearby players. As currently used technologies have scalability (Bluetooth) or energy (Wi-Fi) limitations, opportunistic networks are considered a viable solution to engage large numbers of players in a larger area. However, it remains unclear how the increased latency and probabilistic message forwarding introduced by opportunistic networks will affect the player experience. Maggiorini et al [43] addressed these issues by simulating the deployment of a connection-based game on opportunistic networks provided by public transportation systems in 3 cities: Milan (Italy), Edmonton (Alberta, Canada), and Chicago (Illinois, United States). Moreover, they studied an opportunistic cooperative version of a well-known independent game for playability and scalability reasons. The emphasis on this particular game promotes the use of public transportation systems. Emerging pervasive games use sensors, graphics, and web technologies to provide immersive gameplay interactions integrated with the real world. Existing pervasive games typically rely on the device screen to provide game-related information and ignore opportunities to include new types of contextual interactions such as jumping, punching gestures, or even voice as game input. Sra and Schmandt [41] presented the design of *Spellbound*, a team-based physical mobile game, to help us understand how to design pervasive games that foster a spirit of togetherness. Sra and Schmandt [41] also briefly discuss how solidarity and playfulness transform physical movements into an ideal activity. *Spellbound* is an outdoor, team-based physical game. It takes advantage of the aforementioned opportunities to combine real-world movements such as jumping and spinning with the web-based world. It also replaces touch-based input with voice interaction. It uses custom hardware to provide tactile feedback, embodying the true spirit of social play that characterizes traditional children's games.

They believe that *Spellbound* is a form of digital outdoor play anchoring enjoyment in physical movement, social interaction, and tangible feedback.

Industry Application

Pervasive games have also contributed in terms of industry domains. Coenen et al [47] presented a case study of *MuseUs*, a popular pervasive game for museums that operates as a mobile phone app. During the museum visit, players are encouraged to create their exhibits and are guided through the process by application. The aim was to provide a learning effect during a museum exhibit visit. The core of the *MuseUs* experience is that it does not require a predetermined path through the museum and does not interfere with the exhibit itself. In addition, the application encourages visitors to see elements of cultural heritage in a new light, enabling a personal narrative while building a personal exhibition. Moreover, Sekhavat [34] described the architecture of *KioskAR*, a pervasive AR game. This game introduces a new business model that enables players to use AR to display their artworks in a web-based kiosk while enjoying the game. In addition to the competition, this game requires social interaction between players to earn more points. A user study evaluated the presence and usability of the application. The experiment showed that *KioskAR* could achieve a high level of usability and presence.

Interaction Mode

Creating pervasive games using emerging interactive technologies is becoming increasingly popular. Lv et al [38] designed and evaluated a touchless motion interaction technique for developing interactive and AR games on vision-based wearable devices. Users interact with AR games by making dynamic hand or foot gestures in front of the camera, which triggers interactive events with objects in the scene. As evidence, 3 elementary AR games with 11 dynamic gestures were created using the proposed touchless interaction technique. Finally, they presented a comparative evaluation to demonstrate the social acceptability and usability of the touchless approach running on a hybrid wearable frame or Google Glass and assess workload, user sentiment, and satisfaction. Recently, developments in interactive surfaces and tangible user interfaces offer new opportunities for pervasive games that combine traditional board games' social affordances with the interactivity of video games. Mora et al [33] proposed a strategy centered on tokens, constraints, spatial representations, and interactive events in this research area. Rather than using interactive surfaces as the primary interaction medium, this approach relies on physically manipulating interactive, computer-enhanced game components on standard surfaces. Furthermore, AR in mobile game development, where computer-generated graphics are used to enhance the player's view of the physical world, is becoming increasingly common.

AR Overview

In AR applications, it is common for objects to be partially or completely obscured by physical objects; if not handled properly, the visualization of obscured objects can often mislead the user's perception. Kasapakis and Gavalas [30] presented 3 alternative geolocative raycasting techniques designed to help outdoor pervasive game developers solve the occlusion problem by integrating real-time building recognition to generate a realistic field of view for the player. The geographic raycasting approach has been implemented in the location-based pervasive game *Eliminate Order*, which uses publicly available free building data to calculate the player's field of view in real time. The proposed algorithm applies to many sensor-based AR applications and can be ported to any real-world environment. A few years earlier, Evans et al [42] examined the design of the *Malthusian Paradox* and highlighted how it redefines the framework of performance in sometimes disturbing ways by blurring the traditional roles of performer and audience. Players engage with the game through various interactive channels, including performative group performances and one-on-one interactions with game characters in public settings, using low-end and high-tech physical and web-based artifacts such as customization and third-party websites. Players and game characters communicate in planned and unplanned ways via phone and social media. We reflect on the production and choreography of the game, including the dynamic nature of strong episodic narratives driven by professionally produced short films that attempt to respond to the player's actions and the difficulties of designing for engagement across hybrid and time-dilated performance spaces.

Realistic 3D environments, such as existing city models, have the potential to serve as a bridge between the physical and the environments in pervasive games. Smooth attention shifts and transitions between these 2 realities are largely unexplored in the context of pervasive games. Alavesa et al [19] conducted 2 field experiments using a pervasive live-action role-playing game to investigate the effects of transitions between the web-based and physical environments on coexistence and memorability. Although there were few differences in copresence during play, they highlighted the subtleties in the social structure of the universal game. 3D environments are more memorable because of their spatial similarities to the physical world. We then identified 2 important factors to consider when integrating web-based environments into pervasive games: the structuring of social interactions and spatial realism. The emerging genre of pervasive games combines reality with computation. Bellotti et al [20] explored the concept of "reality-enhanced games" through a simple set of pervasive games. A reality-enhanced game is a model that links game mechanics to the outcomes or measurements of real-world activities. The prototype game was created as part of the TEAM Industrial Research Project, which aims to develop mobile apps for flexible and collaborative mobility. The proposed game is an example of various user interfaces that are believed to be useful for various important scenarios, goals, and user types, particularly for improving driving styles. This concept allows pervasive game developers to focus on their game logic while seamlessly leveraging a variety of in-field sensors, and it is generic.

AR is an emerging technology that superimposes objects onto the physical world. Recent computer and mobile technology advances have made AR increasingly accessible in education. Costa et al [21] described an educational mobile AR platform. The platform includes a mobile app consisting of a pervasive game designed to encourage learning about the universe. In addition, it includes a backend that enables teachers to present information about celestial bodies and create multiple-choice questions to assess students' knowledge of the participants they are studying. The mobile app provides users with real-world physical movement and social interaction while playing the game; therefore, it falls within the paradigm of pervasive games. In addition to engaging students to play games, they believe that this platform can be implemented in both informal and formal learning environments. Mobile AR applications are gaining prominence in education, but there is a need to design educational games that are both appropriate and enjoyable. Costa et al [16] described an interactive information system to facilitate the implementation of a pervasive game for game-based learning. *PlanetarySystemGO* includes a location-based mobile AR game that facilitates learning about cosmic objects and planetary systems and a web application that interacts with mobile device apps. This resource can be used for web-based and face-to-face classes, which are useful in socially isolated situations, such as those caused by the COVID-19 pandemic. In addition, adding web applications with a backend to the information system allows for the inclusion of curriculum content based on the student's grade level. Similarly, teachers are expected to use the information system to incorporate content that they feel is appropriate for their teaching grade level. Therefore, it is critical to provide them with the professional development they need to use this resource. Teachers found this resource helpful in motivating students to learn, recognizing that the web application facilitated the introduction of appropriate curriculum content and was useful in assessing student performance in games.

Users and Experience

Children's User Experience

There is a growing body of research on pervasive outdoor games, with most studies focusing on adult mobile phone players. Most published assessments of player experience in such games are based on anecdotal descriptions and postgame surveys. The latter approach is particularly difficult to implement when the game testers are children. Until now, observations of games have been ad hoc and based on unstructured observations, making it difficult to draw reliable conclusions from observations and compare games. The Outdoor Play Observation Scheme and GroupSorter are 2 methods developed specifically to assess the player experience of children's outdoor play [51]. They discussed their application in 3 case studies and concluded that Outdoor Play Observation Scheme is useful for quantifying various play behaviors in outdoor play. GroupSorter adds qualitative data about play experiences. Moreover, the application of GroupSorter is not limited to game development; it can be used to collect user input in other contexts. In the same year, Papagiannakis et al [50] described the design, development, and evaluation of AmI Playfield, a technical framework for learning applications designed to create challenging learning conditions through play. An AmI Playfield is a guided ambient intelligence. It emphasizes using kinesthetic and collaborative technologies in a natural, play-based learning environment. It also incorporates performance measurement techniques. The *Apple Hunt* application was created to test and evaluate AmI Playfield, engaging child learners in arithmetic thinking through kinesthetic and collaborative play. Simultaneously, AmI technology observes behind the scenes. *Apple Hunt* has been assessed using a combination of methods suitable for young testers, and the Children's Commission is presented as a promising assessment method for children. The results indicate the system's high capacity to stimulate thinking and enjoyment, thanks to the learners' whole-body kinesthetic play and teamwork.

Acquiring literacy skills requires developing phonological awareness, a metacognitive skill. This allows thinking about and manipulating language structures from an early age. Learning requires multisensory stimulation as well as curiosity and interest. Communication technologies play an important role in this, as learning-oriented use can stimulate interest and thinking in current digital natives. Oliva-Maza et al [17] described a pervasive game with tangible technology that can be used for interventions and diagnostic, formative, and summative assessments. Multiple case studies were conducted with 4 kindergarteners over 2 weeks to test the user experience. They were given a multimedia pervasive adventure game in which they had to use tangible technology to solve phonological awareness challenges to reach the final goal. Observations were recorded in an evaluation model for posttriangulation data analysis and subsequent qualitative analysis of pre- and postintervention data. The results showed improvements in phonological awareness and traces of gamified experiences. These encouraging results justify the application of these methodologies to a learner-centered education model.

Adults' User Experience

The emergence of pervasive technologies has sparked an interest in designing and developing pervasive games. There are numerous designs of pervasive games for adult users. Chamberlain et al [45] presented *Them and Us*, a pervasive indoor game that uses dramatic processes to encourage social interaction within the context of the game. The *Them and Us* gameplay brings a group of people together in a space to interact with each other. At the same time, location-based technology reveals *us* the locational nature of the social interactions occurring in the space (who, where, and when). It allows *us* to score based on these interactions. *Them and Us* took a narrative-based approach in which a script instructed participants on how to play the game and how their social behaviors were incorporated into the game mechanics. This new interactive game-based artwork blends the player's physical and web-based worlds to create a new and exciting experience for *them*. Designed specifically for adults, the pervasive game—*Them and Us*—emphasizes the use of audience and performer tracking as a means of encouraging interaction within the play space.

The pervasive game has also made a significant contribution to the education of adults. Providing pervasive game-based learning scenarios for at-risk students is effective and motivating. Schmitz et al [44] provided a detailed example of an educational environment in which a mobile game is combined with a PC browser game. They evaluated how this pairing helps the target group engage and learn. The study surveyed 19 people, ranging in age from 17 to 21 years, who participated in the game and explored it. The results of the 7-week game study suggest that pervasive games can increase learners' interest in a topic while also supporting learning activities. Other studies have been conducted in the context of intense debate about how pervasive games can be used to provide new constructivist learning opportunities for students. Jong [32] developed a theoretical foundation for the Virtual Interactive Student-Oriented Learning Environment (VISOLE). It was a pedagogical framework for implementing constructive web-based gamified learning in teaching formal curricula. In addition to highlighting the pedagogical features of VISOLE, Jong [32] discussed the Stages of Concern model, which investigates 118 teachers' concerns about this educational innovation in terms of 5 categorical concerns: evaluation, information, management, consequences, and refocusing. All participants had completed introductory VISOLE training before taking the Stages of Concern survey. He was also able to develop more precise interventions tailored to the actual needs of teachers to help him use this *diagnostic* knowledge to implement VISOLE in their schools. The findings also shed light on how to design, develop, or adapt pervasive games to aid learning and teaching in the classroom.

Older Adults' User Experience

Promoting active lifestyles among older adults can have a significant positive impact on their quality of life. Pervasive games aim to create more fun and engaging experience by incorporating real-world elements into the game. The innovative mechanics of pervasive games, combining real and web-based worlds, can further engage and motivate older adults to achieve this goal. They can be a powerful strategy to encourage physical activity among older adults as they are integrated into players' lives and naturally promote more casual play. Santos et al [26] designed and evaluated the feasibility of a pervasive game using social interaction as a case study to understand how game design elements can influence the physical activity levels of older adults. They created a mobile, location-based pervasive game and tested its feasibility as an experimental system among community-dwelling older volunteers in Kyoto, Japan. Participants found the theme and visual style of the game appropriate, and the rules and objectives of the game were easy to understand. The game was praised for its challenging and entertaining nature. Further research suggests that future iterations of the system will require special attention to the complexity of the controls and new ways to connect players when few people are playing or when they are too far apart.

In the same year, the goal of Santos et al [25] was to test the impact of changing a specific design element of a popular game for older adults, namely social interaction, on physical activity levels. Therefore, they experimented by comparing 2 variations of the same popular game over 4 weeks: the test group received social interaction, whereas the control group received no social interaction. In both versions, players had to walk to physical locations to collect cards, but the socially interactive version allowed people to cooperate in obtaining more cards. The impact on each group was assessed using the number of steps taken per week, and the number of places visited was used to measure game activity. A total of 32 people were recruited for the experiment (no social interaction=15; social interaction=17); 18 people persisted until the end (no social interaction=7; social interaction=11). The experiment found that the social interaction design element of the popularity game may have had some positive effects on promoting physical activity. Subsequently, in 2021, Santos et al [18] continued with the same study, comparing 2 variations of the same pervasive game over 4 weeks with the same purpose and type of experiment: the test group received social interaction whereas the control group did not. In this test, 20 participants were recruited for this experiment (no social interaction group, n=10; social interaction group, n=10), 18 of whom remained active until the end of the study (no social interaction group, n=9). After several tests of pervasive games with older adults, they concluded that the social interaction design element of pervasive games might positively affect physical activity. Although other factors may have influenced this effect, it has tremendous implications for the fitness and health of older adults.

Evaluation and Service

Evaluation in the Area of Health

Recently, games have gained attention as a medium for changing health behaviors. However, current projects on healthy games face a major obstacle: the evaluation methods used to assess and formally evaluate such games do not adequately measure the acceptability and integration of the games into participants' lives. These are important components of ensuring participants adhere to the games to induce behavior change. El-Nasr et al [40] described the data-driven retrospective interviewing method that we developed for formative evaluations. Used in a naturalistic setting, the data-driven retrospective interviewing examines how participants embrace the game and integrate it into their lives. The procedure consists of several steps. First, a game is designed to collect behavioral data, which are then analyzed to provide a basis for developing interview questions that retrospectively understand and reflect participants' behavior. The contribution of this paper lies in its assessment methodology and application to *SpaPlay*, a universal health game [52]. As a result of this investigation, designers could rethink and improve their game design as they discovered that users were not using the game as initially envisioned. Such results would not have been possible with traditional evaluation techniques.

Self-monitoring, goal setting and coaching, education, and social support are daily care strategies for patients with chronic diseases. Various tools, such as mobile digital coaching systems linked to wearable sensors, pervasive games, and patient portals for personal health records, have been developed to assist patients with chronic conditions and their caregivers in achieving the ideal of self-management. Klaassen et al [28] described a platform that integrates these tools to help young patients self-manage their diabetes through educational games, monitoring, and motivational feedback. The platform's design references health care, persuasive system design, and serious game design principles. A coach is a game guide that provides personalized feedback on the user's daily care-related activities and helps them progress in the game world. User evaluations with patients under pediatric supervision suggest that using mobile technology in conjunction with web-based elements is feasible. However, assumptions about how users connect to the platform are not met in practice, resulting in a suboptimal user experience. They discuss the challenges and provide recommendations for advancing the integration of coaching and gamification platforms prevalent in medical practices.

Evaluation in Other Areas

Some scholars have explored a new approach to conducting user evaluation trials for pervasive games. In a case study, Kasapakis et al [5] examined the evaluation process of the pervasive role-playing game *Barbaros* consisting of preliminary and main implementation phases. The former is freely accessible to anyone and can be played at any time or place without the investigator's team's organizational and coordination investment. The latter defines 3 interdependent player roles that must cooperate in the scavenger hunt to achieve a common game goal. Players' eligibility to participate in the main game phase is determined by their position in the previous phase. Using concepts from cultural theory, they designed the preparation phase as a dynamic environment from which potential evaluators would emerge. The main hypothesis being investigated is that implementing such a cost-effective preparation phase could recruit highly qualified participants for user trials of the pervasive game study prototype, thereby increasing the reliability and quality of evaluation results.

The requirement's engineering community has not yet given enough attention to games. It becomes even more critical as we move toward newer forms of games, such as pervasive games. Pervasiveness (the characteristic that distinguishes traditional digital games) can mean being everywhere, pervading something, or propagating something through physical space. Each time a game is played, the boundaries of the game expand from the fictional world to the real world, indicating pervasiveness. Pervasive games, also known as alternate reality games, transmedia games, and cross-media games, are a new type of digital entertainment that has developed in various forms. The rapid development of this new type of digital product can be attributed to sensor technologies, networking capabilities, AR systems, computer vision technologies, the internet, and, in particular, mobile devices. Valente et al [7] defined it as pervasive games played on mobile devices. Mobile devices are currently the main drivers for the promise of pervasive games. Using various information sources, they compiled a list of interrelated characteristics critical to the success of these games. They presented a 2-level conceptual map of nonfunctional requirements based on these fundamentals to help achieve pervasiveness in pervasive mobile games.

Furthermore, Valente et al [29] proposed a new method for evaluating the quality of pervasiveness in pervasive games that can be adapted and applied to other pervasive applications. This approach produces a quality report consisting of a quality spreadsheet (containing metric values and comments) and a quality vector (representing the game quality profile in the form of a histogram). In addition, they can compare quality vectors based on similarity criteria. They applied the proposed approach to commercial and academic prototype games to elucidate their universality characteristics and identify ways to improve the overall quality of these games. In this sense, what distinguishes them from traditional digital games is the universality.

Discussion

Principal Findings

The analysis and results of the systematic literature review broadly divided these articles into 4 directions. These 4 directions are the direction of design and development, the direction of interaction and technology, the direction of the user and experience, and the direction of evaluation and service. These 4 directions appear to be independent of each other, but they are interdependent, which is consistent with the idea of this study. At this point, these directions can be correlated to the research objectives of this study one by one. Therefore, after abstracting and simplifying the themes of these literature analysis results, it is possible to sublimate them into corresponding design fields. Namely, the direction of design and development corresponds to the field of game design; the direction of interaction and technology corresponds to the field of interaction design; the direction of user and experience corresponds to the field of experience design; and the direction of evaluation and service corresponds to the field of service design. Therefore, these 4 design fields are the 4 research objectives to be analyzed in this study: game design, interaction design, experience design, and service design. They are also important indicators for analyzing the pervasive game from the perspective of different design thinking.

The game design aspect of pervasive games presents polymorphic research, which can be roughly divided into 3 categories: the development mode of game design, the development tool of game design, and the development direction of game design. Because pervasive games are a class of games, they naturally have a game design and development properties. As early as 2015, Kasapakis and Gavalas [36] introduced the historical development lineage of pervasive games, player acceptance factors, game development principles, and future development trends by analyzing 2 generations of 18 successful pervasive games. Subsequently, scholars have proposed different toolkits for developing pervasive games, enriching the toolbox of pervasive game design [15,22,31]. Moreover, the development direction of pervasive game design has never stopped research from 2013 to 2021. Inside these ideas are those that let players create game content directly [49], those that let designers find inspiration in the field [48], and those that let the game itself incorporate smart homes [23]. Furthermore, some research studies pervasive games from a storytelling and narrative perspective. This approach guides designers and developers through the different stages of game development, providing tools to define narrative elements, locations, and interactions between users and the game [15,39]. It is evident from looking at various aspects of pervasive game design, a popular focus of scholars' research, showing a promising trend of multifaceted and multidimensional development.

The interaction design aspect of pervasive games has been the most studied by scholars, comprising 15 articles. It is only natural that this is the case, as pervasive games are a large category of games, and players must have a variety of interaction designs or interaction technologies in them when they play. First, pervasive games are location-based games, so there is a large body of scholarship on how they use interactive technology to interact outdoors [24,37,41,43,46]. Second, there were scholars in industrial applications to study how pervasive games can increase interactive communication of artworks and how to improve interactive communication of cultural heritage in museums [34,47]. Touchless interaction is then used in designing the interactive interface and physical user interface of pervasive games [33,38]. Finally, scholars have mostly studied pervasive games combined with AR [16,19-21,30,42]. Furthermore, it can be seen that the technological development factor in the interaction design of pervasive games is influenced. Owing to the limitations of mobile technology in the early years, the interaction design of pervasive games was most explored by SMS text messaging and Bluetooth [42]. By 2021, scholars were exploring ways to integrate AR into the interaction design of pervasive games [16]. Nevertheless, these studies continue to expand the boundaries of interaction design for pervasive games.

The design of the pervasive game experience involves gamers of all ages. Among these articles, pervasive games are designed for children mainly to exercise their reaction and thinking skills [50,51]. Subsequently, there are pervasive games designed for adults, teachers, and students to learn [32,44]. At the same time, there are pervasive games for older adults, indicating some positive effects on promoting physical activity [18]. From the literature, it can see some hints of the research tendencies of scholars: in the early days, they studied the pervasive game design experiences of children users, followed by the pervasive game design experiences of adult users, and in recent years, they focused on the pervasive game design experiences of older adult users. In particular, Santos, a Japanese scholar, and his research team have been studying the effects of social interaction mechanics in pervasive games on the physical activity levels of older adults in recent years [25]. They used multiple experimental measurements to thoroughly analyze older users' perceptions of a pervasive game designed specifically for them, ranging from the game theme and visual style to game complexity and sociality. The direction of Santos's research is very similar to the direction of this study, which is to investigate the effects of pervasive games on fitness among older adults, except that the players' countries are different, the methods used are different, and the details of the specific participants studied are different. However, the research topics are very similar in terms of the effects of pervasive games on fitness among older adults. Nevertheless, the research conducted by Santos et al [25] is of great reference value to this study.

There are also some studies on service design for pervasive games, mainly from the evaluation perspective. This is probably because the service design concept is relatively new and has gradually emerged in design thinking and academic research in recent years. Perhaps it is therefore that the academic research perspective on pervasive games is still limited to simply evaluating the game itself. However, while evaluating the pervasive game itself, scholars are also exploring ways to improve and upgrade the pervasive game under study, which can be seen as an important manifestation of the service design concept. For example, refining the details of game mechanics and upgrading the details of game experience can be considered as research manifestations of service design for pervasive games. As in the case of El-Nasr et al [40] and Klaassen et al [28], the pervasive game for health programs was evaluated and measured for acceptability and integration into the participants' lives, and at the same time, the pervasive game they studied was optimized and iterated. It is the best example of the service design philosophy running through the pervasive game. Of course, other studies also included such early concepts of service design.

Limitations

The first limitation of this study is the database. This study only targeted 3 mainstream literature databases and did not include other databases, such as gray literature or PubMed. This may foreshadow the fact that, although the results obtained in this study through a systematic literature review method are authoritative, they could be more extensive and comprehensive. Another limitation of the study was that the search was conducted up to April 2022, and no articles were found in 2022 at the time of conducting the search, leaving an impression that the search left out publications of 2022.

Future Studies

After a systematic analysis, it was found that none of the themes in this literature were related to branding design. However, the article by Kasapakis and Gavalas [36] on the pervasive game's status, trends, and design principles can be considered a review of the existing successful pervasive games as branding. Pløhn et al [39] studied a dynamic and popular narrative approach to creating stories that can reinforce a sense of game maintenance and the brand of pervasive games. Valente et al [7] emphasized the need for nonfunctionality and highlighted aspects, such as cultural awareness, which can be seen as designing a brand strategy for pervasive games. Therefore, this literature does not explicitly go into the brand design of pervasive games but only touches on it to a greater or lesser extent. These results and findings were not coincident with the research object of brand design in this study. Thus, we believe that this systematic literature review has identified a research gap for branding design research on pervasive games and that it could be a future study direction.

Conclusions

A new generation of applications that blend the real and digital worlds, such as pervasive games, presents daunting obstacles for software developers. This type of game has recently become a worldwide phenomenon, with thousands of people using their mobile phones to interact with the surrounding physical environment while walking down the street.

At the beginning of the *Introduction* section, an accurate description of the current situation of the game industry is provided, explaining the entertainment nature and economic value of the pervasive game. In the *Methods* section, this study adopted a rigorous systematic literature review research process with graphs and tables. This study identified 4 themes: design and development, interaction and technology, user and experience, and evaluation and service. Each of these 4 themes was subdivided into subsections and interpreted. Finally, in the *Discussion* section, the 4 themes are explained in terms of this study's objectives: game design, interaction design, experience design, and service design. It also provides ideas for future research directions in pervasive games based on brand design.

Abstract

Background: AIDS, which is caused by HIV, has long been one of the most significant global public health issues. Since the beginning of the HIV epidemic, various types of nonelectronic communication tools have been commonly used in HIV/AIDS prevention and care, but studies that apply the potential of electronic games are still limited.

Objective: We aimed to identify, compare, and describe serious games and gamified systems currently used in HIV/AIDS prevention and care that were studied over a specific period of time.

Methods: A scoping review was conducted into serious games and gamified systems used in HIV prevention and care in various well-known digital libraries from January 2010 to July 2021.

Results: After identifying research papers and completing the article selection process, 49 of the 496 publications met the inclusion criteria and were examined. A total of 32 articles described 22 different serious games, while 17 articles described 13 gamified systems for HIV prevention and care.

Conclusions: Most of the studies described in the publications were conducted in the United States, while only a few studies were performed in sub-Saharan African countries, which have the highest global HIV/AIDS infection rates. Regarding the development platform, the vast majority of HIV/AIDS gaming systems were typically deployed on mobile devices. This study demonstrates the effectiveness of using serious games and gamified systems. Both can improve the efficacy of HIV/AIDS prevention strategies, particularly those that encourage behavior change.

(JMIR Serious Games 2023;11:e39915) doi:10.2196/39915

KEYWORDS

HIV; serious game; gamification; public health; primary health care; patient care; behavioral health

Introduction

HIV can cause a chronic infection that leads to disease. Without appropriate medical care, many people with HIV develop immunodeficiency syndrome within 10 years of infection [1]. HIV has long been one of the major global public health issues. In 2018, the estimated numbers of people living with HIV in Africa, Southeast Asia, the Americas, and Europe were 25.7 million, 3.8 million, 3.5 million, and 2.5 million, respectively [2]. Because HIV is a communicable infection that can affect the health status of large groups of people, early detection and treatment for one person can prevent future HIV transmission to other individuals, providing benefits for the overall population [3]. Since the beginning of the HIV epidemic, various international organizations have used different types of communications, such as TV advertisements, billboards, school-based events [4], and technology-based health intervention and prevention tools to educate societies [5-7].

Serious games are digital games created with the purpose of entertaining and achieving at least one additional goal [8]. While digital video games are commonly used in the health care domain for purposes such as training health care professionals [9-14], studies that apply the potential of games as HIV/AIDS intervention and prevention tools are still limited. In contrast with serious games, the term *gamification* is described as "the use of game-design elements in non-game contexts" [15]. Additionally, a gamified system is not a game in itself, while a serious game has elements of a real game and looks and feels like a real game [16]. Gamification interventions can be described by their "game mechanics"—the mechanisms that define how the intervention works [17]. They are a powerful tool to engage employees, customers, and the public that can change behaviors, develop skills, and drive innovation [18]. This approach may be one of the most important social and commercial developments in the next 50 years [19]. The difference between a serious game and a gamified system can be seen in their output formats. If the tool has the clearly declared purpose of enhancing the game players' performance, it is a serious game. In contrast, if it is an application with embedded game elements, is a gamified system.

The benefits of this scoping review include presenting a compilation of HIV care techniques and best practices. Currently, the available reviews in the HIV literature only address detection, treatment, and prevention [20,21]. However, there is no research that identifies game applications as either serious games or gamified systems. The purpose of this review is to identify, compare, and report on the situation of serious games and gamification for HIV interventions from January 2010 to July 2021. It also provides informative sources for an organization or game developers who intend to use games as communication or education tools for social services for HIV/AIDS prevention and care.

Methods

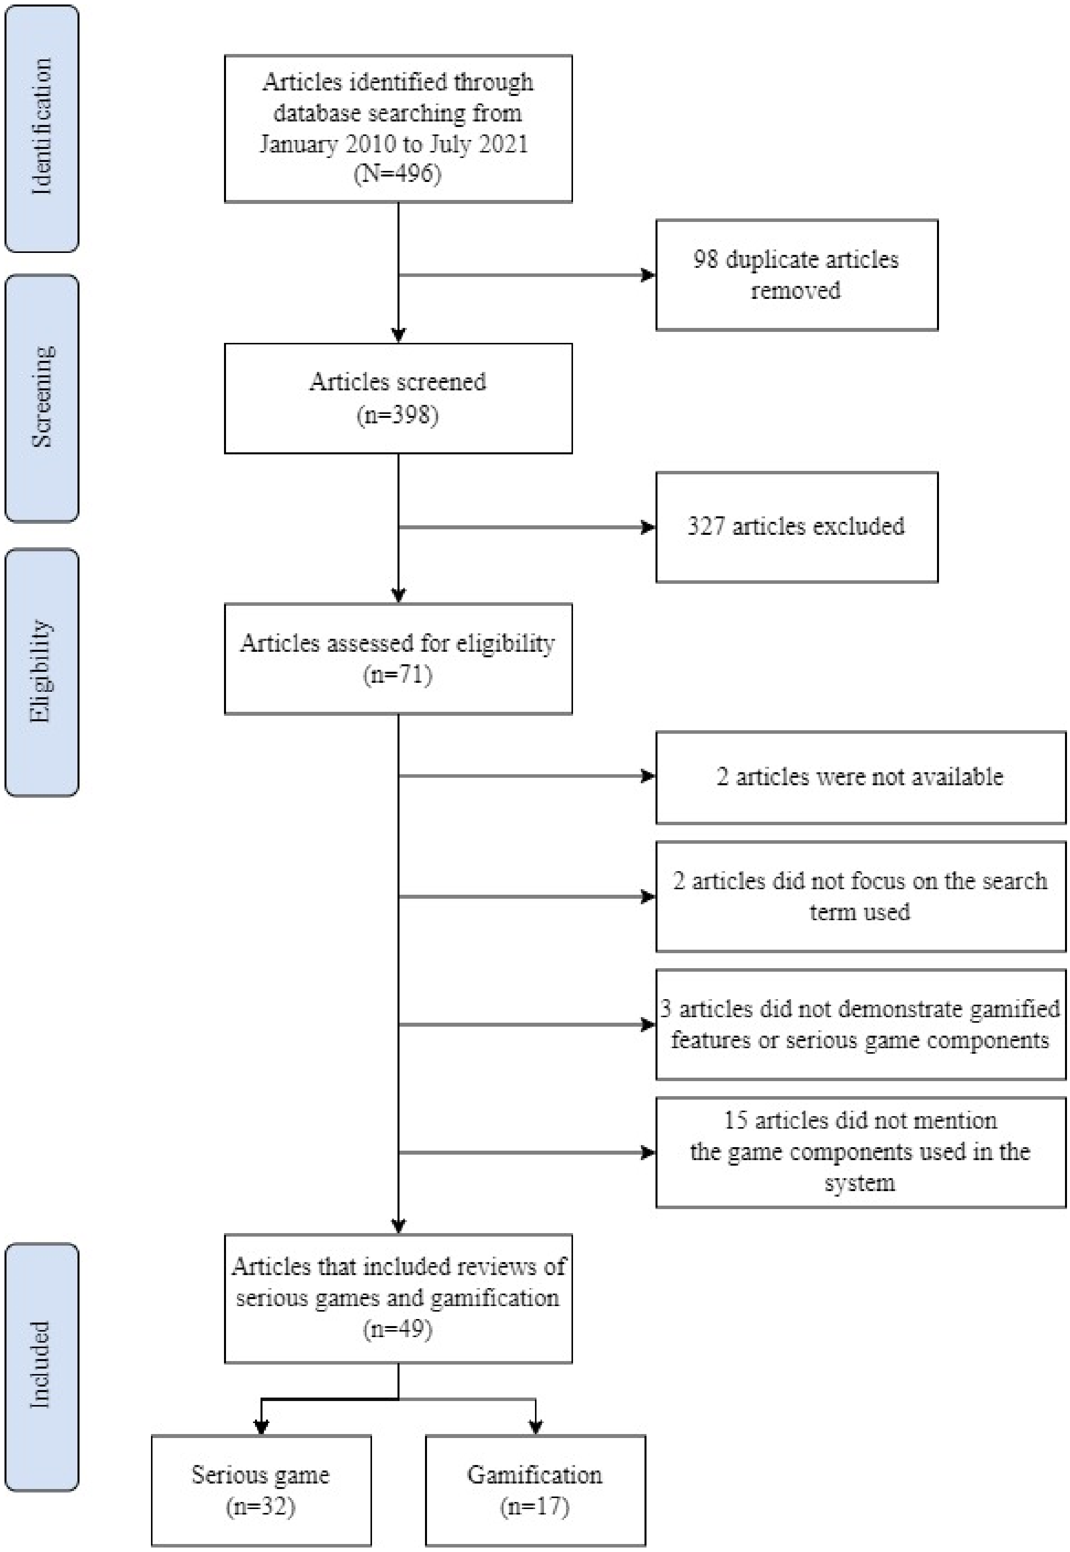
The review was conducted using the databases PubMed, Web of Science, and Scopus.

Although there are various definitions of the terms *serious game* and *gamification*, we decided to use the following search terms: (serious gam* OR videogame* OR video gam* OR gaming OR gamification) AND (HIV). The search results included only articles published in English between January 2010 and July 2021. The procedure is shown in Figure 1.

The criteria that we used to distinguish articles about serious games were as follows: (1) the article included the words (case-insensitive) *serious game* or *serious video game* in its title, keywords, abstract, or main text and (2) the article described a digital game, computer game, or video game created for a purpose related to HIV/AIDS care and prevention. Articles matching either criterion 1, 2, or both were included in this survey.

The criteria that we used to differentiate articles about gamification from those about serious games were as follows: (1) The article included the word (case-insensitive) *gamification* in its title, keywords, abstract, or main text and (2) the article described the use of a gaming approach and game-design components or game elements in a nongame context related to HIV/AIDS care and prevention. Articles matching either criterion 1, 2, or both were included in this survey.

Figure 1. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram.



Results

After the article selection process was conducted, we found that 49 of the 496 publications were eligible for inclusion. Of these, 32 articles were on serious games and 17 articles were on gamified systems for HIV prevention and care. We identified the locations where the research was conducted, what platforms were used for serious games, gamification approaches, the purposes of implementing a serious game or gamification, and outcomes.

Study Sites

There were 32 serious games and 17 gamified systems described in the 49 articles. The majority of articles (36/49, 74%) mentioned that the study's scope was limited to the United States. Moreover, 2 of 49 (4%) studies took place in Uganda, 1 (2%) in Swaziland, 2 (4%) in Kenya, 1 (2%) in Tanzania, and

2 (4%) in other sub-Saharan African countries (these were studies that designed and developed digital gamified systems for evaluating students' perceptions about sexual education). Outside Africa, 1 of the 49 (2%) studies took place in the Philippines, 1 (2%) in Indonesia, 1 (2%) in Ireland, and 2 (4%) in Spain. These results indicate that researchers pay more attention to making use of games and gaming in HIV/AIDS prevention and care in the United States than in other countries.

Video and Nonvideo Game Systems in HIV Prevention and Care

There were a total of 35 electronic gaming systems developed for the 49 studies. Of these, 22 (63%) were serious games and 13 (37%) were gamified systems.

Platforms Used for Serious Games and Gamification

A platform is the hardware or electronic system used to run a game [22]. The most pervasive game platforms were the PC (desktop computers and laptops), mobile devices (tablets and smartphones), and game consoles (Nintendo Wii, Sony PlayStation, and Xbox). Mobile devices were the most common platform, with 13 studies using this platform for serious games and 11 for gamified systems. There were 8 serious games and 1 gamified system developed for the PC platform. One study on a serious game and one on a gamified system did not clearly indicate whether they used mobile devices or PCs.

Purposes of Serious Games and Gamified Systems

Table 1 demonstrates the objectives of serious games and gamified systems. The key objectives of eligible gaming systems were identified. We discovered that serious games for HIV/AIDS prevention and care emphasized education, while gamified systems were aimed at promoting HIV testing and screening. The objectives of each gaming system are elaborated in the "Serious Game and Gamified System Implementation" section of this paper.

Table 1. Purposes of serious games and gamified systems used in HIV/AIDS prevention and care.

	Serious games, n	Gamified systems, n
Education on prevention	6	2
Reducing risk behaviors	3	3
Building peer resistance skills	1	0
Promotion of HIV testing and screening	3	4
Encouragement of pre-exposure prophylaxis	2	2
Cognitive rehabilitation	3	0
Physical rehabilitation	1	0
Adherence to and engagement in HIV care	3	3

Serious Game and Gamified System Implementation

Because the implementation of serious games and gamified systems can differ, this section describes and discusses serious games and gamification separately.

Serious Games

The implementation of serious games includes 2 important factors: game genre and outcomes (results), as described in the following sections. Table 2 summarizes these factors, as well as the target populations.

Table 2. Summary of serious games used for HIV prevention and care.

Title	Genre	Target	Purpose	Results
PlayForward: Elm City Stories [23,24]	Role-playing	Young minority Spanish adolescents	To help players learn about risk behaviors, particularly sexual risk	Significant
Secret of Seven Stones [25]	Adventure	Young adolescents aged 11-14 years	To help prevent unintended pregnancy and sexually transmitted infections	Significant
Socially Optimized Learning in Virtual Environments [26]	Role-playing	Young MSM[a]	To reduce sexual shame among MSM and increase HIV testing rate	Significant
Untitled [27]	Role-playing	Adolescents and young adults	Improve HIV testing and pre-exposure prophylaxis access	Preliminary
BattleViro [28]	Action-oriented adventure	Youth living with HIV	To help increase adherence to antiretroviral treatment	Preliminary
Battle in the Blood [29]	Role-playing	Young populations in the Philippines	To influence behavior determinants of HIV	Preliminary
ViralCombat [30]	Action-oriented adventure	Young MSM	To transmit knowledge, behavior, and skills for increased pre-exposure prophylaxis adherence and HIV prevention	Preliminary
My Future Begins Today [31]	Not identified	Secondary school students in sub-Saharan Africa	Sexual health education	Preliminary
Tumaini [32,33]	Role-playing, simulation	Young Africans in high HIV prevalence settings	To help prevent HIV by delaying first sex and increasing condom use at first sex	Preliminary
Insight (including 5 different games and exercises) [34]	Not identified	Cognitively vulnerable adults with HIV	Improving cognitive and everyday functioning in the target population	Preliminary
Game-based training program [35]	Exergame	Older people living with HIV	To ameliorate some aspects of frailty in individuals with HIV	Preliminary
HealthMpowerment [36]	Not identified	Young MSM&T[b]	To promote HIV-related knowledge and behavior with acceptance of individuals with HIV to prevent the spread of infection	Preliminary
DRAMA-RAMA [37]	Role-playing	Adolescents	To build peer resistance skills to avoid being pressured into risky behaviors such as early sexual behavior	Significant
Brain Powered Games [38]	Not identified	At-risk African children	Cognitive training and rehabilitation	Significant
Captain's Log (BrainTrain Corporation) [39]	Not identified	Children with HIV	Cognitive training and rehabilitation	Significant

[a]MSM: men who have sex with men.

[b]MSM&T: men who have sex with men and transgender people.

Genres of Serious Games

We identified 15 serious games specifically designed for HIV prevention with 4 different genres, as presented in Table 2. There was 1 untitled game. Role-playing was the predominant category of serious games that focused on HIV prevention (n=6). Among role-playing games, there were 4 educational games, including Play Forward: Elm City, Tumaini, SwaziYolo, and Battle in the Blood [29], and 2 games aiming to reduce risk behaviors, including Socially Optimized Learning in Virtual Environments (SOLVE) and DRAMA-RAMA, the latter of which focused on strengthening peer resistance skills. The second most popular game genre was adventure (n=3), including an educational game called The Secret of Seven Stones (SSS) and an action-oriented adventure game called ViralCombat [30] designed to encourage the use of antiretroviral medications to reduce the risk of acquiring HIV infection. Another game was BattleViro, which encouraged adherence to prescribed antiretroviral treatment (ART). Other genres of serious games among these studies included (1) racing (Fast Car: Travelling Safely around the World, a game that sought to educate adolescents on HIV prevention), (2) a collection of party games (The Test [40], which promoted HIV testing), and (3) an untitled exergame that promoted physical rehabilitation. Another game, My Future Begins Today, which promoted sexual well-being in low-technology settings, had an unidentified genre. [31] Three serious games for cognitive rehabilitation and one collection of games specifically developed to increase adherence to ART also had unidentified genres.

Outcomes of Studies on Serious Games

To classify the outcomes of the studies using serious games for HIV intervention and care, we defined 2 types of outcome. The first type was "preliminary results"; these studies focused on proofs of concept for the intervention. Typically, these studies were conducted in a laboratory setting. The second type of outcome was “significant results”; these studies implemented and tested the solution in real-world environments.

Serious Games Studies With Preliminary Results

In a pilot study, a theory-based smartphone game titled Tumaini [32] was designed to delay the age of a couple having their first sex and to promote condom use in young Kenyans. The preliminary results indicated that participants who played Tumaini for an average of approximately 27 hours showed significant gains in sexual health–related knowledge and self-efficacy, behavioral intentions for risk-avoidance strategies, and sexual risk communication. This pilot study suggests the need for further research to assess the efficacy of game-based interventions. Another study examined the preliminary effects of Insight [34], a computer program that consists of 5 different games designed to improve cognitive and everyday functioning in older adults living with HIV. The study found that those who performed more poorly at baseline on a useful field of view (UFOV) test that measures visual speed of processing and a test of timed instrumental activities of daily living (TIADL) had more training gains in response to the intervention. In addition, the results revealed that a higher HIV viral load and insufficient medication adherence were predictive of greater TIADL training gains. These results illustrate that middle-aged and older adults with HIV who experience problems with speed of cognition and everyday functioning may benefit from this type of training. Another study evaluated the effectiveness and acceptability of a novel game-based training program (ie, an exergame) [35] aiming to improve various aspects of physical frailty in 10 older persons who were living with HIV. The initial results showed a significant reduction in center of mass sway, a significant increase in gait speed during a motor-cognitive assessment, and a remarkable reduction in reported pain. Other studies examined games aimed at enhancing HIV prevention behaviors and adherence to pre-exposure prophylaxis (PrEP). Viral Combat, a novel and entertaining game or app focused on increasing PrEP adherence and imparting HIV prevention knowledge and skills, was first evaluated through qualitative interviews with 20 young men who have sex with men (MSM). Then, a randomized trial with 60 participants preliminarily tested the game’s effectiveness by evaluating knowledge acquisition, behavior change, and skill improvement after the gaming intervention among young MSM.

Although the Viral Combat study is ongoing, it has returned significant data on changes in motivation to increase PrEP adherence and decrease HIV infection. A mobile game called Battle in the Blood was developed as a role-playing game to influence behavior related to the use of HIV services. During a 12-month study period, the game was installed on 3325 unique devices.

The game received a positive response among casual gamers during playtests. The game’s narrative is a key part of its strategy for delivering HIV knowledge. Another project launched a randomized controlled trial (RCT) to examine the initial effects of an action-oriented adventure game called BattleViro [28], which was developed as a tool to improve adherence to ART, decrease viral load, and increase relevant knowledge in 61 youth living with HIV. The study demonstrated promising results but no significant improvements in HIV knowledge, ART knowledge, or social support. However, those who recently started ART (in the past 3 months) and used BattleViro had a greater decrease in viral load, better ART adherence, and more HIV and ART knowledge than the control group.

One game we identified, in the study by Castel et al [27], never started testing as an intervention by the time that the paper was published, as it was still in a participant recruitment stage. Another game, called My Future Begins Today, was developed for sexual health education and was improved based on user responses in a low-technology setting. The 348 participants (193 boys and 155 girls) were students in secondary school aged 11 to 15 years. The results show that groups using a gamified learning approach outperformed those that used a conventional learning approach. Moreover, a game designed for low-technology settings could be more helpful in delivering sexual health education than formal educational approaches.

Other studies have examined mobile health apps and nonvideo serious games that serve as self-learning tools. These include an app called HealthMpowerment (HMP) [36] and an mHealth app [41] to increase users’ knowledge of HIV and social support pertaining to caring for HIV-positive people and living behaviors of HIV-positive people. The contents were evaluated by a group of young MSM and transgender women in the United States and Indonesia. After testing with the target group, the authors determined that the app-based intervention was easily accessible and could support people with HIV in the long term, resulting in a significant increase in comprehension and knowledge of HIV.

Serious Games Studies With Significant Results

We identified 6 serious games with significant results, including PlayForward: Elm City Stories, SOLVE, DRAMA-RAMA (an avatar-based virtual reality game for peer resistance skill building), SSS (a web-based adventure game), and games focusing on cognitive rehabilitation called Captain’s Log and Brain Powered Games.

In a study to evaluate PlayForward [24], a video game that was specifically developed as an HIV prevention tool targeted at HIV risk behaviors (ie, substance use and sex) in young adolescents, the authors showed that after 6 weeks of playing the game, the intervention group had higher knowledge scores than the control group at 6 weeks and at 3 months. Moreover, an analysis of 1,289,903 events in log files of the game revealed that the number of game levels completed was positively correlated with gains in knowledge measured at 6 weeks and at 3 months. These findings demonstrated that PlayForward increased HIV risk–related knowledge among adolescents and that exposure to the video game’s content was highly correlated with knowledge. Another study of the same game [23] analyzed log files from 166 participants in an RCT and showed that higher knowledge scores for substance use at 3- and 6-month follow-ups were related to successfully completing more of the game levels, rather than to total gameplay time.

Another study aimed to investigate the effects of SOLVE [26], a role-playing video game focused on sexual shame reduction among MSM. MSM in the SOLVE intervention reported more shame reduction than MSM in the control condition. Moreover, greater reductions in shame among participants in the SOLVE treatment condition in turn predicted reductions in risky sexual behavior at follow-up. Additionally, SOLVE was the first intervention to significantly reduce shame and risks for MSM from unprotected anal intercourse.

DRAMA-RAMA [37] is an avatar-based video game focusing on peer resistance skill building in teenagers. An RCT was conducted to assess how positively the game was perceived by 45 young Hispanic girls. Separate analyses of covariance showed a significant difference between pre- and posttest scores for peer resistance self-efficacy measured after the game play session, but these findings were not repeated at a 2-month follow-up. The results provided preliminary support for the hypotheses that playing an avatar-based virtual reality technology game would strengthen peer resistance skills and that early adolescent Hispanic girls would have a positive response to this game.

SSS [25] is a web-based adventure game for teenagers aged 11 to 14 years in the United States aimed at education to prevent unwanted pregnancy and sexually transmitted infections. SSS emphasizes educational training to acquire knowledge about sex-related topics and is based on an intervention mapping approach. It can be used at home and is an intergenerational communication channel with parents.

We found 2 studies that examined the efficacy of serious game interventions for cognitive rehabilitation in African children. In the first study, 33 African children with HIV who lived in rural Uganda and were aged between 6 and 12 years played 45-minute sessions of Brain Powered Games several times a week for 2 months. After the intervention, participants demonstrated clinically significant changes on specific Test of Variables of Attention and CogState measures, reflecting processing speed, attention, visual-motor coordination, maze learning, and problem solving. The second study evaluated the neuropsychological and behavioral benefits of Captain's Log [39], a computer program specially designed for cognitive training and rehabilitation in children living with HIV in Uganda. The 159 participants were randomized to 1 of 3 treatment groups over a 2-month period and were assessed at enrollment, immediately following a 2-month computerized cognitive rehabilitation training (CCRT) course, and 3 months after CCRT completion. The CCRT groups, which used Captain's Log, had significantly greater gains at the 3-month follow-up compared to a passive control group in an overall mental processing index measured with the Kaufman Assessment Battery for Children, Second Edition (KABC-II); they also showed gains in planning and knowledge. A group that received limited CCRT with the same games rotated randomly from simple to moderate levels of training performed better than a passive control group receiving no training. Moreover, both CCRT arms had significant improvements in CogState Groton maze learning.

Gamified Systems

Our examination of gamified systems aims to understand 4 important factors: types of gamification approaches, elements of gamification, rewards and incentives used, and effectiveness outcomes, as described in the following sections.

Types of Gamification Approaches

In contrast with serious games, gamification is an approach that applies game mechanics in nongame settings. It is used in a broader context and has more specific outcomes. There are typically 3 types of gamification [15]: internal, external, and behavior-change gamification. Internal gamification targets users within an organization, aiming to improve productivity and increase innovation. External gamification is generally driven by marketing objectives to improve relationships between businesses and customers and improves engagement by clients. Finally, the purpose of behavior-change gamification is healthy habit formation among a population. After removing duplicate and conceptual articles describing the initial development phase of gamification projects that lacked a system prototype, we identified 13 different electronic gamified systems in 17 publications. The majority (n=11, 85%) of the surveyed studies used a behavior-change gamification approach and a minority (n=2, 15%) used external gamification. Six mechanics can be distinguished among behavior-change gamification techniques as defined by Werbach and Hunter [15]: challenge, rewards, feedback, resource acquisition, cooperation, and competition. Challenge aims to motivate users to make an effort with content unlocking and requires users' effort to complete a list of objectives to be fulfilled; rewards are an indicator of players' achievements; feedback provides information to players about their progress and status during the game through leaderboards or other visual or informational displays; resource acquisition is intended to motivate users to collect and own useful tools; cooperation uses team-building and requires collaboration between players to achieve an objective that is not possible alone; and competition motivates in-game contention between users.

Elements of Gamification

We examined the game mechanics that underlie various game components; these directly affect gamification designs [42], as illustrated in Table 3.

The game components used in the surveyed studies comprised avatars, levels, content unlocking, leaderboards, virtual goods, achievements, badges, points, and teams.

Table 3. Game mechanics and behavior-change strategies used in behavior-change gamification.

System name	Game mechanics [42]						Behavior change strategies [43]
	Challenge	Rewards	Competition	Cooperation	Resource acquisition	Feedback	
Bijou [44]	No	Yes	No	No	No	Yes	Provide feedback on performance
Sexual health education programs on the Moodle platform [45]	No	Yes	Yes	No	Yes	Yes	Compare progress; provide feedback on performance
UBESAFE [46]	No	Yes	Yes	No	No	Yes	Capacity to overcome challenges; provide feedback on performance; reinforcement
A community-based HIV and sexually transmitted infection testing system [47]	No	No	No	No	No	No	None
Epic Allies [48,49]	Yes	Yes	Yes	Yes	Yes	Yes	Provide feedback on performance
AllyQuest [50]	Yes	Yes	No	No	Yes	Yes	Goal setting and social connectivity
P3 [51]	Yes	Yes	No	No	Yes	Yes	Goal setting; social connectivity; provide feedback on performance
HealthMpowerment [52,53]	No	Yes	No	No	No	No	Goal setting; social connectivity
Stick To It [54,55]	No	No	Yes	Yes	Yes	Yes	Compare progress; provide feedback on performance
Thrive with Me [56]	No	Yes	Yes	No	Yes	Yes	Social connectivity; provide feedback on performance
Game Plan [57,58]	No	Yes	No	No	No	No	Goal setting

Avatars are visual representations of players in the game. They are presented to learners as their visual representations and future selves. The avatar component of gamification is used to activate the reward mechanic. In the surveyed studies, we found avatar use in gamified systems including Epic Allies, AllyQuest, P3, HMP, Stick To It, Thrive with Me, Bijou [44], Dot [59], and Game Plan.

Levels show the player's position at any point during the game to serve as feedback. For example, Besoain et al [46] embedded an experience bar, visualized as medals, that was incremented when users had a significant interaction with the system. In Bijou [44], a completion bar was used to give feedback on the level of completion.

Content unlocking allows a player to access game content or narrative without meeting certain points or specific criteria. The component of content unlocking serves the mechanics of challenge, feedback, and reward.

A leaderboard is a list that shows a ranking of players according to their scores and collections after in-game assessment. The leaderboard allows players to monitor their own ranking and compare it with that of others. The leaderboard component is used to initiate competition and feedback mechanics.

Virtual goods are valuable items that players can purchase during the game in exchange for their points. A representative use of virtual goods was in the game Epic Allies, which used "virtual cards" that players can buy and upgrade using points earned by engaging in other parts of the app. This component is used for the resource acquisition mechanic.

Achievements are rights and rewards given to the player in return for accomplishing an objective; they serve the mechanic of rewards. An example is the gems that are used to signify achievements in Bijou [44].

Badges are commonly used for setting goals, providing explanations about learning activities, identifying players who have shared experiences, and providing users with status. For instance, a badge that shows the level of engagement is given to users in UBESAFE [46]

Points are used to measure success and quantify player progress. In the surveyed studies, users earn points if their responses and in-game actions support healthy behavior and are consistent with HIV prevention measures. Players also earn points in a form of in-app virtual currency in the games AllyQuest and P3. Points can also be earned in the form of scores, as in sexual health education programs with a gamification technique [45] and mobile apps. This component serves the mechanics of resource acquisition and feedback.

Teams represent cooperation to achieve common objectives in the game. Participants can recruit team members to achieve in-game challenges in the games Epic Allies and Stick To It. This component serves the mechanic of cooperation.

Additionally, we found that 6 of 7 gamification strategies for health behavior changes determined by behavioral science [43] were discussed in the surveyed articles. The 7 gamification strategies and validated behavior changes were (1) goal setting, (2) increasing capacity to overcome challenges, (3) providing feedback on performance, (4) providing reinforcement, (5) comparing progress, (6) providing social connectivity, and (7) providing fun and playfulness. Only the strategy of providing fun and playfulness was not found to be used in any games. Game mechanics and behavior change strategies that were used in behavior-change gamification in the studies examined here are shown in Table 3.

Moreover, among the surveyed studies, we found one that described a community-based HIV and sexually transmitted infection (STI) testing system [47] that mentioned using gamification techniques, but that article did not clearly explain the game components, game mechanics, or behavior change strategies, except to state that they automated text messages and graphical quizzes. The system appears only to have integrated quizzes into existing systems.

After examination, we found that gamified systems had both educational and advertising purposes using points or scores as the primary element to attract and engage nonpatients who shared similar goals. However, avatar and level elements were commonly used to improve ART adherence in HIV patients.

Rewards and Incentives

We found patterns of reward use based on in-game or virtual reward systems [48,50,51] and physical reward systems that allowed exchanging virtual points and in-game currencies into cash prizes or tangible gifts [52-54,56], as illustrated in Table 4.

In addition, there were 3 systems that were classified as using external gamification, that is, social marketing techniques related to a web page's visitors or use of particular online tools to improve the attitudes of a population toward an HIV testing service and encourage people to physically visit an HIV clinic [60,61] (Table 5).

Table 4. Behavior-change gamification, game mechanics, and reward use.

System name	Reward use
Sexual health education programs on Moodle platform [45]	None
Community-based HIV and sexually transmitted infection testing system [47]	None
Epic Allies [48,49]	Buy and upgrade virtual cards using points
Ally Quest [50]	Earn and redeem in-app currency to unlock new app features
P3 [51]	Earn and redeem in-app currency to unlock new narratives and new app features
HealthMpowerment [52,53]	Built-in rewards can be redeemed for physical prizes from the HealthMpowerment online store
Stick To It [54,55]	In-game points increase chance of winning prizes that cost US $5
Thrive with Me [56]	App use can be exchanged for a weekly prize of a US $25 online gift card
Game Plan [57,58]	None

Table 5. External gamification and reward use.

System name	Reward use	Game component	Behavior changes strategies
Testing is Healthy [60]	Points can be converted into real-world prizes (eg, food and drinks)	In-game points	Social connectivity (sharing on social media)
Untitled intervention activities [61]	Points can be redeemed for gifts or exchanged for raffle tickets	In-game points	Social connectivity (making use of social marketing principles and social networking sites)

Outcomes of Studies of Gamified Systems

Gamified Systems Studies With Preliminary Results

We identified examples of studies with preliminary outcomes related to the effectiveness of gamified systems that examined the following apps and systems: Stick To It, AllyQuest, Game Plan, a gamified website (HMP), and UBESAFE.

A pilot study assessing Stick To It determined whether an intervention using gamification was acceptable to young MSM in California and effectively increased repeat HIV screening. The preliminary outcome was that engagement in the intervention was moderate; however, the inclusion of game elements was motivating. Additionally, young MSM who enrolled in a clinic were more strongly engaged than young MSM who registered online. Moreover, the repeat HIV screening rate among the subset of participants who were recruited in the clinic was higher than a comparison group of similar young MSM attending the same clinic the previous year. Another pilot study assessed the feasibility and acceptability of AllyQuest [50], a novel smartphone app designed to improve engagement in HIV care and social support among young MSM living with HIV. A pilot trial conducted with 20 participants showed high levels of app use that were positively correlated to HIV self-management outcomes. There was also a statistically significant relationship between the number of days logged into the app and knowledge and confidence in taking HIV medications. These primary outcomes raised the possibility that AllyQuest could impact long-term HIV ART adherence among HIV-positive young MSM. Moreover, a 4-week pilot trial conducted with young Black MSM and transwomen tested HMP [53], a mobile-optimized intervention that included game-based elements to reduce sexual risk behavior by providing information. In this pilot trial, HMP showed promise for being able to deliver a sufficient intervention dose and maintain exposure and engagement over time sufficient to achieve behavioral change. In this qualitative assessment of 15 participants, the researchers found a correlation between the number of times the intervention site was used and stages of behavioral change. Another study explored the initial effectiveness of Game Plan [58], a tablet-based brief motivational intervention for alcohol use and HIV risk. Over 3 months of follow-up, the participants who used Game Plan reported fewer drinking days, fewer binge drinking days, fewer alcohol problems, and fewer new anal sex partners compared to those in the control group. These initial results suggest that web-based brief motivational interventions could be a promising tool to help MSM reduce HIV-related risk behavior. Additionally, a feasibility evaluation of UBESAFE [46] indicated that the gamified features encouraged users to interact more with the system, by up to 100%.

Gamified Systems Studies With Significant Results

There were 3 studies of gamified systems with significant results (Table 6), including a pedagogical framework called Motivation, Attitude, Knowledge, and Engagement (MAKE), a promotional campaign aimed at STI and HIV prevention called Testing is Healthy, and the gamified website HMP.

Table 6. Results of studies on gamified systems used in HIV prevention and care.

Title	Target	Game's purpose	Results
Motivation, Attitude, Knowledge, and Engagement framework [45]	Adolescent students aged 11-15 years	Provide pedagogy for sexual health education/improve sexual health education programs for adolescent students	Significant
AllyQuest [50]	Young MSM[a]; mean age of focus group participants was 23 years	Support engagement in care and medication adherence for HIV-positive young MSM	Preliminary
HealthMpowerment [52,53]	HIV-positive and negative young Black MSM and transwomen aged 18-30 years	Use behavior change and gaming theories to reduce risky sexual behaviors and build community with a mobile phone–optimized intervention	Significant
Stick To It [54,55]	College students (aged 18-24 years)	Increase HIV screening among young MSM	Preliminary
Game Plan [57,58]	MSM aged 18-53 years	Help MSM reduce their HIV risk and alcohol use	Significant
Testing is Healthy [60]	Young adults aged 20-29 years	Use digital gaming as a medium for preventing sexually transmitted infections and HIV	Significant

[a]MSM: men who have sex with men.

An RCT was conducted to investigate the extent to which game-based learning and the gamified MAKE framework [45] could improve sexual health education among 120 young students in Tanzania. The adolescents were divided into groups that received teaching with 1 of 3 methods: game-based learning, gamified MAKE, and the control group, which used a conventional teaching method. The results suggested that the first 2 teaching approaches delivered better learning outcomes than the conventional teaching method and could be used as tools to improve sexual health behavior and increase HIV/AIDS knowledge in young students.

The evaluation of Testing is Healthy [60] used a technology-based platform called Cineplex TimePlay that included gaming elements to engage people who often go to the cinema to answer STI/HIV-related questions. The system also provided a clinic finder service on a website. Although this was the first time this platform was used for sexual health promotion, the campaign received a great response, with 548,410 views and 77,149 plays. Additionally, server-side rendering web analytics showed a significant increase in the clinic finder page's unique page views between the first and second campaigns. The results demonstrate that this technique could be used to reach a large population at a low cost.

The last study [52] was an RCT that compared the efficacy of the HMP intervention to an information-only control website. The results indicated that the rate of self-reported condomless anal intercourse at 3 months was 32%, suggesting that exposure to an online intervention can reduce the rate of condomless anal intercourse among young Black MSM, at least in the short term.

Discussion

In order to provide a comprehensive map of the available evidence on HIV prevention and care, we used a scoping review methodology to conduct this review. The literature included in this study adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) standard, which facilitated the inclusion of extensive information on serious games and gamified systems. Nevertheless, this scoping review was restricted to providing answers to particular issues. Therefore, a future systematic review would enhance and enrich our knowledge.

The results of this scoping review show that 74% (36/49) of study sites, as reported in 16 articles that examined serious games and 10 that examined gamification, were in the United States. A small minority of reviewed studies were performed in sub-Saharan African countries, which have the highest global HIV/AIDS infection rates. Because of the unavailability of electricity and communication facilities, the level of technological solutions in rural areas of Africa is very low [62]. Therefore, researchers need to make the most of their resources by applying other communication tools and methods that focus on users' behaviors and lifestyles instead of depending on digital technology and gaming.

Moreover, the majority of the serious game and gamified systems used mobile platforms. This confirms that improvements in mobile computing hardware and wireless networking improve outcomes and not only make interventions accessible for users but are also beneficial for game developers, as they allow them to create dynamic and realistic worlds and characters [63].

The major purpose of serious games and gamified systems applied in HIV/AIDS studies is to enhance the effectiveness of HIV/AIDS prevention strategies by reducing sexual risk behaviors and increasing the HIV/AIDS screening rate. The surveyed results are consistent with findings from previous studies [64,65] that indicate that early diagnosis and prevention of HIV infection is more cost-efficient than lifetime HIV treatment. Moreover, 6 of the 16 serious games we identified were in the role-playing genre, of which half were designed for educational prevention and reducing risky behaviors.

For our analysis of game elements in gamified systems, we followed the categories proposed by Werbach and Hunter [15] because there is no universal standard to classify game elements in gamified systems. Their taxonomy of game elements is one of the most widely used taxonomies in research on gamified systems [66-69]. The taxonomy includes 15 game components that can represent specific mechanical forms or can be dynamic, including achievements, avatars, badges, boss fights, collection, combat, content unlocking, giving, leaderboards, levels, points, quests, social graphs, teams, and virtual goods. We then attempted to match the selected studies to this taxonomy to determine the characteristics of gamified system components in the HIV domain. The common patterns we observed in the development of gamified systems for HIV are consequently a guide for future studies.

The majority (11/13, 85%) of the surveyed approaches were classified as using behavior-change gamification, which is a technique that seeks to encourage healthy sexual habits in a given population. Some fundamental game components are embedded in the kinds of systems we reviewed here, such as points, badges, leveling, and rewards. However, some systems claimed to incorporate gamification despite the fact that they only used graphical quizzes and had no other defined game elements or strategies. This reflects the complexity of the gamification concept, as well as its application; both the concept and its application are in the introductory stages in the domain of HIV/AIDS prevention and care. Our findings also show patterns of reward use, including in-game rewards and physical prizes, that have the same behavioral change objectives for HIV/AIDS care and prevention.

The in-depth analysis of the effects of game mechanics and behavioral change strategies used in behavior-change gamification shown in Table 3 reveals that the first-ranked, most frequently used game mechanic was rewards. Kocadere and Çağlar [42] indicate that rewards serve as a gauge of a player's performance; the components of the reward mechanic are badges, achievements, avatars, and content unlocking. Moreover, rewards can be used for players to progress and to create player emotions, including apprehension, excitement, grief, and happiness with dynamic use of constraints, emotions, progression, and relationships [15].

Feedback was the second-ranked mechanic. Feedback is data presented to the player regarding their performance in the game. The feedback mechanic serves the dynamics of progression and emotions. Feedback can be both formative (badges, levels, leaderboards, content unlocking) and summative (points, badges, leaderboards, levels) [42]. The reason that rewards and feedback are used in behavior-change gamification is that player progress and emotions are largely influenced by the rewards and feedback they receive. Therefore, if the goal of the gamified system is to improve the behavior of users, a mechanism for providing rewards and feedback should be considered when developing a behavior-change gamification system.

Conclusion

As the reach of the internet and cell phones improves, their use as health intervention and prevention tools has increasingly been researched to strengthen their impact on behavior and social change in HIV/AIDS prevention and care. However, the study sites of research on serious games and gamified systems mentioned in articles from 2010 to 2021 were mostly in the United States. This contrasts with the small number of studies undertaken in sub-Saharan Africa, which has the highest global HIV/AIDS infection rate. We also discovered that the majority of serious games use mobile platforms. This finding demonstrates that improvement in mobile computing hardware and wireless networking has made them more accessible for users.

The majority (11/13, 85%) of the surveyed studies were classified as using a behavior-change gamification approach. This is a technique that seeks to form healthy habits among the population. Additionally, the results highlight the intricacy of gamification and its applications, which are still in their infancy in the field of HIV/AIDS prevention and care. Furthermore, the survey results show that the most important goal of serious games and gamification is to improve the effectiveness of HIV/AIDS prevention efforts. This is consistent with findings from previous studies that indicate that early prevention and early ART of HIV/AIDS infection are more cost-efficient than lifetime HIV/AIDS treatment. This study identifies, compares, and describes serious games and gamified systems currently used in HIV/AIDS prevention and care. The study results reveal the situation in the studied period pertaining to common popular study sites, game platforms, and gamification approaches among serious games and gamified systems used in HIVAIDS prevention and care. The contributions of this review should provide a resource of information for organizations, game developers, and other parties who intend to use games as communication or education tools for HIV/AIDS.

Acknowledgments

We are grateful and would like to express our heartfelt thanks to everyone who participated in this project. This study has taken more than a year to complete and needed funding. We are therefore most thankful to the Center of Data Analytics and Knowledge Synthesis for Healthcare and the College of Arts, Media and Technology at Chiang Mai University, Thailand, for providing financial support for the project.

Abstract

Background: Many studies have started integrating virtual reality (VR) into neurorehabilitation for children with cerebral palsy (CP). The results of the effects of VR on motor skill learning, including the short- to long-term results of relevant studies, must be pooled in a generic framework.

Objective: This systematic review and meta-analysis aimed to investigate the short- to long-term effects of therapies including VR on motor skill learning in children with CP.

Methods: Two examiners followed the inclusion and exclusion criteria of the "Participant, Intervention, Control, and Outcome" framework. Randomized controlled trials (RCTs) and non-RCTs were considered if they compared VR-included interventions with control groups on motor functions and daily life activities in children with CP. PubMed, ScienceDirect, Embase, and IEEE Xplore databases were searched. The modified Downs and Black assessment was used to assess the methodological quality of the included studies. Meta-analyses and subgroup analyses for RCTs were conducted whenever possible.

Results: A total of 7 RCTs, 2 non-RCTs, and 258 children with CP were included. The priority focus of 78% (7/9) of the studies was upper limb functions. There was a significant short-term effect of adding VR to conventional therapies on upper limb functions when compared with conventional therapies (*P*=.04; standardized mean difference [SMD]=0.39, 95% CI 0.01-0.76). The overall medium- to long-term effects showed a trend toward favoring the VR group, although the difference was not statistically significant (*P*=.06; SMD=0.37, 95% CI −0.02 to 0.77). For balance (*P*=.06; SMD=1.04, 95% CI −0.04 to 2.12), gross motor functions (*P*=.30; SMD=2.85, 95% CI −2.57 to 8.28), and daily life activities outcomes (*P*=.21; SMD=0.29, 95% CI −0.16 to 0.74), the overall effect in the short term also showed a trend toward favoring the VR group, but these results were not statistically significant.

Conclusions: VR seems to have additional benefits for motor skill learning in children with CP. Studies with follow-up outcomes of VR training focusing on balance and gross motor functions in patients with CP were quite limited. Future research on balance and gross motor function outcomes should target particularly long-term results of therapies including VR on motor skill learning.

KEYWORDS

cerebral palsy; virtual reality; motor skill learning; long-term effect; daily life activities; motor functions

Introduction

Background

Cerebral palsy (CP), the leading motor disability in childhood with a worldwide prevalence of 2 per 1000 live births, is a group of permanent movement and posture disorders caused by an early brain lesion during pregnancy, childbirth, or shortly after birth [1,2]. In addition to the motor consequences, sensory and cognitive functions affecting daily life activities may also be impaired [2]. From the rehabilitation perspective, motor skill learning–based approaches have shown encouraging efficacy in improving motor functions in children with CP in recent years [3]. Interventions based on motor skill learning principles (more intensity, performance of daily living activities, repeating functional tasks, individually tailored, progressively challenging, and motivating feedback) have been shown to promote persistent motor skill acquisition and neuroplasticity (practice-induced brain changes) [4,5]. In addition, it is now well established that sustaining children's attention, interest, and enjoyment for a long time is one of the critical factors, but it is also challenging for optimizing rehabilitation outcomes and neuroplastic changes [6]. Consequently, researchers have focused on how to foster neuroplastic changes and functional improvements with more intensity and diversity of practice without a trade-off in terms of entertainment.

Thus, with the results of recent studies and the increase in access to computer-assisted technologies, the use of virtual reality (VR) as a means of neurorehabilitation for children with CP has been encouraged. VR refers to a computer-generated simulation that may vary in complexity and reality owing to the rapidly evolving nature of technology [7,8]. The VR environment can be experienced through a variety of display hardware, including standard monitors, flat screens, projection screens, and head-mounted displays. The method of interacting with the VR system may also vary from simple activation of computer keyboard keys, mouse, or joystick to more advanced motion camera interfaces [9,10]. Consequently, VR devices used in rehabilitation can be classified as immersive, semi-immersive, and nonimmersive depending on the level of immersion [11,12]. Furthermore, certain devices are specifically designed for rehabilitation purposes, whereas commercially available devices and games are also used in the rehabilitation of various disorders. A systematic review on the clinical utility of VR in neurorehabilitation reported that CP is the second most studied neurological disorder in VR rehabilitation [13]. In addition, You et al [14] and Golomb et al [15] showed cortical reorganization after VR therapy in children with CP and the association of the cortical changes with functional abilities. The advantage of using VR in rehabilitation is not only to increase entertainment with playful interactive games but also to have games with individually tailored, progressively adjustable difficulty levels and to provide active repetition in an enriched environment [9]. Thus, with these advantages, VR may well correspond to the challenges in rehabilitation such as the use of motor skill learning principles to develop long-lasting motor skill acquisition in children.

Objectives

Several systematic reviews investigated the effectiveness of VR on upper and lower limb functions, gross motor functions, and postural control in children with CP in the short term, that is, immediately after treatment [16-18]. They showed a promising potential of adding VR into CP interventions for improving motor functions. However, the long-term effects of VR interventions on motor skill learning remain unclear, although durable retention of acquired skills is one of the crucial factors for rehabilitation objectives. Consequently, this systematic review and meta-analysis was conducted to examine the effect of VR on motor functions and daily life activities of children with CP from the short term (immediately after the intervention) to the medium term (≥1 week to <12 weeks after the end of the intervention) or long term (≥12 weeks after the end of the intervention).

Methods

Protocol and Registration

We followed the guidelines of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 statement to conduct this systematic review and meta-analysis and reported our results according to PRISMA 2020 checklist [19]. The protocol of this review was registered in the PROSPERO database (CRD42021227734).

Eligibility Criteria

Inclusion criteria of the studies were defined after discussion among all authors according to the PICO (Population, Intervention, Comparison, and Outcome) framework [20]. As a result, studies (1) with a population of children with CP aged <18 years; (2) using VR for main intervention; (3) comparing the experimental group (therapy involving VR) with any control group (another intervention except VR, nonintervention, placebo effect, or different cohorts); and (4) including baseline, postintervention, and follow-up assessments by using outcome measures on motor functions and daily life activities were included. We excluded studies if they (1) involved populations other than children with CP aged <18 years; (2) used VR only for assessment or focused on the development of VR devices; (3) used different outcome measures than on motor functions and daily life activities; (4) were not published in English; (5) were reviews, meta-analyses, commentaries, protocols, and conference abstracts; and (6) did not have follow-up assessment (ie, had only baseline and postintervention assessments). In this review, we decided to include studies involving commercially available VR devices or those specifically developed for therapy, regardless of the degree of immersive experience, type of display hardware, or the method of interaction with the VR system.

Information Sources and Search Strategy

Two authors systematically and independently searched PubMed, ScienceDirect, Embase, and IEEE Xplore databases in September 2021 using predetermined keyword combinations, which were "virtual reality," "virtual environment," "videogaming," "computer game," "Kinect," "Wii," "PlayStation," "cerebral palsy," "CP," "rehabilitation," "therapy" and "motor skill learning." The results of the search in the 4 databases were transferred to the EndNote (version 9; Clarivate), and duplicates were removed by 1 author. The search strategy used for each database is detailed in Multimedia Appendix 1. We did not apply any restriction regarding the date of publication for our search strategy.

Study Selection Process

After detecting and eliminating duplicated studies obtained from the searches, 2 authors first screened titles and abstracts according to the inclusion and exclusion criteria. After several discussions and resolving the conflicts between authors, full texts of studies that have the potential to be included were obtained. Then, the eligibility of the studies was assessed using full-text screening. All screening and study selection processes were performed by the same 2 authors who were blinded to each other using Rayyan web-based software (Qatar Computing Research Institute) [21].

Data Collection Process and Data Items

The following information was extracted by 2 authors independently to a predesigned Microsoft Excel (Microsoft Corp) sheet: characteristics of the study (first author, year of publication, and study design), characteristics of the participants (number of participants, CP type, age, Manual Ability Classification System [MACS], and Gross Motor Function Classification System [GMFCS] level), characteristics of the VR interventions and comparison interventions (name, duration, frequency, length, total hour, priority focus, and motor skill learning principles involved in experimental interventions), characteristics of outcomes measures (timing and measures), and main outcomes. In addition, to collect the data from the included studies, another predesigned Microsoft Excel sheet was used, with the following content: mean and SD of experimental (VR) and control groups at postintervention and follow-up points and sample sizes of both groups. When there was no information about the means and SDs of results, they were calculated from SE, CI, *t* test, or *P* value as recommended by the Cochrane handbook [22]. Disagreements between the data collectors were resolved by a discussion.

Methodological Quality Assessment

Two authors independently assessed the methodological quality of the included studies using the modified Downs and Black checklist. This is a valid and reliable tool to assess the quality of both randomized controlled trials (RCTs) and non-RCTs [23]. Conflicts were resolved by discussion. This checklist comprises 27 items on the quality of reporting (10 items), external validity (3 items), internal validity (bias and confounding; 13 items), and statistical power (1 item).

The highest possible score for the original checklist was 32. However, as item 27 was complicated to score (from 0 to 5), a modified version of the scoring method was proposed, as observed in previous studies [17,24,25]. Thus, each item was scored as 0 (no) or 1 (yes), except for the fifth item that was scored as 0 (no), 1 (partially), or 2 (yes). Consequently, scores on the modified Downs and Black checklist corresponding to quality levels ranged between "excellent" (scores of 24-28), "good" (scores of 19-23), "fair" (scores of 14-18), and "poor" (scores of ≤13) [26,27].

Effect Measures and Synthesis Methods

We conducted a meta-analysis for the RCTs that met the criteria for eligible design and outcomes. The results from the studies on motor functions and activities of daily living were extracted into a Microsoft Excel sheet. For continuous data, standardized mean difference (SMD) with a 95% CI, which refers to the effect size, was measured using a random effects model because of the different clinical tests used in the included studies. For the interpretation of effect sizes, we followed Cohen rule in which 0.2, 0.5, and 0.8 represent small, medium, and large effect sizes, respectively [28]. Statistical significance was set at .05, and statistical heterogeneity was examined using the I^2 statistic. Heterogeneity was rated as low (I^2≤25%), moderate (25%<I^2<75%), or high (I^2≥75%).

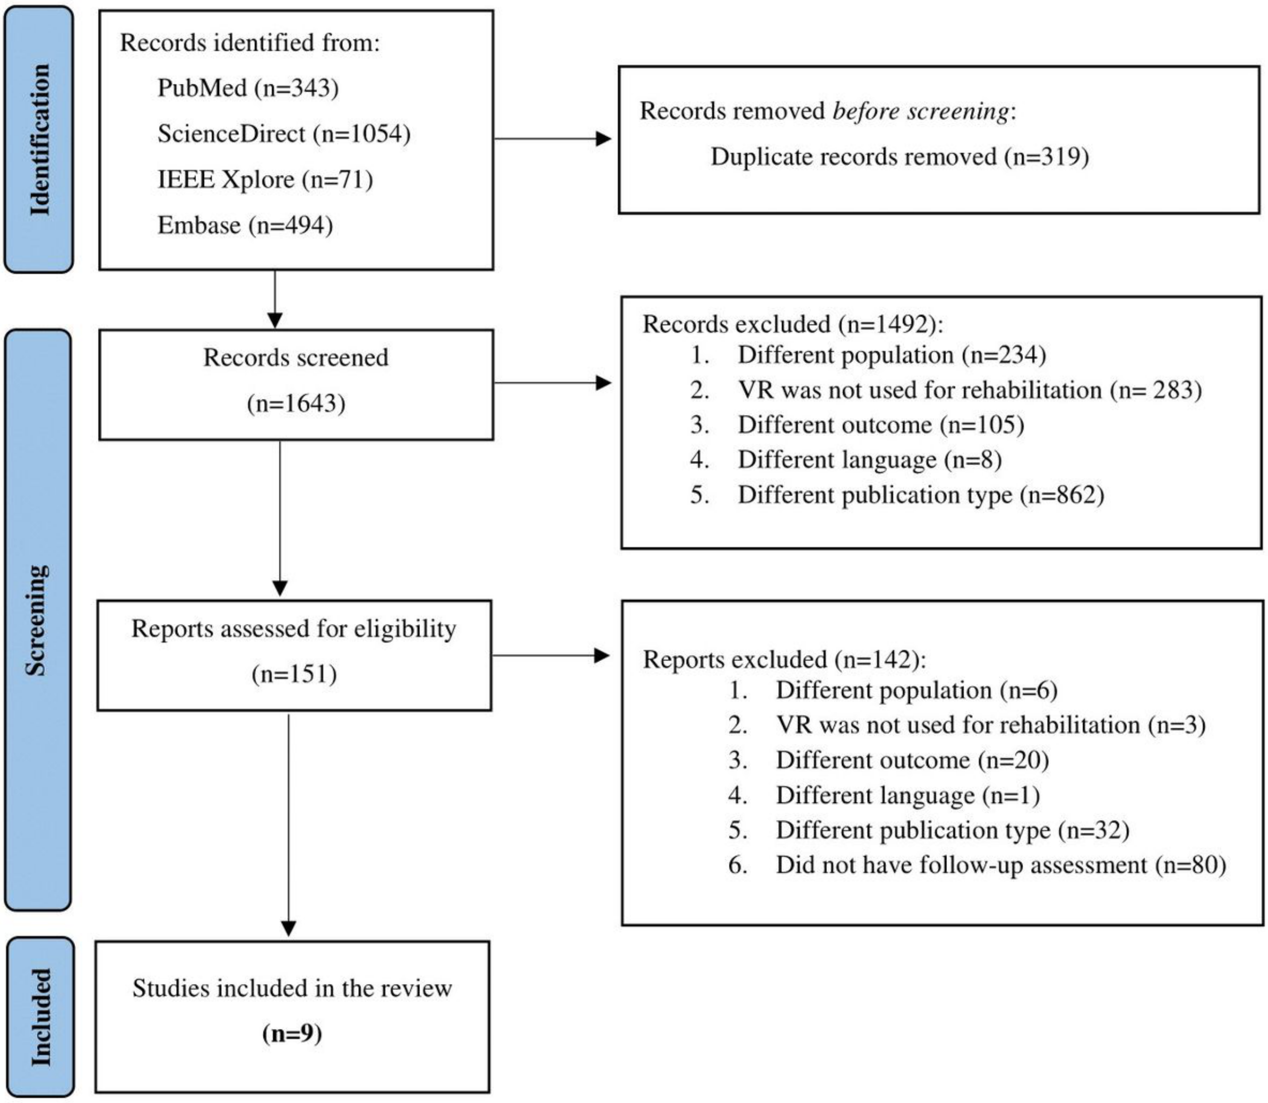
To explore whether the duration and intensity of VR training (more intensive: more therapy time per week, which is obtained by the higher frequency of sessions or longer duration of each therapy session) as well as the type of VR had some influence on the results, subgroup analyses were performed (when possible) according to the following criteria: duration (<30 min per session, ≥30 to <60 min per session, or ≥60 min per session), intensity (≤120 min per week or >120 min per week) and VR type (specifically developed for therapy or commercially available). The software Review Manager (version 5.4.1; Cochrane) for Windows was used to conduct the analyses of the included studies.

Results

Study Selection

Our database search resulted in 1643 studies after removing 319 duplicate records. After title and abstract screening, we excluded 1492 records for the reasons specified in Figure 1. Full texts of the remaining 151 studies were assessed for eligibility, and finally, 9 studies met the inclusion criteria, 7 (78%) of which were RCTs.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the study selection process. VR: virtual reality.



Study Characteristics

Overview

The 9 included studies involved 258 children, 163 with unilateral CP and 95 with bilateral CP (BCP), aged between 3 and 18 years. Four studies reported the gross motor functions of children, classifying them from levels I to V according to the GMFCS [29-32]. Five studies classified children from level I to V regarding the use of their hands when handling objects in daily activities using the MACS [29,32-35]. The characteristics of the included studies are presented in Tables 1-3.

Table 1. List of study characteristics.

Study	Participants	Experimental group			Control group			Outcomes measures: timing and measures	Main outcomes
		Intervention	Duration, frequency, length, and total time of VR[a]	Priority focus	Intervention	Duration, frequency, length, and total time	Priority focus		
Choi et al [33], 2021	34 children with unilateral CP[b] and 44 children with bilateral CP, age: 3-18 years	VR (RAPAEL Smart Kids) + conventional occupational therapy (stretching, strengthening, and task-oriented training)	30 min, 5 sessions, 4 weeks, and 10 h	Upper limb	Conventional occupational therapy	60 min, 5 sessions, 4 weeks, and 20 h	Upper limb	Baseline, postintervention, follow-up (8 +1 or −1 weeks after completion of intervention); MA-2[c], ULPRS[d], and PEDI-CAT[e]	More improvement in VR group in MA-2 and performance of activities of daily living domain of PEDI-CAT. Improvements were retained at follow-up.
Preston et al [34], 2016	14 children with unilateral CP and 1 child with bilateral CP, age: 5-12 years	VR (computer-assisted arm rehabilitation gaming technology) + conventional therapy + botulinum toxin	7 min per session, 6 weeks, and 1 h 39 min	Upper limb	Conventional therapy + botulinum toxin	6 weeks	Upper limb	Baseline, postintervention, follow-up (6 weeks after completion of intervention); ABILHAND-Kids questionnaire, and COPM[f]	No improvement in both groups in ABILHAND-Kids, and no difference between groups at any time point. Improvement in all participants in COPM.
Peper et al [35], 2013	6 children with unilateral CP, age: 7-12 years	VR (computer games with Lissajous feedback) + conventional therapy (if any)	30 min, 3 sessions, 6 weeks, and 9 h	Upper limb	Conventional therapy	6 weeks	—[g]	Baseline, postintervention, follow-up (6 weeks after completion of intervention); AHA[h]	No improvement at group level in AHA.
Rostami et al [36], 2012	32 children with unilateral CP, age: 6-12 years	VR group: VR (E-Link Evaluation and Exercise System) + conventional therapy, VR + mCIMT[i] group	90 min, 3 sessions, 4 weeks, and 18 h	Upper limb	Conventional therapy	30 min, 2 sessions, 4 weeks, and 4 h	Upper limb	Baseline, postintervention, follow-up (12 weeks after completion of intervention); PMAL[j], and speed and dexterity subtest of BOTMP[k]	More improvement in VR + mCIMT group in PMAL and BOTMP. Improvements were retained at follow-up.
Kassee et al [29], 2017	6 children with unilateral CP, age: 7-12 years	VR (Nintendo Wii)	40 min, 5 sessions, 6 weeks, and 20 h	Upper limb	Resistance training	36-48 min, 5 sessions, 6 weeks, and 18-24 h	Upper limb	Baseline, postintervention, follow-up (4 weeks after completion of intervention); MA-2, ABILHAND-Kids questionnaire, and grip strength	No statistical analysis to determine group differences.

Study	Participants	Experimental group			Control group			Outcomes measures: timing and measures	Main outcomes
		Intervention	Duration, frequency, length, and total time of VR[a]	Priority focus	Intervention	Duration, frequency, length, and total time	Priority focus		
Psychouli and Kennedy [37], 2016	9 children with unilateral CP, age: 5-11 years	VR (computer game with a joystick) + mCIMT	20 min, 7 sessions, 4 weeks, and 9 h	Upper limb	mCIMT	4 weeks	Upper limb	Baseline, postintervention, follow-up (4 weeks after completion of intervention); MA, and QUEST[l]	More improvement in VR + mCIMT group in MA, QUEST. Improvement in MA was retained at follow-up.
Decavele et al [30], 2020	32 children with bilateral CP, age: 6-15 years	VR (Open-Feasyo games with Wii Balance Board) + conventional therapy	At least 15-20 min, 2 sessions, 12 weeks, and approximately 5 h	Upper and lower limb, trunk control	Conventional therapy	32.6 min, 20.6 sessions (total),12 weeks, and approximately 11 h	—	Baseline, postintervention, after washout period (12 weeks after), after control period; GAS[m], TCMS[n], PBS[o], and GMFM[p]-88	More improvement after intervention period (VR + conventional therapy) compared with control period (conventional therapy) in GAS, TCMS, PBS, GMFM-88. Improvements were not retained at follow-up.
Pin and Butler, 2019 [31]	18 children with bilateral CP, age: 6-14 years	VR (TYROMOTION force plate) + conventional therapy	20 min, 4 sessions, 6 weeks, and 8 h	Postural control	Conventional therapy	6 weeks	—	Baseline, midpoint of intervention (week 3), postintervention (week 6), follow-up (6 weeks after completion of intervention); PRT[q], GMFM-66, and 2-min walk test	No significant difference between the groups at any time and in any of the assessments. Improvements in both groups in GMFM-66 after 6 weeks of the intervention.

Study	Participants	Experimental group			Control group			Outcomes measures: timing and measures	Main outcomes
		Intervention	Duration, frequency, length, and total time of VR[a]	Priority focus	Intervention	Duration, frequency, length, and total time	Priority focus		
Chiu et al [32], 2014	62 children with unilateral CP, age: 6-13 years	VR (Wii Sports Resort) + conventional therapy	40 min, 3 sessions, 6 weeks, and 12 h	Upper limb	Conventional therapy	6 weeks	—	Baseline, postintervention, follow-up (6 weeks after completion of the intervention); coordination (elbow and finger), grip strength, Nine-Hole Peg Test, JTTHF[r], and FUS[s]	No significant difference between the groups in coordination, Nine-Hole Peg Test, and Jebsen-Taylor Test. Trend for the experimental group to have more grip strength and FUS quantity.

[a]VR: virtual reality.

[b]More improvement (not retained at follow-up) in the experimental group compared with the control group.

[c]No improvement in the experimental group or no significant difference between the groups (experimental and control groups).

The types of VR devices used for the experimental groups in the studies varied considerably. Two studies used Wii training [29,32], and 1 study used the OpenFeasyo software platform (rehabilitation-specific gaming software) using the Kinect sensor and the Nintendo Wii Balance Board [30]. One study used the TYROMOTION force plate, which was specifically designed to assess and treat postural control [31], whereas another study used the RAPAEL Smart Kids [33], which was developed for rehabilitation purposes. Computer games with Lissajous feedback, targeting particularly bimanual coordination [35]; E-Link Evaluation and Exercise System [36]; and a computer game with a joystick [37] were used in the other studies. In one of the studies, the VR device was reported as a computer-assisted arm rehabilitation gaming technology [34].

Overall, most of the devices used in the studies (6/9, 67%) were specifically developed for therapy, whereas one-third (3/9, 33%) of the studies used commercially available VR devices. No safety issues or adverse events associated with VR training were reported.

The primary focus of VR interventions for most studies (7/9, 78%) was on the upper limb. Only 2 studies included trunk control training [30,31]. Similarly, the outcome measures in the studies included in this review were mainly related to upper limb functions and performance.

The duration of each VR session varied from 15 to 90 minutes, and the participants performed the VR intervention 2 to 7 times a week. In 1 study, participants' compliance with the duration of VR interventions could not be fixed, and the mean daily duration of VR sessions was only 7 minutes [34]. As a result, the total amount of VR intervention of the included studies in this review was a minimum of 1 hour 39 minutes and a maximum of 20 hours.

In general (7/9, 78%), VR as the experimental group was mostly combined with conventional therapy and compared with a control group receiving only conventional therapy [30-36]. In one of these studies, there was >1 experimental group, with one group undergoing VR with conventional therapy (VR group) and the other following VR with modified constraint-induced movement therapy (mCIMT; VR + mCIMT group) [36]. One study applied VR therapy alone in the experimental group [29], whereas in another study, the experimental group participated in functional activities and the computer game while wearing the constraint (VR + mCIMT) [37].

The included studies had various outcome measures on motor functions and daily life activities at baseline (before intervention), after intervention, and at follow-up, which ranged from 4 to 12 weeks after completion of the interventions.

Upper Limb Functions

Overall, 78% (7/9) of the studies included in this review used a variety of outcome measures related to upper limb functions and performance. Furthermore, 3 studies used the Melbourne Assessment of Unilateral Upper Limb Function [29,33,37] and 2 studies used the ABILHAND-Kids questionnaire [29,34]. The Upper Limb Physician's Rating Scale [33], Pediatrics Motor Activity Log, Speed and Dexterity subtest (subtest 8) of the Bruininks-Oseretsky test of Motor Proficiency [36], Nine-Hole Peg Test, Jebsen-Taylor Hand Function Test, Functional Use Survey [32], Assisting Hand Assessment [35], and Quality of Upper Extremity Skills Test [37] were also used in the studies.

Regarding the results of upper limb functions and performance, Kassee et al [29] did not conduct statistical analysis to determine group differences for the Melbourne Assessment and the ABILHAND-Kids questionnaire owing to the small sample size (n=3 for each group). Choi et al [33] and Psychouli and Kennedy [37] found a significant improvement in both experimental (VR with conventional therapy and VR with mCIMT, respectively) and control groups (conventional therapy and mCIMT, respectively) in the Melbourne Assessment after the intervention, but the VR groups showed more improvement in both studies. These improvements were retained at follow-up, after 4 or 8 weeks [33,37]. Moreover, Psychouli and Kennedy [37] found further improvement in the VR group in the Quality of Upper Extremity Skills Test after the intervention [37]. Rostamia et al [36] also demonstrated significant improvements in the experimental groups (VR and VR + mCIMT) in the Pediatrics Motor Activity Log and the Bruininks-Oseretsky test of Motor Proficiency but not in the control group (conventional therapy) [36]. The combined group (VR + mCIMT) showed the most significant improvements, which were maintained at the 3-month follow-up assessment [36].

Neither group improvements nor group differences in the ABILHAND-Kids questionnaire were found by Preston et al [34]. Chiu et al [32] did not find a difference between the experimental and the control group after the intervention or 6 weeks after the interventions in the Nine-Hole Peg Test and the Jebsen-Taylor Hand Function Test [32]. They also assessed elbow and finger coordination, and grip strength. As a result, there was a trend of mean difference for the experimental group to have more grip strength and Functional Use Survey (quantity) score [32]. In Assisting Hand Assessment scores at a group level, no significant improvements were observed by Peper et al [35].

Balance, Trunk Control, and Gross Motor Functions

Only 2 studies evaluated balance and trunk control using the Trunk Control Measurement Scale, Pediatric Balance Scale, or Pediatric Reach Test, and they also reported gross motor function results with Gross Motor Function Measure (GMFM; GMFM-66 or GMFM-88) [30,31]. Decavele et al [30] observed more improvement in Trunk Control Measurement Scale, Pediatric Balance Scale, and GMFM-88 after the intervention period (conventional therapy including rehabilitation-specific gaming) compared with the control period (conventional therapy), but the results did not persist after the 12-week follow-up [30]. Pin and Butler [31] found no significant difference in changes in the Pediatric Reach Test and the GMFM-66 between the 2 groups [31].

Daily Life Activities

Overall, 3 studies reported outcomes on daily life activities using the Goal Attainment Scale (GAS) [30], Pediatric Evaluation of Disability Inventory Computer Adaptive Test (PEDI-CAT) [33], or Canadian Occupational Performance Measure [34]. Decavele et al [30], in the GAS, and Choi et al [33], in the daily activities domain of the PEDI-CAT, found significant improvements in the VR group compared with the control group after intervention. The improvement in the PEDI-CAT was maintained at the 8-week follow-up [33] but not in the GAS at the 12-week follow-up [30]. Preston et al [34] found no significant differences in the changes on the Canadian Occupational Performance Measure between the 2 groups.

Methodological Quality

All studies in this review (7 RCTs and 2 non-RCTs) were included in the methodological quality assessment. The total score of these studies ranged from fair to excellent. Of these 9 studies, 3 (33%) studies were classified as excellent-quality studies [32,34,36], 4 (44%) as good-quality studies [30,31,33,37], and 2 (22%) as fair-quality studies [29,35]. Table 4 presents the 4 main subscales and the total scores of the modified Downs and Black checklist. Scoring of all 27 items for the included studies is provided in Multimedia Appendix 2.

Table 4. Results of the quality assessment of included studies based on the modified Downs and Black checklist.

Study	Study type	Quality of reporting score (out of 11)	External validity score (out of 3)	Internal validity score (out of 13)	Statistical power score (out of 1)	Total score (out of 28)
Choi et al [33], 2021	RCT[a]	11	0	11	1	23

[a]RCT: randomized controlled trial.

Results of Meta-Analysis

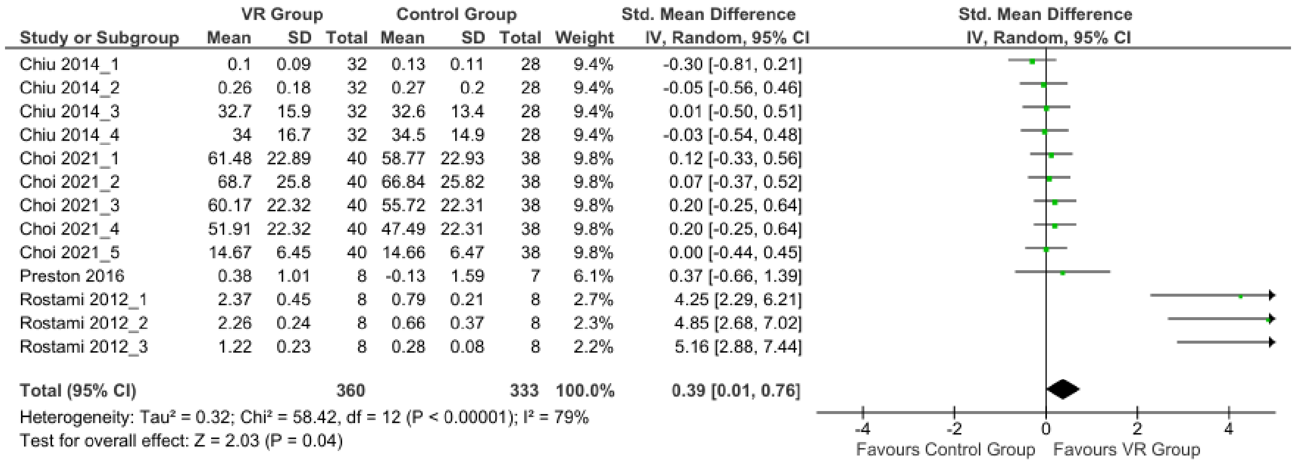
Overview

We performed meta-analyses with 6 RCTs supplying the essential data and classified them as good- to excellent-quality studies [30-34,36]. The upper limb function results of 4 studies were included in the meta-analysis [32-34,36], whereas results on balance, trunk control, and gross motor functions of only 2 studies were included [30,31]. Similarly, changes in daily life activities were documented in only 3 studies. However, as 1 study did not report the group mean scores separately [34], the results of 2 studies were used in the analysis [30,33]. In general, in all studies included in the meta-analysis, the results used for analyses were the postintervention and follow-up outcomes of the VR group (conventional therapy with VR training) and the control group (conventional therapy). Meta-analyses on follow-up results and subgroup analyses were conducted only for the studies with the outcomes of upper limb functions because there were enough studies (n=4) and results. We did not use any test to assess funnel plot asymmetry (reporting biases) because at least 10 studies included in the meta-analysis were required for meaningful results [38].

Effects of VR and Intervention of Control Group on the Upper Limb Functions of Children With CP From Short Term to Long Term

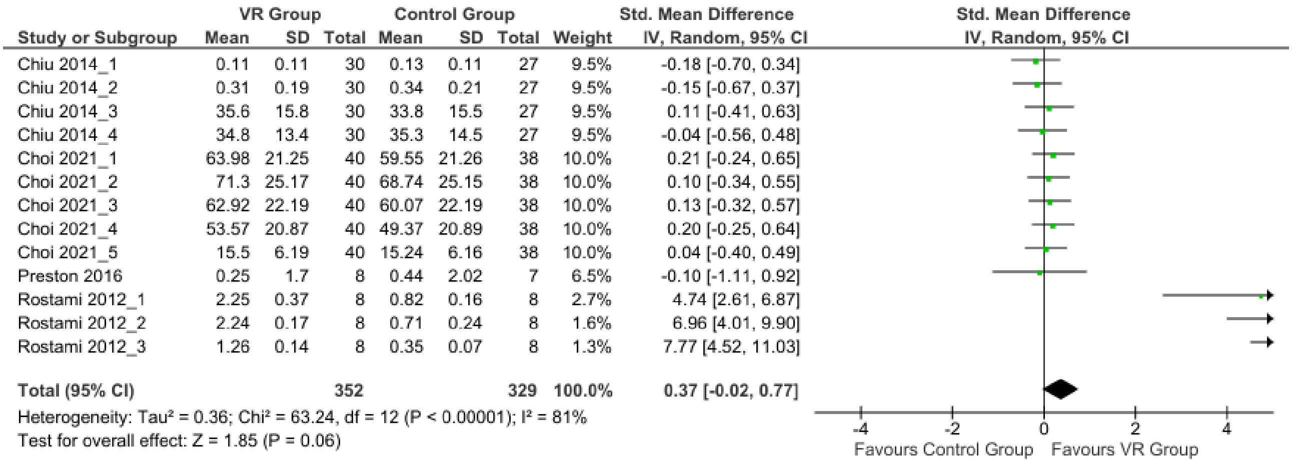
The overall effect size was 0.39 (small effect; 95% CI 0.01-0.76; random effects model) with high heterogeneity (I^2=79%). The results showed that after the intervention, overall effect on upper limb functions and performance in children with CP was in favor of the VR group when compared with the control group (*P*=.04; Figure 2 [32-34,36]).

Figure 2. Forest plot of the postintervention upper limb functions outcomes [32-34,36]. Control group: conventional therapy; IV: inverse variance; VR group: virtual reality with conventional therapy.



Concerning the medium- to long-term effects of interventions, the overall effect size was 0.37 (small effect; 95% CI −0.02 to 0.77; random effects model) with high heterogeneity (I^2=81%). The overall effect showed a trend toward favoring the VR group 6 to 12 weeks after the completion of the interventions (*P*=.06; Figure 3 [32-34,36]), but the result was not statistically significant.

Figure 3. Forest plot of the follow-up upper limb functions outcomes (from 6 to 12 weeks after completion of the intervention) [32-34,36]. Control group: conventional therapy; IV: inverse variance; VR group: virtual reality with conventional therapy.

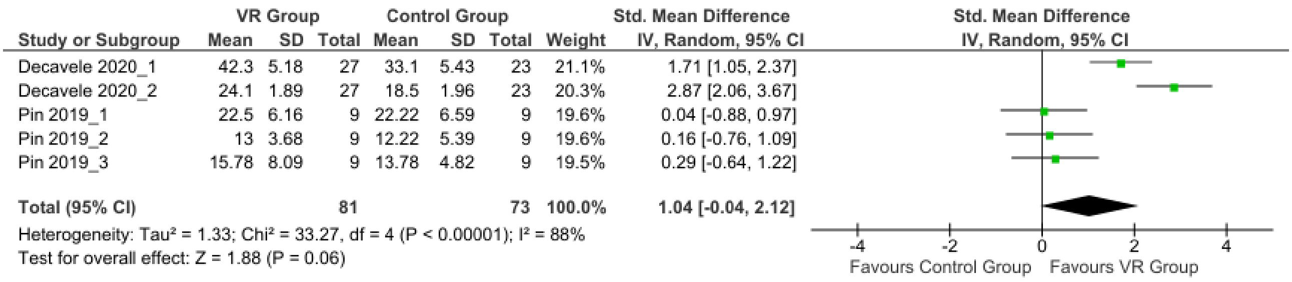


The subgroup analyses of both postintervention and follow-up results of upper limb functions showed that the duration and intensity of VR intervention and VR type were significant factors (*P*<.01). Studies that included more intensive and higher duration (≥60 min) of VR interventions had larger effects. Moreover, a larger effect was found when VR devices specifically developed for therapy were used compared with commercially available apparatuses. The figures are provided in Multimedia Appendix 3 [32-34,36].

Effects of VR and Intervention of Control Group on the Balance and Trunk Control of Children With BCP

The overall effect size was 1.04 (large effect; 95% CI −0.04 to 2.12; random effects model) with high heterogeneity (I^2=88%). The postintervention overall effect on balance and trunk control in children with BCP showed a trend toward favoring the VR group compared with the control group (*P*=.06; Figure 4 [30,31]), but the result was not statistically significant.

Figure 4. Forest plot of the postintervention balance and trunk control outcomes [30,31]. Control group: conventional therapy; IV: inverse variance; VR group: virtual reality with conventional therapy.

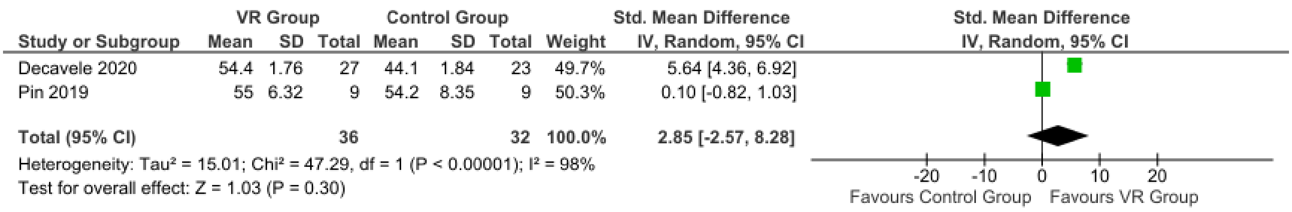


Effects of VR and Intervention of Control Group on the Gross Motor Functions of Children With BCP

The overall effect size was 2.85 (large effect; 95% CI −2.57 to 8.28; random effects model) with high heterogeneity (I^2=98%).

The postintervention overall effect on gross motor functions in children with BCP showed a trend toward favoring the VR group compared with the control group (*P*=.30; Figure 5 [30,31]), but the result was not statistically significant.

Figure 5. Forest plot of the postintervention gross motor functions outcomes [30,31]. Control group: conventional therapy; IV: inverse variance; VR group: virtual reality with conventional therapy.

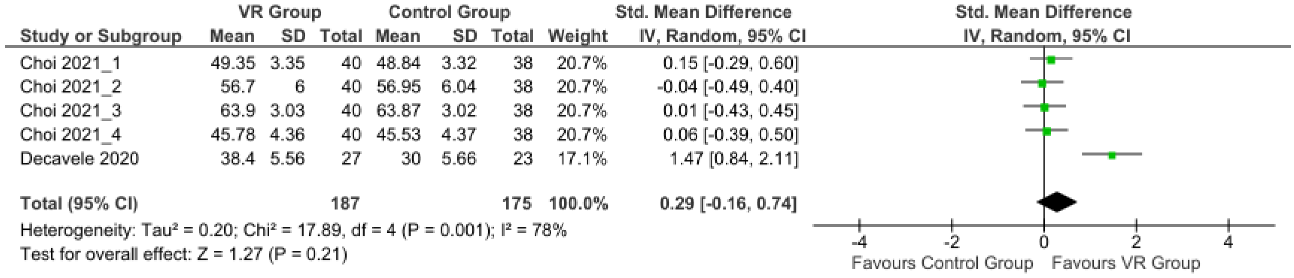


Effects of VR and Intervention of Control Group on the Activities of Daily Life of Children With CP

The overall effect size was 0.29 (small effect; 95% CI −0.16 to 0.74; random effects model) with high heterogeneity (I^2=78%).

The postintervention overall effect on daily functions of children with CP showed a trend toward favoring the VR group compared with the control group. (*P*=.21; Figure 6 [30,33]), but the result was not statistically significant.

Figure 6. Forest plot of the postintervention activities of daily life outcomes [30,33]. Control group: conventional therapy; IV: inverse variance; VR group: virtual reality with conventional therapy.



Discussion

Principal Findings

This systematic review and meta-analysis aimed to investigate whether VR-included therapies are effective on motor skill learning in children with CP compared with a control group, with special attention to the middle- and long-term effects. Overall, the results on upper limb function and performance showed the benefits of adding VR to CP rehabilitation in terms of postintervention improvements and supported that these acquisitions were mostly retained at follow-up. The meta-analysis results on upper limb functions and performance confirmed these benefits. In particular, Rostami et al [36] and Psychouli and Kennedy [37] used VR with mCIMT for 4 weeks, and greater improvements have been shown in the upper limb functions after VR with mCIMT compared with conventional therapy or mCIMT alone. Choi et al [33] matched VR with conventional occupational therapy for 4 weeks, and similarly, greater improvements have been shown in the upper limb functions following the intervention including VR compared with conventional occupational therapy alone [33]. In addition, these improvements were maintained at follow-up. It should also be noted that the contents of experimental interventions were shaped with motor skill learning principles (more intensity, the performance of daily living activities, repeating functional tasks, individually tailored, progressively challenging, and motivating feedback) in these 3 studies, which showed greater and long-lasting improvements in the VR groups (Table 2) [33,36,37]). Choi et al [33] and Rostami et al [36] applied these motor skill learning principles in VR game sessions, whereas Psychouli and Kennedy [37] used them mostly in mCIMT sessions and added a computer game as motivating feedback at the end of the intervention. Therefore, we concluded that incorporating motor skill learning principles into interventions including VR, through VR or therapy, induces greater benefits in motor function improvements in the long term. In addition, in the motor skill learning–based, VR-included interventions, VR has a substantially effect on maintaining motivation and eventually ensuring more intensity and repetition of child-initiated active movements during the interventions.

Furthermore, in line with our results from the subgroup analysis, applying more intensive VR training (involving more total hours in a shorter time, 4 weeks vs 6 weeks) had a significant influence on these larger improvements in the VR group both after the intervention and at follow-up compared with the other studies reporting no significant benefit of adding VR [32,34]. Thus, a higher intensity of VR training with either a longer duration or a higher frequency of training appears to be another essential factor for enhancing motor skill learning through VR. These findings were similar to the results of previous systematic reviews and meta-analyses [16,39-42]. They highlighted some principles of VR use in the neurorehabilitation of children with CP [13]. Rathinam et al [16] and Chen et al [39] also noticed in their reviews that more intensive VR training has more potential to result in improvements of functions in children with CP immediately after the intervention.

Furthermore, a study included in our review stated that parents were asked to encourage their children to use VR for 30 minutes daily. However, they played the games only for 7 minutes as a mean daily amount because of children's low interest and motivation for the games in VR games [34]. This may explain why they did not find any improvement after VR-included therapy. In other words, maintaining interest and motivation also helps active participation in gaming in VR therapy and provides the expected therapy duration.

We also performed a subgroup analysis to determine whether VR types affected the upper limb function improvements. The results demonstrated that VR devices specifically developed for therapy have more potential benefits on the training of upper limb functions in children with CP when compared with the commercially available VR device (Nintendo Wii). In addition, VR devices specifically developed for therapy had a greater potential to make acquisitions persistent in the medium or long term. As explained by Chen et al [39], it seems more feasible to provide individually tailored interventions with active repetition in various contexts by integrating motor skill learning principles into VR devices when they are specifically developed for therapy purposes.

Concerning the outcomes of balance, trunk control, gross motor functions, and daily life functions induced by therapies combined with VR, we found only 2 studies that met the eligibility criteria of this systematic review and meta-analysis [30,31]. In addition, these 2 studies had different results. Decavele et al [30] found more improvement (though impermanent) after the VR combined period, whereas Pin and Butler [31] observed no significant difference between the groups. Even so, with the postintervention meta-analysis results of 2 good-quality studies, we showed that adding VR into therapy may offer additional benefits on balance and trunk control (SMD=1.04; P=.06) and likely in gross motor functions (SMD=2.85; P=.30) in children with BCP. Our findings were consistent with those of other reviews on balance and gross motor functions after VR interventions [18,43,44]. However, the very limited number of studies and small number of participants (<50) made it difficult to conclude the follow-up effects. Thus, it remains unclear whether there is more potential in VR-included therapy to facilitate long-lasting acquisitions in balance and gross motor functions in children with CP. The fact that both studies [30,31] only included children with BCP with GMFCS III-IV levels may also have affected the results. Further studies are needed to address the long-term effects of VR intervention on balance and gross motor functions in children with different severity of CP. The number of studies with long-term results that included daily functions was also very low (n=3) [30,33,34]. In fact, 2 out of 3 studies noted that changes in daily living activities after therapies with VR were significantly different between groups, with a tendency toward the VR group [30,33]. Similarly, the meta-analysis results were in favor of the VR group (SMD=0.29; *P*=.21). Considering that there are insufficient results on whether the acquisitions are long lasting, more studies on the daily function outcomes are also needed.

Limitations

First, we found a limited number of studies and participants that met our inclusion criteria, especially for medium- and long-term outcomes. Only 7 RCTs and 2 non-RTCs were included in our systematic review, and most of them (7/9, 78%) had a relatively small sample size (<50). In addition, many studies did not report the MACS and GMFCS levels of the included children. The studies that reported the levels also included children with a relatively wide range of functional abilities. For instance, 1 study included children with GMFCS I-II level [29], whereas another study included children with GMFCS III-IV level [30]. As a result, this heterogeneity may have affected the results, but we could not perform a subgroup analysis because of the limited number of studies. Regarding the outcome measures, wide variations were used in the studies, and this heterogeneity of the outcome measures made it difficult to combine and interpret the results. Another limitation of this study is that if a study included in our review used different clinical tests to determine similar outcomes (upper limb functions, balance and trunk control, gross motor functions, and activities of daily living), all results were included in the analysis. Although the outcome measures were different, the intervention process of VR was identical in the same study. In addition, as one of the studies [30] had a crossover design, at the end of the study period, a control group (the group that did not receive VR) did not exist to allow comparison with the follow-up results of the VR group. Therefore, we were unable to conduct a meta-analysis of follow-up outcomes for balance, gross motor functions, and daily life activities, as there was only one study providing follow-up results on these outcomes.

Conclusions

This review shows that adding VR into upper limb rehabilitation of children with CP offers additional benefits in motor skill learning and enhances the maintenance of obtained improvements when the VR included training that cooperates with motor skill learning principles, with the inclusion of functional tasks as well as repetitive practice, more intensity, individual adjustment, progressive challenge, and motivation. For these reasons, it appears more appropriate to make use of VR devices specifically developed for therapy. In terms of balance, trunk control, gross motor functions, and daily life activity outcomes, combining VR with therapies can help induce more improvements in children with CP. However, the priority focus of most of the interventions with VR (7/9, 78%) in the included studies, and their outcomes, was upper limb functions. The effect size on motor skill learning of adding balance-focused VR devices into different therapies in children with CP is still not entirely clear; therefore, studies with long-term outcomes are needed.

Acknowledgments

SK was funded by the Republic of Turkey, Ministry of National Education, for her PhD program.

Authors' Contributions

All the authors contributed to deciding the protocol and PICO (Population, Intervention, Comparison, and Outcome) framework of this study. SK and BS performed the search, study selection, data extraction, and methodological quality assessment. SK performed the meta-analysis and drafted the initial manuscript. BS, RA, and YB critically reviewed and edited the manuscript. All the authors approved the final manuscript.

Abstract

Background: Augmented reality (AR) has emerged as a promising technology in educational settings owing to its engaging nature. However, apart from applications aimed at the autism spectrum disorder population, the potential of AR in social-emotional learning has received less attention.

Objective: This scoping review aims to map the range of AR applications that improve social skills and map the characteristics of such applications.

Methods: In total, 2 independent researchers screened 2748 records derived from 3 databases in December 2021—PubMed, IEEE Xplore, and ACM Guide to Computing Literature. In addition, the reference lists of all the included records and existing reviews were screened. Records that had developed a prototype with the main outcome of improving social skills were included in the scoping review. Included records were narratively described for their content regarding AR and social skills, their target populations, and their outcomes. Evaluation studies were assessed for methodological quality.

Results: A total of 17 records met the inclusion criteria for this study. Overall, 10 records describe applications for children with autism, primarily teaching about reading emotions in facial expressions; 7 records describe applications for a general population, targeting both children and adults, with a diverse range of outcome goals. The methodological quality of evaluation studies was found to be weak.

Conclusions: Most applications are designed to be used alone, although AR is well suited to facilitating real-world interactions during a digital experience, including interactions with other people. Therefore, future AR applications could endorse social skills in a general population in more complex group settings.

Introduction

Background

Digital technology has begun to move beyond the constraints of static, screen-based media toward more dynamic, immersive environments such as virtual reality (VR). One specific technology that is embedded in the concept of VR and is being increasingly used in various sectors is augmented reality (AR). AR creates visual situations where virtual components overlap with the real world, inviting the user's complicity in the illusion that these virtual components exist in the real world. As such, AR does not create a virtual environment per se but acts as a digital supplement to the real environment [1], clearly distinguishing it from VR. Its accessibility makes it easier to use than, for example, VR while still immersing the user in a partly virtual world. A wide range of technology supports AR. Although in the early stages, AR was a form of VR with a head-mounted display [2], current advanced hardware and software deliver AR through handheld devices, including tablets and mobile phones [3]. AR can be either marker based (activated through a specific physical image pattern, such as a QR code) or markerless. Markerless AR uses location-based AR (eg, via GPS), projection-based AR (tied to a specific physical space), or superimposition AR (replacing an object with an augmented view, eg, a real face with a cartoon face).

These advances have made AR a successful technology for commercial gaming (the most popular being the 2016 Pokémon Go by Niantic) and for informal learning sites, such as exhibits or museums to increase interaction with showcased topics [4]. In addition, the use of AR in formal educational settings such as classrooms has increased because of the cost-effective, interactive, and innovative features of AR (for literature reviews, refer to studies by Koutromanos et al [5] and Laine [6]). In their review of AR and education, Garzón et al [7] found that most AR technology is used in the field of natural sciences, highlighting the focus of current educational AR applications.

Social Skills

Social skills are crucial throughout life for social functioning [8] and for forming and maintaining relationships and reacting appropriately in social interactions through successful communication and socioemotional functions [9]. Furthermore, social skills relate to other important concepts: during childhood, they influence learning motivation and academic achievements and competences [10,11], whereas a lack of social skills can lead to mental health difficulties [12] such as depression [13]. Moreover, social competence in childhood is significantly related to adult well-being [14].

There is no commonly shared definition for social skills. Various terms are often used synonymously to refer to the concept of social skills, including *social competence*, *soft skills*, *emotional learning*, or *social behavior* [15], although some authors argue that these terms cannot be used interchangeably [16]. Most definitions of social skills include successful communication and adaptive interactions with others, and researchers agree that social skills are acquired through specific learned behaviors that are also socially reinforced [17]. For example, Bedell and Lennox [18] described social skills as "the ability to (a) accurately select relevant and useful information from an interpersonal context, (b) use that information to determine appropriate goal directed behavior, and (c) execute verbal and nonverbal behaviors that maximize the likelihood of goal attainment and the maintenance of good relations with others." Grover et al [19] synthesized existing definitions into 4 core social skill areas for a general population: communication skills, emotion regulation, cognitive skills, and social problem solving. In the literature search for this review, we concentrated on the 2 terms *social* and *communication* as the vital parts of social skills [9,17].

Social Skills and AR

Analog social and emotional skills training interventions have been successfully implemented, for example, in preschool children. The results of a meta-analysis showed small to medium effects of these interventions on social skills development and problem behavior reduction [20], demonstrating the potential of using interventions to improve social skills. Furthermore, serious games without an AR focus also cover so-called *21st-century skills* [21], such as media and technology skills or learning and innovation skills (eg, critical thinking and collaboration). Although social-emotional learning trainings are often developed for a nondigital classroom setting, AR could also be particularly interesting in the field of social-emotional learning. First, using a digital approach with AR allows a controlled setting while still only partly immersing the user in a digital environment, thus making the setting more realistic. Second, it harnesses people's increasing interest in digital tools while still being able to engage them in real-world complex social interactions. A look at the positive effects of existing commercial AR games on sociability offers promising results; for example, Ewell et al [22] found in a 7-day diary study on the commercial AR game *Pokémon Go* that the time spent with the game was connected to more social interactions, and Ruiz-Ariza et al [23] found that *Pokémon Go* significantly increased sociability levels and good social relationships.

In the field of psychology, AR is primarily used as a successful form of exposure therapy for phobias such as fear of small animals, for example, cockroaches and spiders [24], or as an additional tool to treat posttraumatic stress disorder [25]. Little focus has been put on improving social or emotional skills. In terms of social-emotional learning, most existing literature related to AR focuses on improving social skills in populations diagnosed with autism spectrum disorder (ASD). In a systematic review of AR applications for children and adolescents with autism by Khowaja et al [26], 20 of 30 included studies reported outcomes related to social skills and competences. Considering the existing deficits in social skills in people with autism [27], it makes sense to develop and implement interventions specifically for this population. Yet, social skills are generally essential for all populations. Consequently, the question arises if and what AR applications that improve social skills are being developed without a specific focus on an autistic population.

This Study

The challenges of identifying relevant literature due to the interdisciplinarity of the topic, the different denominations of social skills, and the existing focus on ASD in existing reviews highlight the need to map out the existing literature on AR and social skills. Thus, the aim of this scoping review was to systematically identify the range and characteristics of records that report the use of AR to improve social skills. Specifically, within this literature, our objective was to answer the following questions: what are the characteristics? What are the target groups? What types of AR are being used? What social skills are being targeted? What social settings are being targeted? What are the methodological characteristics of the studies evaluating the applications? We followed the guidelines for conducting systematic scoping reviews by Peters et al [28]. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist can be found in Multimedia Appendix 1.

Methods

Data Sources and Search Strategy

Initial Limited Search

The first step was to identify the strings and terms that identify most of the relevant literature to answer the research question. We used a nonsystematic literature search to come up with our search strings for social skills, “social” and “communication.” We further started manually with a few articles that we found through existing reviews and an initial search that would fit our inclusion criteria; looked at their keywords, references, and the terms they used; and collected the most used and most relevant terms.

Included Databases

We used 2 main databases for our search: one was intervention focused, that is, PubMed, and the other leaned toward computer science, that is, IEEE Xplore. After double-checking and realizing that some of our initial articles could not be found in either of these databases, we decided to also include a third database: the ACM Guide to Computing Literature. We selected these databases to comprehensively cover all relevant disciplines.

Primary Search

Our final search terms included “augmented reality” plus “social” or “communication” (derived from definitions of social skills) or “collaboration” or “cooperation” (derived from keywords related to AR). The decision to not use the word “skill” in the search was intentional to capture a wider range of relevant terms, such as “social competence.” We limited our search to the period from 2010 to December 2021. Owing to advancements in technology, AR has only become available for use on everyday smartphones during the last decades, and nowadays, applications are hardly comparable with the first versions of AR in the 1990s and 2000s. Specific search strings for each database are listed in Table 1. The search strategy was supervised by an experienced researcher (KW).

Table 1. Search strings used in the different databases.

Database	Search string	Filters
PubMed	(“augmented reality”) AND ((soci*) OR (collaborat*) OR (communicat*) OR (cooperat*))	≥2010
IEEE Xplore	(“Abstract”: “augmented reality”) AND ((“Abstract”:soci*) OR (“Abstract”:collaborat*) OR (“Abstract”:communicat*) OR (“Abstract”:cooperat*))	≥2010
ACM Guide to Computing Literature	[Abstract: “augmented reality”] AND [[Abstract: soci*] OR [Abstract: collaborat*] OR [Abstract: communicat*] OR [Abstract: cooperat*]] AND [Publication Date: (01/01/2010 TO *)]	—[a]

[a]Not available.

Additional Search

In addition to the primary search, we screened existing recent reviews on AR [7,26,29-41] as well as reference lists of all included papers for additional references and searched for follow-up papers of records that were excluded because they did not reach the development phase of the application.

Citation Management

All references were imported and processed using EndNote20 (Clarivate) [42]. Duplicates were removed using the program’s function to find duplicates and by manually going through all references. In the first step of screening, 2 independent reviewers (GM and VZ) screened all references on a title, and in a second step, 3 independent reviewers (GM, VZ, and a group of 3 research group members) screened all references on an abstract level. In the third step, the reviewers screened the remaining references on a full-text level. Discrepancies between reviewers were resolved through discussions after each step.

Eligibility Criteria

The eligibility criteria were developed before the screening process and applied to all stages of the review. Some modifications were made to the eligibility criteria during the screening process, as described in the *Results* section. This review included all records that met the inclusion criteria, as described in Textbox 1.

Textbox 1. Eligibility criteria.

Inclusion criteria

- Studies related to the research questions, that is, described the use of augmented reality (AR) to improve social skills, defined as successful communication and adaptive interpersonal interactions
- The application has at least reached the end of prototype development
- Social skills were the goal of the application and the main outcome of the study (added after the first round of abstract screening)
- Records were in English, German, Portuguese, or Spanish

Exclusion criterion (added after the first round of abstract screening)

- The AR applications scaffold aspect of social functioning without actually improving a social skill in a transferable manner

Data Characterization

For all included articles, the following study characteristics were retrieved: general characteristics (authors, title, year, country of origin, sector, and paper length); application information (type, name, description of application, description of AR part, development software, duration, description of social skill, description of social setting, description of other outcomes if any, and co-design if any); study information (population, setting, design, methods, analysis, results, and effect sizes if any); and challenges and limitations. The data were summarized in an Excel (Microsoft Corporation) spreadsheet. Statistical analysis was performed using SPSS Statistics 27 (IBM Corp).

Results

Search and Selection of Articles

The primary search was conducted on December 2, 2021, and yielded 2748 potential records. The main reason for exclusion at the abstract level was that the AR system did not address social skills as an outcome. For example, although many articles had keywords in their abstracts, "collaboration" was only used as a means to teach other outcomes, "cooperation" tackled human-machine interactions, or "communication" related to a technical term (eg, network communication). The low reviewer agreement after the first round of abstract screening (500 vs 69 included records after abstract screening) resulted in refining the eligibility criteria and repeating the abstract screening process. Specifically, the initial inclusion criteria included all records that had social skills as one outcome instead of the main outcome. This change was made because many included references had little to do with social skills (>900). Furthermore, an exclusion criterion was added to exclude AR applications that only supported existing communication by adding AR elements (such as adding an AR avatar to a web-based communication tool or including information about the current conversation partner, such as their hobbies), as we argue that these applications only support communication in that specific situation instead of improving social skills in a transferable manner.

After refinement of the eligibility criteria, in addition to the 2 main reviewers GM and VZ, a group of 3 research members collectively screened all abstracts and full texts to ensure the sufficiency of the new criteria. This was done to include naive reviewers, as the new eligibility criteria were developed by the first 2 reviewers who may have been more likely to agree. Decisions during the screening process were categorized as "yes (include)," "maybe," or "no (exclude)." Cohen weighted κ was used to evaluate the reviewer agreement, and linear- and quadratic-weighted κ coefficients were reported to specify the shape of the disagreement distribution for the 3-ordinal scale ("yes," "maybe," and "no") [43]. Table 2 presents the agreement between the 3 reviewers at the abstract and full-text levels. The agreements ranged from moderate (Cohen weighted κ=0.594) to almost perfect (Cohen weighted κ=0.861) [44]. After full-text screening, a total of 17 records were included in this review (for the selection process, see Figure 1).

Table 2. Reviewer agreement on the abstract (second round) and full-text levels.

	Abstract level (linear-weighted κ/quadratic-weighted κ)	Full-text level (linear-weighted κ/quadratic-weighted κ)
Reviewer 1 (GM)–Reviewer 2 (VZ)	0.594/0.689	0.766/0.842
Reviewer 1 (GM)–Reviewer 3 (RG[a])	0.628/0.817	0.794/0.861
Reviewer 2 (VZ)–Reviewer 3 (RG)	0.775/0.640	0.792/0.820

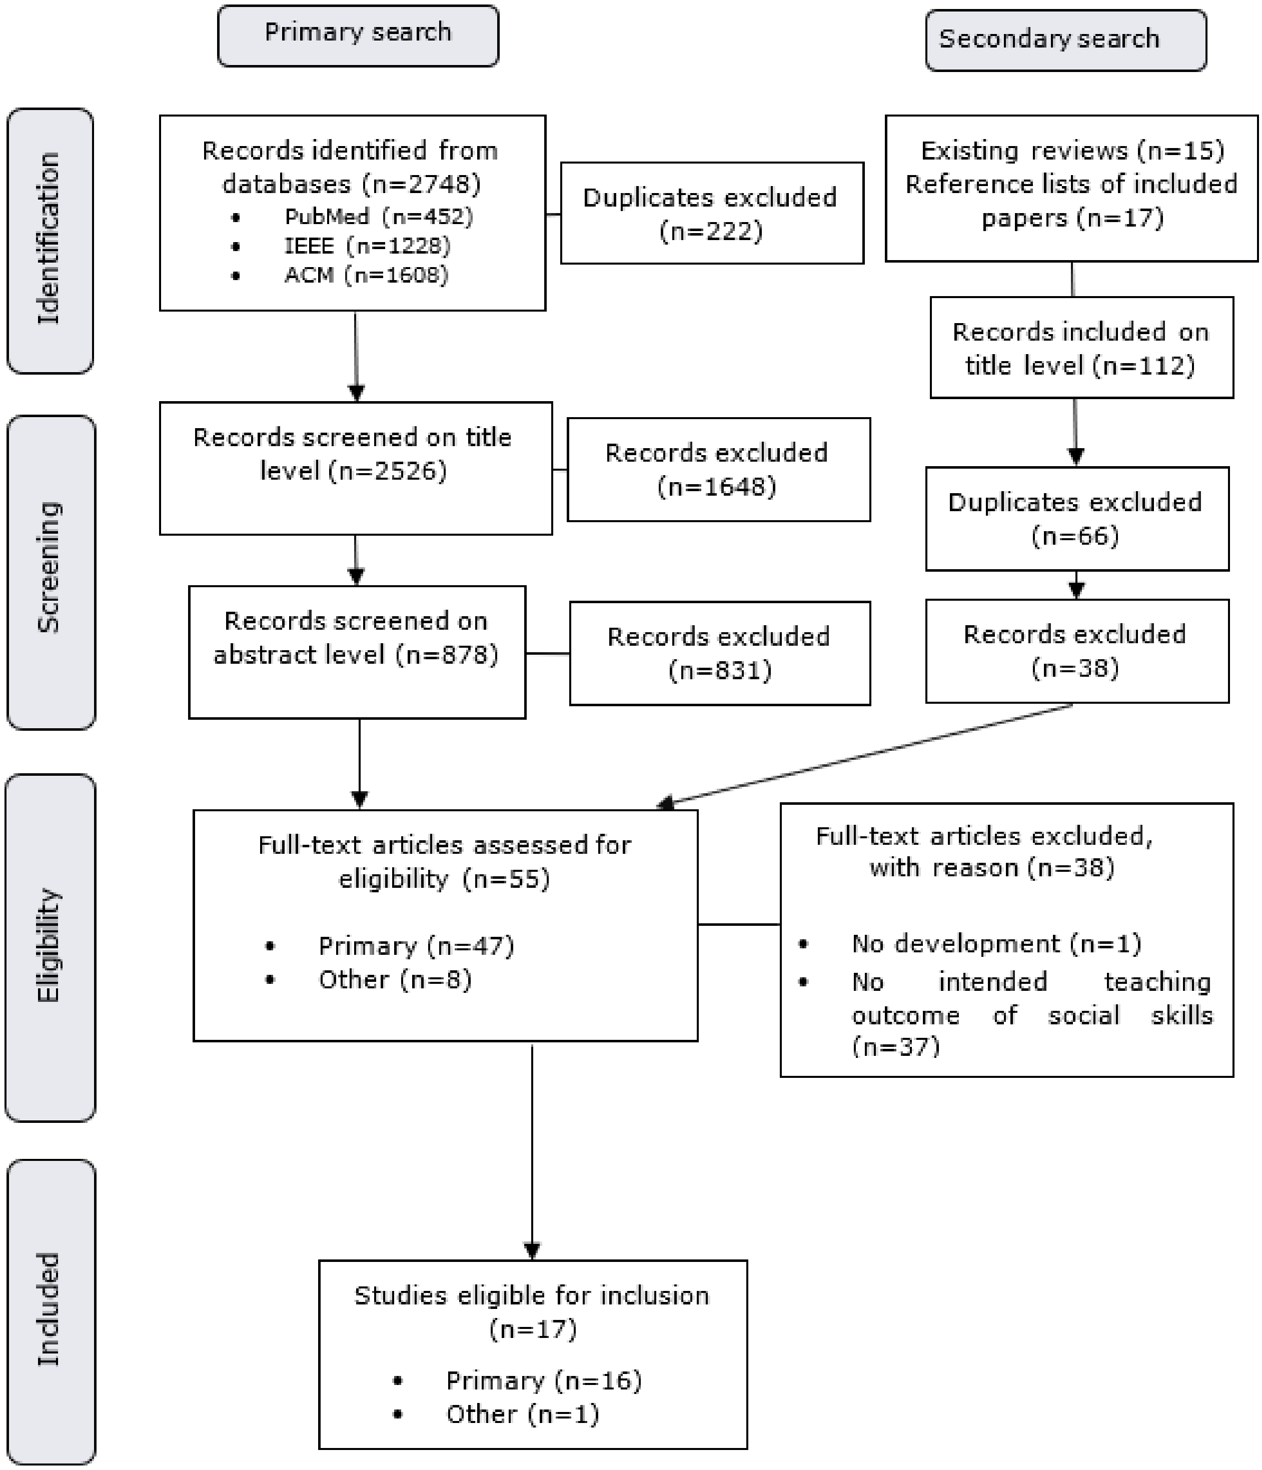
Figure 1. A flowchart of the record selection process.



General Characteristics of Included Records

The general characteristics of all included records are presented in Table 3. All included records were published between 2012 and 2021, although notably, only 2 included records were published before 2015, emphasizing the recent increase in the interest in AR. Most records have their origins in Asia and North America, and the majority have been published via conference proceedings (with journals primarily publishing with a focus on an autistic population), although they were relatively evenly spread between the social sciences, computer science, and interdisciplinary sectors.

Table 3. General characteristics of included records (N=17).

	Values, n (%)	Reference
Year of publication		
2010-2014	2 (12)	[45,46]
2015-2017	8 (47)	[47-54]
2018-2021	7 (41)	[55-61]
Origin of reference		
Asia	8 (47)	[45,48,52,53,55,57,60,61]

Interdisciplinary	8 (47)	[45-47,49,52,57,58,60]

Characteristics of AR Applications to Improve Social Skills in Autistic Populations

Of the 17 included records, 10 targeted autistic populations. As AR applications for this population have already been the subject of different reviews (although not specifically focused on social skills) and because of the unique social challenges faced by individuals with autism, we examined their characteristics separately to provide an overview of applications designed for autistic populations (Table 4). All records included in the autistic populations describe applications developed for children. Most of the applications (n=4) aimed to teach facial or emotional expressions as a social skill, often focusing on the basic emotions (happiness, sadness, fear, disgust, surprise, and anger). For instance, in *FaceMe* [55], children play minigames in which players must remember virtual expressions, identify expressions, choose the right expression, and imitate expressions. Similarly, in *Brain Power System (BPS)* [54], children learn to identify facial expressions in a gamified environment by selecting the right emotional expression for a virtualized human, and in *GameBook* [51], the emotional expressions are picked for a fictional character. In *augmented reality-based self-facial modeling* [48], the participants see their own virtual faces that can be overlaid with AR facial expressions in fictional scenarios, and in *augmented reality-based video modeling storybook* [52], social cues are taught by using a storybook that can be augmented with additional AR video clips.

Table 4. Characteristics of augmented reality application for an autistic population (n=10).

Study, year	Name	Type	Targeted social skill	Description of application	Target group (all individuals with autism)
Chen et al [48], 2015	ARSFM[a]	Mask or self-facial modeling	Facial or emotional expressions	Users choose facial masks that fit to emotions of a short story and see their faces overlaid with the emotion	Age 10-13 y
Chen et al [52], 2016	ARVMS[b]	Virtual book	Facial or emotional expressions	Users train to recognize significant social cues in a digital storybook and short video stories	Age 11-13 y
Cunha et al [51], 2016	GameBook	Virtual book	Facial or emotional expressions	The user learns to identify and choose emotions of a fictional character in different parts of the story	Children
Escobedo et al [46], 2012	MOSOCO[c]	Smartphones	Communication skills, gaze or eye contact	Phones detect cues in real-life social situations, give feedback for social missteps, and offer advice	Age 8-11 y
Lee [60], 2020	Kinect training system	Video	Social greeting behavior	Trainer "plays" virtual characters in different social interactions with the user to teach appropriate social greeting responses	Age 7-9 y
Lee et al [57], 2018	AR-RPG[d]	Tabletop	Social greeting behavior	Users role-play different social events and different greeting scenarios	Age 7-9 y
Lee et al [61], 2018	ARCM[e] training system	Tabletop and screen	Social greeting behavior	The user plays roles of different avatars in social situations and needs to choose correct greeting behaviors	Age 8-9 y
Li et al [55], 2021	FaceMe	Touchscreen	Facial or emotional expressions	Minigames, where the user has to remember, choose, and make facial expressions	—[f]
Liu, Salisbury [54], 2017	BPS[g]; FaceGame and Emotion Game	Smart glasses	Facial or emotional expressions, gaze or eye contact	Users learn to gaze at another person and identify emotions of another person's detected face	Age 8-9 y
Vahabzadeh et al [59], 2018	Empowered Brain or Face2Face module	Smart glasses	Communication skills, gaze or eye contact	Users get prosocial cues through smart glasses during interactions with a trainer, social performance can be seen in digital web portal	Age 6-8 y

[a]ARSFM: augmented reality-based self-facial modeling.

[b]ARVMS: augmented reality-based video modeling storybook.

[c]MOSOCO: mobile social compass.

[d]AR-RPG: augmented reality-tabletop role-playing game.

[e]ARCM: augmented reality concept mapping.

[f]Not available.

[g]BPS: Brain Power System.

Other applications aim to teach gaze direction, such as engaging in mutual eye contact during interactions and being attentive. In *Empowered Brain* [59], the user wears smart glasses while interacting with a facilitator who provides feedback on their head positioning relative to the facilitator and rewards attentive gaze. Similarly, in *BPS* [54], the user is rewarded with points to look at their virtual interaction partners and even receives higher rewards for looking at the socially salient central region of the face. In total, 3 records describe applications for teaching social greeting behavior [57,60,61], in which children learn to identify and use 6 different greeting behaviors (such as nodding their head, shaking hands, or hugging) in role-play scenarios or with virtual characters. Finally, *mobile social compass (MOSOCO)* [46] is the most versatile of the found applications: in this mobile app, 6 basic social skills are trained in a real-world environment by pairing children with autism with interaction partners (without a diagnosis of ASD). The system then detects, for example, eye contact to provide feedback and hints on how to behave in this situation. Other targeted skills include spatial boundaries, conversation initiators, shared interests, appropriate disengagement, and identifying potential communication partners.

Characteristics of AR Applications to Improve Social Skills in General Populations

We found 7 records describing AR applications in the general population (Table 5). Applications for the general populations are more diverse in terms of outcome goals and target a wider age range than applications for autistic populations. In total, 3 applications were designed for primary school children, whereas 4 targeted an adult population.

Table 5. Characteristics of augmented reality application for a general population (n=7).

Study, year	Name	Type	Targeted social skill	Description of application	Target group
Bai et al [47], 2015	FingAR Puppet System	Tabletop	Theory of mind, emotion expression, and understanding	Users use puppets (markers) and a magic wand to see or change the puppets' emotional expressions on a screen in social pretense play scenarios	Age 4-6 y
Kyungwon et al [45], 2014	AR Petite Theater	Virtual book or smart glasses	Empathy and perspective taking	Users read a story and author the story via changing emotional expressions and dialog, which can also be watched in an animated version	Age 7 y
Lin et al [58], 2020	Empathics System	Smart glasses	Emotion recognition	Smart glasses detect and feed back emotions of conversation partner in real time and visualize emotions for postsessions	Adults
Lorusso et al [49], 2016	Giok	Mobile game	Positive social interactions	Users steer the behaviors and social strategies of Giok the alien to achieve positive outcomes in various social situations	Age 4-5 y
Silva et al [50], 2017	Schizophrenia Simulator	Smart glasses	Stigma reduction and perspective taking	Users experience typical psychotic symptoms of schizophrenia	Students
Swearingen et al [56], 2021	The Woods	Mobile game	Positive social interactions	Collaborative game teaching about social isolation and the importance of social connectedness	Age 8-78 y
Metsiritrakul et al [53], 2016	UP2U	Screen	Gaze and phubbing awareness	Generated avatars show gaze direction of present persons and system teaches about phubbing behavior if people look down instead of to each other	Age 18-58 y

Applications for children target preschool and first-year graders (age 4-7 y). In *AR Petite Theater* [45], children read a story and can then choose suitable emotions for the characters and role-play these emotions, which makes them train their empathic behavior. Similarly, in *FingAR Puppet System* [47], children use a wand to change puppets' expression while they see themselves and the puppets in a magic mirror. Finally, in *Giok* [49], children followed a fictional character and decided their behavior through multiple-choice questions to lead it through social situations.

UP2U [53] describes an application that teaches people about phubbing behavior (ie, focusing on a mobile phone instead of people in a social situation) in public places. The system recognizes the present people and creates an avatar on a screen. Through head tracking, people receive feedback when their heads are not turned toward each other (screen goes red), and a video is played that educates them about phubbing behavior. Lin et al [58] described *Empathics System*, smart glasses that can be used during physician-patient communication (by both physicians and patients). The glasses collect real-time facial emotion information regarding the conversation partner and provide feedback to the user. Although this application mainly supports the current communication situation (ie, supporting performance rather than training), we included this paper because of the described postsessions in which the emotions are visualized so that the user can analyze them after the conversation. Participants also mentioned that the tool has the potential to serve as an educational tool for emerging physicians to learn about emotional cues and their effects. In their *Schizophrenia Simulator*, Silva et al [50] used smart glasses and an immersive AR environment to give users without schizophrenic symptoms an impression of what schizophrenia feels and looks like, with the intention of reducing the stigma around schizophrenia. Finally, *The Woods* [56] is a mobile smartphone game played by 2 players. Unlike other applications, it has a more holistic approach to teaching the importance of positive human connections. Players need to choreograph their movements to interact with virtual objects while engaging in a story about social isolation and reconciliation.

AR Applications to Improve Social Skills in Both Autistic and General Populations

Of the included records 2 describe applications involving both the autistic and general populations. First, *Empathic Systems* could be used by both patients diagnosed with ASD and physicians. The authors described that participants with autism had many concerns with smart glasses and concluded that their system needs to undergo some adaptations for an autistic population but shows potential in supporting real-life interactions by exemplifying emotions. Second, in *MOSOCO*, children with autism are paired with potential interaction partners without an ASD diagnosis. Although the general population was not the main target group of the study, the authors found that the application supported children without a diagnosis of ASD by destigmatizing missteps of children with autism and reacting in adaptive ways, which led to less teasing.

Types of AR Used in the Included Applications

The main development software used for the development of the applications was Unity or Vuforia. The included applications used a variety of AR types. Although *FaceMe* and *Giok* use marker-based AR to control virtual expressions and activate gameplay, respectively, and *The Woods* uses projection-based AR to guide players in the room, most of the included applications rely on superimposition AR. They overlay physical objects, other people interacting with the user, or the users themselves with an augmented view.

In the case of physical objects, AR overlays real-world physical scenes, such as books (*AR Petite Theater* and *augmented reality-based video modeling storybook*) or board games (*AR-RPG* and *ARCM*), with virtual scenes that either highlight specific parts or are used to manipulate the real scene. In *augmented reality-based self-facial modeling* and *FingARPuppet System*, users see themselves in a virtual scene to change their facial expressions and see themselves in an AR environment. *UP2U* uses computer vision to create avatars of a group of people that are then displayed on a screen. Finally, some applications use AR in their environment and interaction partners. In *Kinect training system*, the environment is augmented with the required visual background, and in *Schizophrenia Simulator*, psychotic symptoms are reproduced with AR. In *BPS*, human faces are overlaid with an AR cartoon face to engage the user, and *Empowered Brain* uses AR to keep the user attentive to the conversation partner. In *MOSOCO*, AR detects partners and provides support during real-life social situations, and in *Empathics System*, smart glasses detect the partner's emotions.

Social Setting of Included AR Applications

Considering the topic of social skills, we also examined the social settings of the applications. Of the 17 included applications, 10 were used as a single-player experience. In addition, 6 applications are performed in dyads, including both interactions with a human facilitator, therapist, or teacher who knows the system and experiences for pairs of naive users (eg, 2 children use the application together [*FingAR Puppet System*] or cooperative gameplay [*The Woods*]). Finally, 1 application (*UP2U*) uses a group setting by analyzing and teaching people to be more attentive to each other.

Methodological Characteristics of Evaluations of the AR Applications

A summary of the methodological characteristics of the evaluated studies is presented in Table 6. All the included applications have finished prototype development, and only 1 record [51] did not report any kind of evaluation. Most records report some form of co-design for their applications. Applications for autistic populations often include interviews with parents or teachers of the included children. In general, the quality of the evaluation studies was rather low. The paper length varied considerably (between 3 pages and 20 pages, mean 9.5, SD 5.5). Often, authors described the study as "prestudy," "pilot tests," or "preliminary tests." Only 2 studies had a sample size larger than 20 (with 21 and 25 participants). The level of detail reported for how the applications were evaluated varied considerably, including references that stated that it has been tested with users [56] to fully describe the methodology.

Table 6. Methodological characteristics of included augmented reality applications (N=17).

[c]Age 8-78 years.

Both usability and intended outcomes were generally positive in all the studies that tested the applications. A total of 12 records reported usability outcomes. We describe usability as a term that includes usability, feasibility, and acceptability. Moreover, 2 records report that there were no adverse effects and no conflicts; 4 records report that the users were able to understand and complete the intervention (especially in autistic populations), and 8 of the records report that participants found the application interesting and engaging or that users rated the application highly ("excellent" or "brilliant"). Only 1 record (*UP2U*) described the feasibility of the technical side of the application.

A total of 13 records described some form of testing for the intended outcomes. All of them reported positive results concerning their expected outcomes, for example, an increase in social behavior, a decrease in (ASD) symptoms (related to social skills), or verbal affirmation by participants that the application promotes and helps with the intended outcome.

Additional Findings

Although one of our eligibility criteria was that the application had to have an intended and transferable effect on social skills, during our review process, we found a variety of records that show how AR can be used as support in situations that require social skills or skills related to social skills. As our aim with this scoping review was to give an overview of existing literature, in this section, we want to give some examples of applications supporting users in social situations.

For instance, AR has been found to improve narrative skills during storytelling compared with non-AR story creation, possibly because of the engaging nature of AR [62]. In addition, AR can be used to track the emotions of an audience during a public speaking scenario to reduce fear of speaking by providing direct feedback to the speaker [63]. Furthermore, there is a thin line between improving social skills and just playing a collaborative game. One could argue that just by collaborating, social skills are endorsed and relationships are supported. Some games, for example, *BloxAR* [64], a social game in which teams compete to build AR block structures, use this concept. As we had to balance resources and breadth of inclusion, for this review, we focused on applications that focused on improving social skills in a transferable manner. Further reviews should adopt broader eligibility criteria.

Discussion

Overview

In this systematic scoping review, we mapped existing literature on AR applications that improve social skills. We found 17 records that fit our inclusion criteria, that is, reporting AR applications intended to improve social skills as the main goal. As expected due to existing reviews, most AR applications that teach social skills were developed for an autistic population (10/17, 59%). These applications aim to improve emotional expression recognition, social greeting behavior, or gaze direction in children. Applications for the general populations are more diverse and include emotional expression recognition, perspective taking, and empathy, as well as more specific topics such as destigmatization or antiphubbing behavior for both children and adults.

Principal Findings and Comparison With Prior Work

Most of the records we reviewed focused on developing applications for children with autism, which is reasonable, given that social skills deficits are 1 of the 2 defining characteristics of autism [65]. Our findings are consistent with those of previous reviews, indicating that numerous approaches are being developed for this population. However, we did not find any applications that target adults, suggesting a potential area for future research. When comparing AR applications for autistic populations and general populations, this review showed that facial expressions or emotion recognition and gaze behavior can be found as an outcome goal for both autistic and general populations. Although the application targeting phubbing behavior phrases the outcomes differently, it teaches gaze behavior similar to applications for populations with autism. Applications targeting children are similar for autistic and general populations in terms of intended learning goals and ways to teach these goals. For example, emotional expressions are the main topic addressed in applications for all populations, and allowing children to choose between different emotions is a popular way to teach these expressions.

The Use of AR in Social Skills Interventions

AR is considered a promising tool for teaching because of its potential for interaction between the virtual and real worlds and its ability to facilitate visualization [66]. The results from our scoping review show that AR for social skills applications is used in 2 different ways: first, as an indispensable part of the application that is crucial for its effects, such as smart glasses that scan the environment and other's faces, and second, as an additional tool to emphasize important information, animate the scenarios, and generally make the experience more exciting for the user. In these cases, the application does not necessarily rely on AR. Both approaches are valuable, and the positive results concerning usability and intended learning outcomes indicate that AR has a potentially positive effect on learning. However, because most of our included records did not evaluate their applications with a control group, it is not certain whether AR is essential for the intended outcomes. One of our included records [45] compared the AR condition with a non-AR condition for their application and found a significant difference in perspective taking, with children in the AR condition showing higher scores in perspective taking, as well as more engagement. Their sample consisted of 12 children, which shows the need for replications with larger samples.

Strengths and Limitations of the Included Records

Strengths lie in the inclusion of the target group in the design and development process, the iterative process that many records describe, and the creative detail and hard work that often goes into the development of a serious game or intervention. Limitations are mostly found in the methodology of evaluation of the applications, especially in the small sample size of studies targeting an autistic population, where fewer than 5 children were tested. Evaluations rarely follow rigorous methodology (such as randomized controlled trials). Although iterative development for technical applications is necessary and reporting of preliminary results and evaluations is desirable, our results suggest that systematic and methodologically rigorous evaluations of AR applications for promoting social skills are still lacking.

Strengths and Limitations of This Scoping Review

This review was conducted in a structured and transparent manner, and the authors tried to eliminate mistakes by repeating screening at the abstract level. The main limitation of this scoping review is that due to the broad field of social skills, our search criteria might have missed some AR applications related to social skills. For example, emotion regulation and empathy are vital skills for adaptive interpersonal relations and should thus be included in the field of social skills. However, owing to the large number of additional records, we did not include these strings as separate search strings. Although being a limitation, some facts show that our search strategy yielded results that appropriately reflect the social skills training field. First, our final data set contains studies related to empathy, which shows that our search had the potential to also find records with this specific skill. In addition, all but one of the records identified through our additional search of existing reviews, reference lists, and follow-up studies were duplicates or had to be excluded, indicating that our search terms were adequate. Further reviews could broaden the search and include specific terms such as "emotional learning" or "empathy." Second, the interdisciplinarity of the topic and consequent limitations in the databases and search terms used might have resulted in the overlooking of certain records. Finally, the heterogeneity of the included records posed challenges in the synthesizing of the findings. However, different aspects revealed the focus of the current literature, for example, the emphasis on children with autism, which can be valuable for guiding future research.

Future Directions

Our findings suggest that AR applications have the potential to enhance social skills, as indicated by the evaluations of player experience and usability. Although the intended outcomes were only preliminarily tested in most of the included studies, AR applications can be highly engaging tools for social-emotional learning in psychological, digital, and educational settings.

The search strings "cooperation" and "collaboration" were included because of their common appearance as keywords in

AR contexts. The results showed that these 2 strings were not very relevant for our final included records. Social skills are mostly taught in a single-user setting or with a human facilitator. Considering the advantage of AR in easily enabling cooperative or collaborative situations, future research could explore ways to improve social skills in pairs or even groups. The times have passed when the digital world was not social. Nowadays, most digital tools, such as apps and online gaming, include or are exclusively for connecting with other people. However, many of these web-based interactions happen while both or all people are at different locations. AR not only has the advantage of interacting with digital components in the real world but also has the potential for the user to interact with other people while using a digital tool in real life. AR offers the exciting possibility of playing a digital game or interacting with a digital tool while being in the same room with other people who the player interacts with, as such, aiming to improve skills in complex and real-time social situations. As an example, one of our included records, *MOSOCO*, uses AR to teach social interaction skills to children with autism during real-time conversations with other children. Their results show that the app helps both children with autism and neurotypical children during their social interactions with each other. Although the sample size in their study was small, this shows the great potential of such applications to reduce stigma and lead to better social connections in real-world and real-time complex social settings in autistic, general, and mixed populations.

Conclusions

This scoping review describes the range and characteristics of applications using AR to improve social skills. Applications have been developed for autistic and general populations. Most often, they target emotion recognition, although this varies. The evaluations show promising results in terms of both the usability and intended outcomes of these applications. In future work, more focus should be placed on high-quality evaluations to further substantiate these results, and more complex social interactions in real-world settings should be explored.

Acknowledgments

The authors thank Juan Fernando Garzon Alvarez for sending us additional information on their augmented reality reviews and Alexander Topic, Claudia Pushpanathan, and Grace Burden for their help in screening records. This work was supported by the Ludwig Boltzmann Society and Karl Landsteiner University of Health Sciences.

Abstract

Background: The use of serious games for rehabilitation has been an emerging intervention in health care fields, referred to as an entertaining and positive activity. Although related studies have been conducted on patients with chronic obstructive pulmonary disease (COPD), a more comprehensive study that summarizes and evaluates its effects in this area is needed.

Objective: This review aimed to systematically evaluate the effects of serious games in promoting rehabilitation and related outcome measures of serious game–based engagement in patients with COPD.

Methods: This review adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement. Searches were performed in the following databases: PubMed, Scopus, Embase (via Ovid), CINAHL, Science Direct, and China Biology Medicine disc. Only quantitative studies were included in this review, and the methodological quality and bias of the included studies were evaluated using related tools. Several outcomes, including clinical outcomes and serious game–based engagement outcomes, were ultimately collected in this review. The results were summarized and evaluated using descriptive methods due to significant heterogeneity.

Results: In total, 11 studies were included. Serious games played a potentially positive effect on pulmonary function and exercise capacity. However, no consistent findings were reported on dyspnea and psychological status. Additionally, serious game engagement showed favorable findings on adherence, enjoyment, and acceptability. Furthermore, no serious adverse effects were identified in all included studies.

Conclusions: This review preliminarily indicated the potential benefits of serious games in promoting rehabilitation for patients with COPD, despite the limited quality of the included studies. More studies with high methodological quality are needed to further explore the effects of serious games in this field.

chronic obstructive pulmonary disease; COPD; serious game; rehabilitation; review; mobile phone

Introduction

Background

Chronic obstructive pulmonary disease (COPD) is a serious health condition that affects millions of people worldwide. It is characterized by progressive and irreversible obstruction of the airways, which leads to difficulties in breathing, reduced lung function, and increased risk of exacerbations [1]. COPD is currently the most common chronic respiratory disease worldwide [2] accounting for approximately 7% of deaths worldwide [3]. Pulmonary rehabilitation (PR) is an important tailored intervention involving several components that include but are not limited to exercise training, education, and breathing exercise in COPD management, as it can help patients improve their physical function, quality of life, and overall health outcomes [4]. Currently, PR has been widely recommended as an effective treatment but relies on continuous adherence for patients with COPD. However, despite the anticipated benefits of PR, the attendance, adherence, and completion rates of PR in patients with COPD are as low as 70%, 50%, and 40%, respectively [5-7], particularly for those who live in remote or underserved areas [8]. There are several potential barriers stopping patients from performing PR, such as low motivation, a lack of social support, transportation difficulties, and interest [7,9,10]. Hence, it appears essential and crucial to overcome these barriers and provide support for patients with COPD to engage in PR. Serious games, also known as therapeutic games, have emerged as a promising alternative therapy. Serious games encompass a broad concept that entails using distinct game elements to educate or induce changes in experiences or behaviors consisting of diverse forms such as video games and exergames [11]. These games, which may either be designed specifically for health purposes or be designed commercially for leisure exercise, use digital and engaging gameplay to deliver therapeutic interventions and promote healthy behaviors. Serious games have been used to address a wide range of health conditions, including mental health, chronic pain, and stroke rehabilitation [12,13]. In recent years, with the further widespread use of serious games, there has been a growing interest in the use of serious games for assisting patients with COPD in performing PR interventions. One of the potential reasons for the increasing popularity is that serious games may attract patients' attention away from briefly boring repetition of rehabilitation intervention and enhance their enjoyment [14,15]. Additionally, extra advantages of serious games over traditional PR have also been identified, such as objective data on performance and progress, low cost, enhanced motivation, and adherence [16]. However, the relationship between serious games and effectiveness in patients with COPD still remains poorly understood.

To date, there is only one systematic review that specifically examines the effects of active video games in patients with COPD [17]. However, this review, proving a potentially positive role of video games in terms of adherence, enjoyment, and various clinical outcomes, has limitations. First, it overlooks several relevant studies [18-22] that were published after the review was conducted. Second, the review only focuses on video games and lacks the inclusion of diverse types of serious games. As mentioned before, video games are a narrower category within the broader scope of serious games [23]. Third, the review lacks attention to certain outcome measures, such as pulmonary function and acceptability.

Additionally, 2 other reviews with a broader scope in respiratory conditions (asthma, COPD, emphysema, bronchiectasis, etc) separately reported consistent results in adherence and enjoyment [24] as well as exercise capacity and quality of life [25]. However, another review focused on respiratory diseases claimed no improvement in dyspnea or exercise capability [26].

Based on current evidence, the effects of serious games on patients with COPD remain unclear due to several limitations, including a limited number of enrolled original studies, a restricted scope of serious games, and inadequate and inconsistent reporting of results. A more comprehensive review is needed to further systematically evaluate the available evidence on the effects of health-related serious games for patients with COPD. Therefore, this review aims to include more eligible studies, a wider range of serious game types, and diverse outcomes to offer a comprehensive and unbiased overview of the current state of the evidence and identify areas for future research by using systematic methods.

Objectives

The overall aim of this review was to evaluate the effects of serious games for two categories of outcomes: (1) clinical outcomes, including pulmonary function, exercise capacity, daily steps, dyspnea, patient-reported outcome measures, and psychological condition, as well as adverse effects, and (2) related outcome measures of serious game–based engagement, including adherence, enjoyment, and acceptability.

Methods

Data Sources and Search Strategies

PICO, which stands for Participant, Intervention, Control, Outcome, was the most commonly used framework to guide review questions and facilitate searches [27]. In this review, the modified framework of "PICOs," which stands for patient problem, intervention, comparison, study of design, was used to explicitly state and derive the search terms that included subject headings and keywords in each part. However, it should be noted that due to differences in the expression forms of subject headings in diverse databases, the subject headings were adapted to fit each database accordingly. Additionally, the search strategy only used "P," "I," and "S" to broaden the search scope. The search strategies were separately searched in 6 electronic databases, which were PubMed, Scopus, Embase (via Ovid), CINAHL, Science Direct database, and China Biology Medicine disc, from inception to December 20, 2022. The search was initially undertaken in PubMed and then tailored and applied to the other 6 databases. Furthermore, the reference lists of eligible studies were also screened to identify studies. Multimedia Appendix 1 summarizes the search strategies that were used in all included databases.

Inclusion and Exclusion Criteria

The inclusion criteria were as follows: (1) quantitative studies, including randomized controlled trials (RCTs) and pre-post studies; (2) studies, in which participants had been clinically diagnosed with COPD without limitations of age, gender, and ethnicity; (3) intervention involving serious games for therapeutic purposes using any electronic platform (tablets, computers, consoles, smartphones, televisions, or any other digital devices); (4) no control groups or the control group used usual care or nonserious games; (5) results included health-related outcomes such as exercise capacity, pulmonary function, dyspnea, or adverse effects, as well as serious game–based engagement outcomes such as adherence, enjoyment, or acceptability; and (6) studies must be peer-reviewed and be in English or Chinese.

The exclusion criteria were (1) duplicate records; (2) studies focused on measurement, diagnostic methods, serious game theory, or game development; (3) nondigital games and serious games used for other purposes, such as screening, or nonhealth educational purposes; or (4) conference abstracts or studies for which full texts could not be derived.

Study Selection and Data Extraction

Two authors (HH and QC) independently screened the titles and abstracts of relevant studies using EndNote software (version X9; Clarivate Analytics). The full texts of eligible studies were then independently identified by the same authors according to predefined selection criteria. Any conflicts that arose between the 2 authors were resolved through discussion. If a consensus could not be reached, a third author (M Huang) was consulted to make a final decision. A data collection form was created to extract various characteristics of the studies, including the authors, study design, setting, participant demographics, intervention, comparators, frequency of the course, outcome measures, and instruments used. Additionally, a serious game intervention protocol form was developed to summarize the details of the interventions, including the serious game modalities, source of the serious games, procedure of the serious game modality, duration, length, and frequency of the intervention. The data extraction procedure was as follows: 2 authors (HH and QC) independently extracted data using predefined forms. Any discrepancies were addressed through discussion, and a third author (M Huang) was consulted to reach a final decision. Two electronic documents of the extracted data were created and managed by HH and QC.

Quality Assessment of Included Studies

The Cochrane Library's RCT assessment tool [28] was used to evaluate the methodological quality and risk of bias in RCTs. This tool consists of 7 domains: sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome reporting, incomplete outcome data, selective outcome reporting, and other biases. The JBI quasi-RCT assessment tool [29] was used to assess pre-post studies. The assessment of methodological quality and risk of bias was carried out by 2 authors (HH and M Huang), and a third author (QC) was consulted to make a final decision if any discrepancy occurred.

Data Synthesis

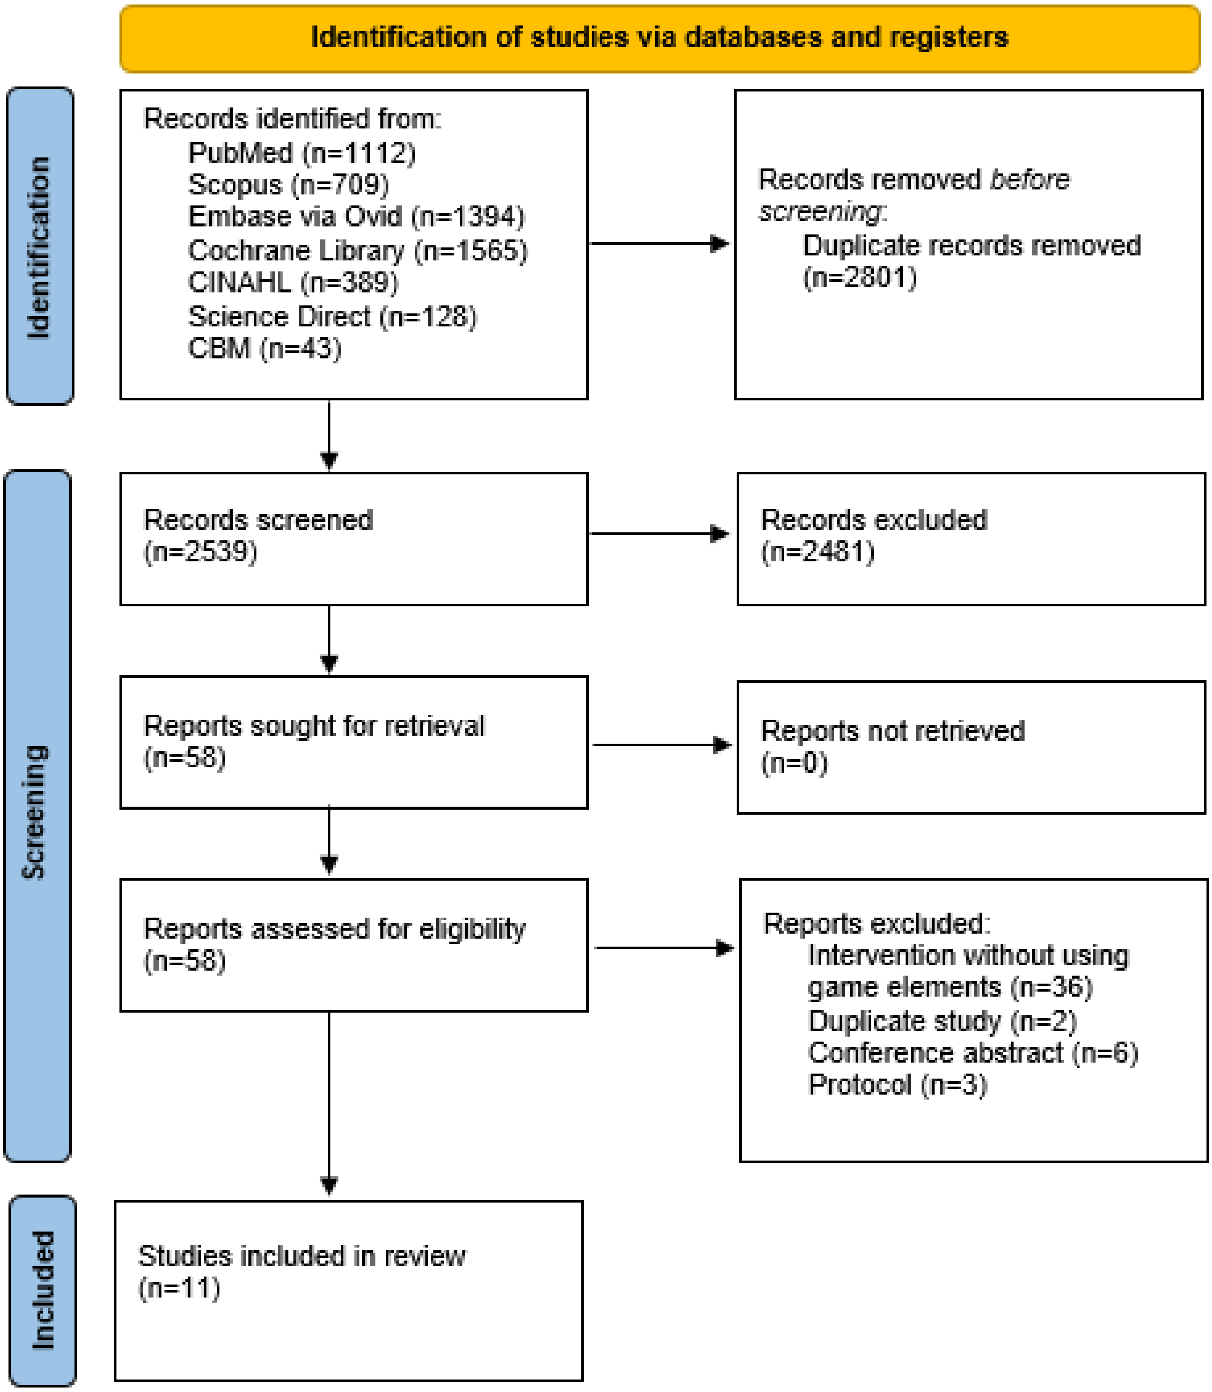
A meta-analysis was initially expected to calculate pooled effects. However, the significant clinical heterogeneity identified in the types of studies, comparisons, intervention protocols, and varied outcomes deemed it an inappropriate method for undertaking quantitative synthesis. Therefore, descriptive analysis was used to summarize the effects of serious games on rehabilitation in patients with COPD. The process of conducting descriptive analysis to present the research results involved tabulating various characteristics, such as participants, intervention details, comparison groups, outcomes, sample size, and study designs, from the original studies. This information was independently extracted in a predefined Excel (Microsoft Corp) form by HH and M Huang. Subsequently, the collected data were thoroughly reviewed and verified by the 2 authors to ensure accuracy and reliability. In case of any disagreements, consensus was reached through discussion. Finally, the data were compared against the planned studies for each specific outcome, facilitating a comprehensive evaluation of the findings. Specifically, the theme of identifying the relationships between serious game interventions and patient outcomes (eg, pulmonary function, exercise capacity, daily steps, dyspnea, psychological status, adverse effects, and measures of game-based engagement) was summarized.

Results

Search Results

The database search yielded 5340 publications in total. A total of 2801 duplicate items were excluded using EndNote (version X9), and another 2481 items were further removed after reading through titles and abstracts. The full texts of the remaining studies were retrieved for a more detailed assessment, of which 47 were removed for the following reasons: (1) intervention without using game elements (n=36), (2) duplicate study (n=2), (3) conference abstract (n=6), and (4) study protocol (n=3). As a result, a total of 11 studies were finally included in this review. Figure 1 illustrates a flowchart of the study screening process.

Figure 1. Flowchart of studies screening. CBM: China Biology Medicine.



General Characteristics of Included Studies

The key characteristics of the enrolled studies are shown in Multimedia Appendix 2. This review eventually consisted of 11 studies published between 2011 and 2021 with 8 RCT studies [18-22,30-32] and 3 pre-post studies [33-35]. Of the 11 studies, 3 were published in Chinese [21,22,32], and the remaining were reported in English [18-20,30,31,33-35]. The countries undertaking the interventions varied greatly, including mainland China in 3 studies [21,22,32], Canada in 2 studies [30,35], the United States in 2 studies [33,34], Australia in 1 study [18], Italy in 1 study [31], Poland in 1 study [19], and Indonesia in 1 study [20]. The studies' sample sizes ranged from 10 to 130 with most studies having fewer than 50 participants, and only 2 studies having sample sizes greater than 100 [19,21]. The mean age of participants was beyond 60 years in all included studies. Regarding the intervention protocols, 10 experimental studies [19-22,30-35] separately used commercial software containing game elements as intervention tools, and the most commonly used software was the Wii Fit system (Nintendo). Only 1 study [18] developed serious game software. The duration of the interventions ranged from 2 to 18 weeks in all experimental studies reporting intervention duration [18-21,31-34]. Meanwhile, the frequencies of using the interventions varied significantly across the studies.

Methodological Quality and Risk of Bias of the Included Studies

The results of the methodological quality of all studies except the descriptive one are presented in Tables 1 and 2. For RCT studies, randomization allocation was mentioned in all 8 studies, and 6 studies [19-22,30,32] reported the details on random sequence generation using random number tables or computer-generated number sequences or web-based number sequences. Allocation concealment was mentioned in only 1 study via sealed opaque envelopes [19]. Four studies [18-20,31] described blinding of participants and personnel as not applicable, and the remaining studies did not describe that blinding. Only 1 study stated blinding of outcome assessment [19]. All 8 studies stated participants' dropout rates, and all participants who completed the intervention were incorporated into the data analysis. In addition, all RCT studies were considered low risk of selective outcome reporting. For "other bias," 3 studies reported a sample size calculation. All studies conducted baseline assessment reporting without significant differences. Inclusion criteria, exclusion criteria, end points, and method of data analysis were clearly reported in all 8 studies. Only 2 studies described adverse events during the period of intervention [21,31]. For pre-post studies [33-35], 3 studies met all criteria except for a comparison group.

Is it clear in the study what is the “cause” and what is the “effect” (ie, there is no confusion about which variable comes first)?	✓[a]	✓	✓
Were the participants included in any comparisons similar?	N/A[b]	N/A	N/A
Were the participants included in any comparisons receiving similar treatment or care other than the exposure or intervention of interest?	N/A	N/A	N/A
Was there a control group?	×[c]	×	×
Were there multiple measurements of the outcome both pre and post the intervention or exposure?	✓	✓	✓
Was follow-up complete and if not, were differences between groups in terms of their follow-up adequately described and analyzed?	✓	✓	✓
Were the outcomes of participants included in any comparisons measured in the same way?	✓	✓	✓
Were outcomes measured in a reliable way?	✓	✓	✓
Was appropriate statistical analysis used?	✓	✓	✓

[a]Yes.

[b]N/A: not applicable.

[c]No.

Current Serious Game Intervention Protocols of PR

The serious game intervention protocols used in the included studies are summarized in Table 3, including serious game modalities, source of serious game, the procedure of the serious game modality, duration, length, and frequency of the intervention. Of them, only 1 study [18] developed a serious game modality for the purposes of the study.

Table 3. Details of SG[a] intervention protocol.

Study	SG modalities	Source of SG	Procedure of the SG modality	Duration	Length and frequency
Simmich et al [18]	• HW[b]: Fitbit • SW[c]: grow stronger AVG app	Purpose-built	• Fitbit paired to SW on smartphones and tracked steps, physical activity, and heart rate • Game modes on SW • (1) Complete and report upper and lower body physical activity, (2) grow a garden, and (3) a cooperative multiplayer game visiting multiple well-known Australian destinations	3 weeks	Each day
Sutanto et al [20]	• HW: a balance board accessory • SW: game activities of Wii Fit system	Off-the-shelf	• Yoga: deep breathing and half moon • Strength training • Aerobic exercise	6 weeks	30 min per session, 3 times per week
Hu et al [32]	• HW: not reported • SW: game activities of BioMaster virtual reality digital rehabilitation training system	Off-the-shelf	• Upper body physical activities: housework activities, kitchen cooking, etc • Lower body physical activity: cycling	12 weeks	5-15 min per day
LeGear et al [30]	• HW: a balance board accessory • SW: game activities of Wii Fit system	Off-the-shelf	• Marching, dancing, and 2 air punching exercises in sequence	N/A[d]	15 min per session
Rutkowski et al [19]	• HW: the console, a Kinect motion sensor, and a projector with speakers • SW: game activities of Kinect somatosensory digital games	Off-the-shelf	• Rafting, cross-country running, hitting a ball in the direction of a player on the screen, and a mountain wagon ride	2 weeks	20 min per day, 5 days per week
Mazzoleni et al [31]	• HW: haptic sensor–based controllers and a balance board • SW: game activities of Wii Fit Plus	Off-the-shelf	• Two 5-min sessions of "yoga" activity consisting of deep breathing • Jogging Plus consisting of feedback aided 10-min running • Twisting and squat: 10-min trunk twisting and arm and leg squatting	1 week	60 min per day
Zhou et al [21]	• HW: console, Kinect motion sensor, and projector with speakers • SW: game activities of Kinect somatosensory digital games	Off-the-shelf	• Trail running, rafting, hitting, and mountain riding in sequence	18 weeks	30 min per day, 5 days per week
Jin et al [22]	• HW: remote controls • SW: game activities of somatosensory digital games developed by Chinese company	Off-the-shelf	• Kitchen knife, ping pong exercise, and swimming in sequence	Admission within 48 h to discharge from hospital	20 min per day
Albores et al [33]	• HW: haptic sensor–based controllers and a balance board • SW: game activities of Wii Fit unit	Off-the-shelf	• Basic run: warm-up exercise • Bird's eye • Bull's eye: mostly upper arm exercise • Free step: mostly lower extremity exercise • Obstacle course: upper and lower extremity exercise • Basic run: cool-down exercise	12 weeks	5 or more days per week

Study	SG modalities	Source of SG	Procedure of the SG modality	Duration	Length and frequency
Wardini et al [34]	• HW: a balance board accessory • SW: game activities of Wii Fit system	Off-the-shelf	• Basic run, basic step, obstacle course, and island cycling for lower body training • Boxing and canoeing for upper body training	3 to 4 weeks	3 times per week
Parent et al [35]	• HW: a console and a controller • SW: game activities of Kinect	Off-the-shelf	• A running game (Stunt Run), a boxing game (Arctic Punch), a core twist game (To the Core), and a squat game (Squat Me to the Moon) in sequence	N/A	30 min per session

[a]SG: serious game.
[b]HW: hardware.
[c]SW: software.
[d]N/A: not applicable.

Commercial Game Software Combined With Hardware

In total, 10 studies [19-22,30-35] used commercial serious game systems, of which 5 [20,30,31,33,34] used Wii game systems (Nintendo), 3 studies [19,22,35] used Kinect game systems (PrimeSense), 1 study [22] used a Chinese brand game system, and the remaining [32] used the BioMaster virtual reality digital rehabilitation training system. Serious game modalities in each study comprised 2 key components, hardware and software except one study [32] that did not report the details of hardware. Specifically, software provided game contexts and images, whereas hardware was responsible for capturing and conducting movements in the games. The procedure of the serious game modality greatly varied from different studies, but all included multiple sessions of games in regard to training the upper body, lower body, or breathing exercises. In total, 7 studies reported that the duration of the interventions varied from 2 to 18 weeks [19-21,31-34]. However, 2 studies [30,35] did not report the duration of the intervention, and 1 study [22] only reported the duration from admission within 48 hours to discharge, which made it impossible to confirm the duration. Regarding the length and frequencies of undertaking serious games across the studies, a consensus was not reached in the trials that reported this parameter, ranging between 5 and 60 minutes per day in length and between 3 days per week and each day in frequency.

Purpose-Built Game Software Combined With Hardware

Only 1 study [18] specifically developed its serious game modality combined with a Fitbit and games that was produced by a combination of researchers, patients with COPD, and clinicians with experience in PR. Fitbit was used to track steps, physical activity, and heart rate in participants with COPD, whereas a game with 2 game modes was developed to guide physical training. The duration of intervention was reported to be 3 weeks, and the frequency was just briefly stated as every day.

Relationships Between Serious Game Interventions and Patient Outcomes

The results of serious game interventions were presented using descriptive analysis for this review.

Pulmonary Function

In total, 2 of the 12 studies separately examined the outcomes of the index of pulmonary function using FEV (forced expiratory volume) 1%predicted and FEV1/FVC (forced vital capacity) at different time points. FEV1%predicted, indicating the severity of diseases, refers to FEV in 1 second predicted, and FEV1/FVC is the ratio of the amount of air that a person can forcefully exhale in 1 second (FEV1) to the total amount of air that can be exhaled (FVC) over the course of a full exhalation, revealing that the airways are obstructed or narrowed for respiratory diseases [36]. One study [32] comparing the BioMaster virtual system with the conventional PR program showed no significant difference in FEV1%predicted and FEV1/FVC at 4 weeks but presented significant improvements at 8 weeks and 12 weeks after the intervention, respectively ($P<.05$). Similarly, another study [21] reported consistent results in which the somatosensory game digital training group had a significant improvement compared with the traditional exercise training group after 18 weeks of the intervention.

Exercise Capacity

In total, 7 studies [19-22,31-33] examined physical exercise capacity with varied measurements, of which 5 [19-21,31,32] used a 6-minute walk test, 1 [22] used a brief balance evaluation system test, 1 [33] adopted the endurance shuttle walk test and arm-lift and sit-to-stand repetitions, and 1 [19] applied senior fitness test. Additionally, the protocols between groups highly varied, which were BioMaster virtual system versus the conventional PR program [32], Wii versus exercise training on a cycle ergometer [20], Wii versus the conventional PR program [31], somatosensory game digital training versus traditional exercise training [21], somatosensory game digital training versus usual care [22], endurance exercise training versus virtual reality training [19], and Wii only [33]. Four studies separately showed significant improvements in the 6-minute walk test at 1 [31], 2 [19], 12 [32], and 18 weeks [22], whereas 1 study [20] showed a reverse result at 6 weeks of the intervention between groups. In addition, the results in 2 studies showed a significant improvement between groups in the senior fitness test at 2 weeks [19], the endurance shuttle walk test and arm-lift and sit-to-stand repetitions at 12 weeks [33]. Furthermore, 1 study [22] found a significant improvement in the brief balance evaluation system test of somatosensory digital games from admission within 48 hours to discharge from the hospital of the intervention compared with the usual care group.

Daily Steps

Only 1 study [18] collected continuous data on daily steps using Fitbit devices. The protocol involved purpose-built serious games combined with Fitbit in the experimental group and Fitbit alone in the control group [18]. The result stated that participants in both groups had high adherence to wearing Fitbit, recording steps on >80% of days, and showed opposite trends between the 2 groups in daily steps across 3 weeks, which indicated a significant improvement in the experimental group and a decrease in the control group [18].

Dyspnea

In total, 6 studies [20,21,30,31,34,35] evaluated dyspnea using 2 different tools, of which 4 studies [21,30,34,35] used the Borg dyspnea scale, and the remaining 2 studies [20,31] used the Medical Research Council score. Currently, there are conflicting results. Specifically, 2 RCTs [21,30] in the Borg dyspnea scale and 2 RCTs [20,31] in the Medical Research Council reported no significant improvements between groups, and 1 pre-post study [35] also obtained a similar result in the Borg dyspnea scale. However, another pre-post study [34] presented an opposite result that showed a significant improvement after intervention in the Borg dyspnea scale.

Patient-Reported Outcome Measures and Psychological Evaluation

In total, 3 studies [20,31,33] evaluated psychological status, including quality of life with the Saint George's Respiratory Questionnaire in 2 studies [20,31] and the Chronic Respiratory Questionnaire in 1 study [33], and depression with the Beck Depression Inventory in 1 study [31]. Two studies [20,31] showed no significant improvements in Saint George's Respiratory Questionnaire between groups, whereas 1 study had the opposite result in which there was a significant increase in Chronic Respiratory Questionnaire after the intervention. In terms of depression, no statistically significant improvement in Beck Depression Inventory was identified between groups [31].

Adverse Effects

Most studies did not report adverse effects, but only 2 studies [33,34] revealed chest pain and decreased oxygen saturation in the process of intervention. No serious adverse effects were identified in any of the studies.

Related Outcome Measures of Serious Game–Based Engagement

Adherence and Use of Serious Games

Two studies [21,34] reported adherence, which was highly varied. The adherence rate was 64% in a pre-post study [34] to test Wii serious games with an intervention duration of 3-4 weeks, whereas it accounted for 83.61% in an RCT study [21] to evaluate somatosensory game digital training after 18 weeks. One study reported game use frequency as participants who were involved in the study automatically recorded activities on 58.6% (82/141) of the days during the 3-week intervention [18]. Additionally, another study obtained adherence data from self-reported patient diaries, reporting that patients used serious games for a total of 36 hours and 5.7 days per week with a mean number of hours per week ranging from 2.6 to 3.4 [33].

Enjoyment

Four studies reported outcome measures of enjoyment of serious games with different instruments [18,30,34,35]. One study [30] used a 5-question Likert scale to evaluate enjoyment and found that 90% of participants enjoyed using the Wii exercise program. Similarly, another study [35] assessed the enjoyment of Kinect game activities using a 5-question Likert scale and reported consistent results that participants were more likely to enjoy the games. Moreover, a 10-cm visual analog scale was used to measure overall enjoyment based on the Wii Fit system [34]. The results demonstrated that participants had a mean score of 8 out of 10. Participants also reported a mean score of 8 out of 10 when asked about their willingness to recommend serious games to another patient with COPD. Additionally, a subscale on the Intrinsic Motivation Inventory was used to test enjoyment with a mean score of 5.4 out of 7 [18]. In summary, participants in these studies found serious games enjoyable.

Acceptability

Only 1 study [31] reported using a Likert scale to test the acceptability of serious games. This study found a higher score of 42.4 out of 49 in the group that participated in digital video game–aided exercises, which was similar to the score of the standard PR group. However, no significant difference was identified between the 2 groups.

Discussion

Principal Findings

To the best of our knowledge, this review is not the first to systematically investigate the effects in this field. However, it provides a broader insight, contributing to the understanding of the effects of serious games by rigorously examining a greater number of original studies, various types of serious games, and outcomes. This review indicated a promising role of serious games in the rehabilitation of patients with COPD. Nevertheless, the findings should be interpreted carefully considering that relevant evidence on serious games in this area was deemed not fully conclusive due to the wide variation in the design of studies, serious game modality, characteristics and duration, study comparisons, outcomes, and high risks of bias identified in some included studies.

The findings showed that serious games could be beneficial to pulmonary function, indicating that serious games may be a potentially effective alternative or complement to traditional rehabilitation in improving pulmonary function for individuals with COPD. It is commonly believed that serious games can be tailored to the individual needs of the patient, allowing for more personalized and effective treatment [37]. Additionally, the use of serious games can provide a more engaging and digital experience for patients, which may lead to increased adherence and motivation to exercise [38]. Therefore, increased physical exercise in intervention groups may contribute to better pulmonary function compared to control groups. However, it is important to note that more research is needed to examine the long-term effects of serious games on pulmonary function.

The findings in this review indicated a potentially beneficial role of serious games on exercise capacity. Most studies reported consistent results in favor of significant improvement when using serious games compared to the control group, which was in line with the findings of a previous review [17]. Furthermore, continuous monitoring data on daily steps also supported the effectiveness of serious games [18]. It is likely that participation in serious games provides a more engaging and digital form of exercise, which motivates patients and facilitates engagement [38]. This has been identified as a key factor in increasing adherence to interventions [39-42]. Additionally, compared to traditional forms of exercise as walking on a treadmill or cycling on a stationary bike, serious games are less boring and more appealing to patients, providing explicit instructions for patients to perform physical exercises as well [43].

It appeared that current findings have not found evidence that serious games have a positive impact on dyspnea in patients with COPD. Most studies [20,21,30,31,34,35] included in the review focused on physical exercises combined with serious games rather than using breathing techniques or exercises. In addition, the findings may be limited by varied measurement tools and the quality of studies. Therefore, it remains unclear whether serious games alone have any impact on dyspnea in patients with COPD. Additional research that specifically examines the use of breathing techniques or exercises in serious games may provide more insights into potential benefits for patients with COPD in the future.

Findings regarding the impact of serious games on quality of life and depression in patients with COPD were inconclusive, which indicates there was no consistent improvement observed in these areas and serious games may not have a significant impact on psychological status when compared to other interventions [20,31,33]. It should be highlighted that improvements in human well-being and depression are probably influenced by multiple factors [44,45], and the studies included in this review primarily focused on physical levels rather than other components, such as health education, and self-management. This may result in the lack of observed improvements. Additionally, it is unclear whether significant improvements would be found with long-term intervention.

Safety outcomes associated with serious games were not reported in the majority of studies included in this review. Only 2 studies [33,34] described adverse effects, including chest pain and decreased oxygen saturation. This suggests that potential adverse reactions have not yet been fully identified, highlighting the need for future research to focus on evaluating the safety outcomes of serious games and identifying any potential adverse effects that may occur.

Current findings on serious games' impact on adherence, enjoyment, and acceptability highlighted positive outcomes. It is recognized that PR entails numerous benefits; however, adhering to the program is currently one of the most significant challenges [4,44,45]. Insights into patients' continuous attendance are essentially significant, and both patients' acceptability and enjoyment are valuable indicators of this [46,47]. The current studies [18,30,34,35] have reported a high level of enjoyment, whereas only one study [31] has mentioned acceptability, which was found to be higher in the serious games group. These findings may be attributed to the concept that serious games provide a fun virtual environment for the patients, combining physical exercises with games to make the patients have fun, thus improving patient enjoyment and acceptability [17]. Then, the high level of acceptability and enjoyment contributes to good patient adherence, as reported in this review. Additionally, the findings in this review also show that the somatosensory game digital system, which uses body movements and gestures as input, had a higher adherence rate than the Wii serious games system, which relies solely on hand-held controllers for interaction [21]. This suggests that the use of a more immersive and physically engaging system may lead to increased participation and engagement from users, resulting in a higher adherence rate. This highlights the importance of considering the type of digital system used in serious game interventions, as it may have a significant impact on the effectiveness of the intervention [11]. Additionally, the adherence rate may vary depending on the population and specific intervention being used [48], and further research is needed to fully understand the impact of digital systems on adherence rates in serious game interventions.

Significant variation involving intervention modality, the procedure of the intervention modality, duration, length, and frequency was observed in all studies. Commercial serious game systems were the most frequently used modalities compared to purpose-built game systems among all studies. In addition, Wii game systems involving economic cost were the most popular in all included studies. Additionally, the intervention modalities varied greatly among studies. Furthermore, significant variation in duration, length, and frequency was also identified. The considerable variation in serious game protocols among the included studies indicated that an optimal evidence-based serious game protocol in this area is lacking, and further study is therefore warranted to recognize the best available evidence to develop a research-based serious game protocol to promote rehabilitation.

Comparison to Prior Work

In comparison with the previous review [17], this study effectively addresses the limitation of omitting relevant studies published after its completion [18-22] by incorporating them into the analysis. Moreover, unlike the previous review, which exclusively concentrated on video games, this study embraces a more comprehensive range of serious games, acknowledging that video games represent only a subset of the broader category [23]. Furthermore, this review systematically considers supplementary outcome measures, such as pulmonary function and acceptability, which were inadequately addressed in the earlier review.

Strengths and Limitations

Strengths

This review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) reporting guideline (Multimedia Appendix 3) [49]; thus, it can be viewed as a transparent and reproducible review. The findings in this review are more likely to be comprehensive and provide implications for further understanding the effects of serious games in this area. There is a low risk of publication bias in this review, as the search was conducted to identify as many eligible studies as possible by searching relevant databases using a broad search strategy. Additionally, the risk of selection bias in this review is minimal, as the research process, including study selection, data extraction, and assessment of study quality, was carried out independently by 2 reviewers.

Limitations

Although this review identified that serious games are encouraging interventions for promoting rehabilitation in patients with COPD, research evidence of the effects remains inconclusive due to the following limitations in this review and the included studies. First, meta-analysis was not conducted in this review given the significant clinical heterogeneity of the included studies in terms of study design, serious game characteristics, comparisons, and duration, which was one of the main reasons for the inconclusive research evidence found in this review. Second, it is likely that language bias may exist due to the enrollment of only English and Chinese studies in this review. Third, methodological limitations were also found in the included studies. For example, most studies in RCT designs with a small sample size lacked sample size calculations, random allocation of participants, and the use of blinding methods. For pre-post studies, the present studies were limited by the sample size and the absence of an intervention and control group with traditional intervention. Fourth, the effects of serious games involving other vital rehabilitation components in patients with COPD, such as breathing exercises and disease-related health education, are lacking.

However, these limitations mentioned earlier, which could not be addressed in this review, provide significant implications for further studies to enhance the evidence on serious games in this field.

Implications for Future Research and Practices

An evidence-based serious game protocol should be developed to improve the health of patients with COPD, including an appropriate serious game modality tailored to personalized demands, optimal duration, and frequency, based on the research evidence. Additionally, rigorously designed, large-scale RCTs should be developed to determine the effects of serious games on rehabilitation in patients with COPD, such as random distribution, allocation concealment, and the use of blinding. Moreover, future research should also focus on exploring the effects of serious games on other components of COPD PR, such as breathing exercises or health education in patients with COPD, as knowledge in this area is still insufficient. Furthermore, a more robust systematic review, which includes higher quality studies, addresses language bias, and uses a meta-analysis method, is warranted in the future.

Conclusions

This review comprehensively summarized and indicated the potentially beneficial role of serious games in enhancing outcomes in patients with COPD. However, these findings should be interpreted with caution due to the unsatisfactory quality of the included studies. It is recommended that more research with rigorous methodological quality is necessary to further determine the role of serious games in promoting rehabilitation.

Acknowledgments

This work was supported by the Chinese Nursing Association, Luzhou Science and Technology Bureau, and Sichuan Provincial Health Commission (grants ZHKYQ202114, 2022-SYE-54, and CGY2021-1503).

Authors' Contributions

HH independently conceived and developed the idea while also formulating data collection methods based on the included studies in collaboration with M Huang to devise statistical analysis plans and prepare the original paper. RW and M Hayter meticulously conducted a comprehensive review and editing of the paper, ensuring intellectual clarity, coherence, and content accuracy. Furthermore, HH, M Huang, and QC adeptly generated graphical representations and figures to effectively illustrate the data. Throughout the review process, RW and M Hayter provided invaluable oversight, guidance, and mentorship. It is crucial to highlight that each author extensively examined and endorsed the final version of the paper.

Abstract

Background: Innovative technologies such as game consoles and smart toys used with games or playful approaches have proven to be successful and attractive in providing effective and motivating hand therapy for children with cerebral palsy (CP). Thus, there is an increased interest in designing and implementing interventions that can improve the well-being of these children. However, to understand how and why these interventions are motivating children, we need a better understanding of the playful elements of technology-supported hand therapy.

Objective: This scoping review aims to identify the playful elements and the innovative technologies currently used in hand therapy for children with CP.

Methods: We included studies that design or evaluate interventions for children with CP that use innovative technologies with game or play strategies. Data were extracted and analyzed based on the type of technology, description of the system, and playful elements according to the Lenses of Play, a play design toolkit. A total of 31 studies were included in the analysis.

Results: Overall, 54 papers were included in the analysis. The results showed high use of consumer technologies in hand therapy for children with CP. Although several studies have used a combination of consumer technologies with therapeutic-specific technologies, only a few studies focused on the exclusive use of therapeutic-specific technologies. To analyze the playfulness of these interventions that make use of innovative technologies, we focused our review on 3 lenses of play: *Open-ended Play*, where it was found that the characteristics of ludus, such as a structured form of play and defined goals and rules, were the most common, whereas strategies that relate to paidia were less common. The most commonly used *Forms of Play* were physical or active form and games with rules. Finally, the most popular *Playful experiences* were control, challenge, and competition.

Conclusions: The inventory and analysis of innovative technology and playful elements provided in this study can be a starting point for new developments of fun and engaging tools to assist hand therapy for children with CP.

KEYWORDS

technology; cerebral palsy; play; children; hand therapy

Introduction

Background

Children with hand motor skills deficiencies face challenges daily. They may have difficulties with daily activities such as eating, getting dressed, or socializing with friends and families. Physical and occupational therapies can ameliorate the motor skills of these children [1]. One group with hand motor skills deficiencies is children with cerebral palsy (CP). Despite therapists' efforts, the interventions available for this group are repetitive and thus perceived as demotivating [2]. Providing therapy via a motivating activity positively impacts improving motor skills, as patients are more willing to take part and adhere to the treatment. Therefore, rehabilitation researchers and therapists constantly look for ways to innovate and improve existing therapies.

Challenges of current therapy at home include lacking the means for personalization, monitoring of progress of the exercises, and high cost of devices. Children with CP present with a diverse degree of motor function, and no 2 children will be affected in the same way. Therapists therefore adjust the exercises according to each child; however, this type of personalization is challenging if the therapy is to be performed at home. In addition, therapists need to provide tailored and timely feedback for the child to sustain motivation and increase adherence when performing therapy at home. Trying to provide this help at home can increase the workload and pressure on the therapists and caregivers.

New technologies, such as the E-link, the HandTutor, or the surface electromyography, present advantages in hand rehabilitation such as data analysis, customization, feedback, and adaptability to the home environment [3]; however, their high cost means that families cannot make use of them easily. Two known approaches to increase motivation are the use of new technologies and play. The benefits of play in the development of children have been widely studied, showing that the motivational nature of play encourages children to participate and learn. Thus, one of the approaches that therapists have successfully used in rehabilitation centers is to perform exercises through play [4]. One successful example of play-based therapy is Pirate Therapy [5], which highlights the importance of motivating children to work toward a goal through playful activities. Researchers have also studied the use of new technologies, such as virtual reality (VR), augmented reality, game consoles, and robots, which are familiar and appealing to children because they provide opportunities for play via interactive games while enriching the therapeutic experience [3].

Furthermore, these new technologies provide monitoring and automatic feedback on performance, the opportunity for repetition to improve motor skills, and sharing experiences between children and others. These are also financially accessible technologies that require low technical support, making them appropriate for use at home. Some examples of successful studies on hand therapy for children with CP and other motor disabilities are the studies conducted by Reid [6] and analyzed in the review by Pereira et al [7]. They concluded that VR is suitable for supporting hand therapy. Koutsiana et al [8] concluded in their review that serious games are an alternative to provide motivation in therapy. Moreover, Winkels et al [9] showed positive results in participants' usability, user satisfaction, and enjoyment in gaming with the Nintendo Wii sports games, boxing, and tennis. In their review, Ayed et al [10] highlighted that the interest in the field of VR systems for rehabilitation is increasing. However, none of these studies provide an overview of the extent and range of the research on playful technological interventions. There does not seem to be a systematic approach to how and when we use technology and play in therapy for children. Many studies have experimented with available technologies that can be adjusted for therapy without paying much attention to the play elements that can be applied. Therefore, there is a need to have an overview of what the field has been doing for the last decade and to deepen our understanding of the use of play in therapy.

Objectives

The range of playful technological interventions can be studied along multiple dimensions. First, the type of technology (motion sensing, game consoles, etc) can be used to categorize the research. Second, the type of playful elements (competition, rules, fantasy, etc) can help structure the analysis. Therefore, in this scoping review, we aim to identify which innovative technologies are part of playful hand therapies and what are the playful elements used in these interventions. This information will provide researchers, designers, and practitioners with an overview of current therapies for children with CP that make use of innovative technologies and play. Furthermore, we aim to provide starting points to design new therapies that are supported by innovative technology and play (which makes them suitable for other environments than just the rehabilitation center) and that engage and motivate children.

Designing Playful Interactions

To analyze and determine whether and which playful elements have been applied in technology-supported hand therapies for children with CP, we used the Lenses of Play [11]. The Lenses of Play is a design toolkit used to create playful interactions. For example, Almahmoud [12] used the Lenses of Play to design a toy for children with autism. We have chosen to use it as our framework because it provides multidimensional examination of play beyond traditional therapist-centered approaches, making a distinction between games and free play [13] and providing a diverse set of playful elements such as control and competition among others. Other frameworks or models used in therapy, such as Theraplay [14] or SCOPE-IT [15], refer more to the behavior of children in connection with their caregivers and occupational performance. Although play is an essential element, these frameworks lack the focus on what makes an activity or object playful for children. The Lenses of Play focus on the object, game, and user interaction. This framework will help us to better understand how playfulness is used and identify the necessary ingredients to design new playful experiences for therapy. In the future design of playful therapies, this can lead to a common and more specific language to be used by the different stakeholders involved in innovative, technology-supported therapies, including clinicians, children, and their parents, as well as technology developers.

First, we briefly describe the technologies used in this review. Subsequently, identifying the playful elements used within therapies that use new technology will support a more systematic reflection and understanding of the potential benefits of using these technologies.

Methods

A scoping review aims to compile the relevant literature and map the critical concepts of a specific topic. For this scoping review, we used the five-stage framework proposed by Arksey and O'Malley [16]: (1) identifying the research questions; (2) identifying relevant studies; (3) study selection; (4) charting the data; and (5) collating, summarizing, and reporting the results.

Identifying the Research Questions

In line with the main objectives of this scoping review, we aim to answer the following research questions:

- Question 1. Which innovative assistive technologies are used in hand therapies for children with CP?
- Question 2. Which playful elements are embedded in the technology-supported therapy to motivate children with CP?

Identifying Relevant Studies

To identify relevant studies, we performed comprehensive searches in the Scopus, Web of Science, and CINAHL databases for medical and human-computer interaction studies published in English between January 2009 and December 2022. The final search was performed on January 17, 2023. The keywords used were as follows: "cerebral palsy OR cerebral paresis OR cerebral palsies; AND play* OR game OR gamification OR toy; AND child OR children; AND therapy OR rehabilitation OR treatment; AND hand OR upper limbs." The queries that were run on all the databases are presented in Multimedia Appendix 1.

Study Selection

After removing duplicates, the titles and abstracts were analyzed according to the inclusion and exclusion criteria set by 2 reviewers (AB and TVPC). The inclusion criteria for the analyzed articles were as follows: (1) study participants were children (aged 0-18 years) with spastic CP; (2) the therapy described was focused on hands or upper limbs motor skills; (3) the therapy used innovative technology (ie, electronic tools, systems, and devices); (4) the therapy used playful elements such as video games or toys; and (5) the publications consisted of peer-reviewed academic articles or conference proceedings that were published between 2009 and 2022. The exclusion criteria included (1) insufficient information about the game or play activity or referred to traditional therapies without the support of technologies (eg, bimanual, constrained-induced movement, and Pirate Therapy), (2) lack of focus on the treatment used, (3) written in a different language than English, (4) unavailability to access the full text at the time of analysis, and (5) incomplete inclusion criteria. Disagreements between reviewers with regard to the exclusion criteria were resolved through discussion.

Charting the Data

The data extracted from the selected studies included authors, date of publication, research questions or aim, sample size, frequency, time and duration of therapy, hand movement, intended environment (home or rehabilitation center), the technology used, description of the system, and playful elements according to the Lenses of Play.

Collating, Summarizing, and Reporting the Results

The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [17] were followed for reporting the results; the PRISMA-ScR checklist is included in Multimedia Appendix 2. The protocol was registered with the Open Science Framework. The authors (TVPC, BK, BS, and GL) met to determine the categories of technologies, evaluate the playful elements of the Lenses of Play, and analyze the extracted data. To determine the categories of technologies, we investigated their functionality and determined commonalities. For example, Kinect and Leap Motion are used to detect movement; hence, we created a motion sensor category. To identify the playful elements used in the interventions, we analyzed the information provided for each intervention through each of the Lenses of Play. To do so, we examined the design principles, play mechanisms, and goals that were included in the interventions and described in the paper. For commercially available games and technologies, we also investigated the information provided on the developers' websites [18-23]. For example, when analyzing a study with the Lens of Play *Playful experiences*, if the intervention described a game where the player had to grab a specific number of virtual butterflies and place them in a jar, the game will be categorized under the playful experience *completion* because the player must complete a task. The same was performed with the other lenses by following the definitions of each element of the Lenses of Play.

Results

Overview

The total number of studies found on Scopus was 166, whereas 126 studies were found on Web of Science (including MEDLINE) and 58 studies were found on CINAHL, resulting in 350 studies, including duplicates. The first author (TVPC) removed duplicate studies, resulting in 239 studies. The first 2 authors (TVPC and AB) conducted the analysis of titles and abstracts based on the inclusion and exclusion criteria. This yielded a total of 66 studies whose full text were reviewed for data extraction by 1 of the authors (TVPC). Figure 1 depicts the number of studies identified at each process stage following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. Finally, 54 studies were included in the study (Table 1).

In recent years, there has been an increase in the interest in developing and researching hand therapies that use innovative assistive technology and playful elements. Figure 2 shows the distribution of the selected papers from 1999 to 2022.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of search process.

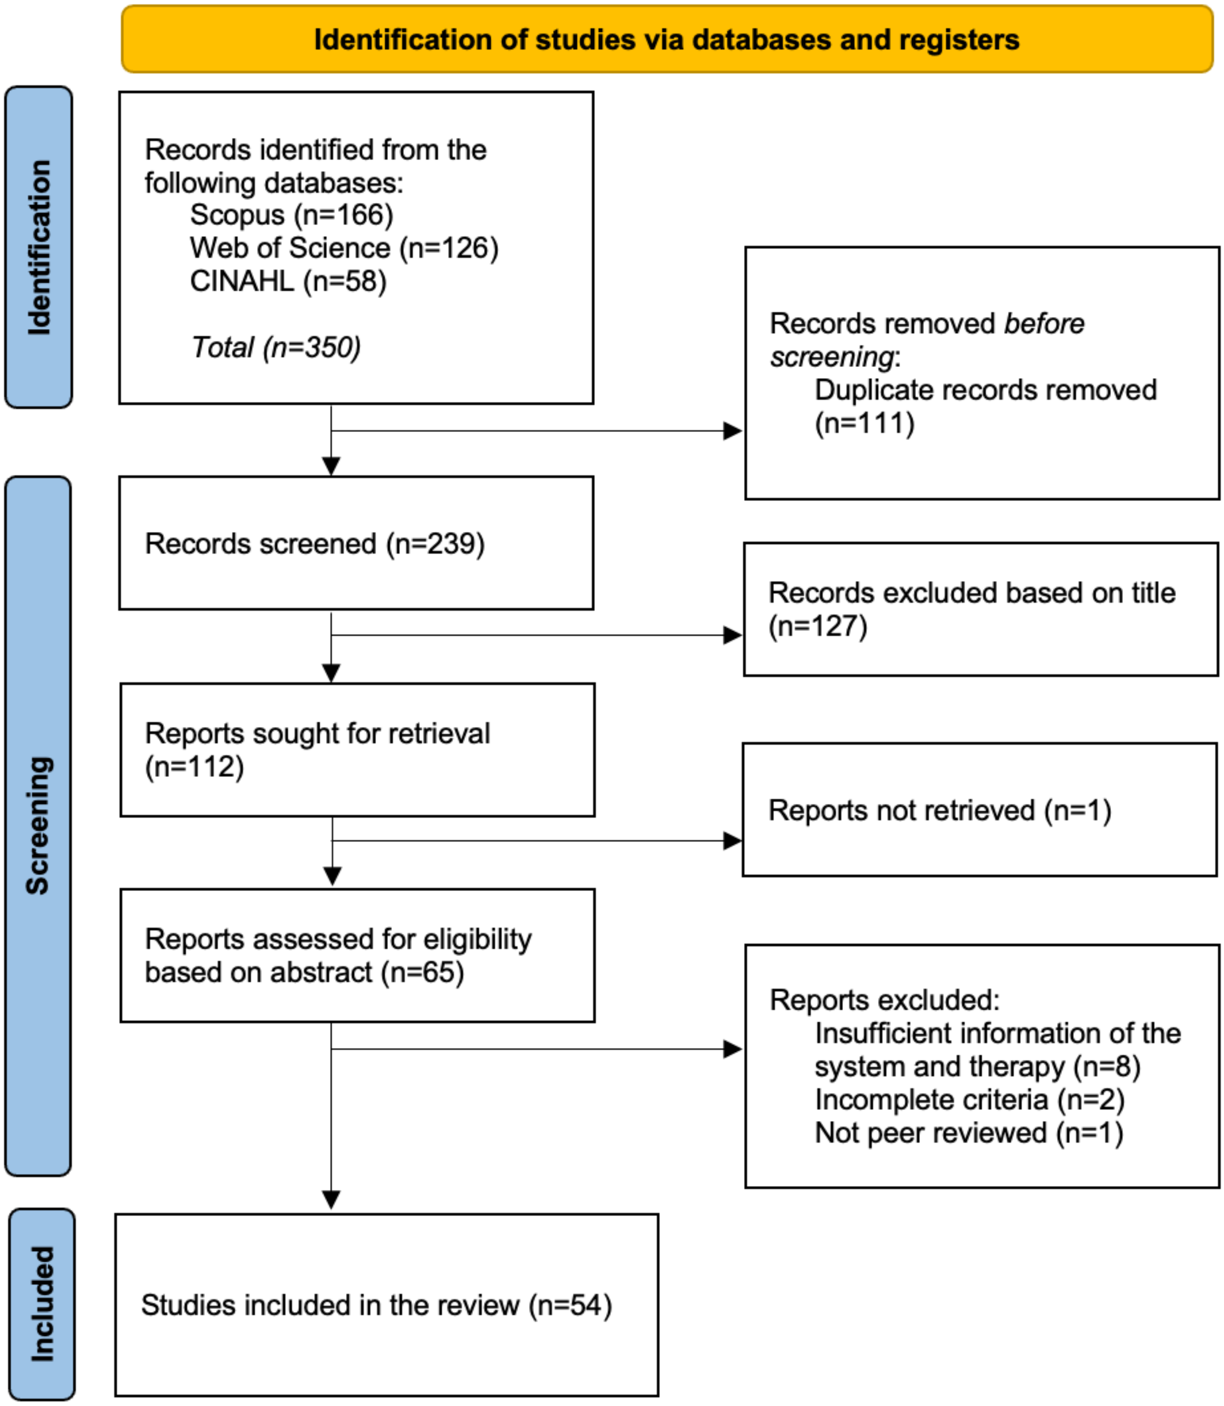

Table 1. Summary of analyzed studies and assistive technology (original purpose of the technology and type of hardware).

Study, year	Study		Technology
	Goal	Participants	Category and system
Category 1: therapeutic-specific technology			
Bian et al [24], 2020	To develop toy modules in combination with Lego blocks to support hand and arm training	5 children, aged 5-10 years; 1 with amentia and 4 with hemiplegia	• Category: Smart Tangibles (smart blocks) • System: path building with the smart blocks and Lego blocks
Guberek et al [25], 2009	To evaluate the level of cooperation and satisfaction of children when practicing arm and hand movements during play-like activities in a physical environment	Children aged 5-12 years	• Category: Motion Sensing (IREX[a]) • System: the IREX system with the game Zebra Crossing, the child attempts to touch as many stars as possible while advancing the crosswalk
Mandil et al [26], 2015	To use a tangible user interface in designing tabletop activities to help motivate children with motor disabilities to increase the number of exercises and improve the motor proficiency and quality of life	4 children with CP[b], aged 6-14 years; 3 physiotherapists	• Category: Smart Tangibles (PhysiTable) • System: PhysiTable with 3 different paths defined with LEDs. Music and color used for feedback. The player uses a cube to trace the path.
van Delden et al [27], 2012	To study the use of tangible, interactive games for the repetitive training of upper limbs in the therapy of children with CP	4 therapists; 16 children with CP, aged 2.5-8 years; 14 non-CP children aged 8-9 years	• Category: Smart Tangibles (smart toys and TagTiles) • System: the smart toys are used to manipulate the TagTiles
Wu et al [28], 2022	To develop an Interactive Story Box to facilitate rehabilitation of speech, cognition, and motion	4 children with CP, aged 4-8 years	• Category: Smart Tangibles (interactive story box) • System: Raspberry PI, RFID[c] readers, and tangible objects to create an interactive box. Story maps are controlled with characters in the shape of a puzzle.
Category 2: consumer technology			
Acar et al [29], 2016	To investigate the efficiency of Nintendo Wii games in addition to neurodevelopmental treatment in patients with CP	30 children with CP, 16 female participants, aged 6-15 years	• Category: game consoles • System: Nintendo Wii, with the VR[d] games (tennis, baseball, and boxing)
Avcil et al [30], 2021	To compare the effects of neurodevelopmental therapy and video game–based therapy for upper extremities	30 children with CP, aged 6-15 years	• Category: game consoles (Nintendo Wii) and motion sensing (Leap Motion) • System: 2 video games to improve hand and grip functions. "CatchAPet" to touch rabbits with repetitive wrist flexion or extension movements and "Leapball" to grasp a virtual ball with all fingers and throw it by finger extension.
Chen et al [31], 2021	To evaluate the feasibility of a Kinect-based constraint-induced therapy	10 children with CP in phase 1 and 8 children with CP in phase 2	• Category: motion sensing (Kinect), computers • System: video game where the child is a warrior defending their island. The Kinect detects the hand movements to throw cannonballs.
Chiu et al [32], 2014	To investigate whether Wii Sports Resort training is effective and if any benefits are maintained	62 children with hemiplegia aged 6-13 years	• Category: game consoles (Nintendo Wii) • System: Nintendo Wii, with Wii Sports Resort games, from easiest to hardest: bowling, Air Sports, Frisbee, and Basketball. 10 minutes per game.

Study, year	Study		Technology
	Goal	Participants	Category and system
de Oliveira et al [33], 2016	To develop a VR game using Unity 3D to aid motor and cognitive rehabilitation in children with CP	8 clinical experts	• Category: computer (PC), motion sensing (Leap Motion), and wearables (Mind wave) • System: 6 phases of a video game in a PC controlled by Leap Motion. Mind wave used to keep track of player's attention.
El-Shamy and El-Banna [34], 2020	To investigate the effect of Wii training on hand function	40 children with hemiplegic CP, aged 8-12 years	• Category: game consoles (Nintendo Wii) • System: playing 4 Wii games: tennis, boxing, bowling, and basketball
Elsaeh et al [35], 2017	To develop a high-level control in which the human brain is stimulated by the visual, audio, and tactile sensation to transmit instructions to the affected upper limb's joints	2 children with hemiplegia, 1 7 years old female participant, and 1 10 years old male participant	• Category: computer (PC), controller (Novint Falcon) system: 3 video games on a PC using the Novint Falcon controller
Garcia-Hernandez et al [36], 2021	To examine how the subjective experience of seeing and controlling a half-body avatar or an abstract hand representation in a virtual environment for training upper limb movements may affect motor performance	19 children aged 7-9 years	• Category: computer and motion sensing (Kinect) • System: a video game with body or hand representation where participants have to reach and grab a ball
Gieser et al [37], 2015	To recognize and classify static gestures from Leap Motion by comparing classification techniques, decision trees, support vector machines, and k-nearest neighbors. Create and evaluate a game to detect hand gestures.	Volunteers and experts	• Category: computer (PC) and motion sensor (Leap Motion) • System: virtual game developed on Unity for PC and controlled via Leap Motion.
Golomb et al [38], 2009	To describe the learnings of providing home telerehabilitation to people with CP and to suggest ways to address some of the barriers to home telerehabilitation in this population	3 adolescents with CP	• Category: console (PlayStation 3) and controller (5DTD Ultra sensing glove). • System: custom games programmed in Java3D for PlayStation 3 and controlled with a 5DT5 Ultra sensing glove.
Golomb et al [39], 2010	To investigate whether in-home remotely monitored VR video game–based telerehabilitation in adolescents with hemiplegic CP can improve hand function and forearm bone health and demonstrate alterations in motor circuitry activation	3 patients with severe right hemiplegic CP, aged 13-15 years	• Category: console (PlayStation 3) and controller (5DTD Ultra sensing glove). • System: the 5DT5 Ultra sensing glove has 5 fiber optic sensors in each of the 5 fingers; it is connected to a PlayStation 3 with Linux, and the games were programmed using open source Java3D API[e].
Goyal et al [40], 2022	To report the use of a VR gaming system and haptic feedback and its effectiveness	1 child, aged 6 years	• Category: game consoles (PlayStation) • System: a driving simulation game with PlayStation 4
Gregory et al [41], 2012	To enable play for children with CP that continuously entertains, which will allow extended play over long durations	N/A[f]	• Category: smart tangibles (Pleo) and controller (Wii Nunchuk) system: a Wii Nunchuk is used to teach dance movements to Pleo.
Hernández et al [42], 2018	To test the usability of the gaming station with clinicians and children with CP and to establish the feasibility in a 12-week clinical trial	6 therapists and 6 children with CP, aged 7-16 years	• Category: controller (Novint Falcon) • System: force feedback Novint Falcon game controller, custom grips, arm and wrist supports, and software to be used with mainstream games
Hsieh et al [43], 2020	To improve hand performance while playing with Chinese puppets modified with Lego robots	42 children with CP	• Category: smart tangibles (Lego Mindstorms NXT) • System: modified puppets with Lego, using servo motors, sensors, and connecting cables

Study, year	Study		Technology
	Goal	Participants	Category and system
Hung et al [44], 2018	To study the feasibility and possible efficacy of a suite of motion-controlled games designed for upper-extremity training in children with CP using Kinect2Scratch	13 children with CP; mean age 6.9 years	• Category: computer (PC), motion sensor (Kinect) system: 3 video games in a PC with a screen with a Kinect sensor • Scratch visual programming and Kinect2Scratch software
Kassee et al [45], 2017	To compare a Nintendo Wii intervention to single-joint resistance training for the upper limb	6 children with spastic hemiplegic CP aged 7-12 years	• Category: game Consoles (Nintendo Wii) System: experimental group: Nintendo Wii controllers, and selected games. Control group: TheraBand, Elite band and squeeze ball with a list of exercises.
Kottink et al [46], 2017	To assess the feasibility, in terms of gaming experience, a mixed-reality system for rehabilitation of the arm and hand function	5 children aged 7-12 years with CP and 10 adults aged 30-70 years with stroke or brain injury	• Category: motion sensing (Kinect), computers (PC) • System: HandsOn game—reaching, grasping, and releasing a physical object to control a PC video game using Kinect
Leal et al [47], 2020	To verify if there was any performance improvement in a task performed in a virtual environment and if it is transferable to the real environment	28 children with CP, aged 6-15 years	• Category: motion sensing (Kinect), computers, and smart tangibles (touchscreen) • System: Check Limit Game, pop bubbles with the touchscreen or gestures
Li et al [48], 2009	To assess if a low-cost VR therapy home-based system can promote movements of the hemiplegic upper extremity that the child finds difficult	5 children with CP aged 8 years	• Category: motion sensing (EyeToy) and game console (PlayStation2) • System: VR therapy home-based system that consists of video games (Secret Agent and Mr Chef) for PlayStation2 and controlled with EyeToy
Macintosh et al [49], 2020	To assess the feasibility of an intervention that combines a cocreated gaming technology with biofeedback and coaching	19 children, aged 8-18 years	• Category; wearables (MYO Armband) and computers • System: Dashy Square video game played with the use of electromyography and an MYO armband
Macintosh et al [50], 2022	To describe the design and evaluation of a biofeedback virtual game	9 children	• Category; wearables (MYO armband) and computers • System: Dashy Square video game played with the use of electromyography and an MYO armband
Nai et al [51], 2019	To analyze the use of Vive trackers to estimate forearm axial rotation for the purpose of supporting interaction with serious games	8 healthy participants aged 21-31 years	• Category: motion sensing (HTC Vive trackers) and computers (PC) • System: HTC Vive trackers attached to a wrist bracer to control a serious game system on a PC. One tracker used around the palm and another around the center of the forearm.
Pruna et al [52], 2017	Evaluate the use of a haptic device and VR games in upper limb rehabilitation in children	5 children with mild spasticity, aged 7-12 years; 4 children with Down syndrome and difficulty of movement in upper limbs, aged 9-12 years	• Category: controller (Geomagic Touch) and VR headsets (Oculus Rift) • System: 2 interactive virtual environment games (watering plants and order objects). The haptic device (Geomagic Touch) acquires the movement generated by the user, and an Oculus Rift provides immersion in the use of the system.
Stansfield et al [53], 2015		1 boy aged 10 years	

Study, year	Study		Technology
	Goal	Participants	Category and system
	To further investigate whether improved measures of motor performance will be seen with the use of motion-based VR gameplay		• Category: computers (PC) and wearables (Polhemus Liberty) • System: PC with the Polhemus Liberty tracking sensor, a screen, and a memory game played alone, in cooperation or competition
Tarakci et al [54], 2020	To study the potential efficacy of an 8-week program with the Leap Motion controller-based training as a therapeutic method for upper-extremity rehabilitation in comparison with conventional rehabilitation programs in children with CP, juvenile idiopathic arthritis and brachial plexus birth injury.	Group 1 (CP: n=15; JIA[g]: n=18; and BPBI[h]: n=9). Group II (CP: n=15; JIA: n=25; and BPBI: n=10). Aged 5-17 years.	• Category: motion sensing (Leap Motion) and computers (PC) • System: 2 rehabilitative video games on PC using Leap Motion: Fizyosoft CatchAPet and Fizyosoft Leapball
Winkels et al [9], 2013	To explore the effect of the Nintendo Wii training on upper-extremity function in children with CP	15 children with CP	• Category: game consoles (Nintendo Wii). System: children played the boxing and tennis games provided in the Nintendo Wii Sports video game console.
Yildirim et al [55], 2021	To investigate the effect of leap motion–based exergame therapy	20 children with CP, aged 8-15 years	• Category: motion sensing (Leap Motion) and computers • System: 2 video games controlled with a leap motion. Leap Ball: grab a ball and throw it into a box of matching color. Catch a Pet: touch the moles in a certain order
Zoccolillo et al [56], 2015	To investigate the effectiveness of video game therapy with respect to conventional therapy in improving upper limb motor outcomes	22 children with CP, aged 4-14 years. GMFC[i] between I and IV.	• Category: game consoles (Xbox) and motion sensing (Kinect) • System: a videogame of the console Xbox using the Kinect device for motion capture. Six games available: “Space pops,” “20.000 Leaks,” “Rally Ball,” boxing, volley, and bowling.
Category 3: therapeutic and consumer technology			

Study, year	Study		Technology
	Goal	Participants	Category and system
Amonkar et al [57], 2022	To evaluate the feasibility of implementation, acceptance, and perceived efficacy of a joystick-operated ride-on-toy intervention to promote upper-extremity function	11 children with CP, aged 3-14 years; 11 caregivers; and 6 clinicians	• Category: joystick ride-on-toy • System: children rode the ride-on-toy (car) navigating with the spastic hand and performing a task throughout the path (collecting objects, throwing balls, and avoiding obstacles)
Bortone et al [58], 2020	To determine the efficacy of immersive virtual environments and wearable haptic devices	8 children with CP or developmental dyspraxia	• Category: wearable (haptic device for the fingertip) and VR headsets (Oculus Rift VK2) System: collecting coins in a VR environment and placing them in a moving piggy bank. Slide a token out of a virtual labyrinth with the finger. Difficulty changes with time.
Choi et al [59], 2021	To investigate the efficacy of a VR rehabilitation system of wearable multi-inertial sensors for upper limb	80 children, aged 3-16 years with brain injury including CP	• Category: wearable (Neofect Smart Kids) and computers • System: games with activities of daily living promoting wrist and forearm articular movements using wearable inertial sensors.
Cifuentes-Zapien et al [60], 2011	To study if a video game can be used as an interface for a robot for the rehabilitation of the pronation and supination movements of children with CP	1 healthy right-handed child aged 11 years.	• Category: computers (PC) and robotics (robotic arm). • System: a PC video game developed for an upper limb rehabilitation robot for children with CP. The video game simulates a formula one race car on a racetrack. The car's horizontal position is controlled by the pronation and supination motions.
Crisco et al [61], 2015	Evaluate play activity recorded by the controller for 2 toys and 3 computer games.	20 children aged 5-11 years	• Category: controller (arm and elbow remote), smart tangibles (smart toy: car and dog), and computers (PC). • System: a specially designed arm and elbow remote controller was used to interface wirelessly with 2 smart toys. • System: A specially designed arm and elbow remote controller was used to interface wirelessly with 3 video games.
Crisco et al [62], 2015	To develop and evaluate the measurement accuracy of innovative, motion-specific play controllers that are engaging rehabilitative devices for enhancing therapy and promoting neural plasticity and functional recovery in children with CP	6 typically developed children (3 male participants and 3 female participants aged 5-11 years)	• Category: controller (arm and elbow remote) and smart tangibles (smart toy: car) • System: the play arm and elbow remote controller was designed with a conformable, ergonomic handle to accommodate varying levels of contractures among children with CP and control a car.
Dunne et al [63], 2010	To describe the hardware platform, present the design objectives derived from iterative design phases and meetings with clinical personnel, and discuss the current game designs and identify areas of future work	Expert clinicians on CP	• Category: wearables (accelerometer) and smart tangibles (multitouch display, tangible objects). • System: 3 games played (Find the bone, Spelling, and Catch the butterflies); the tangible objects control the game in a multitouch display. An accelerometer measures body changes and modifies the game, for example, butterflies fly off the jar.

Study, year	Study		Technology
	Goal	Participants	Category and system
Fu et al [64], 2020	To determine if children could tolerate 9 laboratory treatment sessions and administer up to 7.5 h/wk of CCFES[j] video game therapy at home	3 children aged 8-11 years with hand hemiplegia	• Category: computer, wearables (arm sensors and electrical stimulation electrodes) • System: 4 video games (Paddle Ball, Sound Tracker, Skee-Ball, and Marble Maze)
Hernandez et al [65], 2021	To explore the effectiveness of interactive computer play with haptic feedback	13 children with CP, aged 7-16 years	• Category: controllers (Novint Falcon and Custom levers) and computers • System: 4 commercial video games to train wrist movement: Crazy Rider, Swooop, Funky Karts, and Lil Mads and the Gold Skull. 5 video games to train elbow and shoulder movement: Looney Tunes Dash, Heroes of Loot, Bird Brawl, Pac-Man, and Save the Day.
Minh et al [66], 2021	To test a design of 2 interactive toys and an open game	4 children with CP, aged 2-3 years	• Category: computers and smart tangibles (smart toys) • System: a stuffed stick toy with a 6-DOF inertial measurement unit (IMU) and force sensor–incorporated gloves to squeeze a ball used to play “Catch the worms in the garden”
Mirich et al [67], 2021	To assess the efficacy of VR rehabilitation	1 child aged 4 years	• Category: wearables (Neofect Smart Kids) and computers • System: a functional activity game with different activities such as turn pages, painting, wiping a table, and playing ping pong selected based on the needs of the patient
Mittag et al [68], 2020	To present the design and implementation of a tangible device for hand training	N/A	• Category: wearables (arm sensors) and computers • System: a video game controlled by the sensors and interactions with the tangible controller.
Parmar et al [69], 2021	To improve rehabilitation programs for children and adults with neurodevelopmental disorders in a game-based telerehabilitation.	6 children with CP; 10 adults recovering from a stroke	• Category: wearables (motion therapy mouse) and computers • System: the motion mouse is attached to different objects such as a ball, to control movement in a commercial video game (Big Fish Game).
Peper et al [70], 2013	To examine the potential effects of the training on bimanual coordination and identify if the training had beneficial effects on the affected arm’s performance	6 children with CP aged 7-12 years	• Category: controller (custom levers) and computers (laptop) • System: 2 horizontal levers, a laptop computer, and an additional monitor. Left-hand movements produce vertical displacements, and right-hand movements produce horizontal displacements.
Preston et al [71], 2016	To study the feasibility of using computer-assisted arm rehabilitation computer games in schools, their preference for single player or dual player mode, and changes in arm activity and kinematics	9 boys and 2 girls with CP aged 6-12 years; mean age 9 years	• Category: robotics (robotic arm) and computers (PC) • System: an assistive robotic arm connected to a computer with cooperative and competitive games
Psychouli et al [72], 2017		Non-CP children and 3 groups of CP children (CIMT, RT[l], and CIMT+RT), aged 5-11 years	

Study, year	Study		Technology
	Goal	Participants	Category and system
	To propose a system that can enhance children's motivation during the implementation of a CIMT[k] session and that could explore differences in compliance rates, motivation levels, and intervention feasibility		• Category: wearables (arm sensors) and smart tangibles (smart toys) • System: arm and hand with sensors (accelerometer, magnetometer, gyroscope for upper and lower arm, and flex sensors on the wrist and fingers) that control the 4-wheeled robotic vehicle (DFRobot Cherokee)
Sabry et al [73], 2020	To develop a low-cost VR rehabilitation system with a data glove and virtual games	8 children with CP, aged 5-12 years	• Category: wearables (data glove) and computers • System: a data glove is used to play video games: "Grasp the ball"
Stroppini et al [74], 2022	To determine the feasibility and efficacy of the MusicGlove to motivate hand function	3 children with hemiparetic CP, aged 6-17 years	• Category: wearables (MusicGlove) and computers • System: a video game is controlled with the glove. The patients tap their fingers to make musical notes according to the notes that show up on the screen.
van Loon et al [75], 2011	To test a set of video games, developed to loosen the coupling between the hands of children with CP	7 children with spastic unilateral CP, aged 7-12 years	• Category: controller (custom levers) and computer (PC) system: 3 computer games that challenged the participants to move their hands according to 6 different bimanual coordination patterns executed with custom levers.
Weightman et al [76], 2011	To compare upper limb kinematics of children with CP using a passive rehabilitation joystick with adults and able-bodied children to better understand the design requirements of computer-based rehabilitation devices	9 adults (aged 23-30 years), 9 children (aged 7-9 years), and 7 children with CP (aged 5.5-7 years)	• Category: a controller (joystick) and computers (PC) • System: a computer game in which the child controlled a "spaceship" collecting "satellites" with the use of a joystick.

Innovative Assistive Technology

The authors identified 2 ways to classify the innovative assistive technologies used in the analyzed studies: the original purpose of the technology and the type of hardware.

Original Purpose of the Technology

This first type of classification refers to therapeutic-specific technology, consumer technology, and the combination of therapeutic and consumer technology. Table 1 shows the details of the studies per category. Therapeutic-specific technology was developed for the sole purpose of being used in hand therapy and has been used in 5 studies. An example of this type of technology is the immersive rehabilitation exercise, which is a video gesture control technology that allows patients to be immersed in a video game where users can exercise by interacting with the elements of the game [25]. Consumer technology is a commercially available technology used in entertainment or other fields but that has been modified to be used in hand therapy, consumer technology was used in 29 studies. The authors of the included studies identified this type of technology as potentially beneficial and motivating because of its existing functionalities, interactions, familiarity, and lower costs [54]. For example, Acar et al [29] investigated the efficiency of Nintendo Wii games together with neurodevelopmental treatment in patients with CP. They analyzed “out-of-the-box” games, such as tennis, baseball, and boxing, focusing on the upper extremities. In addition to the observed improvements in speed and functional independence, the children perceived the use of the Nintendo Wii as a reward.

The rest of the studies (20 in total) made use of a combination of therapeutic-specific technology and consumer technology; an example is presented in the studies by Golomb et al [38,39], where custom games were developed to be used with the PlayStation 3 console (consumer technology) in combination with the 5DT Ultra sensing glove (therapeutic-specific technology). The games encouraged hand movements such as opening and closing or thumb extension; speed was also trained by challenging the player to chase a butterfly by flexing or extending the fingers rapidly.

Types of Hardware

This second type of classification refers to a more general category of hardware or technologies, such as VR headsets, game consoles, wearables, motion sensing, controllers, smart tangibles, and robotics (Table 2). When analyzing the types of hardware, it was found that the most common technologies used were computers (32/54, 59%), as they were often used to deploy a video game and to connect with other types of technology. Wearables were one of the most used technologies (19/54, 35%); wearables are continuously in close contact with the body to capture the movement of the hand or arm while they can provide direct haptic feedback. Some of these technologies include gloves such as 5DT Ultra sensing gloves, the Neofect Smart Kids, the Data glove, and the Music glove. Smart tangibles were used in 15 studies, including smart toys such as the TagTile, a device similar to an electronic board game [27], and the dancing dinosaur Pleo! Dance! [41]. Motion-sensing technology was also frequently used (14/54, 25%); a device that belongs to this category is the Kinect, which was used in the studies by Hung et al [44], Kottink et al [46], and Zoccolillo et al [56] because of its ability to capture the upper extremities and movements of the users from a distance. Another widely used type of hardware was controllers (11/54, 11%), for example, the Novint Falcon, a haptic device that acts as a controller similar to a computer mouse but with a shape that allows for higher degrees of freedom. This device, which allows for resistive force feedback on the spastic hand, was used by Elsaeh et al [35] and Hernández et al, [42,65], where limitations of movements and direction are adapted to the interactions needed in the virtual games used and the possibilities of the spastic hand. The full list of types of hardware used in the studies can be found in the Multimedia Appendix 3 [9,24-76]. Some studies focused on using only one type of innovative assistive technology. In contrast, most studies (43/54, 80%) used a combination of ≥1 type, such as PCs with robotic arms [60], smart toys with an arm and elbow remote controller and a PC [61], wearables and smart tangibles [63], and custom levers with a PC [75]. The complete list of studies that used a combination of different types of hardware is provided in Multimedia Appendix 4 [27,30,31,33,35-39,41,42,44,46-76].

Lenses of Play

Overview

Bekker et al [11] defined the Lenses of Play as a toolkit that includes different perspectives on play that can inform design decisions throughout the design process. Initially, 4 lenses were defined: *Open-ended Play*, *Forms of Play*, *Stages of playful interactions*, and *Playful experiences*. In a later publication, Bekker et al [77] introduced a fifth lens, *Emergence*, which relates to the system's perspective and how it can provide meaningful interactions. This analysis focuses on the *Open-ended Play*, *Forms of Play*, and *Playful experiences* (Figure 3) lenses, and the *Stages of playful interactions* and *Emergence* lenses have been omitted because little information was provided about these aspects of play in the studies included in this review. It was possible to identify the playful elements used in the proposed interventions for the other lenses (Table 3).

Figure 3. Lenses of Play; the size of the circles represents the frequency of use of the play element in the publications.

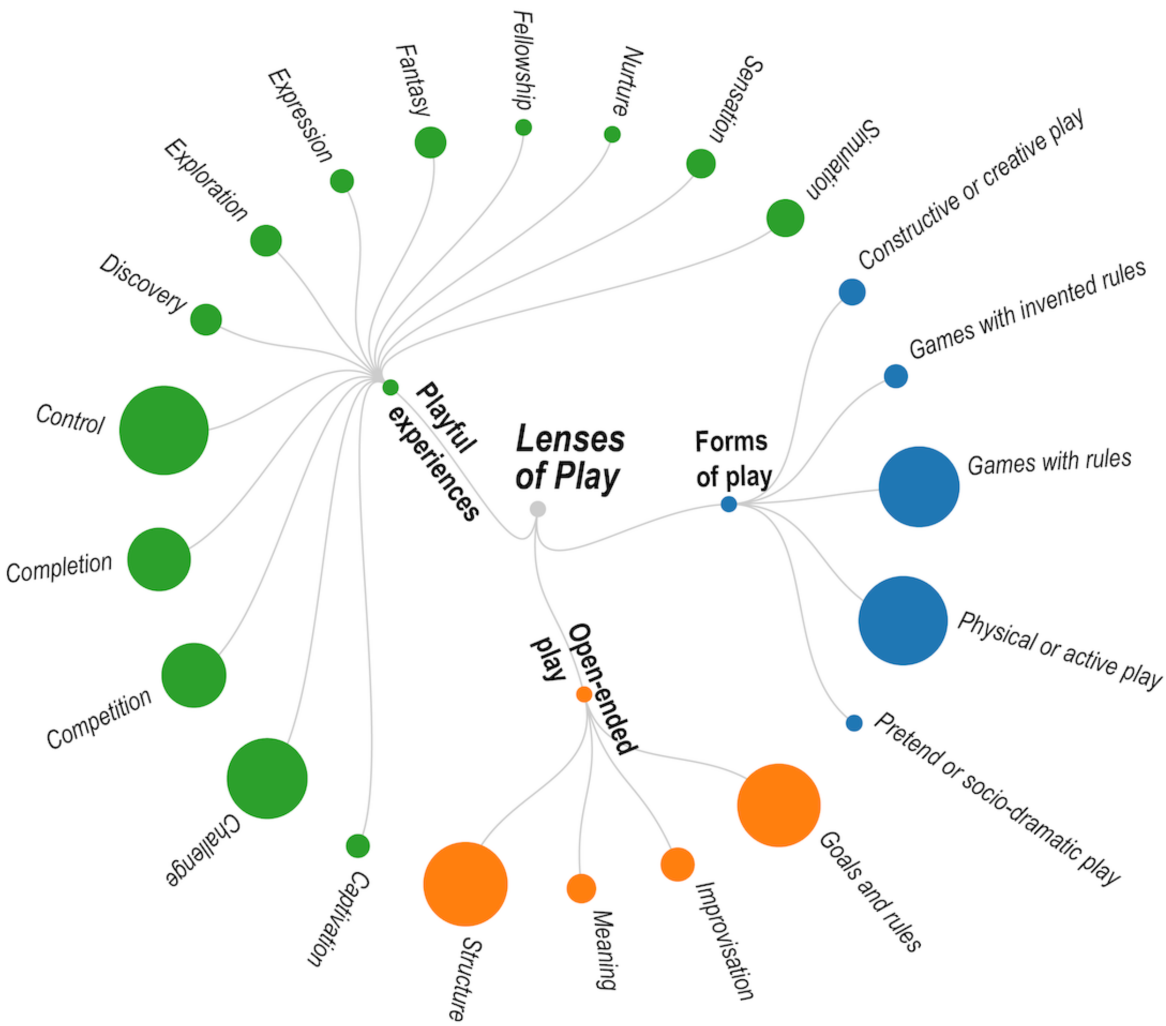

Table 3. Summary of analyzed studies by Lenses of Play.

Lens and play element	Categories		
	Therapeutic-specific technology	Consumer technology	Therapeutic and consumer technology
Open-ended Play			
Improvisation	[24]	[41,43]	[57,61,62,67,72]
Structure	[25-28]	[9,29-40,42,44-56]	[57-61,63-71,73-76]
Goals and rules	[25-28]	[9,29-40,42,44-56]	[57,58,60-65,67-71,73-76]
Meaning	[24]	[41,43,52]	[61,72]
Forms of Play			
Constructive or creative play	[24,28]	[41,43]	[74]
Pretend or sociodramatic play	—[a]	[41,43]	—
Physical or active play	[24-28]	[9,29-56]	[57-76]
Games with rules	[25-27]	[9,29-40,42,44-52,54-56]	[57-61,63-65,68-71,73-76]
Games with invented rules	—	[28]	[61,62,72]
Playful experiences			
Captivation	[28]	[41,43,52]	
Challenge	[25-27]	[9,29-39,42,44-56]	[57-61,63,64,67-76]
Competition	[24-27]	[9,29-34,40,42,44,45,47,48,51,53,55,56]	[58,61,63-65,67-71,74]
Completion	[26-28]	[30,31,35-37,40,47,49-53,55]	[57-59,64-67,69,71,74-76]
Control	[24-28]	[9,29-56]	[57-76]
Discovery	[24,28]	[33,43]	[61,62,72]
Exploration	[24,26]	[33,41,43,46]	[61]

Fantasy	[28]	[41-44]	[70,76]
Fellowship	—	[53]	[71]
Nurture	—	[41]	[70]
Sensation	—	[35,42]	[58,59,72,74]
Simulation	—	[35,40,42,44,45,48,56]	[60,63,74]

[a]No articles in this category make use of this play element.

Lens 1: Open-Ended Play

According to Bekker et al [11], “Open-ended play can be positioned somewhere between paidia and ludus.” In paidia or free play, there is no end goal; it is chaotic, and there is space for improvisation and spontaneity, allowing for expression, meaning, and playing for its sensation. At the same time, ludus refers to games with fixed rules, structure, end goals, and challenge or competition. The *Open-ended Play* lens refers to the 4 properties that characterize paidia and ludus: improvisation, structure, goals and rules, and meaning, as defined by de Valk et al [78]. Players can create their own game during *improvisation* without preparation, whereas *structure* leaves little room for chaos or spontaneity in a game. If *goals and rules* have been defined, the game will have a finite status with a fixed process. Finally, players can add *meaning* to the interaction possibilities that the designers have established.

As shown in Table 3, most interventions presented in the articles have characteristics that refer to ludus, a structured form of play (49/54, 90%) with defined goals and rules (48/54, 88%). In contrast, elements that refer to paidia, such as improvisation (8/54, 15%) and meaning (6/54, 11%), were found in fewer studies. For example, Dunne et al [63] used 3 video games—Find the bone, Spelling, and Catch the butterflies—on a multitouch screen where tangible objects are used to play the games. An accelerometer measures body changes that indicate changes in inclination and use of compensatory movements. Changes in body posture modify the game, for example, butterflies fly off the jar. The 3 games have a clear structure and set of rules (ludus) that the player must comply with to reach a goal, such as catching all the butterflies inside a jar.

In contrast, Crisco et al [61] proposed a system where a robotic car and a robotic dog were controlled using a play controller. Children can play with the toys by performing different wrist motions in this system. There is no set of rules (paidia) besides the type of movements the controller allows. The interaction with the toys is not fixed and can rapidly change according to the children's interests (improvisation and meaning).

Lens 2: Forms of Play

This lens refers to children's development of skills through different forms of play. There are 4 primary forms of play according to Bekker et al [11]; a description of the forms is provided in Table 4. All the analyzed papers refer to an intervention with a physical or active form of play as they all aim to provide physical therapy for the players. Most interventions also presented games with rules (45/54, 83%); the only interventions that did not have games with rules were those that had more of an open-play approach assisted with a toy for example [24,28,41,61,62]. The intervention proposed by Gregory et al [41] contains 3 forms of play, constructive or creative play, pretend or sociodramatic play, and physical active play, where the player interacts with Pleo! Dance! the dinosaur and teaches it to dance using a remote control.

Table 4. Properties of Play Lens 2: Forms of Play.

Forms of play	Description [11]
Constructive or creative play	Creating and constructing something from objects.
Pretend or sociodramatic play	Acting out roles, often using toys and props.
Physical or active play	Sensory motor play with objects. In preschool years, this may involve rough-and-tumble play. Older children engage in play with a more vigorous component to test strengths and skills.
Games with rules	Playing games in social groups with fixed predetermined rules
Games with invented rules	Playing games with modified or rule sets invented

Lens 4: Playful Experiences

According to the Play Lens 4: *Playful experiences*, there are 20 different types of playful experiences: captivation, challenge, competition, completion, control, discovery, eroticism, exploration, expression, fantasy, fellowship, nurture, relaxation, sadism, sensation, simulation, subversion, suffering, sympathy, and thrill. We identified 13 out of the 20 playful experiences in the included studies, as described in Table 5. Control was the most used playful experience (the complete summary can be seen in Table 3). Control could be found in interventions that relied on structure and rules and in those with a more open-play form. For example, the study by Gregory et al [41] consisted of playing and teaching a dinosaur to dance, where playful experiences of captivation, control, exploration, expression, fantasy, and nurture could be found. At the same time, other interventions relied on more competitive (29/54, 54%) and challenging (45/54, 83%) experiences against avatars in the system, another player, or oneself, similar to those in Wii Sports [9,29,30,32,34,45].

Table 5. Properties of Play Lens 4: Playful experiences.

Type of Playful experiences	Description
Captivation	Experience of forgetting one's surroundings
Challenge	Experience of having to develop and exercise skills in a challenging situation
Competition	Experience of victory-oriented competition against oneself, opponent, or system
Completion	Experience of completion, finishing and closure, in relation to an earlier task or tension
Control	Experience power, mastery, control, or virtuosity
Discovery	Experience of discovering a new solution, place, or property
Exploration	Experience of exploring or investigating a world, affordance, puzzle, or situation
Expression	Experience of creating something or expressing oneself in a creative fashion
Fantasy	Experience of make-believe involving fantastical narratives, worlds, or characters
Fellowship	Experience of friendship, fellowship, communality, or intimacy
Nurture	Experience of nurturing, grooming or caretaking
Sensation	Meaningful sensory experience
Simulation	Experience of perceiving a representation of everyday life

Discussion

Principal Findings

This scoping review aimed to provide an overview of the innovative technologies used in hand therapies for children with CP and to identify the playful elements used in such interventions. The 54 analyzed studies showed that therapists and researchers are investigating a broad diversity of technology combined with play to make therapy more pleasant, engaging, and effective for children and to overcome some of the challenges and needs encountered in hand therapy such as the lack of personalization; monitoring of progress; high cost of devices; and the need for tailored feedback, increased adherence, and motivation.

The results of this study show high use of consumer technologies such as the Nintendo Wii, PlayStation, Leap Motion, and several smart toys, to name a few, as a response to the need for financially accessible technology for therapy. This can help lower the therapy costs while allowing to practice in different contexts, such as at home or at school. In addition, considering the familiarity and interest children already have with these types of technology, they could be more easily accepted and adopted. Another important finding was the variety of technologies used; we identified at least 41 different devices. These devices come with a diversity of characteristics such as motion tracking (Kinect, Leap Motion, immersive rehabilitation exercise, etc) and haptic feedback (smart tangibles, TagTiles, Geomagic Touch, controllers, etc) or can be more general support systems (PC, laptop, and game consoles) that can easily be used to deploy a video game. Interestingly, 80% (43/54) of the studies used a combination of hardware; for example, de Oliveira et al [33] used Leap Motion in combination with Mindwave and custom software developed for the explicit purpose of therapy. The combination of commercial and custom hardware brings together the strengths of a robust technology that requires low technical support and can be used at home without extensive financial burden, with the requirements that specific treatments can bring.

From our analysis of play elements, we see different approaches to how play has been implemented and the type of technology used to enhance motivation and adherence: via video games, where the participants had to execute an action with their hands to advance in the game, and via toys or other types of tangible devices that allowed for a more open form of interaction to engage the user while performing the exercises. The findings show that under Play Lens 1: *Open-end Play*, “structure” and “games and rules” were most used in video games. The opposite can be observed in games with toy-like tangibles such as Pleo [41], TagTiles [27], Lego Mindstorm [43], and PhysiTable [26], which allow for a more open-play approach, where there is a structure of the game in terms of narrative. Yet, there is plenty of space for the players to explore and create their own rules, adding space for improvisation and meaning. Although not all the studies reported on motivation and improvement of skills, those that did showed that play has a vital role in motivating children to do their therapy while helping them improve their motor skills. This further supports the idea that *play* is a valuable factor in therapy because it appeals to children. Once they are in a state of flow or immersion in the game, they can perform different hand movements with repetition without becoming burdensome. Moreover, they can share their experience and create bonds through play with other children and family members.

One anticipated finding was that all the studies fit into the Play Lens 2: *Form of Play*, “physical or active play,” which refers to sensory motor play with objects and the test of strength and skills, which is paramount in physical therapy. Furthermore, there should be a flexibility in this “physical or active play” to be personalized to the skill level of children with CP and the use of technology can provide this personalization through the use of sensors and intelligent systems. The other *Form of Play* that was identified the most was “games with rules,” where participants often encounter a predefined goal and a clear set of rules that they had to comply with to play the game. Control (54/54, 100%) and challenge (45/54, 83%) were the most commonly used Play Lens 4: *Playful experiences*. They are often characteristics of video games and are also found in traditional therapy with toys guided by a therapist. The commonality of these approaches is that the participant had to accomplish a task by controlling an object in the virtual environment or a physical object. This control was strongly linked with the exercise that had to be performed with the spastic hand. In the case of therapy at home, it is challenging to achieve the guidance that therapists provide, but the use of technology can help solve this problem [31].

Design New Therapies Supported by Innovative Technology and Play

From this analysis, we cannot draw strict conclusions regarding the impact of using one technology over another. We are also left with questions on how best to use open play or games with goals (Play Lens 1) and how to choose a specific play experience (Play Lens 4). Nonetheless, the playful elements and technology inventory gathered here can be a starting point for designers, researchers, and clinicians who wish to develop new interventions for children with CP. Researchers and designers should first be aware of the consequences and affordances of using one specific technology and the type of play they want to provide with the intervention. The analyzed interventions present toys and video games that offer different types of play and play experiences with their advantages and disadvantages. Although commercially available video games can be easier to develop and access, they might not fit the child’s specific level of disability.

In some cases, combining such technology with specialized software can provide better training. In contrast, toys can provide haptic feedback, allow object manipulation with both hands, and provide more freedom in the type of play, giving room for creativity. When designing new interventions, it is essential to consider certain aspects such as the type of play experience, level of challenge, competition, and physical activity. This kind of play experience could be games with rules or open play. The level of challenge should not frustrate the child but keep them motivated. With competition, we can provide the possibility to compete against themselves or someone else.

Further research can include comparing the effectiveness of different play strategies (for motivation and improvement of motor skills) and designing new interventions that use smart toys or other physical and digital play tangibles to broaden the knowledge base. Another interesting area of focus would be to study in more depth how hand therapy for children with CP can benefit from using new technologies, including artificial intelligence. The possibilities of using artificial intelligence in this area are broad; four examples are as follows: (1) the application of artificial intelligence for personalization (tailored to the skills of the user), (2) adaptive play complexity (changing complexity depending on the progress made in therapy or skills),

(3) balanced play (the skills of different participants are leveled out), and (4) the use of data to help the therapists and caregivers to provide adequate support to the patients or create competition within a community to develop a shared experience. Many opportunities can make the experience of hand therapy more entertaining for children, and the combination of technology and play is a direction that can help achieve this.

Strengths and Limitations

This paper provides a comprehensive review of the current state of hand therapy for children with CP, with a focus on the use of innovative technologies and playful elements. With this review, we have synthesized a wide range of the literature and identified key technologies and approaches in the field. We are also proposing a novel approach by including the Lenses of Play to analyze and understand the application of playful elements in technology-supported hand therapy. This framework provides a new perspective on play and offers a diverse set of elements that can inform the design of new therapies.

We acknowledge that this scoping review has limitations, and first is the lack of details of the interventions. The Lenses of Play allowed us to examine the papers from different perspectives. However, because the main goal of the research papers was to study the effectiveness of the interventions or propose new types of interventions, they did not contain a complete description of all the features of the games or toys, their design process, and the play experience. This could have added bias because we relied on the limited information provided in the studies and on the experience and knowledge of our team and the publicly available information of some of the technologies. Another limitation is the lack of scientific publications on other games, toys, and commercially available technology that therapists include in their program. A further limitation is that we only included studies written in English, excluding studies published in other languages.

Conclusions

With this scoping review, we found that the role of play in the interventions that use innovative technologies in hand therapy for children with CP is to create an enjoyable activity for children that can also help them improve their motor skills. We have provided an overview of how and which technologies are available and which playful elements are part of the interventions. Currently, the field shows diverging strategies and a variety of playful experiences that are supported by technology. Whether via a video game or a toy, with rules and structure, or open play, repetition becomes fun and engaging. While playing, children enjoy the activity and forget that they are performing repetitive hand movements. Technology is an appealing medium to support play; it provides advantages such as measuring hand and arm movement and integrating them in the interaction with the games. In addition, it has functionalities for personalization according to the degree of spasticity of the child and their personal preferences. Technology can also provide feedback to guide the therapy and the game and improve the play experience while collecting valuable data for the therapists, the caregivers, and the children. The implementation of personalized and adaptive therapies in the home or school environment can help relieve the workload on the caregivers and rehabilitation centers. Together with play, innovative, assistive technologies provide an intrinsic incentive to exercise and continue with therapy.

Abstract

Background: Exergames are promising exercise tools for improving health. To the best of our knowledge, no systematic review has compared the effects of commercial exergames and conventional exercises on improving executive functions (EFs) in children and adolescents.

Objective: This study aimed to investigate the effects of commercial exergames and conventional exercises on improving EFs in children and adolescents.

Methods: Following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, 5 randomized controlled trial (RCT) databases (PubMed, Web of Science, Scopus, PsycINFO, and SPORTDiscus) were searched from their inception to July 7, 2022, to identify relevant RCTs. The Cochrane Collaboration tool was used to evaluate the risk of bias for each study. GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) was used to evaluate the overall quality of evidence.

Results: In total, 8 RCTs including 435 children and adolescents were included in the analysis. Commercial exergames had no significant benefit on overall EFs compared to conventional exercises (Hedges g=1.464, 95% CI –0.352 to 3.280; P=.06). For core EFs, there was no evidence to suggest that commercial exergames are more beneficial for improving cognitive flexibility (g=0.906, 95% CI –0.274 to 2.086; P=.13), inhibitory control (g=1.323, 95% CI –0.398 to 3.044; P=.13), or working memory (g=2.420, 95% CI –1.199 to 6.038; P=.19) than conventional exercises. We rated the evidence for overall EFs, cognitive flexibility, inhibitory control, and working memory as being of very low quality due to inconsistency (large heterogeneity) and imprecision (low number of people). Additionally, no effects of the intervention were observed in the acute and chronic groups.

Conclusions: We do not have strong evidence to support the benefit of commercial exergaming on EFs because we did not observe a Hedges g close to 0 with tight CIs. Further research is needed to confirm this hypothesis.

Introduction

Background

Executive functions (EFs) are top-down cognitive processes that control and regulate other cognitive processes while performing intricate cognitive tasks [1]. EFs include 3 core functions, namely, inhibitory control, working memory, and cognitive flexibility [2]. Studies have found that EFs are closely associated with mental health [3,4], academic performance [5], and sleep quality [6] in children and adolescents.

It is well-established that adequate and regular exercise can improve EFs in healthy children and adolescents [7,8]. Exergames (or active video games) are emerging and promising technology-based exercise programs that refer to movement-based interactive video games requiring whole-body exercise [9-11]. Common exergames include Wii Fit, Xbox Kinect, Wii Sports, and Dance Dance Revolution [12]; these exergames platforms and devices comprise a class of commercial exergames [13]. These commercial exergames can increase motivation and engagement from users [14-16] due to their special challenge and interest in games and aim to encourage users to exercise [17]. Commercial exergames have recently become a popular exercise activity with which children and adolescents spend their spare time [18,19]. Previous findings have demonstrated the potential benefits of commercial exergames for both physical health (eg, improving muscle strength [20], balance [21], and cardiopulmonary function [22,23]) and mental health (eg, improving mood states [24], self-esteem [25], and self-efficacy [25]) in children and adolescents.

One systematic review showed that commercial exergames can improve cognitive skills (eg, EFs) in children and adolescents [26]. The main reason that commercial exergames have a positive effect on EFs is that they include several games related to cognitive challenges [26]. However, because the systematic review used passive controls in their comparisons, which hindered the evaluation of the effectiveness of commercial exergames compared to traditional methods, it is still not clear whether exergames offer more advantages for improving EFs than do conventional exercises. Another study performed a meta-analysis to compare the effects of commercial exergames and conventional exercises on the cognitive skills of older adults, and the results did not find that commercial exergames offered better benefits for improving EFs (assessed, for example, using the Stroop task) than conventional exercises [16].

Objective

To our knowledge, no systematic reviews have compared the effects of commercial exergames and conventional exercises on improving EFs in children and adolescents. This knowledge gap needs to be filled because younger participants have a close affinity for commercial exergames and are also the main beneficiary group [27]. There could be a role for exergames in improving EFs when children (eg, those with neurodevelopmental disorders) are unable or less inclined to engage in conventional exercise. Therefore, this meta-analysis aimed to compare the effects of commercial exergames and conventional physical activity on EFs in children and adolescents.

Methods

Design

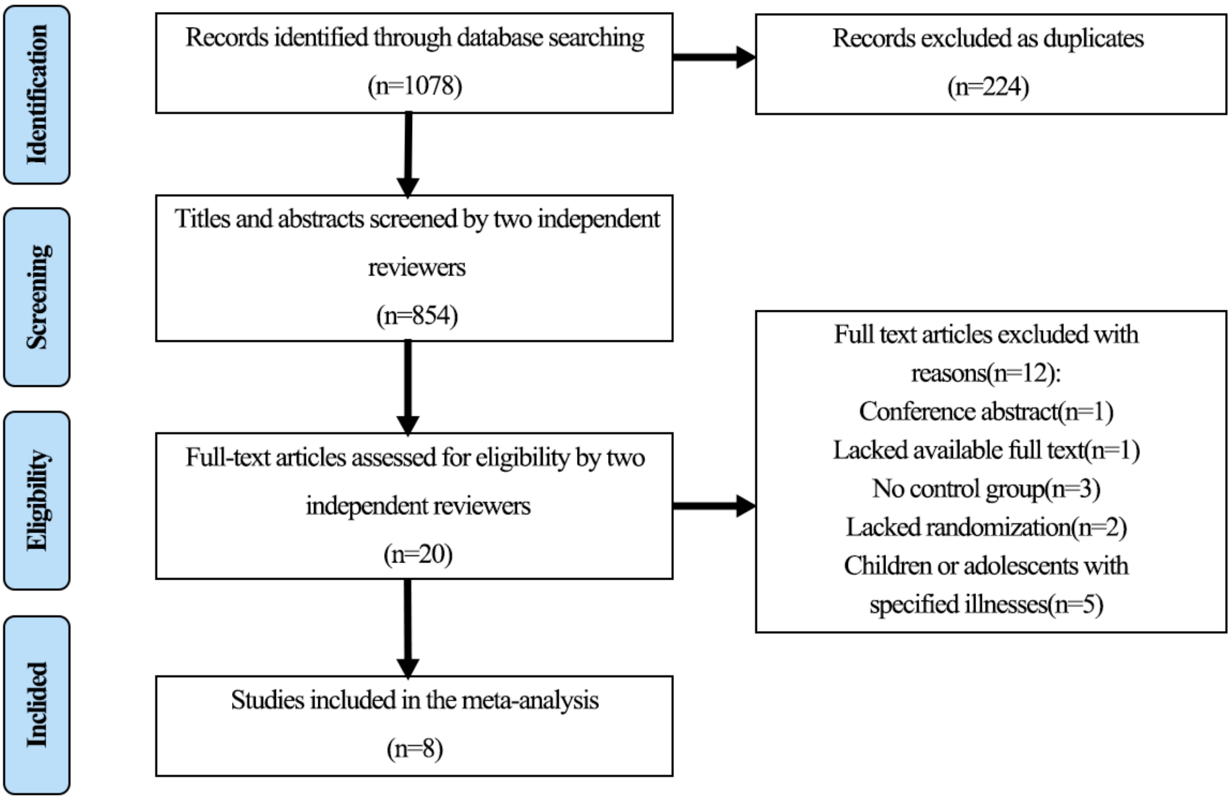
This meta-analysis was performed in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement and its accompanying checklist [28] and was registered with PROSPERO (CRD42022324111).

Study Identification

We searched 5 databases, including PubMed, Web of Science, Scopus, PsycINFO, and SPORTDiscus, for randomized controlled trial (RCT) studies published in English from inception until July 7, 2022, to identify all relevant published articles regarding the effect of exergames on EFs in children and adolescents. The initial search was performed using the following 3 key terms: child/adolescent, exergame, and executive functions. A detailed keyword search strategy can be found in Multimedia Appendix 1. The search keywords for each main term were developed from the search strategies of previous reviews related to commercial exergames, EFs, and children or adolescents [1,29]. Additional literature was identified by searching and reviewing the reference lists of relevant studies.

A total of 1078 records were retrieved from all databases. After removing duplicates and screening titles and abstracts, 854 records were analyzed for eligibility. After full-text screening, 13 articles met the inclusion criteria and were included in this systematic review, and 8 articles were included in the meta-analysis. The article screening process is illustrated in Figure 1.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) study selection diagram.



Eligibility Criteria

All inclusion criteria followed the PICOS (Participants, Interventions, Comparators, Outcomes, and Study design) framework and included the following criteria: (1) studies that targeted children and adolescents up to 18 years of age [28], (2) the primary intervention was exergames with any modality and the control group underwent conventional exercises, (3) the outcomes involved cognitive performance assessments of overall or core (ie, inhibitory control, cognitive flexibility, and working memory) EFs assessed using questionnaires or computer tasks, and (4) the study design was an RCT published in English in a peer-reviewed journal.

Study Selection and Data Extraction

Two researchers independently scanned the titles and abstracts, and studies that satisfied the inclusion criteria were retrieved for full-text assessment. Differences between the two researchers were resolved through discussion. If an agreement could not be reached, the final decision was made through discussion with a third researcher. The data were independently extracted by two researchers. The extracted data were related to the document characteristics (first author, publication year, and country or region), participant description (number and age of participants), details of the interventions (exergame group and conventional exercise group), and outcomes measured. If there were multiple control groups in one study, only the data for the control group receiving the conventional exercise were extracted.

Risk of Bias

We used the revised risk of bias tool described in the Cochrane Handbook version 5.1.0 [30] to categorize the risk of bias of each study, which includes 7 domains, namely, sequence generation, allocation concealment, blinding of assessors, incomplete outcome data, selective outcome reporting, and other sources of bias. The items were rated as having a low, unclear, or high risk of bias. Based on the risk of bias in the individual domains, studies were classified as having a low, unclear, or high risk of bias. Disagreements regarding the risk of bias were resolved by discussion or by consulting a third researcher. The risk of bias for blinding of the outcome assessment was based on the method of outcome assessment (objective or subjective).

Quality of Evidence

GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) was used to evaluate the quality of evidence [31]. GRADE includes 5 subtraction items, namely, risk of bias, inconsistency, indirect evidence, imprecision, and publication bias. According to the results, the quality of evidence was divided into 4 categories: high, medium, low, and very low. In the GRADE evaluation, there was no evidence of a downgrade to high quality, 1 item was downgraded to medium quality, 2 items were downgraded to low quality, and 3 or more items were downgraded to very low quality. The GRADE assessments were applied independently by two reviewers to judge the certainty of the evidence. If there were disagreements, an experienced researcher made the decision [32].

Data Analysis

All analyses were implemented using Comprehensive Meta-Analysis version 3 (Biostat). Specifically, when different instruments were used to measure outcome variables, the effect size in each study was calculated using Hedges *g* with 95% CIs between the groups. Hedges *g* was calculated and weighted through inverse variance, thereby accounting for the respective sample sizes, varying outcomes, and cognitive measures [33]. The magnitude of Hedges *g* values was interpreted as trivial ($g<0.2$), small ($0.2<g<0.5$), moderate ($0.5<g<0.8$), and large ($g>0.8$) effect sizes. Heterogeneity across studies was evaluated and graded using the I^2 statistic (very low: $I^2<25\%$; low: $25\%<I^2<50\%$; moderate: $50\%<I^2<75\%$; and high: $I^2\geq75\%$) [34]. If $I^2\leq50\%$, the research results were considered homogeneous, and a fixed model was used for the meta-analysis. If $I^2>50\%$, then there was heterogeneity among the research results, and a random model was used for the meta-analysis [34]. In addition, the influence of each study on the pooled effect size estimates was examined using a sensitivity analysis. A sensitivity analysis (ie, wherein 1 study was removed) was used to inspect the impact of the retention or removal of outliers and their influence on the overall effect size. As fewer than 10 studies were included in each analysis, publication bias was not investigated. After conducting a meta-analysis for overall EFs, subgroup analyses were performed based on the 3 specific EF domains (inhibitory control, working memory, and cognitive flexibility).

Additional statistical analyses included the following: (1) when studies used ≥2 tests to measure the same variable, the average effect size was calculated; (2) when studies reported ≥2 measurements, only the last measurement was considered; and (3) for studies that reported multiple results on one cognitive task, the result of the more executive demanding condition was included (eg, incongruent trials in the Stroop task) [35].

Results

Descriptive Characteristics

Table 1 summarizes the characteristics of the included studies. In total, we analyzed 8 RCT studies [36-42] involving 435 children and adolescents that investigated the difference in effect between commercial exergames and conventional exercises on improving the EFs of healthy children and adolescents. All included studies were published in peer-reviewed English journals. The trials were conducted in the United States (n=4) [37,38,40,41], China (n=3) [39,42,43], and Spain (n=1) [36]. In all studies, the intervention involved the use of commercial exergames to improve EFs. The exergames devices used included Nintendo Wii (n=4) [37,38,42,43], Xbox Kinect (n=3) [36,39,41], and LeapTV console (n=1) [40]. All participants in the control group underwent conventional exercises. There were 2 acute [36,37] and 6 chronic [38-43] interventions. For the 2 acute exergames interventions, the lengths of the single intervention sessions were 15 and 20 minutes. For the chronic exergames intervention, the intervention durations ranged from 4 to 8 weeks, with a frequency between 1 and 5 times per week. The duration of each intervention session ranged from 10 to 30 minutes. Conventional exercises in the control group mainly included conventional exercises [37,40,42,43], running [36,39], and school-as-usual exercises [41].

Table 1. Summary of the characteristics of the studies included in the meta-analysis.

Study (country)	Participant description					Exergame group		Control group training	Outcome measured
	Recruited from	Age (years), mean (SD)	Female (%)	Intervention group, n		Platform	Intervention duration		
				Exergame	Control				
Flynn et al [38] (US)	Neighborhoods	13.7 (1.4)	48	70	10	Nintendo Wii	120 min (30 min/session, 1 session/week for 4 weeks)	Exercises	EF[a]: D-KEFS[b]

[a]EF: executive function.

[b]D-KEFS: Delis-Kapan executive function system.

[c]NR: not reported.

[d]CE: conventional exercise.

[e]IC: inhibitory control.

[f]CF: cognitive flexibility.

[g]DCCS: dimensional change card sort.

[h]WM: working memory.

Methodological Quality

All the included studies had a low risk of bias in random sequence generation, incomplete outcome data, selective reporting, and other biases. We awarded a high risk of bias for allocation concealment and blinding. Allocation concealment and blinding are difficult in many exercise intervention trials (Figure 2). The overall quality of evidence according to the GRADE approach is presented in Table 2. We rated the evidence for overall EFs, cognitive flexibility, inhibitory control, and working memory as very low quality due to inconsistency (large heterogeneity) and imprecision (low number of people). Details of the GRADE criteria are provided in Multimedia Appendix 2.

Figure 2. Risk of bias graph. Percentages represent the risk of bias.

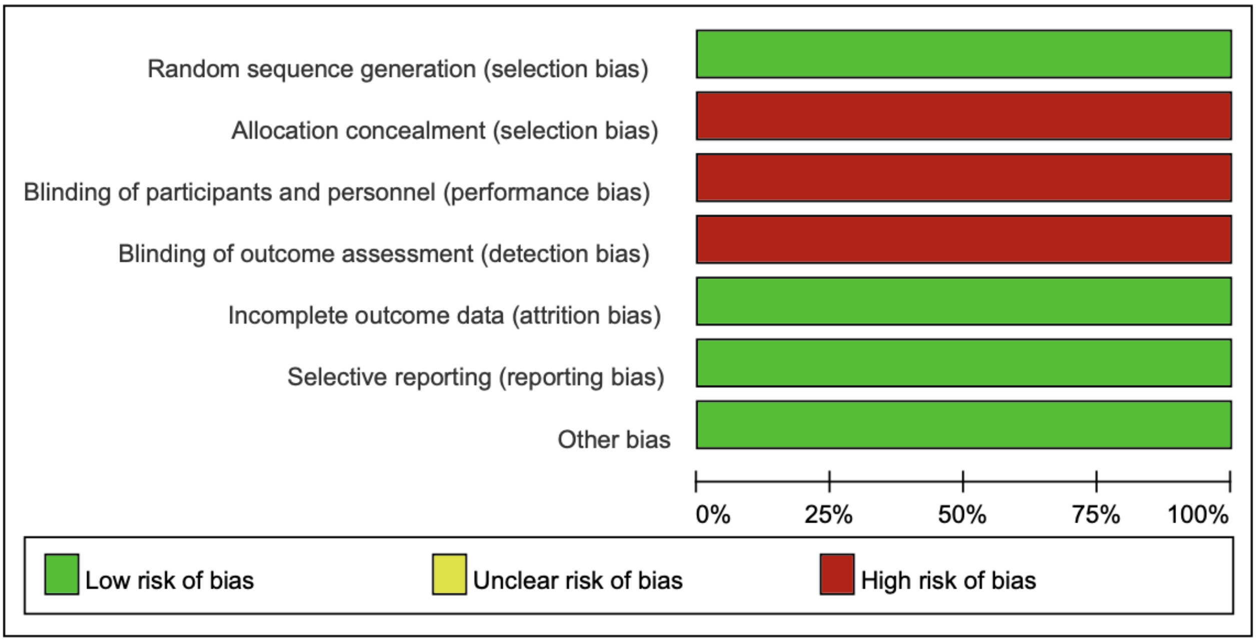

Table 2. Summary of GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) assessment of the effect of exergames on executive functions (EFs).

EF	Certainty assessment						Participants, n		Effect, absolute SMD[a] (95% CI)	Certainty
	Studies[b], n	Risk of bias	Inconsistency	Indirectness	Imprecision	Other considerations	Experimental	Control		
Overall EF	4	Not serious	Serious[c]	Not serious	Serious[d]	None	147	85	1.464 (–0.352 to 3.280)	Very low

[a]SMD: standardized mean difference.

[b]All studies were randomized controlled trials.

[c]Large heterogeneity was observed among the included studies (I^2 >75%).

[d]The overall number of individuals included in the trials was low (<400 individuals in both treatment groups).

[e]CF: cognitive flexibility.

[f]IC: inhibitory control.

[g]WM: working memory.

Meta-Analysis of Effects on Overall and Core EFs

The results of the meta-analysis are shown in Figure 3 [36,38-40,42,43]. Of the 8 studies included, 4 [36,37,39,43] examined the effects of commercial exergames on overall and core EFs. The EF tasks from the 2 included studies were integrated into 3 core EF domains. We used the random effects model for all comparisons because of the high heterogeneity among the included studies. Specifically, the pooled Hedges *g* for overall EFs was 1.464 (95% CI –0.352 to 3.280; *P*=.06), with large heterogeneity (I^2=76%). The subgroup results showed a nonsignificant effect size on cognitive flexibility in 5 studies [36,39,40,42,43] (*g*=0.906, 95% CI –0.274 to 2.086; *P*=.13), inhibitory control in 3 studies [36,39,43] (*g*=1.323, 95% CI –0.398 to 3.044; *P*=.13), and working memory in 2 studies

[39,43] (g=2.420, 95% CI –1.199 to 6.038; P=.19), with large heterogeneity (I^2=94%, 96%, and 98%, respectively). Sensitivity analyses were carried out for overall EFs and cognitive flexibility, and 1 study [39] was found to be an outlier (z=11.272 and 13.141, respectively); thus, a "one study removed" test was performed. The single effect size score specified a change of –0.533 and –0.874, respectively, but was significant (P=.11 and P=.15, respectively) and within the 95% CI.

To further analyze the effect of exergames on overall and core EFs between acute and chronic interventions, we calculated the effect size for these 2 types of interventions (Table 3). The results showed that these findings were not statistically significant among acute and chronic interventions. Notably, the results have high heterogeneity and wide CIs, which can downgrade the consistency and precision of the evidence.

Figure 3. Forest plot for the meta-analysis of the effect of commercial exergames and conventional exercises on improving EFs. EF: executive function.

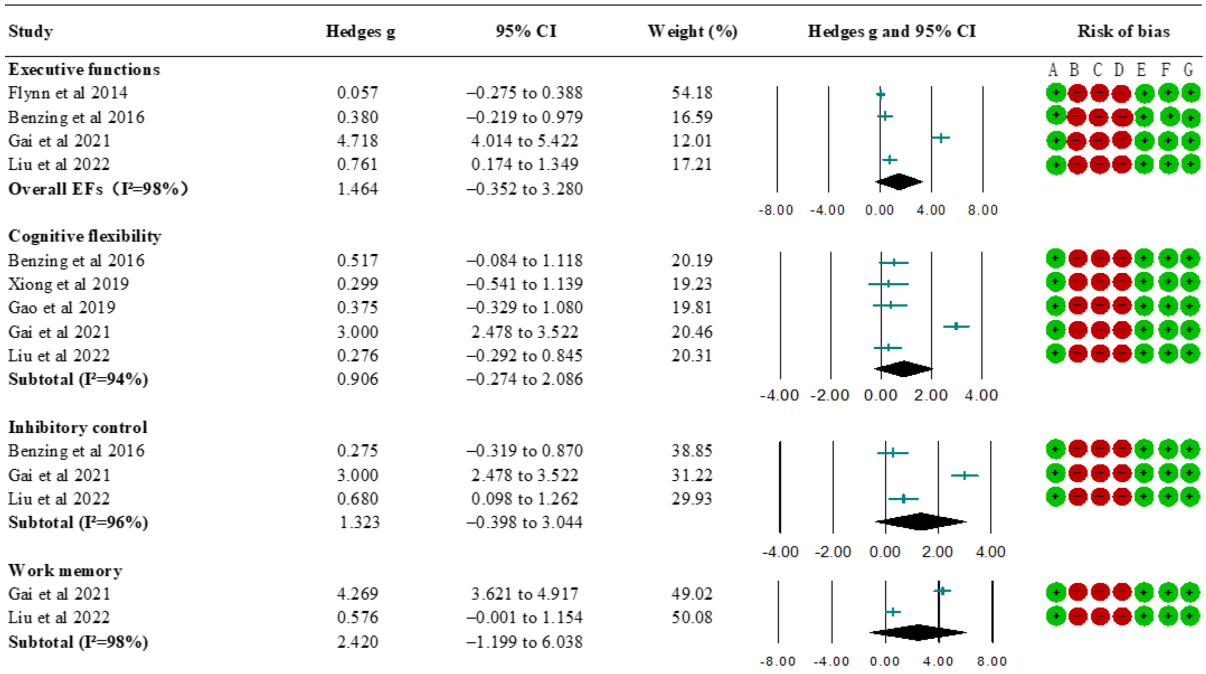

Table 3. Summary of acute and chronic subgroup analyses.

Subgroup	Studies, n	Hedges g (95% CI)	I^2 (%)	P value
Executive functions				
Acute intervention	2	0132 (–0.155 to 0.420)	0	.36
Chronic intervention	2	2.713 (–1.147 to 6.574)	98.602	.17
Cognitive flexibility				
Chronic intervention	4	0.989 (–0.488 to 2.465)	95.483	.19
Inhibitory control				
Chronic intervention	2	1.828 (–0.438 to 4.094)	97.047	.11

Discussion

Principal Findings

The current review investigated the effects of comparing commercial exergames and conventional exercises on improving EFs in children and adolescents based on the outcome data of 8 studies. However, there is a lack of evidence supporting the benefit of commercial exergaming on EFs because of the very high heterogeneity and wide CIs in our results.

To some extent, our results are consistent with those of previous studies. Sala et al [44] performed a reanalysis of a recent meta-analysis in which Stanmore et al [45] claimed that exergames exert a positive effect on cognition, explained the impact of exergames on cognition as small or null, and found no evidence that exergames improve cognitive ability. Notably, the study population was not restricted. Another 2 studies with meta-analyses of RTCs examined the effectiveness of exergames in improving EFs for older people and found that exergames were not superior to conventional exercises in improving EFs among older adults [46,47]. Our findings are consistent with these reviews.

Soares et al [16] conducted a meta-analysis and explained that the difference between exergames and conventional exercises may be related to the intervention of the control group (conventional exercises) with regard to cognitive demand.

Specifically, exergames appear to be more effective for global cognitive performance than conventional exercises with low cognitive demand, in contrast with no advantages in improving cognitive performance when comparing exergames versus conventional exercises with higher cognitive demand. Another study [48] compared virtual reality–based exercises with high versus low cognitive demand and found that exercises with high cognitive demand were more beneficial for EFs than ones with low cognitive demand. Although some studies found that cognitive training with exercise can improve cognitive performance [49,50], it is noteworthy that we only included studies using commercial exergames as the intervention; most commercial exergames platforms and devices (eg, Xbox Kinect and Wii Sports) were not designed to improve one particular cognitive function. Commercial exergames have fewer cognitive components than do professional cognitive training programs. This might be one reason why there was no significant difference between commercial exergames and conventional exercises in improving EFs in children and adolescents in our study.

Another reason may be related to the subjects included in our study. Our study only included healthy children and adolescents rather than children and adolescents with EF impairments (eg, autism spectrum disorder and attention-deficit/hyperactivity disorder). The intervention duration was only 4 to 8 weeks, and based on commercial exergames with low cognitive demands, healthy children and adolescents may require a longer intervention duration to achieve the expected improvement [51]. When the time available for the intervention is limited, healthy children and adolescents may receive the same benefits from commercial exergames and conventional exercises. This may be another reason for the lack of significant differences.

Although these results were not consistent with our expectations, we believe that they are highly encouraging. Given their benefits and advantages (eg, emotional experiences, high feasibility, and usability), exergames can attract children and adolescents to gameplay, keep them physically active, and may play an important role in improving cognitive functions in children or adolescents who are unable or less inclined to engage in conventional exercise. Engaging in exergames is considered a more active lifestyle; thus, we should encourage the development and design of exergame platforms, particularly customized exergames, that is, exergame interventions or platforms designed based on the training or rehabilitation aims of different populations. Studies are needed to examine whether the customization of exergames can help target populations obtain more benefits in cognitive performance.

Limitations

This study had several limitations. First, only 8 RTCs reporting the effectiveness of exergames compared with conventional exercise in improving EFs were included in this study, which may have impacted the precision and variability of the estimates. Second, there was large heterogeneity between the included studies in this meta-analysis, the source of which was not found due to data limitations. These heterogeneities might be related to intervention programs, exergame platforms, or other aspects of the included studies, which may have reduced the quality of evidence and negatively impacted the precision and variability of the estimates.

Finally, because only a limited number of studies were included in this review, we could not identify potential moderators (eg, age). This suggests that more work is needed in the field to further examine and confirm the findings of this study.

Conclusions

There is a lack of evidence of the benefits or harms of commercial exergaming because we did not find a Hedges *g* close to 0 with tight CIs. Further research is needed to confirm this hypothesis.

Acknowledgments

This study was supported by the National Social Science Foundation of China (grant 21BTY092) and the China Scholarship Council Research Project.

Authors' Contributions

JW and LP conceived and designed the study. JW, ZX, HL, and XC selected the articles and extracted the data. JW, LH, and QS contacted the original investigators. JW and ZX analyzed the data. JW and ZX wrote the first draft of the manuscript. LH, YJ, LW, HZ, and LP revised the manuscript. All the authors agree with the results and conclusions of this study.

Abstract

Background: Chronic disease self-management is a public health issue of worldwide concern, and gamification is an emerging strategy to improve patients' participation in chronic disease self-management. Some studies have summarized designs for the gamification of chronic disease self-management from the perspective of eHealth technology, but they have not mentioned differences in design methods, functions, and evaluation methods of gamified designs for self-management in different chronic diseases.

Objective: This scoping review aims to synthesize the characteristics of realization forms, functions, and evaluation methods in chronic disease self-management gamification to improve self-management among the chronic disease population.

Methods: We applied a methodological framework for scoping reviews and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. As of January 7, 2023, we systematically searched 9 databases for relevant studies from January 2012 to December 2022. Related data were extracted based on the research questions. We calculated the frequencies, charted the quantitative data, and coded the extracted material for qualitative content analysis.

Results: We retrieved 16,221 records, of which 70 (0.43%) met the eligibility criteria. In the included research, the target populations for gamified designs for self-management of chronic diseases included patients with stroke, cancer, diabetes, chronic obstructive pulmonary disease, coronary heart disease, obesity, and hypertension. Almost all studies mentioned technical support for gamification (68/70, 97%), mainly in the form of active video games (58/70, 83%); however, less than half of the studies mentioned the theoretical basis for gamification (31/70, 44%). There were 37 concepts or theories relevant to gamification design, most of which were in the field of psychology or were cross-disciplinary (n=33, 89%). Gamification for the self-management of chronic diseases has been widely recognized, including for promoting physical exercise and rehabilitation training (48/99, 48%), increasing initiative for symptom management (18/99, 18%), providing psychological support (14/99, 14%), improving cognitive function (12/99, 12%), and improving medication adherence (7/99, 7%). A total of 39 studies mentioned the gamification effect; however, we did not find a unified evaluation standard.

Conclusions: This scoping review focuses on gamification designs for chronic disease self-management and summarizes the realization forms and functions of gamification in self-management for different patient populations. With practice in a gamified internet-based environment, patients can not only master the knowledge and skills of self-management in fascinating scenarios but also benefit from gaming experience and make better health-related decisions in real life. It is worth noting that a comprehensive evaluation of the users as well as a personalized and targeted intervention should be developed before gamification.

Introduction

Background

Most chronic diseases have obvious behavioral risk factors including smoking, physical inactivity, and unhealthy diet [1]. Therefore, the treatment and management of these diseases increasingly involve cooperation with patients, relying on self-management. Barlow et al [2] defined self-management as the ability to manage symptoms, treatment, physical and psychosocial changes as well as lifestyle changes that patients develop in coping with chronic diseases. However, poor self-management compliance of patients with chronic diseases, such as nonprescribed medication, lack of regular physical activity, and unhealthy eating habits, is a common clinical problem worldwide [3,4]. People with chronic diseases not only cannot see the benefits of self-management in the short term but also endure repeated and monotonous training or changes in past health habits, which is a struggle between low impulses and high cognitive control [5]. With the rapid development of technology, mobile health (mHealth) and telemedicine based on the internet and mobile electronic devices can provide internet-based health services for acute and chronic care, intervention, counseling, and social support for patients with chronic diseases [6]. The process of motivating individuals to find joy in monotonous, repetitive, or uninteresting tasks in a planned, selective way and guiding individuals to make positive changes is called "gamification."

Gamification refers to the application of game design elements to nongame contexts [7]. The specific practice is to integrate game design elements such as points, badges, leaderboards, and avatars into nongame contexts such as marketing [8] and classroom teaching [9] to realize "meaningful play," that is, to achieve serious purposes other than entertainment in an interesting process [10]. When gamification emerges in the field of health care, its serious purposes include, but are not limited to, helping patients with chronic diseases adhere to self-management [11], promoting their basic needs of autonomy, and balancing the unidirectional and paternalistic relationships between doctors and patients [12]. The core of gamification design lies in human-computer interaction and instant feedback, which conforms to the abovementioned difficulties and pain points in the self-management of patients with chronic diseases and is an important measure to break the failure of patients with chronic diseases to adhere to long-term self-management.

Since 2011, there has been an intense discussion about gamification, and the literature on gamification in the health care field has grown rapidly. In the field of rehabilitation and behavioral sciences, gamification attracts patients with cardiovascular disease [13-15], diabetes [16,17], and stroke [18-20] to participate more actively in the management of their long-term health problems with the application of mHealth, virtual reality (VR) technology, and robots.

Objectives

Gamification in the field of chronic disease self-management is at an emerging stage. However, in some studies on gamification design in the field of health care, there is a lack of understanding of gamification as a design strategy, narrowly limiting its application to the use of video games [21] or blindly adding game design elements solely to encourage certain behaviors (such as physical activity) [22]. At present, the theoretical framework design of gamification is a hot topic [23]. Therefore, based on the evidence-based methodologies and from the perspective of gamification design, we integrated the forms, functions, and effect evaluation of gamification in the self-management of patients with chronic diseases to explore the mechanics, dynamics, and experience of gamification design of users with chronic diseases.

Considering the heterogeneity of scientific research design and measurement methods of different studies, we believe that a scoping review is a method of knowledge synthesis that is suitable for discussing large-scale, diverse, and complex heterogeneity themes. For these reasons, a scoping review could be a better choice than a systematic review to quickly describe the research progress of a certain field, showing the scope, depth, breadth, and deficiency and providing more information for the future [24]. Therefore, this scoping review aimed to classify, compare, and synthesize gamification in chronic disease self-management.

Methods

Overall Framework

This study was designed according to the framework developed by Arksey and O'Malley [25]. The five main stages are as follows: (1) identify the research question (RQ), (2) identify relevant studies, (3) search strategy and study selection, (4) chart the data, and (5) summarize and report the results. This scoping review is reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist.

Research Question

This scoping review aimed to describe how gamification design has been implemented in self-management promotion for patients with chronic diseases and how to evaluate the effect of gamification in the self-management of patients with chronic diseases. We articulated the study objectives using the following RQs:

- RQ1: How is the gamification of chronic disease self-management implemented?
- RQ2: What role does gamification play in the self-management of chronic diseases?
- RQ3: How do existing studies evaluate the gamification design of chronic disease self-management?

Eligibility Criteria of Relevant Studies

The research team used brainstorming to establish the eligibility criteria for relevant studies. According to the definition of chronic disease by the Centers for Disease Control and Prevention, we retrieved synonyms for chronic disease and specific disease names for cardiovascular diseases, chronic pulmonary diseases, metabolic syndrome, and cancer. On the basis of the widely accepted definition of gamification [7], relevant studies should apply games or game design elements to promote self-management needs with joyful experiences of patients with chronic diseases. We retrieved cognates and synonyms of gamification, game based, game design elements, game component, game design, and game principle. Given the inseparable connection between the application of gamification and electronic devices, we also retrieved synonyms of video games, computer games, exergames, and VR.

Information Sources and Search Strategy

PubMed, Web of Science, CINAHL, APA PsycINFO, Embase, Cochrane Library, China National Knowledge Network, Wanfang (Wanfang Data), and VIP (CQVIP) were used as the data sources. In the past decade, there has been an increase in health-oriented gamified clinical research and applications [11]. Considering the speed of electronic technology changes, the technology before 2012 does not have a reference value, and we searched for the literature on gamification of chronic disease self-management from January 2012 to December 2022.

The retrieval strategy was based on the combination of subject terms and keywords, and the retrieval scope was the titles and abstracts. The search strategy did not limit any inclusion based on the affiliation of the authors, but the publication language was limited to English and Chinese to ensure an accurate understanding of the research. All databases were run on March 18, 2022, and updated on January 7, 2023. Refer to Multimedia Appendix 1 for the detailed search strategy.

Inclusion and Exclusion Criteria

Under the guidance of an academic librarian, along with a brainstorming session, the research team set the following inclusion and exclusion criteria.

Inclusion criteria were as follows: (1) the research participants or targets were patients diagnosed with chronic diseases aged >18 years; (2) the gamification design in this study must include game design elements; and (3) the study was published in Chinese or English.

Exclusion criteria were as follows: (1) patients with diseases that require long-term rehabilitation owing to trauma (eg, patients with fractures or brain injuries); (2) special research participants such as high-risk groups of people with chronic diseases; groups people with genetic diseases; groups of people with occupational diseases; and special groups such as those who are disabled, sexual minorities, and pregnant women; (3) conference abstracts, patents for an invention, and so on, which only have descriptions but no experimental data; (4) studies for which the full texts are not available.

Synthesis of Results

In total, 2 reviewers (XH and XX) independently screened abstracts and full-text articles with EndNote (version X9; Thomson Corporation) software. In case of conflicting opinions, a third reviewer was consulted (YL) to reach a consensus. The following information was extracted from the articles included in the review: first author, country, publication year, types of study design, objective population (chronic disease type), (if any) sample size and gender distribution, gamification realization forms, theoretical frameworks, game design elements, roles of gamification in chronic disease self-management, and gamification design evaluation tools. All data are presented with data charts suggested by Arksey and O'Malley [25].

To describe the sample and study characteristics, the first author coded papers for the following information using Excel (version 2019; Microsoft Corporation) software: publication year and country of publication (extracted from the paper metadata); types of study designs (extracted from the Methods section); number of patients with chronic diseases and their disease types (extracted from the Results section); and sample characteristics (extracted directly from the Results section or calculated mean value of all sample data).

To describe the application of gamification in chronic disease self-management, the first author coded the paper for following factors: gamification realization (extracted the description of the research tool from the Methods section); gamification evaluation (extracted related outcome measurements from the Methods section); gamification function (extracted verbatim from the "aim" or "objective" statements of each paper).

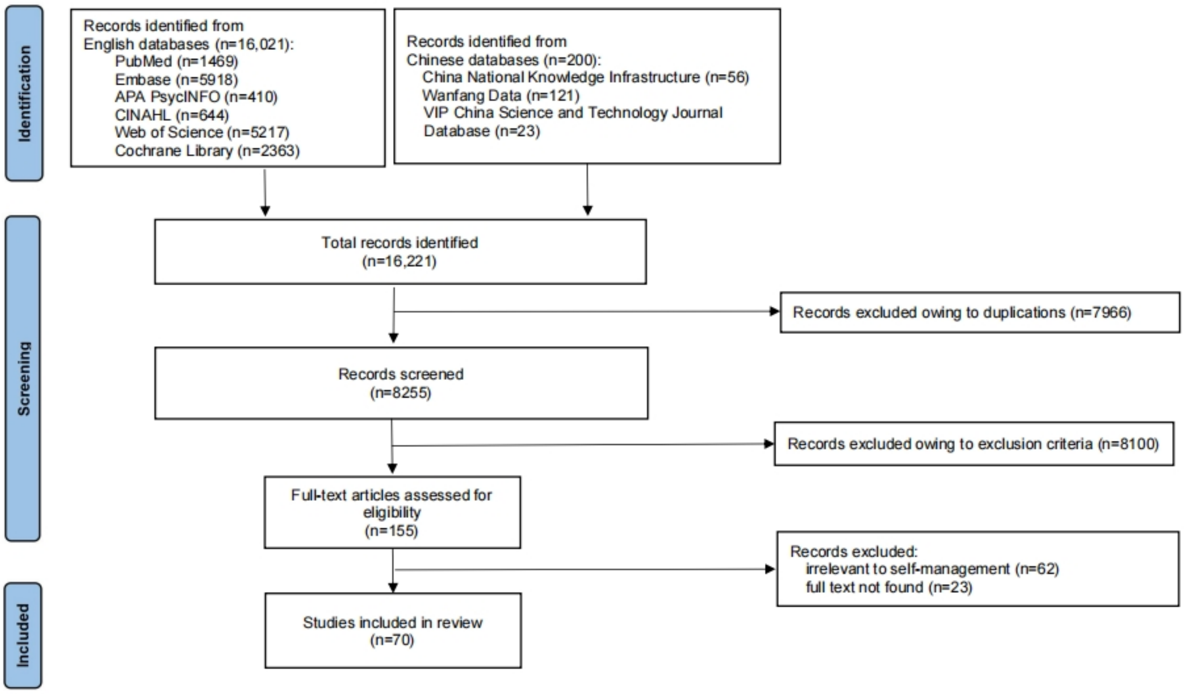
After data extraction, the fourth author calculated the frequencies of the quantitative data and charted the data. The first author coded the extracted material for qualitative content analysis. After 2 coding cycles, subthemes of "gamification forms" emerged, including "technical support" and "theoretical support," and subthemes of "gamification function" emerged, including "symptom management," "medication management," "physical activity and rehabilitation," "cognitive function rehabilitation," and "psychological support."

Results

Search Results

The initial search yielded 16,221 results, of which 7966 (49.11%) were duplicates and 8100 (49.94%) were excluded by reading the titles and abstracts. Of the remaining 155 articles, 70 (45.2%) met the inclusion criteria. The PRISMA-ScR flowchart (Figure 1) shows more detailed information [26].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of study selection.



Basic Information

A total of 70 articles included in this review were mainly from 22 countries. Most studies (56/70, 80%) were concentrated in developed countries. The United States was the country with the most research (18/70, 26%), followed by the United Kingdom (6/70, 9%). There were 5 relevant studies in Canada and Australia and 3 relevant studies in China, Norway, Germany, Spain, Brazil, and Switzerland. The remaining 18 studies were conducted in 12 countries (South Korea, Greece, Iran, France, Malaysia, Portugal, Pakistan, Denmark, Japan, Singapore, Israel, and Indonesia).

Among the included studies, studies within the last 3 years accounted for half of the included studies (35/70, 50%). There were no restrictions on the study designs or chronic diseases in this review. The study design included experimental studies (27/70, 39%), literature studies (18/70, 26%), observational studies (13/70, 19%), and other types of studies (12/70, 17%). Survivors of stroke accounted for the largest number of studies (29/70, 41%), followed by patients with unclassified or multiple chronic diseases (11/70, 16%; Table 1). Except for some studies that only reported the development of gamification designs without data on research participants (26/70, 37%), the review extracted data from 2193 participants, most of whom were female (n=1423, 64.89%). The age distribution of the patients ranged from 33 to 85 years, with the mean age of 55.56 (SD 8.69) years (26/70, 37%). Details are provided in Multimedia Appendix 2 [13-20,27-87].

Realization Forms of Gamification in Chronic Disease Self-Management

Overview

In this study, the gamification of chronic disease self-management cannot be achieved without advanced electronic and information technology but also requires a design supported by the theoretical model.

Technical Support

In this review, the gamification practice of chronic diseases requires the joint support of software (such as applications, active video games, websites, and emails) and hardware (game joysticks, computers, electronic displays, robots, and VR technology devices).

Owing to the derivation of gamification from games, gamification is a methodological approach that enables active video games (AVGs) to be given a purpose other than entertainment. In this study, AVGs were the most common form of gamification practice (58/70, 83%). AVGs are video games that require players to use a certain part of their body as a controller to interact with the game system [13,27]. They can be used as apps for smartphones, tablets, and desktops as well as in combination with hardware facilities such as game joysticks, electronic displays, robots, and VR technology to present AVG content. The top 3 diseases with the highest use rate for AVGs are stroke (28/58, 48%), cancer (8/58, 14%), and unclassified or multiple chronic diseases (7/58, 12%).

As AVGs rely on users' activities in human-computer interaction, most studies (41/58, 71%) mentioned that users can physically interact with avatars in games through various physical activities, such as jogging and boxing, to promote physical activity and extremity function rehabilitation. According to whether AVGs are designed to serve the health care field, AVGs can be divided into commercial games for the general population and experimental games for patients with chronic diseases. The former ones aim for commercial profit, and their rule design and game operation do not have any therapeutic purposes, which has become a limitation in this type of clinical research [28]. In total, 4 qualitative interviews mentioned the gamification needs and preferences of patients with chronic diseases. Patients paid more attention to the health benefits of gamification than AVG points [29,30]. They hoped to integrate more social mechanisms to gain company from relatives and friends in the self-management process [31]. For older patients with chronic diseases, the AVG interface should be as simple as possible, and sound along with video can be used to replace excessive text and button functions [32]. One expert suggested that AVG design for stroke can use a storyline with a sense of purpose to alleviate the impact of significant physical and psychological changes after stroke, thus encouraging patients to participate in rehabilitation [33].

In addition, many hardware or software match (10/70, 14%) with communication media and integrate the game design elements to realize gamification of chronic disease self-management. The form of gamification of "hardware plus communication media" is specifically manifested as a wearable activity tracker combined with email and SMS text messaging [34,35] to provide feedback on exercise steps, which is used for postdischarge activities of patients with cancer [34], exercise, and weight loss for patients with diabetes [35]. The gamification forms of "software+communication media" include web-based interactive community websites [36], self-made mobile apps [37], and mHealth [14,16,38-41], which play an important role in knowledge education and symptom management of chronic obstructive pulmonary disease (COPD), diabetes, hypertension, and other diseases. In a qualitative interview, middle-aged and older patients with chronic diseases were asked how they felt about game design elements. They believe that the first encouragement from family and friends will determine their internal motivation for self-management, and the appropriate frequency of badges, likes, and other reward elements can motivate them to change their daily life habits [40]. Some experts have pointed out that different game design elements are interrelated; therefore, it is necessary to combine the characteristics of patients with their health and well-being and create a relatively stress-free game environment. Let patients enter the state of flow and improve the self-efficacy of self-management.

Theoretical Support

In this review, some studies (31/70, 44%) indicated that relevant theories or concepts guided their gamification practices in the self-management of patients with chronic diseases. A total of 37 concepts or theoretical frameworks were mentioned in the included articles, most of which originated from psychology and cross-disciplinarity (n=33, 89%), such as self-determination theory [38,40,42-44], flow theory [33,45-49], social cognition theory [27,50-52], goal-setting theory [34,43], information-motivation-behavioral technology model of behavior change [32,43], intrinsic motivation [16,53], self-efficacy [17,45], persuasion system design model [54], inhibitory control [55,56], patient-reported outcome [32], co-design approach, and participatory design [57].

Individual studies have started with game design, regarding gamification as a design strategy, and have developed frameworks, such as "mechanics-dynamics-aesthetics" frameworks [33,58], "mechanics-dynamics-emotions" frameworks [23], and "dynamics-mechanics-components" framework [88]. As the theoretical research of gamification is in an emerging direction, the terms are constantly changing.

In the abovementioned theoretical frameworks, the mechanics dimension is central to what defines a game, representing the rules, purpose, and scope of gameplay. The mechanics dimension is the fundamental process that drives game progress and player engagement, such as challenge mechanism [32,58], random mechanism [15,38,59], collaboration mechanism [15,31,37,59,89], and win-or-lose state. In contrast to the concept of mechanics, the dynamics dimension is not a concrete element directly applied to gamification design but rather an abstract motivation that promotes the achievement goals of targeted behavior. The dynamics dimension defines the nature of player interaction within a game, which gives rise to a change in the game state, both in the underlying data and the game's interface. Common dynamics dimension in gamification design includes emotion (evoking players' curiosity, excitement, happiness, or competitive motivation), narration (starting with a series of storylines), progression (recording the development and growth of players), and relationships (promoting family affection, friendship, and other emotions generated in the interaction) [89]. The aesthetics dimension emphasizes the relationship between a player's game experience and their emotional or intellectual response to the game experience. In the included articles, graphics, audio, and haptics can provide sensory feedback and a fun experience for patients with chronic diseases, helping to promote the self-efficacy and response-efficacy of chronic disease self-management [90]. Along with users interacting with the gamified system, they will have emotional responses such as excitement, regret, pleasure, and thrill [23]. Some scholars have changed the word of "aesthetics" to the word of "emotion" (mechanics-dynamics-emotions) [23]. Each component of the gamification frameworks mentioned earlier is causally linked by the game designers and provides the users with pleasure and fun perceptions [91]. In the "dynamics-mechanics-components" framework, points, badges, and leaderboards were concrete game design elements, which only belong to the basic design of the component level in the gamification design. To achieve the maximum value of gamification, game design elements should be applied from the mechanical level preferably to the dynamic level [89].

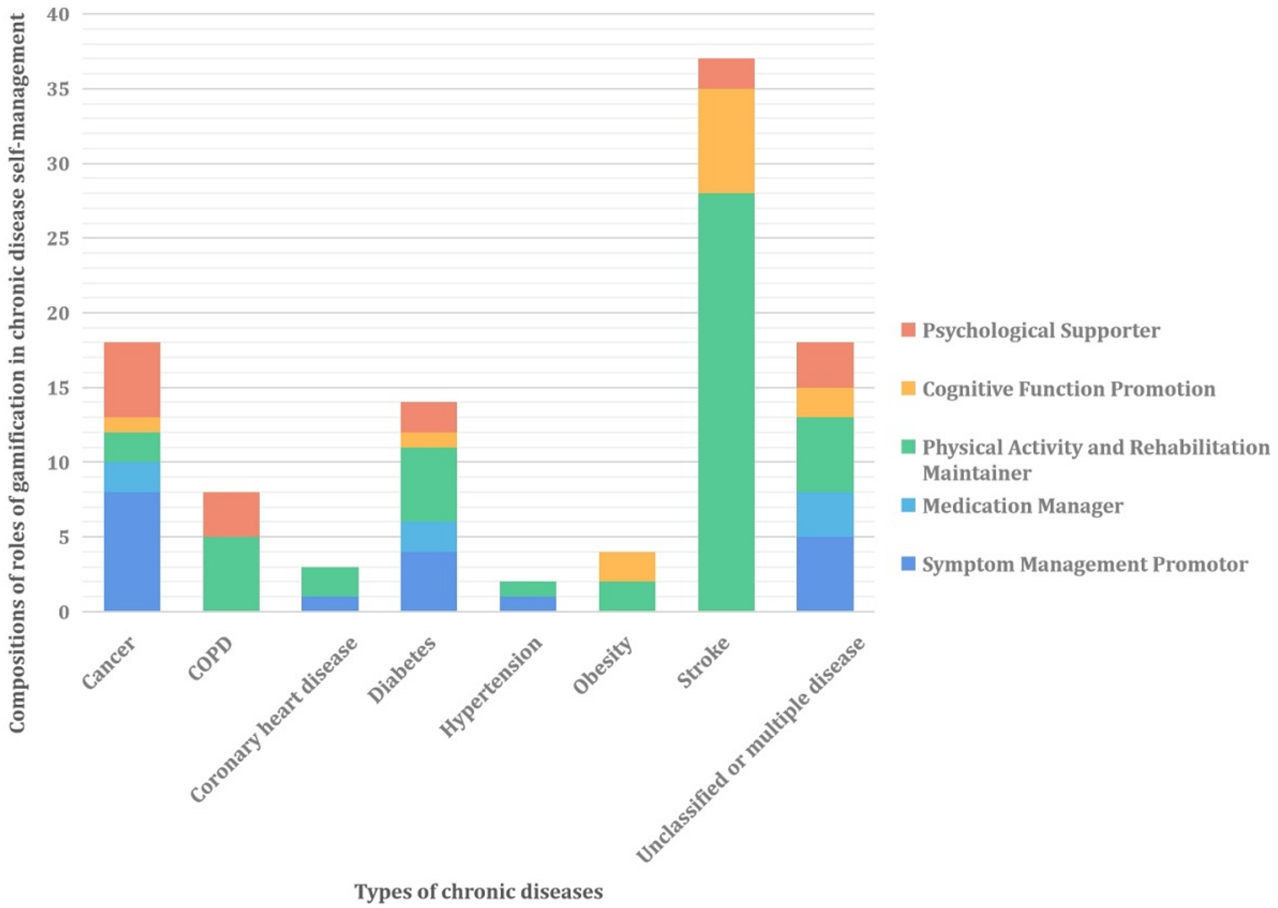
Some studies have discussed the framework of gamification design in the self-management of patients with chronic diseases based on their gamification practice. "The wheel of Sukr" framework was proposed based on the self-management needs of people with diabetes, and the topic definition was summarized through expert interviews, providing practical guidelines for the gamification of chronic disease self-management. This theoretical framework combines behavior change methods and game technology with chronic disease self-management, emphasizing the close correlation among 8 themes: fun, esteem, growth, motivation, sustainability, socializing, self-representation, and self-management. "The wheel of Sukr" framework plays a synergistic role with the game design elements represented under each theme [60]. "The Ayogo model" was derived from the management evidence of patients with diabetes and established patients' self-efficacy and belief in self-management through 3 mechanisms of "narrative," "progression," and "social interaction" [61].

In summary, the gamification design has achieved the purpose of promoting patients gain confidence in self-management through role-playing in games [58], encouraging patients to persist in rehabilitation with relatives or fellow patients [37,88], mastering disease knowledge and skills in an enjoyable and more engagement way [15,31]. For designers, gamification is about designing mechanics that create an aesthetic experience. However, for players, it is about having fun and then figuring out the rules and nonentertaining goals behind the form of game experience. Therefore, the gamification design of chronic disease self-management should be based on game design concepts, psychological or interdisciplinary terms, and immersive technologies such as VR and apply game design elements to provide users with a game experience to better support them in creating overall value in self-management.

Roles of Gamification in Chronic Disease Self-Management

Gamification in the self-management of patients with chronic diseases helped to manage symptoms, improve medication compliance, maintain physical activity and rehabilitation motivation, and provide psychological support (Figure 2).

Figure 2. Roles of gamification in chronic disease self-management. COPD: chronic obstructive pulmonary disease.



Symptom Management Promotor

Within the scope of this review, cancer and diabetes management were prominent in gamification.

For patients with cancer, gamification enhanced the connection between patients with cancer and others through human-computer interaction and social mechanisms [29,32,34,45,51], providing support from health care professionals, relatives, and friends. The progress bar element was applied to record their health condition, self-management measures, and psychological progress [28,34,62], giving users a sense of disease control. In the management of side effects and symptoms after cancer chemotherapy, the project iManageCancer offered survivors of cancer an opportunity to play the role of a mayor with the avatar element. They could master strategies for handling chemotherapy-induced nausea and vomiting after chemotherapy by managing the "Anticancer City" in the game [62]. The avatar element enabled survivors of cancer to better immerse themselves in a virtual environment while playing games and mastering skills to relieve helplessness about chemotherapy-induced nausea and vomiting and other side effects after chemotherapy and alleviate the anxiety about death of survivors of cancer [51,63].

For people with diabetes, game design elements were applied for blood glucose management education. In a study that collected data on 14 gamification practices of diabetes self-management [89], the avatar element was mainly used to simulate insulin injection and diet management to maintain normal blood sugar levels. Take The Didget game for example, the source of AVG points was each reading of the glucose meter, users could exchange these points for game props, characters, and levels to promote timely measurement of blood glucose levels in people with diabetes [89]. It can internalize users' behavior into personal goals during repeated training, improving their self-efficacy and promoting active participation in symptom management in the real world.

In symptom management, the avatar element enabled patients to learn more knowledge about disease management through role-playing [17,57,61-64]. Users were allowed to self-manage trials and errors in the virtual environment with an immersive experience, which cultivated the self-efficacy of self-management in repeated training. Finally, patients with chronic diseases should be guided to apply the disease management methods learned from the virtual environment in the real world and achieve the purpose of secondary prevention of disease.

Medication Manager

This review on medication adherence focused on survivors of cancer, patients with diabetes, and patients with other unclassified chronic diseases.

In the homemade mobile game iLoveBreast, the storyline element promoted patients with breast cancer to gradually complete self-education. The mean value of medication compliance of patients in the game group was higher than in the control group (7.6, SD 0.7 vs 6.5, SD 0.5; $P<.001$). This was because involvement in game medication and reminder alerts had improved users' knowledge of the disease and medication safety [64].

For people with diabetes, insulin use had been taken as a routine [89], so even simple rewards (eg, cumulative points in the form of grades and badges) encouraged people with diabetes to practice glycemic control [40,89]. The time-limited mechanism was convenient for patients with diabetes to play repeatedly at their leisure and constantly consolidated the clinical diabetes education content in repeated processes [52,89].

Among other unclassified chronic diseases, a study retrospectively observed the compliance rate of medication time and dosage in patients with multiple chronic diseases who used the app ("Perx Health") for 3 months and 6 months. This study found a slight downward trend in the 3-month group from the first month to the third month and in the 6-month group from month 4 to month 6 (P=.73) but found no significant differences in medication adherence rates over time (P>.05). In timing adherence subanalysis, the median medication adherence for the first month in the 6-month group was 77.3% (IQR 52.0%-93.1%) and 77.4% for the sixth month (IQR 36.2%-94.4%) [38]. This showed that gamification intervention can promote patients' internal motivation and maintain long-term stability of medication adherence.

Although the number of studies on drug compliance in this review was limited, the results showed that medication education for patients with chronic diseases required a simple gamification design to avoid information overload [40,49]. However, it was necessary to inform the users when to terminate gamification intervention if the gamification design used the element of "points and levels" to record the growth of users. Unless users are intrinsically motivated to stick to medication, missing out on rewards could impair their compliance [38].

Physical Activity and Rehabilitation Maintainer

On the basis of Nintendo Wii series products, Kinect sensors, Microsoft Xbox system, and other mature somatosensory game products and research designs, there were a large number of studies (47/70, 52%) on physical activity and rehabilitation training, including patients with COPD [27,37,65-67], coronary heart disease [13,59,68], diabetes [16,28,35,89], cancers [34,51], and stroke [18-20,30,33,44,47-49,53,54,70-85], making physical activity and rehabilitation training enjoyable.

With the support of AVGs, patients with COPD could meet the exercise requirements of medium- to high-intensity resistance exercise [65,67], and the specific movements of the AVG could be regarded as a therapeutic exercise for patients with cardiovascular disease [13], which improved the compliance of pulmonary rehabilitation and cardiac rehabilitation [13,65,67]. With consideration of the characteristics of exercise intolerance of patients with COPD and coronary heart disease, safety for home use, different levels of difficulty and warm-up exercises were shown in some studies [66,68]. In physical activity interventions for people with diabetes, gamification design mainly promotes walking. Pokemon Go was a good example; its fascinating storyline and the user's devotion to animation inspired the intrinsic motivation of users to use Pokemon Go, which attracted users to increase their steps, walking time, and training intensity during the 24-week intervention period [16]. Thus, gamification design was helpful in maintaining their physical activity, but it was difficult to completely replace therapeutic skills training such as pulmonary rehabilitation [66].

The gamification of rehabilitation for survivors of stroke was one of the breakthroughs in the field of health care, with a specific focus on the rehabilitation of upper limb function (22/70, 46%). For the rehabilitation of the upper arm and shoulder joint, motion sensors were worn to record the range of motion of the shoulder and the amount of shoulder movement, so as to help health care professionals and users judge in a timely manner whether the rehabilitation action was effective [20,30,47,69,70,73,76,78,83,85]. For hand function rehabilitation, game joystick, game gloves, and touch screen could be used to practice grasping, releasing, and pointing

[53,71,73,78] while completing game tasks. For users with weak hand strength and small torso roll angles, commercial game devices cannot record subtle movement changes. Gloves with infrared technology [71] and tangible robots [18,20,44,80] emerged, capturing subtle movements invisible to the naked eye, providing timely feedback on every bit of rehabilitation progress to users, and empowering them to continue. As for functional rehabilitation of the lower limbs, gamification design focused on improving balance functions [42,69,74,84] and activity endurance [48,75,84]. In addition to AVGs, VR technology was combined to construct virtual scenes to train the spatial orientation and cognitive abilities of patients with stroke [18,49,73,74,82].

Overall, “human-computer interaction” was an important game design element in the gamification design of the physical activity and rehabilitation training, providing timely feedback data for both health care professionals and patients such as training duration, intensity, and training action; allowing patients to see physical function changes with exercise rehabilitation; and improving their compliance with exercise and rehabilitation [13,16,19,20,28,30,33,35,37,42,44,46-49,51-56,58-60,64-66,69-83,85].

Cognitive Function Promotion

The studies on cognitive function in the included studies were all conducted in the form of AVGs, which was applied to the attention training of obese patients and the rehabilitation of cognitive function after stroke and cancer chemotherapy.

AVGs come with the effect of cognitive function training. This is because the user learns the rules of the game and processes them quickly and accurately in the game, which keeps the brain active to avoid cognitive decline [45] and improves cognitive control and attention [42]. The time-limited game design element was used to train attention and goal-oriented behavior in obese patients, control the frequency of their consumption of a high-carbohydrate diet (eg, dessert), and strengthen their adherence to a healthy diet [55,56]. Users who received the gaming intervention were more concerned about daily food intake than those who received regular weight management (65.3% vs 33.6%), and the average weight loss in the intervention group was greater than that in the control group (3.4% vs 2.5%) [56].

On the basis of neuroplasticity, rehabilitation of cognitive impairment is possible for survivors after cancer chemotherapy or stroke [19,45,53,86]. A literature review on AVGs in older patients with chronic diseases mentioned that AVGs helped to improve executive functions such as naming, memory, and sense of direction [42]. One neurocognitive learning application was also effective in improving the speed and accuracy of information processing in survivors of cancer with chemotherapy-related cognitive impairment, and the effects could be sustained for some time (at the end of intervention: the average score of perceived cognitive impairment was −7.47, 95% CI −10.80 to −4.13; $P<.001$ and 6 months later: the average score was −6.48, 95% CI −9.85 to −3.11; $P=.001$) [45]. In terms of improving attention and perception, gamification design combined with VR could provide users with an immersive experience with the first-person perspective of game characters [19,49].

It is worth noting that technical interaction should avoid complex design for patients with cognitive dysfunction, which was preferably set as the default setting for self–decision-making (eg, group decision-making and social decision-making) [19,52,77,82,86]. It was also necessary to avoid eye fatigue caused by the long-term use of electronic screens and be aware of the uncanny valley effect of VR [33,72,73].

Psychological Supporter

Patients with chronic diseases usually experience loneliness [29,36], anxiety [33,41,46,63], depression [32,33,42,45,51,60,63,71,80,81], boredom, and pain [17,79] during the rehabilitation process. Some patients with chronic diseases tend to self-isolate [45]. Gamification design provided interesting experiences to distract patients with chronic diseases from negative emotions and provided support and encouragement from friends [14,27,35,37,77], other patients [36,37,44,53], and health care professionals [14,27,29,32,34,36,79].

Owing to the disease characteristics, survivors of cancer have a stronger fear of death than patients with other chronic diseases. They often focus on a vicious cycle of negative conditions and have difficulty getting rid of negative thoughts, leading to further anxiety and depression. One qualitative study mentioned that the points element was used to provide timely feedback on cumulative progression and improve motivation and positive emotions to disperse the fear of death, thus fundamentally shaking the foundation of negative emotions [32]. Another study introduced a web-based community platform (“COPD360 social”), allowing patients with COPD to exchange self-management experiences through the social mechanism and seek help from health care professionals. It enhanced the empowerment of patients with COPD and their caregivers, encouraged them to use the platform actively, created a sense of belonging in web-based communities, and promoted the dissemination of health knowledge [36].

The psychological effects of the gamification interventions were not independent. A systematic evaluation indicated that physical activity games were important components of the effective management of depression in the older adults, significantly reducing the degree of depression in older adults (SD mean difference=−0.60, 95% CI −0.95 to −0.25; $P<.001$) [87]. However, the psychological effects of gamification interventions were limited. If the patient had been diagnosed with depression, the intensity and frequency of the AVG-based intervention were not effective [42].

Evaluation of Gamification Design in Chronic Diseases Self-Management

This review did not find a unified evaluation criteria for the gamification design of chronic disease self-management. The evaluation indicators of gamification design mentioned in the literature have been compiled into Table 2.

Table 2. Evaluation of gamification design (n=39).

Evaluative dimensions and evaluation methods	Studies, n (%)
User satisfaction	
User Satisfaction Evaluation Questionnaire [78]	1 (3)
Self-designed questionnaire [52,61,62]	3 (8)
One-dimensional subjective score [35,51,55]	3 (8)
User experience	
User Experience Questionnaire [58]	1 (3)
Game Experience Questionnaire [53]	1 (3)
Self-designed questionnaire [32,44,49,74,78,91]	6 (15)
Interview [13,16,27,29-31,37,49,58,63,65,69,78,80]	14 (36)
User preference	
User interface features [58]	1 (3)
Self-designed questionnaire [41,77,78]	3 (8)
Interview [13,40,57,58,73,78]	6 (15)
Completion or participation	
Statistical results [55,56,62,68]	4 (10)
Self-designed questionnaire [14]	1 (3)
Accessibility

Acceptance Questionnaire (based on Technology Acceptance Model) [14]	1 (3)
Usability	
System Usability Scale [32,37,84]	3 (8)
Feasibility	
Recruitment rate or retention rate [51,56]	2 (5)
Safety	
Adverse events [35,68,73]	3 (8)
Self-management behavior record	
System log files [14,16,19,20,44,47,65,69,81,91]	10 (26)
Economic cost	
User Satisfaction Evaluation Questionnaire [78]	1 (3)

Of the 70 articles, 39 (56%) reported the evaluation indicators of the chronic disease self-management gamification system. Of the 39 articles, 9 (23%) used existing scales, including the System Usability Scale [32,37,85], Ease of Use Scale [32], Acceptance Questionnaire [14], User Experience Questionnaire [58], User Interface Features Questionnaire [58], User Satisfaction Evaluation Questionnaire [80], and Game Experience Questionnaire [53]. Of the 39 articles, 12 (31%) used self-designed scales to evaluate users' satisfaction [52,64,65], experience [32,44,49,63,76,80], engagement [14], and preference [41,79,80]. Of the 39 articles, 10 (26%) with gamification design through AVGs used system log files to record symptom management strategies [14,63] and their duration [16,20,59,71], activity and rehabilitation training intensity, and related data of users [19,44,47,83].

In total, 17 studies showed user experience and preferences through interviews.

Most users mentioned experiencing pleasure and effectiveness when using gamified systems [29,58,59,66,68,71,80,82]. They could receive timely feedback for error correction or affirmation with human-computer interaction [58,82], stimulate self-efficacy of self-management with the competition mechanism [49,57], and realize personal progress visualization and internal motivation promotion with game design elements such as points and the progress bar [40]. On the basis of mobile devices, users' physical activities and rehabilitation training could be free from the limitations of time, location, weather, or other medical activities, achieving self-management liberalization and confidentiality [16,30,37,66,71]. Using the internet, users could obtain support and supervision from health care professionals and patients more conveniently [27,31,37]. However, some users were older adults, and obstacles in technology and health status were inevitable [75]. They stated that they were unfamiliar with electronic technology and required accompaniment or technical support from their family members or health care professionals [13,27,31,66,71,75]. Owing to the severity of the disease, individual differences in participation and challenge difficulty among different users made it difficult for the gamification design to achieve absolute fairness [27,57]. Therefore, the gamification design of the system interface required comprehensive consideration of users' cognitive and physical functions. This could be simplified by reducing the number of buttons instead of background music to prevent visual information overload [49,57]. Security preparedness was the most important issue when AVG was used for physical activity or rehabilitation training. Without it, users would not have the motivation to use the gamification system [77]. It would be helpful to present action guidance from the first perspective in AVG so that users can operate better and increase their interest, thereby entering a flow state [49]. In terms of competition mechanism and goal setting of gamification design, user engagement and actual situations showed individual differences, preferably allowing users to set their own goals to avoid physical exhaustion and disrupting the fun of exercise itself [27,29].

Overall, the evaluation focused on the experience of patients with chronic diseases, reflecting the self-management motivation, technical novelty, fun of the game experience, and the degree of personalization related to the motivation for self-management [30,82]. Only a few studies reported safety-related outcomes [35,70,75] and adverse events triggered by individual exercises with a gamification system (such as knee pain and low back pain) [70]. We suggest that to promote gamification in chronic disease self-management, health care professionals should pay attention to the safety protection and emergency plan for patients' home use.

Discussion

Principal Findings

This scoping review identified 70 gamification studies on chronic disease self-management conducted from 2012 to 2022. Stroke was the leading disease in gamification research (29/70, 41%), and the field of physical activity and functional rehabilitation was the central research content of chronic disease self-management gamification. In all studies, gamification practice was dominated by AVGs (58/70, 83%), and its theoretical support was mainly derived from existing psychological and cross-disciplinarity concepts or theories. The main functions of gamification were promoting physical exercise and rehabilitation training in patients with chronic diseases (48/99, 48%), especially in the field of poststroke rehabilitation; AVGs have become a rehabilitation tool for survivors of stroke [48] and are used for symptom management (18/99, 18%), psychological support (14/99, 14%), cognitive exercise (12/99, 12%), and medication management (7/99, 7%). Evaluation indicators and qualitative text showed that the use of gamification in chronic disease self-management was widely recognized by patients.

Reflection

Compared with traditional self-management methods, the combination of gamification design and mobile technology has broken through the traditional medical mechanism and experience of patients with chronic diseases, allowing them to have more autonomy in the choice of rehabilitation training time and rehabilitation forms. Therefore, gamification enabled patients with chronic diseases to maintain a high motivation for self-management for 6 months [38], meeting the requirements of disease self-management such as physical activity, symptom management, and disease cognition. In addition, patients with chronic diseases who coexisted with diseases for a long time often had negative emotions such as anxiety and depression, which had a negative impact on their health outcomes, disease management, and quality of life [87]. Gamification used game design elements to create enjoyable experiences, allowing patients to better immerse themselves and complete self-management in a state of flow [46,57,73]. When patients reacted as the requirements of self-management, the gamification would provide timely praise through human-computer interaction, like points accumulation. This timely positive feedback helped to improve the self-efficacy of patients with chronic diseases engaged in self-management, and they sincerely felt happy [79], thereby reducing the conflict between long-term health goals and previous unhealthy habits [50,60], fostering sustainable long-term self-management.

We suggest that health care professionals, developers, and researchers of gamification design should take ethnic characteristics, personal lifestyles, personality, interests, and hobbies into consideration when applying gamification. The most controversial game design element in this study was the competitive mechanism. Competition is bound to result in winners and losers. It is undoubtedly an incentive for patients who win and lead the leaderboard, but if the patient is far behind others, it may make the user give up [57]. This could be a disease characteristic of the susceptibility to fatigue. Patients with cancer and patients with COPD believe that game design elements should be used to build confidence, and even if they want to compete, they should constantly challenge and surpass themselves, rather than emphasizing the competition for patient performance. Patients with different disease severity levels have different perceptions of difficulty in completing the same challenge. For those with severe disease, failure to challenge, especially over a long period, may even lead to depression and a lack of self-efficacy [27,29,45]. For people with diabetes, the fun of competition lies in the fast-paced disease knowledge competition [52,89]. Therefore, the application of game design elements should be related to the frequency of interactions between users and the system or the degree of participation between users and the community to gamify the experience of chronic disease self-management. In addition, patients with chronic diseases of different ages have different preferences for game design elements. Among middle-aged and older adults, users do not want too many rewarding elements such as badges and likes, avoiding making the gamification system of chronic disease self-management like a children's game [40]. Technical barriers should be considered when older patients with chronic diseases use electronic products, which reminds the gamification designer to simplify the game interface and game rules without affecting the user's fun [46,49,52,58,61,77,79].

Therefore, successful gamification design cannot be separated from the following four universal gamification design rules: (1) focus on incentive mechanism, (2) do not terminate games at will, (3) not overemphasizing specific gamification mechanism, and (4) link games with health and happiness [39]. Before the gamification design of chronic disease management, 4 core questions are recommended to be based on the following: Can it provide a good motivation for chronic disease self-management? Is the set target activity meaningful and interesting? Is there a structured pattern of the expected activity behavior? Does the gamification mechanism use potentially conflict with the target behavior?

Future Research

Although this review found that gamification had a positive and universal effect on chronic disease self-management, we still need to view the results dialectically. Most of the gamification intervention periods in the included studies were all within 1 year, and most interventions were within 6 months; therefore, we cannot rule out the novelty effect of technology. We also need to consider that the users included are themselves interested in the study, which inevitably leads to a selection bias. In addition, the gamification of chronic disease self-management involved multiple environments such as clinical settings [73,80] and family settings [30,44,77], which interferes with the effectiveness of gamification interventions. To better explore how gamification promotes self-management in patients with chronic diseases and promotes their expected long-term outcomes, the consistency of the research setting should be controlled, the sample size should be expanded, and the follow-up period should be extended in the future, and more methodological research is encouraged to investigate the extent to which various forms of gamification impact chronic disease self-management.

Limitations

Unfortunately, this review retrieved only the literature published in Chinese or English, omitting valuable data from relevant articles published in other languages. Gray material and unpublished studies were not included in this review. Many health-related applications were privately operated, and their development and evaluation information were not disclosed. The sample sizes of some diseases in the included studies were insufficient and could not represent the entire population. Therefore, in the future, we will expand the search to focus on the literature published in other languages and further study the heterogeneity of disease populations.

Conclusions

This review was based on a definition of gamification, without limiting the type of research, that focused on gamification designs for chronic disease self-management; the study synthesized the differences in the gamification realization forms and functions in self-management of different disease populations, which helped the researchers to completely understand the use experience and opinions on gamification for the self-management of patients with chronic diseases. Before using gamified interventions for chronic disease self-management, researchers must conduct a comprehensive survey of the target group, clarify the shortcomings of the self-management and game preferences of patients with chronic diseases, and stimulate internal motivation through appropriate game design elements. At the same time, it is also necessary to consider the multidisciplinary expert qualifications of the research team and the cost of research interventions, developing attractive chronic disease self-management plans based on the definition of gamification to be applicable to chronic disease management in developing countries.

Abstract

Background: The advent of new technologies has had a profound impact on the labor market, transforming the way we work and interact with each other. With the rise of digital tools and platforms, gamification has emerged as a powerful technique for enhancing productivity and engagement in various fields, including human resource management. In particular, gamification has been found to be effective in developing and assessing soft skills, which play a critical role in determining the success of individuals, teams, and organizations.

Objective: We present a serious game that identifies the most sought-after skills in the job market and offers feedback, and we provide a set of guidelines for the creation of serious games.

Methods: We present the serious game Among the Office Criticality (AOC). The AOC game structure involves a set of sequence analysis techniques, which is known as process mining.

Results: The pilot study findings indicate that the game is both engaging and beneficial to subjects, suggesting that the results align with current theoretical perspectives. Furthermore, the study suggests that the obtained data can be extended to the broader population.

Conclusions: This study illustrates a serious game structured according to the needs of the labor market and developed to put the user at the center, using evaluation techniques consistent with the literature, with the aim of constituting an interdisciplinary approach suitable for adequately assessing users and creating value for them.

Introduction

Background

The field of human resources has transformed traditional and outdated personnel selection methods through technological advancements, paving the way for more technologically advanced methods that reduce hiring costs and optimize the evaluation of candidates during the recruitment process. This is particularly relevant when it comes to millennials and Generation Z. Gamification is among these methods. It can be defined as “a package of services in which a basic service is enhanced by rule-based service systems that provide the user with feedback and interaction mechanisms that aim to facilitate and support users’ global value creation” [1], and in recent years, it has become an increasingly popular trend in nongaming contexts [2] to increase motivation and engagement [3]. Gamification involves the use of structured rules and competitive conflicts to achieve specific goals, and in which a person is fully engaged with the context, losing track of time and experiencing the thrill of doing rather than achieving external rewards [4]. Research has shown that play and games can be linked to positive social behavior [5], the development of important skills such as self-regulation and empathy [6], and the promotion of teamwork [7].

Gamification is often used to enhance services and test gaming experiences and can be a powerful tool for influencing behavior [1]. However, some studies have examined issues related to gamification [8]. This technique is applied in settings related to learning, business, or promoting a product or service [9]. Through elements, such as competition, goal achievement, and reward, gamification can increase users' motivation, engagement, and satisfaction in an activity [10,11].

Many researchers have suggested that gamification and game-based assessments could predict work performance as an alternative to traditional selection methods [12,13]. Fetzer et al [13], according to the concept of "stealth assessment," highlighted the potential of game-based assessments for predicting work performance. Invisible evaluation can accurately and efficiently detect a subject's level of competence, can continuously extract data on their performance during the game [14], and is almost undetectable, reducing test anxiety while maintaining validity and reliability [15]. In this context, a gamified assessment environment could distract candidates from being assessed, promoting unconscious rather than desirable or socially acceptable behavior. Assessment and learning tools that may be created through the use of gamification are known as serious games [16], which are games designed for a primary purpose other than pure entertainment [17], like supporting human capital development [18]. Serious games are designed for educational, training, or informational purposes that combine the playful experience with learning specific skills and competencies [19]. Unlike traditional games, serious games were created to impart knowledge and teach players how to apply those skills in real life by creating engaging and entertaining experiences that prompt users to perform certain actions, improving the effectiveness and efficiency of those activities.

Various sectors, such as education [20], health care [21], mobility [22], marketing [23], and the environment [24], have been equipped with this innovation, simulating situations in which the player must make decisions, solve problems, or develop specific skills. Moreover, owing to the interactive nature of serious games, players can learn actively, receiving immediate feedback on their progress and the correctness of their actions [25].

If the game is user-friendly and realistic, it tends to generate positive responses from candidates [26]. Thus, one of the cornerstones of these games (as well as an aspect this paper will focus on) is the development of awareness related to one's skills, particularly those skills called "soft skills," which are indispensable in the world of work [27].

In relation to the connection between gamification and transversal skills, game elements, such as textures, feedback, avatars, visual effects, and voiceovers, can be effectively used to assess candidates' soft skills [28].

Problem-solving skills, strategic thinking, and adaptation to new contexts are soft skills, also known as "behavioral skills." They are non-technical skills (as opposed to hard skills) important for personal and professional success. Using game mechanics, gamification can make learning these skills more engaging and effective. Serious games play a key role in developing soft skills (such as problem solving, planning, and analytical thinking) in the world of work [27]. Certain elements, such as a risk-free environment, predispose users to a setting conducive to experimentation and exploration, activating stimuli, such as curiosity, learning by discovery, and perseverance [29].

Serious games are playful and interactive tools often used in education with pedagogical goals, which are designed to teach skills, notions, and strategies [30,31]. Serious games offer active involvement, immediate feedback, experiential learning, collaborative learning, and learning personalization, which enhance positive learning effects [32]. The scenarios designed for serious games have a positive relationship with student engagement and academic performance [33]. Despite their potential, serious games still pose a challenge to the educational world, and there is a need for more emphasis on less formal and traditional models that are suitable for teaching today's generation of students [34]. Serious games are an important resource for the world of training and education, facilitating the learning of specific disciplines.

Transversal skills often overlap with digital skills, which have become increasingly necessary for performing tasks due to the growth of technology in recent years. Digital skills involve the use of information and communications technology (ICT) tools and can be classified as operational, formal, informational, or strategic skills [35].

Based on these premises, this research proposes an innovative method for addressing an issue dear to companies, the recruitment process. Recruiting an unsuitable candidate can be very costly, both in terms of money and nonproductive time. Therefore, many companies are looking for innovative ways to improve their recruitment process to attract and identify the most suitable candidates for available positions. This involves the use of cutting-edge recruiting techniques and an increased focus on assessing candidates' skills and qualities [36].

Psychological tests that measure cognitive abilities and personality tests, which are traditional selection methods, can somewhat predict job performance [37]. As previously mentioned, the game is an attractive and valid alternative to traditional selection methods, and gamifying these tests can be a way to assess candidates with the benefits stated above.

The COVID-19 pandemic has prompted a shift in the labor market toward Industry 5.0 to the New Normal Era, a time of collaboration between advanced technology and human creativity to address business, social, and environmental challenges [38]. This has had an impact on the labor market, affecting both demand and requirements, as well as leading to the emergence of the "great resignation" phenomenon, in which individuals across countries and industries are exhibiting a heightened awareness of work conditions and opportunities [39,40].

To successfully adopt artificial intelligence (AI), organizations and individuals must embrace transformative changes in their practices, recognizing the foundational role of connected technologies in driving increased digitization in business and management worldwide. Key factors for successful AI adoption include team coordination, organizational culture, governance strategy, and AI-employee integration strategies. Furthermore, the integration of serious games and AI provides new computational tools for social research. Soft skills, such as communication, problem solving, critical thinking, and creativity, are crucial for successful AI adoption, while leadership plays a vital role in setting a vision and strategy for its implementation [41,42].

Recent studies have emphasized the importance of soft skills and talent in the New Normal Era, where work has changed significantly and new methodologies, such as smart working and remote working, are becoming increasingly prevalent. As a result, soft skills are now a top organizational priority [43].

State of the Art

Industry 5.0: Impact of Emerging Technologies on Gamification and the Labor Market

With the increasing adoption of new technologies, such as AI, virtual reality, metaverse, blockchain, augmented reality, and collaborative robots, it is crucial to understand the transition from Industry 4.0 to Industry 5.0 for creating sustainable business and management practices. Industry 4.0 was characterized by automation technologies, the Internet of Things, and smart factories, while Industry 5.0 involves the collaboration between advanced machinery and human creativity to solve business, social, and environmental issues. The adoption of transformative changes in practices is essential for organizations and individuals to understand as these connected technologies provide the foundation for increased digitization in business and management worldwide. While the use of serious games and gamification has become increasingly popular in recent years, some of these emerging technologies, particularly AI, have the potential to be disruptive for the world of work and have a significant impact on human resources, recruitment, and corporate life [38].

Team coordination and organizational culture are also crucial elements that organizations must consider when adopting AI. Effective coordination between team members is essential for successful AI implementation, and organizational culture plays a critical role in supporting this coordination. An innovation mindset is also necessary to foster a culture of experimentation, learning, and continuous improvement, which are all essential for successful AI adoption.

Governance strategy is another key area that organizations must consider when adopting AI. Effective governance ensures that AI is being used ethically, responsibly, and in compliance with legal and regulatory frameworks. AI-employee integration strategies are also important, as they help to ensure that employees feel comfortable working with AI systems and are equipped with the necessary skills to do so [41].

Pérez et al [42] suggested that the integration of serious games and AI offers new computational tools for social research. By developing and applying gamification with an eye toward both design and efficacy, organizations can increase productivity and promote better decision-making processes in the workplace. The use of gamification and serious games in the workplace can be a promising tool to enhance motivation, engagement, and decision-making processes among employees.

An evidence-based approach to gamification considers its effectiveness to be dependent on the use of scientifically proven principles and tactics that can impact outcomes [44]. Optimistic results have been found in the integration of some of the newest technologies, as AI, virtual reality, and serious games are being increasingly used in several industries, such as the healthcare industry where there was a great effort concerning new technologies and research during the COVID-19 pandemic, yielding favorable outcomes for the treatment of various health conditions as well as for medical education and training [45-47]. Moreover, Schönbohm and Zhang [48] revealed the effectiveness of serious games in facilitating strategic decision-making in the context of the COVID-19 pandemic.

In the era of the new normal, the global workforce is experiencing an unprecedented phenomenon known as the “great resignation.” This phenomenon is characterized by individuals in various countries and industries exhibiting a heightened awareness of work conditions and opportunities, which is indicative of an overall increase in people’s awareness of work. However, this phenomenon has also brought about uncertainty, challenges, and opportunities for organizations due to external factors such as the gig economy and the implementation of technology [39,40].

Recent research by Duch-Brown et al [49] investigated the relationship between market power, AI, and online labor markets. They showed that market-designing platform providers can influence labor demand and supply elasticities on online labor markets by setting specific terms and conditions on the platform. The study also revealed a significantly higher demand for AI-related labor and a significantly lower supply of AI-related labor, indicating the need for further exploration of the role of AI in online labor markets. Similarly, Deranty and Corbin [50] highlighted the potential societal impacts of AI deployment in work, particularly in the areas of technological unemployment and wealth polarization.

This presents new challenges and opportunities for soft skills [51], as well as technical skills and fusion skills [52], which are those skills and attributes required for individuals to thrive in the fusion environment of the 21st century. Therefore, staying updated with technological advancements and market-specific demands is essential for individuals employed in data science–related fields (more so than others) to enhance and maintain their employability, especially in the digital renaissance. Additionally, real-time identification of market demands plays a crucial role in balancing the adequate supply and demand of talent in this era [53].

The Future of Work Relies on Soft Skills in the New Normal Era

A new technological revolution is going on, and many organizations are eager to adopt new technologies in order to gain a competitive advantage. However, implementing new tools, like AI-based tools and technologies, is not enough to achieve success. A recent review on human resource management conducted in March 2023 revealed that organizations need to look beyond technical resources and focus on developing nontechnical resources as well [41]. The review highlights several nontechnical resources that are critical to successful AI adoption. These include human skills and competencies, such as communication, problem solving, critical thinking, and creativity, which are essential for effective collaboration with AI systems. Additionally, leadership is vital for setting a vision and strategy for AI adoption and ensuring that it aligns with the organization's overall goals and values. In conclusion, the review underscores the importance of developing nontechnical resources in addition to technical resources when adopting AI. By investing in human skills and competencies, leadership, team coordination, organizational culture, innovation mindset, governance strategies, and AI-employee integration strategies, organizations can fully realize the benefits of AI adoption and gain a competitive advantage in the marketplace [41].

The 2023 Pulse of the Profession report by Project Management Institute highlights that power skills, which are soft skills built upon a solid foundation of technical skills, are a top organizational priority [43]. Developing these skills can lead to delivering results that add value to both the organization and its customers.

Redefining work requires more than skill development, as skills have inherent limitations. Simply retraining workers to perform different routine tasks or adapting to new technologies to complete the same tasks does not address the underlying challenges for workers or capture the potential benefits for companies. The vision of redefined work involves shifting workers' focus from routine tasks to identifying and resolving hidden issues and opportunities. While automation can facilitate this shift, it is not just about automating tasks or using technology. It does not involve changing the workforce composition or retraining employees for different domains, and it does not require employee suggestion boxes, 20% work time for innovation or entrepreneurship, or innovation centers. Workers must develop and use their human abilities to identify issues, solve problems, implement solutions, and iterate to recognize and resolve hidden issues and opportunities. A key characteristic of this work vision is its continuous evolution. Problem identification and solution methods are typically used to correct processes, address deviations, or eliminate inefficiencies, with the goal of incorporating feedback into more structured and defined work. Loosening the structure is only a temporary measure to advance the process [51].

The job market has undergone a significant transformation due to the pandemic, which has been expedited by the emergence of new technologies. To thrive in this new era, possessing soft skills, such as communication, problem solving, creativity, and collaboration, as well as the ability to adapt to change, is crucial [54], even if digital and technological skills are vital for enhancing a firm's performance. Moreover, Akrim [55] stressed that while knowledge is important, soft skills cannot be overstated when it comes to securing one's future.

To gain a competitive edge in the job market, integrating talent and knowledge management strategies is imperative [56], and to succeed in the future of work, prioritizing soft skills and talent management strategies in recruitment and training processes is essential. Identifying unique talents and skills is crucial to gaining a competitive advantage. High demand for soft skills, such as creativity, emotional intelligence, critical thinking, and problem solving, necessitates their recognition and prioritization in organizations' development efforts [57].

The Pedagogical Side of Serious Games

Serious games serve as an effective and result-oriented medium, utilizing interactive and playful forms of engagement [30]. They represent tools designed with the goal of teaching something, such as skills, notions, and strategies, and offer the possibility for the user to identify with learning and formative situations, and thus, it can be said that they pose pedagogical goals [31]. Serious games are associated with multiple advantages from pedagogical and formative points of view, including active involvement, as the player becomes the protagonist of learning and is stimulated to explore, experiment, and reason independently [29]. Another advantage is immediate feedback, as they provide a timely and accurate response on the player's actions, allowing learning based on error and its correction. Other advantages include experiential learning related to scientific literacy [58], as they allow for real-world situations to be experienced and simulated, providing a direct and engaging educational experience; collaborative learning, as they can be used to foster cooperative learning, stimulating participation and information sharing even in educational settings between teachers and students [59,60]; and learning personalization [61], as they can be designed to adapt to each player's cognitive needs and abilities, sparking and maintaining player interest and motivation and enhancing positive learning effects [32]. In addition, there is a positive relationship between the scenarios designed for serious games and the expected outcomes of the learning experience [62] considering, as part of this process, student engagement and academic performance [33].

Despite the potential of these tools, they still pose a challenge to the educational world [34]. It is important to place more emphasis on less formal and traditional models that are more suitable for teaching, which can be projected to the generation of students experiencing school today. Serious games, according to this perspective, represent an important resource for the world of training and education, and are facilitators for learning specific disciplines.

Soft Skills in the Labor World

Soft skills refer to a range of personal attributes, social abilities, and communication competencies that are necessary for success in the workplace. These skills, which are distinct from technical skills, include qualities such as positive attitudes, good communication, and strong interpersonal skills. They are also described as the “human skills” or “people skills” needed to effectively use technical knowledge and expertise in a professional setting [63].

Several studies have focused on identifying the key soft skills that are valuable in the labor market [64]. Several international studies have shown that soft skills are critical to our future success, and their importance is recognized by education providers, academics, human resource departments, and businesses [65-68].

This research aims to understand how companies and economic organizations that recruit, hire, and develop professionals at a medium to high-level view and value soft skills in their human resource development process [69].

According to the study, the most important soft skills for different groups, determined based on criteria such as significance, relevance, availability in the job market, and negative impact if lacking, are as follows: problem solving (for the group focused on achieving results), team working (for the group focused on mastering social skills), and time management (for the group focused on making progress in the workforce).

In order to examine the testability and relevance of certain soft skills, it is also useful to analyze communication and decision-making in greater depth. Additionally, problem solving may be linked to self-directed learning and communication for goal orientation, and both of these skills may be considered when discussing digital skills [70]. Therefore, it is advisable to carefully analyze these 5 skills, which were identified through a classic assessment. To assess communication [71], the communicative style (aggressive, passive, or assertive) [72-74] was adopted, and for problem solving, models, such as DMAIC (Define, Measure, Analyze, Improve, and Control) [75] and Problem Solving Inventory (PSI) [76], were used. Team working and related skills developed in group environments are highly sought after by recruiters when hiring [77]. The research was inspired by the Comprehensive Assessment of Team Member Effectiveness (CATME) [78], and for decision-making, the cognitive style (a person’s preferred way of thinking and tendency to adopt certain strategies more frequently) [79] was evaluated using the General Decision-Making Styles (GDMS) scale [80]. Time management, as theorized by Lakein [81] and others, was assessed using the time management behavior scale [82]. Soft skills are increasingly recognized as critical to future success and are valued by those in education, academia, and human resource departments. They also help organizations gain new customers, increase revenue, and reduce employee turnover, which is why employers are placing an increasing emphasis on these skills [66].

Purpose of the Study and Origins

This study was conceived within the scope of the SWAG (Skills in Work-life Analysis Game) project. SWAG sets out to democratize the human resource world, through the use of intergenerational language, and it is inclusive and comprehensive of the needs, complexity, and peculiarities of today’s and tomorrow’s talents, connecting the right person to the right position. The SWAG team (involving Altomari Luca, Altomari Natalia, and Vigliaturo Daniele) was created in the context of the first cycle of “UniCaLab” (Contamination Lab of the University of Calabria) in 2019 (path concluded among the 3 winners) and achieved victory in Invitalia’s “#IoRestoAlSudHackathonTour*” contest in the same year.

In this work, a new assessment framework is presented that takes into account the needs of the labor market and is based on gamification, with a focus on the concept of “recrutainment” (a term combining “recruitment” and “entertainment”), which integrates cognitive and aptitude assessment methods into the personnel selection process [83] and is not only partially conceived as a subset of gamification, but also goes beyond it [84]. In this study, a serious game that assesses the most in-demand skills in the job market and provides feedback is illustrated, proposing a set of guidelines for the development of serious games while describing the game design process. The first trial of the game was conducted and positive results were achieved, paving the way for further studies.

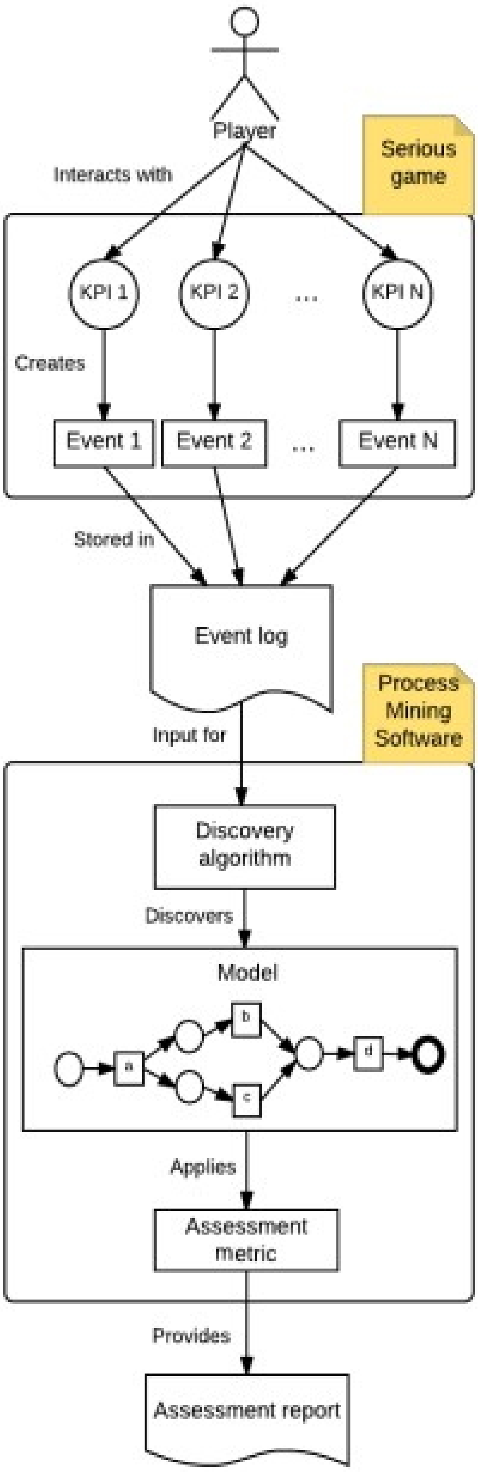
The serious game Among the Office Criticality (AOC) was developed by the SWAG team as a desktop version with the technical support of Artémat.

Methods

Research Methodology and Proposal of a Serious Game

The purpose of this study was to develop a model that can identify and evaluate certain work-life skills (in this case, 5 soft skills that are in high demand in the job market) and provide feedback to the user who uses the tool. Gamification is particularly suitable for this purpose because it allows for the creation of tools that can provide quick, objective, and standardized assessments [85] after an initial design and implementation effort, while also allowing for a more informal approach to the person being evaluated [12,13]. The study presents the AOC serious game, which is able to detect the 5 soft skills mentioned above. The AOC serious game uses a set of sequence analysis techniques, which is known as process mining, to overcome the limitations of traditional skills assessment methods [85]. The user interacts with the game, which tracks key performance indicators (KPIs) based on the user’s choices at each decision point and saves them in an event log at the end of the game. These events and values are processed by process mining software, which generates an output (Figure 1) [85].

Figure 1. Architecture for skill assessment in serious games based on event sequence analysis. KPI: key performance indicator.



The software that analyzes the event log uses an algorithm to read the data in the log and create a model. This model is then used to apply the metrics of the specific evaluation tool to produce the final report.

AOC is a serious game that is structured as a tree graph, with decisional moments represented as nodes. Analyzing the user's choices within the game involves identifying the pattern arcs that connect the nodes. However, analyzing all user actions within the game can cause scalability issues. To address this, the event log only records data related to decisional moments and the duration of the game, rather than all interactions. In this case, sequence analysis can be helpful in solving or mitigating the problem [85]. In the AOC game, metrics are based on a data set of fixed-length numerical vectors and an overall rating formula. These vectors are added together based on the entries in the event log to create a final vector, the values of which are then used in the formula to produce a numerical result. This result, as well as the individual values, can be easily translated into a final report that is provided to the user in both graphical and narrative forms. The design of serious game processes can be performed in 2 steps: context analysis and iterative concept use. The first step involves using user-centered design methods, which focus on the user's intent, situation, activity, and characteristics. The second step involves testing the tool, once it has been defined and materialized as a prototype or mock-up, in order to improve it with a focus on attractiveness, motivation, and support for activities [86]. It is important to keep in mind some fundamental principles of gamification, such as freedom of choice, benefits and relevance, personalized experience, long-term interaction, unwanted side events, and ethical and legal elements [86]. The tree graph structure containing the decisions should also be considered.

AOC Serious Game

AOC is a serious game that assesses 5 soft skills by immersing users in a simulated game context where they can use various tools as needed. The game context places the player directly into a company through a specific delivery at the beginning of the game. In the simulation, the player, who is starting their work experience, begins their journey at a fictious firm with an apprenticeship contract. At the start of the simulation, the user is presented with an organizational chart, and graphic and textual descriptions of the business context. Over the first 6 months of the game, the player must interact with other characters to complete tasks, deal with unexpected events, and make decisions, choosing the means of communication and working with superiors and other team members in order to achieve the best possible result at the end of the simulation. At the end of the game, based on the choices made, the user is presented with a scenario that reflects the path they took. The contract can be converted into permanent employment, extended for an additional 6 months, or terminated.

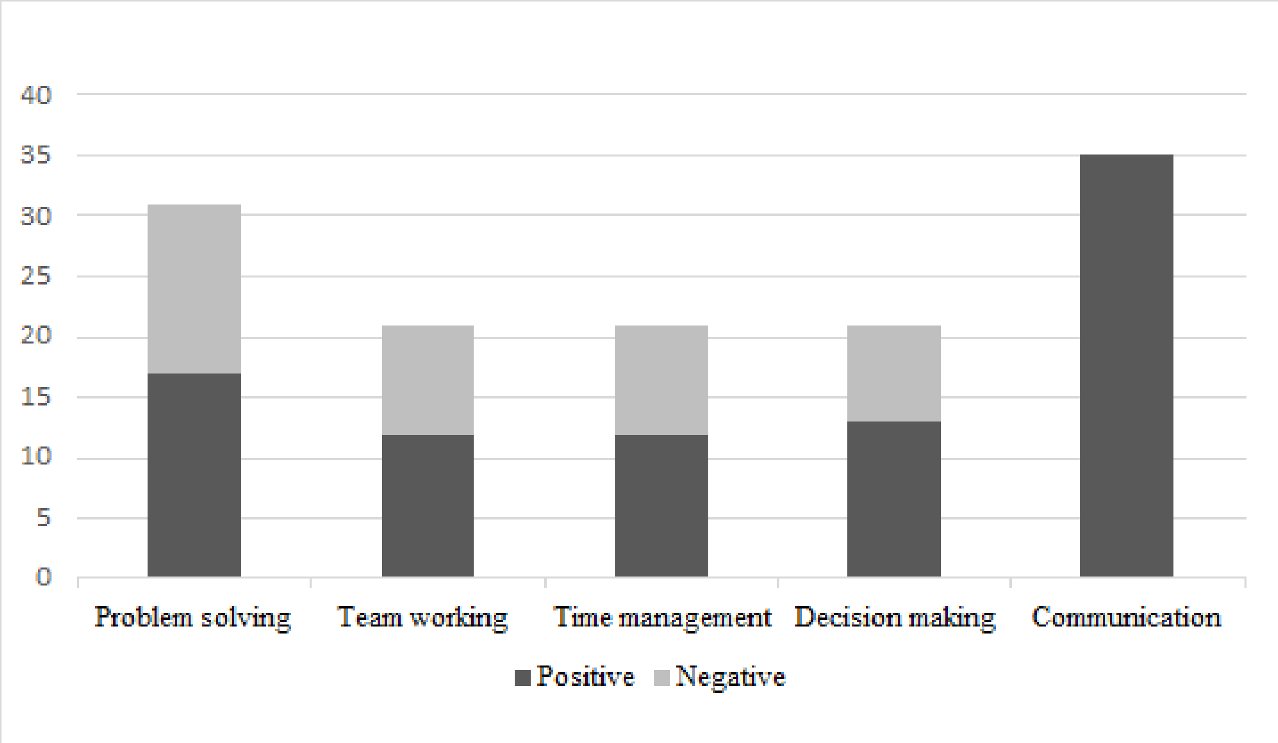
Serious Game Output

In the alpha version of the game, the user is presented with a series of decisions that are related to values for various soft skills. These values are individual variables that are combined into a resultant vector, denoted as R. The R values are then input into the overall evaluation formula, which produces a numerical result, designated as x. This result corresponds to an outcome that is related to the objective of the game. As the user makes decisions, the events of the game progress according to the graph. Each event occurs consecutively and presents the user with contextual choices that are as visual and immediate as possible (eg, a choice between 3 interactive texts). The values assigned to each decision are based on data from previous studies and the literature used to construct the game [87]. The game has a maximum duration of 30 minutes, after which the available time (displayed as a countdown) reaches zero. If the simulation is not completed at this point, the final result is the R vector, which does not consider any subsequent decisional moments and includes a penalty for time management. The "first-person" perspective is intentionally designed to increase the user's engagement and encourage active interaction.

In 2017, van Laar et al [88] conducted a study that examined 75 studies on 21st century skills and found that problem solving and communication were the most commonly mentioned skills, with 24 and 22 quotes, respectively. In this study, communication was defined as the ability to transmit information effectively, while problem solving was defined as the ability to use ICT to understand and process problems and actively use knowledge to find solutions.

The structure of the graph, the assignment of scores, and the analysis of these scores are all built using techniques from the Theory of Graphs, in line with theory and market research that emphasizes the importance of problem solving, which is tested in greater detail than the other skills. This is evident in the analysis of paths that maximize and minimize the variables associated with the skills, which has shown a range of 33 possible values for problem solving. The skills of team working, time management, and decision-making have 21 possible values and make up a total of 48% of the testing (Figure 2). The remaining 52% is composed of problem solving and communication, with this last skill requiring more attention as it is divided into 3 categories: passive communicative style, aggressive communicative style, and assertive communicative style. Variables used to identify the communicative style are also included in this percentage.

Figure 2. Positive and negative possible scores concerning every skill assessed by the serious game Among the Office Criticality. The ranges show the number of possible final resulting skill values.



The slight differences in amplitude within the ranges can be attributed to both psychobehavioral factors and mathematical advantages. The psychobehavioral reason is that each communication style has the potential to generate unexpected events within interpersonal relationships (ordered: aggressive, passive, and assertive). The mathematical advantage is that the 3 variables can never be equal in any of the possible combinations. The outcome for the user consists of a final report that includes both graphical and narrative components (Table 1).The graphical component consists of a 2D diagram that incorporates a polygon, with each vertex representing the user's scaled final scores in the four soft skills: team working, time management, decision-making, and problem solving. This polygon describes a surface of amplitude that is directly proportional to the x value resulting from the overall evaluation formula. The textual component includes a result relating to the final goal (3 possible scenarios) and different sections describing the user's score in each individual skill (low, medium, and high). In the graphical component, the dominant communication style is also explicitly highlighted (aggressive, passive, or assertive).

Table 1. Range width comparison showing "how much" a single skill is assessed.

Skill	Assessment, %
Problem solving	25.19
Team working	16.03
Time management	16.03
Decision-making	16.03
Communication	26.72

Ethics Approval

Ethics approval for the research project, "Innovation in Teaching Methods" was granted by the Ethics Committee of the University of Calabria (COMITATO ETICO DI ATENEO - CEA) on May 9, 2019. The project, which was conducted within the University of Calabria, aimed to assess soft skills using the tool developed by SWAG, alongside human tutors. Adhering to the approved ethical guidelines, the research team ensured participant confidentiality and privacy throughout the data analysis process.

Results

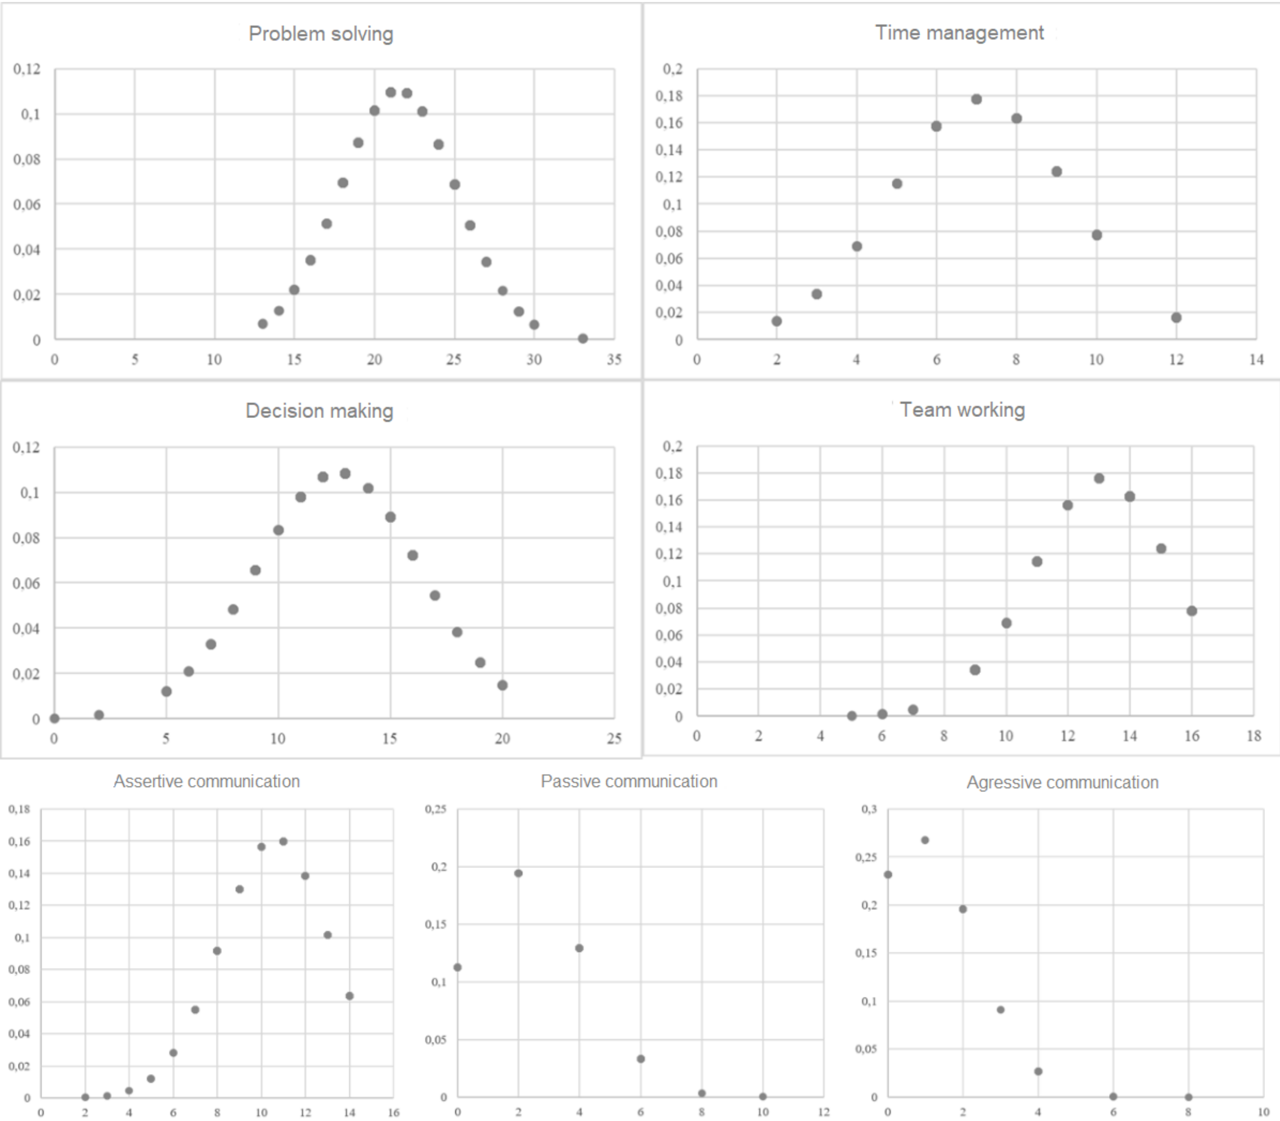
Elaboration and Descriptive Statistical Analysis

To test the serious game, the researchers conducted a pilot study with 160 subjects from the University of Calabria (Italy) who were enrolled in the 2018/2019 academic year. Table 2 and Figure 3 show the results of the preliminary data screening and the normal curve of the collected data. According to the criteria of Curran, West, and Finch [89] (asymmetry greater than |1|=severe nonnormality; kurtosis greater than |3|=moderate nonnormality), the value for aggressive communication was close to being severely nonnormal in terms of asymmetry. This may be due to a small number of data points for individuals who had this type of communication as a result. While only 1 item showed these values, the results of the descriptive analyses can still be considered reliable.

Table 2. Normality indices related to the final scores obtained for each soft skill.

Skill	Score, mean (SD)	Asymmetry	Kurtosis
Problem solving	21.47 (3.615)	0.133	−0.109
Team working	13.10 (2.269)	−1.271	1.261
Time management	7.09 (2.251)	0.059	−0.165
Decision-making	12.68 (3.673)	−0.250	0.395
Assertive communication	10.63 (2.469)	−0.700	0.523
Passive communication	2.15 (2.050)	0.912	0.751
Aggressive communication	0.82 (1.479)	2.120	4.969

Figure 3. Normal distribution curves. The x-axis represents values, and the y-axis indicates probability in the normal curves.



First Try Out: Feedback Analysis

A trial of the AOC experiment was conducted, and at the end of the simulation, users were asked to complete a questionnaire about their experience. The data analysis showed a strong consistency between the user evaluation produced by AOC and the user's self-awareness. Specifically, 88.3% (121/137) of responses to the question "Do you see yourself in the evaluation?" were at least "partly," 70.1% (96/137) were at least "quite," and 29.2% (40/137) were at least "yes." It was also useful to analyze the users' responses to the question "How would you describe the simulation in 3 adjectives?" The most common adjective used was "interesting," with a frequency of 16.1% (63/392) of all adjectives, followed by "fun" (36/392, 9.2%), "useful" (23/392, 5.9%), "engaging" (22/392, 5.6%), "realistic" (22/392, 5.6%), "stimulating" (17/392, 4.3%), and "innovative" (16/392, 4.1%), only considering adjectives with more than 15 repetitions (Table 3).

Table 3. Top unique repetitions of adjectives given as feedback from the assessed users to the serious game "Among the Office Criticality" after an assessment session.

Adjective	Unique repetitions (N=392), n (%)
Interesting	63 (16.1)
Fun	36 (9.2)
Useful	23 (5.9)
Engaging	22 (5.6)
Realistic	22 (5.6)
Stimulating	17 (4.3)
Innovative	16 (4.1)
Sympathetic	15 (3.8)
Effective	10 (2.6)
Appealing	7 (1.8)
Constructive	7 (1.8)
Efficient	7 (1.8)
Rapid	6 (1.5)

We found it useful to group the adjectives used by users into clusters based on their focus during the simulation. These clusters were arbitrarily defined as "involvement" (cluster 1; 120/392, 30.6%), "pleasure" (cluster 2; 73/392, 18.6%), "functionality" (cluster 3; 71/392, 18.1%), "innovation" (cluster 4; 25/392, 6.4%), "truthfulness" (cluster 5; 23/392, 5.9%), "dynamism" (cluster 6; 15/392, 3.8%), "personal growth" (cluster 7; 14/392, 3.6%), "challenge" (cluster 8; 5/392, 1.3%), and "other" (43/392, 11.7%). In this study, the first, second, and third clusters accounted for 67.3% (264/392) of user responses in the survey administered after they played the serious game. We found that these clusters corresponded to other questionnaires conducted after serious games in the literature. A key factor considered, as reflected in the final feedback from users, was fidelity.

Fidelity, referring to the consistency of the game with the real world, is a crucial attribute for reality-based games as it enhances player immersion. Immersion refers to the player's involvement in the "player's world," which is a crucial factor in motivating players to pursue "serious" goals [90]. However, it is important to balance immersion with entertainment elements, as previous studies have shown [27,91,92]. Fidelity can also contribute to the entertainment value of a game.

The enjoyment of playing a video game can increase motivation and lead players to find pleasure in the activities within the game, regardless of their achievements. This is especially relevant when the objectives of the game are perceived as enjoyable by the player [90].

Previous studies have found that user-perceived determinants after playing a serious game include feedback, ease of use and usability, and learning effectiveness, among others. This is consistent with the findings of this study, in which the analysis of the open-ended questionnaire taken by users at the end of the game revealed factors associated with the functionality cluster, such as ease of use and effectiveness [93]. Additionally, the enjoyment and presence-immersion factors identified in the study by Fokides et al [93] can be linked to the pleasure and involvement clusters.

According to a literature review (54 studies, 59 data sets, and 586 variables) conducted in 2019 by Baptista and Oliveira on gamification, the best predictors of acceptance for gamified technology were attitude, enjoyment, and usefulness on intention. The clusters of adjectives that were found to be most significant (involvement, pleasure, and functionality) in this study aligned with these findings, suggesting that the proposed serious game follows the trend of accepted gamification technology.

The results of the study showed that users were particularly interested in the level of engagement and interest generated by the simulation [94], as well as the entertainment value and overall emotional reactions (such as "interesting," "engaging," and "stimulating"). This aligns with the concept of recrutainment, which emphasizes the role of engagement in the recruitment process [95]. In addition, users were interested in the functionality of the assessment tool, as indicated by adjectives like "useful," "effective," and "efficient." These results highlight the importance of designing the tool with users' needs in mind. Overall, about half (193/392, 49.2%) of the adjectives in the involvement and pleasure clusters [86] supported the theory of user-centered design.

Discussion

Role of Gamification in Assessing Soft Skills for Talent Acquisition

This study proposes an immersive serious game model, called AOC, which aims to evaluate 5 important soft skills sought after in the job market, namely, problem solving, team working, time management, decision-making, and communication. The design of AOC was based on the literature and followed a user-centered design approach to create a user-friendly and intuitive environment. The output provided to the user holds significance as AOC was designed to generate value for both the evaluator and the evaluated subject. Therefore, it is essential to show areas of potential growth and increase the user's self-awareness after the simulation. This study found that the proposed serious game model may be considered in line with existing literature. Nevertheless, it is worth acknowledging that this study is not without limitations. One such limitation is the relatively small sample size, which may have implications for the generalizability of the findings. To build upon and strengthen our findings, future studies with larger and more diverse samples are recommended.

Gamification is a viable solution to improve some aspects of personnel selection [95], particularly the concept of recrutainment, which focuses on the candidate's involvement in the selection process [4,83]. Serious games are useful for both education and assessment, and are increasingly used in business and work contexts, as they help reduce selection time, avoid subjective evaluation [70], and reduce cognitive bias. They also allow for employer branding, which can positively influence the user's opinion of the evaluator [84]. According to Diercks and Kupka [84], the use of self-assessment elements in selection can increase the success rate of achieving objectives to 93%, especially when employer branding and personnel marketing are properly carried out. The term "recrutainment," which combines the words "recruiting" and "entertainment," has gained popularity among Generation Y and refers to gamified, user-oriented, and simulation games that aim to improve the quality of suitable candidates through self-assessment procedures [84]. The use of gamification, combined with cognitive and aptitude assessment methods [57], is increasing in the field of recruitment and human resources in general. It is expected to triple from 2020 to 2025, with a focus on its use in personnel selection [95].

However, as noted by Kirovska et al in 2020 [95], implementing a gamification model in the recruitment process carries risks, including the need for constant monitoring. Therefore, many companies outsource it to third-party organizations to benefit from reduced hiring times and increased interaction levels, as well as to delegate risks. Attracting innovative talent is a goal for many organizations and allows them to consider characteristics and attitudes aligned with their brand's aim. Gamification also encourages the user to do more than what is required [96], which can be a competitive advantage. In 2017, Korn et al [83] identified 42 applications (evaluating 60% of them) proposed by well-known organizations that use recrutainment, with a focus on the correlation between the profile and the hiring subject's needs (job relatedness). They also emphasized that a low score in a single game does not necessarily mean poor user skills and that, in fact, each result could identify areas for improvement.

The human resource industry has come to fully understand and use gamification in the talent acquisition process, including from a strategic perspective. While the evaluation of technical skills is important and can be inferred from a candidate's resume, transversal skills, which are intrinsic, innate, or developed through training and life experiences, are more difficult to objectively evaluate. This requires a significant amount of time and energy from human resource professionals [97]. In this context, gamification becomes important as it allows certain characteristics to emerge indirectly, which can be very complicated to discover otherwise [63]. Soft skills can make a significant difference in the business environment, and serious games are particularly effective at evaluating them because they can be assessed in various contexts and methods [12,13], including through self-assessment.

Conclusions and Future Developments

This research presents AOC, a serious game designed to meet the needs of the job market and place the user at the center. Evaluation techniques consistent with the literature were used to create an interdisciplinary approach for adequately evaluating the user and adding value. Initial analysis suggested that the scores obtained by subjects during the serious game can be generalized to the general population. Additionally, feedback from a postgame questionnaire indicated that the game is engaging, enjoyable, functional, innovative, and realistic, and promotes personal growth. The feedback specifically emphasizes the engagement and interest sparked by the simulation, aligning with the principles of user-centered design and recrutainment theory.

In conclusion, we propose the methodologies used in the development of the serious game AOC as a framework for designing serious games that consider the key aspects of the user journey and their relevance to theory and traditional assessment.

Future work may include analyses of the data generated by the serious game, including skills of the studied sample, skill development over time, cross-analysis with other samples, and comparison with data from other serious games evaluating different work-life skills.

Acknowledgments

We would like to thank Daniele Vigliaturo, member of the SWAG (Skills in Work-life Analysis Game) team, who actively participated in the process of design, testing, and realization of the tool, and the concept itself. We would also like to thank

Domenico Ielasi and Angelo Mendicelli (Artémat S.r.l.) for their fundamental effort during the development and realization of the serious game Among the Office Criticality.

Conflicts of Interest

None declared.

Abstract

Background: Virtual reality (VR) can be used to build many different scenes aimed at reducing study-related stress. However, only few academic experiments on university students for preference testing have been performed.

Objective: This study aims to assess the preference of VR games for stress and depression treatment using a discrete choice experiment (DCE).

Methods: A total of 5 different attributes were selected based on the depression therapy parameters and attributes related to VR: (1) treatment modality; (2) therapy duration; (3) perceived remission rate; (4) probability of adverse events; and the (5) monthly cost of adding treatment to a discrete choice experiment. By comparing different attributes and levels, we could draw some conclusions about the depression therapy testing preference for university students; 1 university student was responsible for VR scene development and 1 for participant recruitment.

Results: The utility value of different attributes for “0% Probability of adverse events” was higher than others (99.22), and the utility value of VR treatment as the most popular treatment method compared with counseling and medicine treatment was 80.95. Three parameter aspects (different treatments for depression) were statistically significant (P<.001), including “0%” and “50%” of “Probability of adverse events” and “¥500” (a currency exchange rate of ¥1 [Chinese yuan]=US $0.15 is applicable) of “The monthly cost of treatment.” Most individuals preferred 12 months as the therapy duration, and the odds ratio of “12 months” was 1.095 (95% CI 0.945-1.270) when compared with the reference level (6 months). Meanwhile, the cheapest price (¥500) of depression therapy was the optimum choice for most students.

Conclusions: People placed great preference on VR technology psychological intervention methods, which indicates that VR may have a potential market in the treatment of psychological problems. However, adverse events and treatment costs need to be considered. This study can be used to guide policies that are relevant to the development of the application of VR technology in the field of psychological pressure and depression treatment.

Introduction

According to a report provided by World Health Organization [1], the incidence of depression accounts for about 4.4% of the total world population [2,3]. A detailed report [4] specifically about the prevalence of depression among Chinese individuals was recently published [5]. The China Mental Health Survey estimated that more than 95 million patients have depression in China: 83% of the patients with depression were reported to be older than 35 years old, and 65% of the patients were female [6]. Among Chinese university students, the overall prevalence of depression was 28.4% (n=185,787), and the percentage of depressed individuals was reported to be high [7].

Depression is the emotional expression of a state of ego-helplessness and ego-powerlessness to live up to certain strongly maintained narcissistic aspirations [8]. Individuals with depressive disorders usually feel sad, lonely, or irritable, and in most cases, they are in a bad mood [9]. People with depression usually experience at least five of the following 9 characteristics: (1) people feel sad and unhappy; (2) people have less interest in doing things; (3) individuals do not follow a diet, but their weight losses are obvious; (4) their weights increase, or their appetites change; (5) they suffer insomnia or drowsiness; (6) some people have mental agitation; (7) they feel that life is meaningless, or they feel guilty; (8) they have difficulty concentrating; or (9) they have suicidal thoughts [10,11].

Three categories offer reasons that individuals have this illness: (1) the influence of environmental factors (eg, abuse, criticism, or neglect in childhood); (2) the genetic factors (individuals whose close relatives have been diagnosed with depression are at an increased risk); or (3) the effects of hormones, such as serotonin and norepinephrine [12-14].

At present, the 3 main therapy methods to tackle this issue are drug treatment (antidepressants, antipsychotics), psychotherapy (psychotherapy consultation), and phototherapy (usually suitable for dealing with seasonal depression). Other alternative therapy methods are Chinese herbal medicine, exercise, meditation, self-relaxation, and others. Some antidepressants have side effects, and the cost of psychotherapy is high [15-17].

Virtual reality (VR) technology has *3I* characteristics, namely, immersion, interaction, and imagination [18,19]. In the previous research on VR, as it relates to therapy for depression, a new concept of VR exposure therapy had been used in the treatment of anxiety and depression. The growing body of literature suggests that VR exposure therapy is a successful tool for relieving stress caused by psychological problems [20-22]. For example, the VR gaming experience could be used in conjunction with exercise, using games such as VirZoom, in which a VR exercise bike is compatible with most VR headsets [23,24]. The participant could wear the headset and alleviate stress and depression using the game [25].

According to the literature review, DCE is not widely applied in the field of VR technology. Research on the uses of VR technology has only covered a few areas, such as fire emergency exit testing [26], willingness-to-pay services research [27], and the testing of pedestrian behavior models [28]. By contrast, there are studies on depression and DCE. Lokkerbol et al [29] demonstrated how different components of depression treatment could impact patients' preferences. The study conducted by van Loenen et al [30] showed that DCE could support the preference of genetic testing for the user's willingness-to-pay and help improve depression therapy. Actually, some research suggests that the VR technology is useful in treating depression [22-25]. For example, the result from Schleider et al [31] revealed that using immersive technology, such as a VR headset, may be an efficient strategy for reducing adolescent depressive symptoms. However, to our knowledge, there is no research that investigates the participants' preference regarding using VR technology in treating depression. There is still a big gap in the application of VR technology in DCE, and our experiments could help in this field. The purpose of this experiment is to investigate the preference for VR technology in psychological pressure relief and depression treatment for college students.

Methods

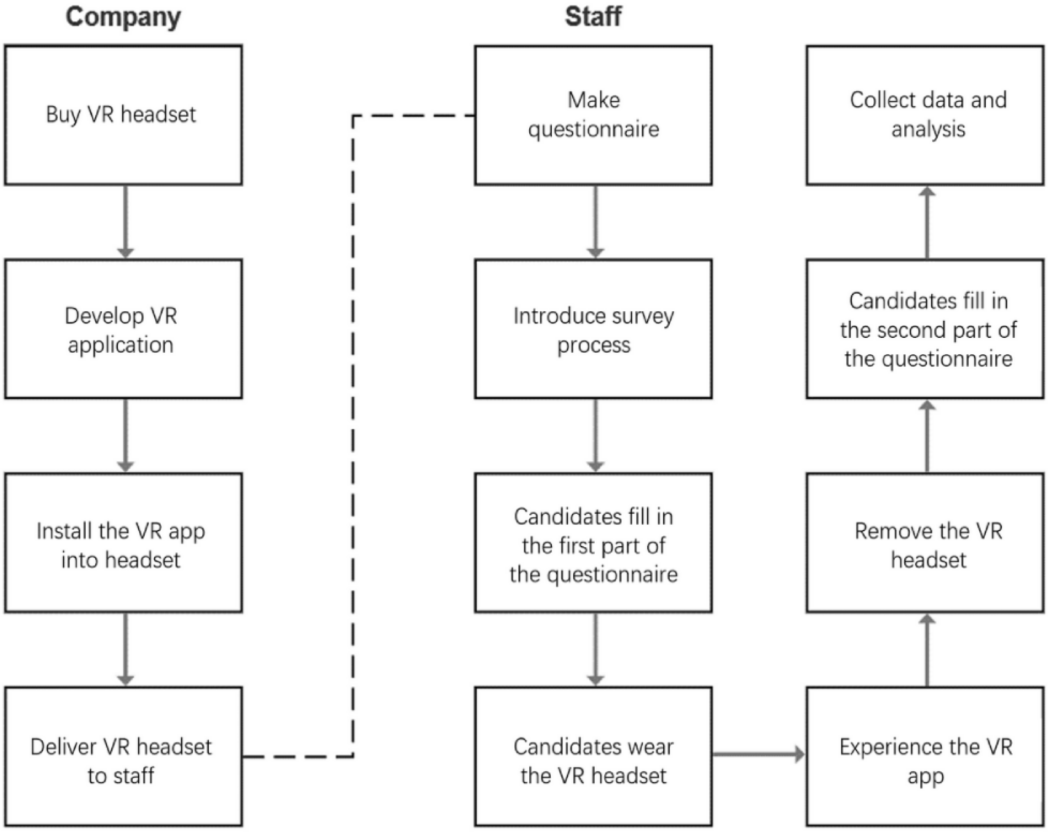
Study Sample

The study was conducted at 2 comprehensive universities in China, Jinan University in Guangzhou and the University of Electronic Science and Technology of China (UESTC) in Chengdu. We recruited our study participants from different majors at the 2 universities. Inclusion criteria included 3 parameters: (1) at least 18 years old; (2) interested in their mental state or with depressive disorders/episodes; and (3) interested in using VR technology to improve mental health problems. Those who did not agree to participate in the study and were suffering from major diseases other than depression and other mental illnesses were excluded.

Process

Figure 1 illustrates our research process. Two groups of students from different areas were enrolled in this study. Students in group 1 came from the UESTC in Chengdu, and students in group 2 came from Jinan University in Guangzhou. The students from the UESTC needed to borrow a VR device as they did not have a VR headset to support app development.

Figure 1. The process of conducting the experiment. VR: virtual reality.



Discrete Choice Experiment

Discrete choice experiment (DCE) is a utility method in the field of economics [32]. The theory is not only applicable to economics but is also widely used in other disciplines, such as in industries, education, software, and medical care [33,34]. Medical applications include prenatal diagnostic testing and myocardial infarction diagnostic testing [35]. We conducted the questionnaire survey and VR game experience and then collected the corresponding statistical data based on the results that were collected [36,37].

VR Platform

Our devices were a Pico Neo 2 (Sichuan Shuyun Technology Co., Ltd) with a head display, earphones, handle, connecting cable, and other accessories. The VR headset also has some disadvantages: when people wear this device for a long time to play games, it may cause dizziness, nausea, eye fatigue, blurred vision, and other problems [38-40]. However, those negative influences will decrease if users just wear the headset for several minutes.

Virtual Reality Applications

Figures 2 and 3 demonstrate the VR device and application panel, respectively. It is obvious that scholars have previously performed some research experiments on static scene VR applications; thus, we selected 2 dynamic and interactive applications in this experiment: (1) VR physical and mental relaxation system and (2) VR music comfort system.

The VR physical and mental relaxation system needs participants to cooperate with the virtual professional psychologist's guidance into scenes to help them correctly and quickly adjust to negative emotions, such as psychological anxiety and tension. First, this system could provide 16 3D realistic natural sceneries (Figures 4 and 5) so that patients can enjoy the beauty of nature without leaving home with the aim of relieving anxiety and maintaining physical and mental health for themselves. Second, based on the logic of relaxation therapy, it can provide a psychotherapist's voice as a relaxation guide to help patients correctly relax their body and mind, and it allows them to become immersed in the atmosphere of nature to quickly eliminate negative emotions and adjust their mentality.

We designed a "VR music comfort system," which included dozens of psychological medical music approaches. Through comfortable music activities, this system could trigger positive experiences in physiology to promote perception, memory, and arousal. This application's key features are as follows: users can choose different scenes according to their preferences and can listen to music to relax. At the same time, users can also turn on the voice guidance function to receive guidance regarding depression and relaxation. The key step here is the user interface design because we must make sure participants could listen to the music from different VR buttons and experience the application without failure. Unity 3D and Visual Studio were used to create the user interface design, and we must make sure participants can wear the headset and click different scenes from the VR buttons correctly. Then, they can listen to music and travel to different environments in VR. At the same time, this system also integrates a positive music interaction system with the aim of promoting people's physical and mental health; thus, music interactive scene training is carried out in the virtual world to relieve emotions [41,42].

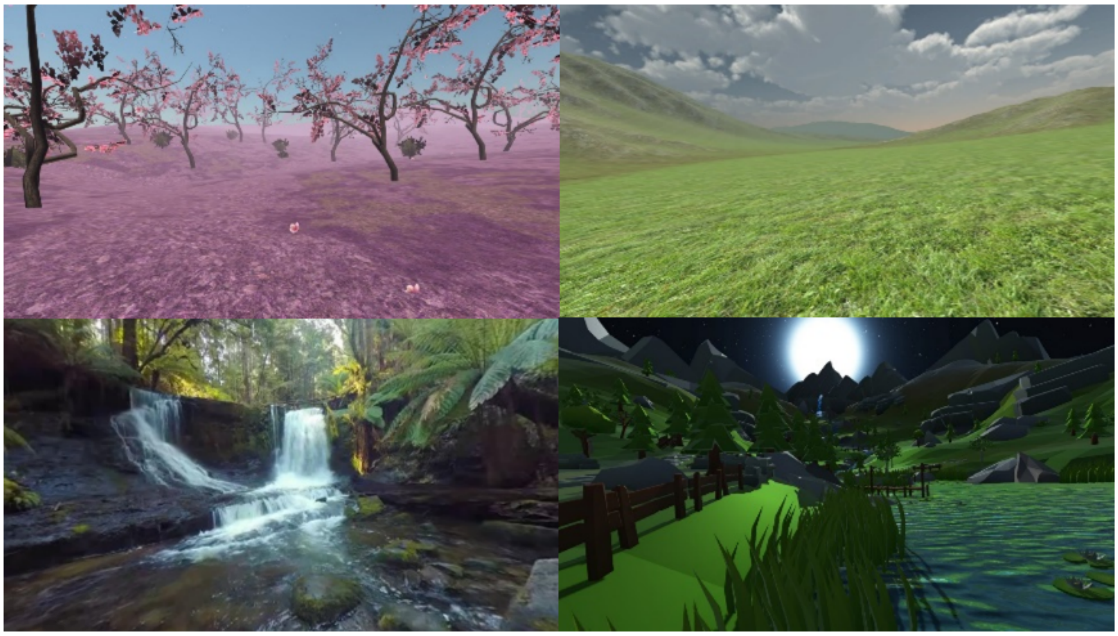
Figure 4. Scene selection interface (includes 16 various scenes, such as historical city, beautiful mountain, waterfall, and peaceful lake).

Figure 5. Scene examples (the first picture illustrates peach blossom, the second scene is a lawn on top of a mountain, the third is a 360° video that we could watch at different angles in the virtual world, and the fourth is a peaceful scene under the moon at night).



Attributes and Levels

In this paper, for the DCE attribute and the level design, we conducted a focus group with the professors in medicine at Jinan University. We came up with 5 attributes and levels. In addition, for details on the setting of the levels, we performed a literature search. There are some studies on the perceived remission rate and the incidence of adverse reactions regarding the selection of depression indicators. Different countries and experts have their own indicator considerations. Possible attributes were identified from a panel of experienced chief physicians from Jinan University. Finally, 5 different attributes were selected: (1) treatment modality, (2) therapy duration, (3) perceived remission rate, (4) probability of adverse events, and (5) the monthly cost of treatment. Based on the academic research experiments for depression therapy, we divided the attributes into several independent parameters concerning therapy duration [43,44], cost [45-48], perceived remission rate [49-55], and probability of adverse events [56-60] with the aim of building different intervals for real life. To eliminate the influence of dimensions between different attributes, the average utility values of all attribute levels were measured using the utility scaling method with zero-centered differences. Attributes and levels are shown in Table 1.

Table 1. Attributes and levels.

Attributes	Levels of attributes
Treatment modality	• kL1 Medication only • L2 Counseling only • L3 VR[a] only
Therapy duration	• L1 6 months • L2 12 months • L3 18 months • L4 Lifetime
Perceived remission rate	• L1 35% • L2 40% • L3 45% • L4 50%
Probability of adverse events	• L1 0% • L2 30% • L3 50%
The monthly cost of treatment	• L1 ¥500[b] • L2 ¥1000 • L3 ¥1500 • L4 ¥2000 • L5 ¥2500

Questionnaire

This questionnaire is collected from the online questionnaire platform. It includes 4 parts: (1) basic information (5 questions: gender, education level, the impact of depression on health, level of understanding of depression, and level of understanding of VR technology); (2) the first DCE experiment; (3) VR experience evaluation feedback (5 questions: effective treatments for depression, the function of this VR app in therapy, defects of VR in psychotherapy, the best time for VR for psychotherapy, and VR scenes preferred to experience); and (4) the second DCE experiment. In the beginning, the users should complete the basic information collection step; then, they will fill in the first part of the DCE questionnaire. After finishing these sections, they will be asked to wear the VR headset and experience the apps. They will then need to finish the VR experience evaluation feedback part and the second DCE questionnaire sequence. Brief introductions for participants to acquire related knowledge at the beginning of each part, such as VR's introduction, DCE procedure, and the meaning of the probability of adverse events, will be included. The duration of the VR applications will be around 5 minutes. Based on completing the questionnaire prior to VR application and pretesting the VR, participants were allowed 20 minutes to complete the research. An interactive design was devised; when the cursor or fingers touch the nouns (perceived remission rate, probability of adverse events), volunteers will see the introduction around the concepts and gain some useful information about them [35,36].

The first part of the DCE was conducted before the participants viewed the VR scenes, and the second part of the DCE was conducted after the participants had viewed the VR scenes. This research compared the 2 different DCE parts to understand whether VR could produce different effects on different participants. Each DCE contained 6 multiple-choice questions with 3 different options: (1) intervention mode 1, (2) intervention mode 2, and (3) other ways. The example questions of DCE are shown in Table 2. For the DCE part, the same DCE design (ie, a random draw of the set of questionnaires from the pool with the same attributes and levels) was used for the "before-and-after" comparison. In this study, we compared the preference "before-and-after" of the participants. Our discussion about the 2 DCE parts has different questions in the "before-and-after" comparison because we subtracted various parameters from the 5 attributes in every DCE's part to discover the user's preference for depression therapy before and after experiencing the VR applications. Some parts of the DCE design are referred to in Ryan and Gerard's [33] experiment, which provides better guidance on disease prevention and treatment using DCE.

Table 2. An example of discrete choice experiment question.

Attributes	Treatment A	Treatment B	Neither
Treatment modality	VR[a] only	Medication only	
Therapy duration	12 months	18 months	Neither
Perceived remission rate, %	35	40	
Probability of adverse events, %	0	50	
The monthly cost of treatment (¥)[b]	500	2000

[b]A currency exchange rate of ¥1 (Chinese yuan)=US $0.15 is applicable.

Statistical Analysis

Latent Class Analysis Model

Latent class analysis was used to interpret the DCE data. The conditional logit regression model was used to quantify the correlation between the participant's choice and the attribute levels of various test profiles for which the choices were used as the dependent variable and the attribute levels of tests as covariates. The levels for the 5 attributes were coded based on effects. The conditional logic model makes statistical inferences based on the weights of the respondents' preferences for various attributes and levels in the questionnaire. The resulting positive and negative coefficients after the regression analysis indicated the direction of the respondent's preference for a given attribute level. Based on the importance and magnitude of the coefficients, the marginal rate of substitution between each attribute and the relative importance of the attributes was calculated, which could measure the willingness to accept a trade-off among different options of respondents. These marginal rate of substitution values allowed for the comparison of different attributes using a common scale [61], and the odds ratios (ORs) of respondents' preferences for different attribute levels were also reported. Sawtooth (Sawtooth Software, Inc.) was used to run the coefficients of all attributes and SEs, and *t* ratios to calculate the P values. For the P value of all levels of attributes, we assumed that if the P value of a level was <.05, this level was then statistically significant; when the P value of a level was <.001, this level was considered highly statistically significant.

Latent Class Model

A latent class analysis was conducted to identify correlations among explicit variables, create the fewest number of classes, and achieve local independence. According to Greene and Hensher [62], this method uses a semiparametric approach to model the correlation structure of the data and identify classes that are more homogeneous in terms of variance structure. This method of analysis can be used to sort individuals into a set of classes with a certain segmented size and scale, and different effects of each class were estimated for different attributes. In addition, this method will help us to measure the differences and similarities of preference across classes of respondents. Akaike information criterion 3 and Bayesian information criteria (AIC3 and BIC, respectively) were used as the main criteria, and after the latent class model was created, the resulting data were classified into the appropriate latent classes.

Software

All statistical analyses were performed using Sawtooth Lighthouse Studio (SSI Web version 9.11.0; Sawtooth Software, Inc.).

Ethics Approval

This study was approved by the Medical Ethics Committee of Jinan University (JNUKY-2021-004).

Results

Survey Participants

A total of 154 people were surveyed, among which 114 completed all the questionnaire contents (response rate 74%). The summary of demographic information and the suggestions and preferences of participants after using VR are shown in Table 3.

Table 3. Summary of demographic information, suggestions, and preferences of participants.

Items	Total (N=114), n (%)	Medical students (n=71), n (%)	Nonmedical students (n=43), n (%)	P value
Gender				.84
Male	65 (57.0)	43 (60.6)	22 (51.2)

Virtual reality scenes preferred to experience				.006[a]
Quiet real virtual environment	64 (56.1)	37 (52.1)	27 (62.8)	
Strange real virtual environment	43 (37.7)	23 (32.4)	20 (46.5)	
Help yourself recall the past	52 (45.6)	26 (36.6)	26 (60.5)	
Experience the good things of the past	53 (46.5)	28 (39.4)	20 (46.5)	
Watching movies and television shows	34 (29.8)	14 (19.7)	16 (37.2)	
Play simple mini-games	31 (27.2)	15 (21.1)	12 (27.9)	
The experience that dreams come true	25 (21.9)	13 (18.3)	29 (67.4)	
Play exciting and fun big games	25 (21.9)	16 (22.5)	12 (27.9)	
Other	14 (12.3)	12 (16.9)	9 (20.9)	

[a]P<.05 indicates statistical significance.

For the VR experience, evaluation feedback results showed that most individuals preferred the choice of VR helmet weight, comfort, and application contents. Students also thought that VR relieves stress and diverts attention. Furthermore, students would choose the immersive scenes, memorable places from their childhood, and beautiful fantasies of the virtual world for the VR depression therapy after the VR experience.

Attributes' Levels and Utility Report

In the study, the utility scaling method with zero-centered differences was used to measure the average utility values of all the attribute levels and the utility gap between different treatment methods; additionally, the probability of adverse events was overt. For example, the utility of VR treatment alone was 80.95, whereas it was −42.66 and –38.30 for the attributes "Medication only" and "Psychological counseling," respectively; for 30% probability of adverse events, the utility value was –13.81%, whereas for 50% adverse reactions, the utility value was –85.41%.

To eliminate the influence of dimensions between different attributes, the average utility values of all attribute levels were measured using the User-based Security Model with zero-centered differences. The highest utility levels of the 5 hypothesized attributes were "VR only" (of "Treatment modality"), "12 months" (of "Therapy duration"), "40%" (of "Perceived remission rate"), "0%" (of "Probability of adverse events"), and "¥500" (of "The monthly cost of treatment"; a currency exchange rate of ¥1 [Chinese yuan]=US $0.15 is applicable). The most important attribute was "Probability of adverse events," indicating that most respondents ranked that attribute the highest (Table 4).

Table 4. The utility report of different attributes.

Attributes and levels	Utility
Treatment modality	
VR[a] only	80.95
Medication only	–42.66
Counseling only	–38.30
Therapy duration	
6 months	6.62
12 months	23.24
18 months	5.72
Lifetime	–35.57
Perceived remission rate	
35%	0.22
40%	10.81
45%	–5.35
50%	0.45
55%	–6.14
Probability of adverse events	
0%	99.22
30%	–13.81
50%	–85.41
The monthly cost of treatment[b]	
¥500	69.44
¥1000	16.18
¥1500	3.64
¥2000	–42.71
¥2500	–46.55
None

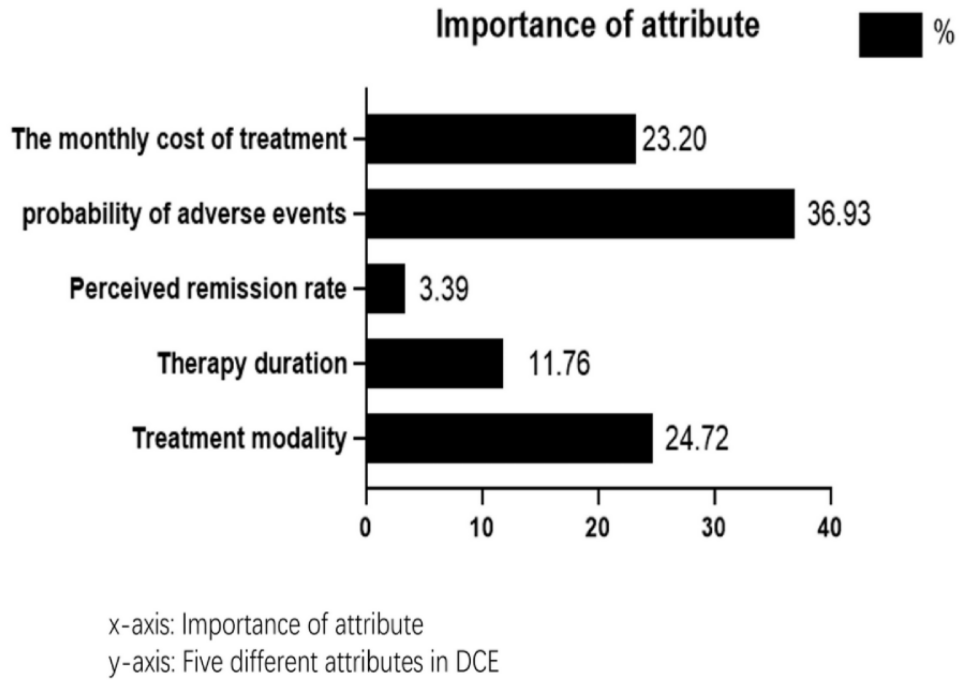
Logit Result of DCE and Attributes' Percentage Importance

As is presented in Figure 6, the percentage importance of the attribute "Probability of adverse events" was the highest, which shows that people reported being most concerned about the probability of adverse events. The attributes "Treatment modality" and "The monthly cost of treatment" ranked second and third, respectively.

Figure 6. Importance of attributes. DCE: discrete choice experiment.



The results of the logit analysis of all attribute levels are presented in Table 5. For treatment modality, the coefficient of the level "VR only" was positive, which indicated that the level "VR only" was positively correlated with people's preferences and use. In addition, the coefficients of the levels "6 months," "12 months," and "18 months" of "Therapy duration" were positive, and "lifetime" was negative. It is clear that people showed a preference for shorter periods of therapy, but not necessarily for the shortest one. For the attribute "Therapy duration," people were more inclined to choose the level of "12 months." For the levels of other attributes, people preferred the lower probability of adverse events and lower treatment costs. However, for the attribute "Perceived remission rate," people unexpectedly preferred a lower perceived remission rate rather than the "55%" option. A reasonable explanation for this phenomenon is that individuals with various degrees of histories, genders, and other backgrounds would have a different understanding of this concept (perceived remission rate). In addition, some of the participants neglected the tips around this concept in our questionnaire. We found that "VR only," "Medication only," and "Counseling only" for "Diagnosis methods" were highly statistically significant ($P<.001$ for all), "0%" and "50%" of "Probability of adverse events" were extremely statistically significant ($P<.001$), and "¥500" of "The monthly cost of treatment" was also statistically significant ($P<.001$).

Taking the level "VR only" of the "Treatment modality" attribute as the reference, the ORs of "Medication only" and "Counseling only" were 0.509 (95% CI 0.452-0.573) and 0.521 (95% CI 0.462-0.588), respectively. The OR of "12 months" of "Therapy duration" was 1.095 (95% CI 0.945-1.270) with the level "6 months" as the reference. ORs for "30%" and "50%" of the "Probability of adverse events" attribute were 0.539 and 0.364, respectively, with the level "0%" as the reference (95% CI 0.480-0.605 and 0.323-0.412, respectively). All attribute levels for "The monthly cost of treatment" were <1, which indicated that the preference weights declined with increasing medical fees.

Latent Class Analysis Result

We compared these potential models, selected the model that maximized the area under the receiver–operating characteristic curve, and minimized the AIC or BIC to compensate for model complexity [63]. According to AIC, 5 classes should have been the best choice for our model. By contrast, BIC favored the 2-class option with the lowest BIC. Under such circumstances, we compared A BIC, that is, sample size–adjusted BIC, which involved sample size values. After comparison, the 2-class option had the lowest value of A BIC. Therefore, the most suitable number of latent classes in our model was 2 (Tables 6 and 7). First, all 114 respondents were divided into 2 classes with segment sizes of 77 (67.5%) and 37 (32.5%), respectively. The average maximum membership probability was around 0.87, and the percent certainty was 26.17, which is relatively low, indicating that a low level of uncertainty according to the respondents is divided into classes.

Table 6. Estimated relative preference weights for the 2 classes.

[a]The table presents general results of the multinomial logit model. Data on preferences of respondents from the 2 classes for psychotherapy intervention attributes are reported (N=114).

[b]VR: virtual reality.

[c]A currency exchange rate of ¥1 (Chinese yuan)=US $0.15 is applicable.

For class 1, the attribute “Probability of adverse events” was the most important factor for respondents with a percentage importance value of 55.29%, followed by “The monthly cost of treatment” and “Therapy duration,” with percentage importance values of 17.20% and 17.04%, respectively (Figure 7). Meanwhile, the span of percentage weights of “Probability of adverse events” was obvious (Figure 8), ranging from −0.72 to 0.79. The span of the attribute “The monthly cost of treatment” ranged from 0.29 to −2.33. The preference weight of “The monthly cost of treatment” decreased with increasing expenses. In addition, the OR of “50%” of the attribute “Probability of adverse events” was 0.219 (95% CI 0.188-0.256), indicating that the majority of patients preferred to pay more attention to the safety of treatment modality with respect to all the levels of the attribute “The monthly cost of treatment” when compared with the reference level “¥500” of <1. At the same time, the OR (Table 7) of the levels of the attribute “Therapy duration” decreased with treatment time, indicating that peoples’ preference for this attribute increased as treatment time decreased.

For class 2, the attributes “Treatment modality” and “The monthly cost of treatment” were relatively important; for respondents in this class, the percentage importance values were 43.43% and 34.36%, respectively (Figure 7). For the attribute “Perceived remission rate,” the percentage importance value was 13.54% (Figure 7). The span of the percentage weights of these 2 attributes is presented in Figure 3. The percentage weights for the attributes “Treatment modality” and “The monthly cost of treatment” ranged from −1.003 to 1.847 and −1.26 to 0.073, respectively (Figure 9). In addition, the OR of “Medication only” of the attribute “Treatment modality” was 0.058 (95% CI 0.041-0.081), which was <1, indicating that the VR method appeared to be the best of the 3 methods. The OR of the levels of “Therapy duration” were all >1, and it was different from class 1. Meanwhile, the OR continued to decrease with the increase in the monthly cost of treatment, which was the same condition as that found in the previous class.

For these 2 latent classes, the attribute “Probability of adverse events” was the most preferred factor in class 1, whereas “Treatment modality” was the most preferred factor in class 2. There were 74 and 34 participants in class 1 and class 2, respectively. Class 1 has a similar number of male (39/74, 52.7%) and female participants (35/74, 47.3%), whereas the number of male participants (21/34, 61.8%) is nearly 2 times than that of female participants (13/34, 38.2%) in class 2. In addition, nearly two-thirds of participants in class 1 were medical students (48/74, 64.9%), with nonmedical students comprising only a minority (26/74, 35.1%). By contrast, the numbers of medical and nonmedical students in class 2 were almost even (18/34, 52.9%, and 16/34, 47.1%, respectively).

Discussion

Principal Findings

Through the investigation of 5 different attributes and several levels in this survey, our preliminary results indicate that the treatment modality and the probability of adverse events will interfere with people's choice of therapy. Although a host of people are willing to choose VR as the treatment method instead of others, the treatment modality is not the element that most concerns them. However, the influential weight of the treatment modality is second only to the probability of adverse events, especially for college students who have used VR devices. Although the VR headset did not cause severe adverse reactions immediately, such as vomiting and diarrhea, the disadvantages of overweight devices and dizziness during use should not be ignored.

People who have previously used a VR headset and have had uncomfortable reactions after experiencing VR may have different preferences than those reported in this survey. After we finish the DCE experiment for university students, we hope to carry out a clinical VR experiment for the treatment of depression. Although VR has many advantages in the treatment of mental diseases, some problems may occur when VR is actually applied in the treatment of severe psychological depression, such as a lack of willingness to wear VR glasses. We are willing to compare the treatment of VR in clinical patients to better improve the use of VR in stress counseling and depression treatment.

Latent class analysis results showed that most participants in class 2 would consider "Treatment modality" as the most important attribute. As the number of male participants is almost 2 times more than that of female participants in class 2, this result may be due to a more receptive attitude toward VR technology and VR therapy among male participants, compared with female participants. Male students are also more likely to play computer games and VR games in daily life, whereas women might pay more attention to the details of the equipment, such as equipment weight, dizziness, and air permeability. In addition, our results revealed that the majority of participants in class 1 would consider the "Probability of adverse events" as the most important attribute. This result is possibly due to the prominent number of medical students in class 1. Because of the specialty of their major, it is common that participants from clinical medicine and related majors would understand more about the side effects of antidepressants and be more aware of the complications of using VR technology. Thus, it is not surprising that most participants in class 2 chose "Probability of adverse events" as the most important attribute.

The results of the DCE experiment in this study are helpful for doctors and researchers to conduct further analysis, so they can devise better clinical strategies for the treatment of depression. We separated different treatment methods and compared the effects of individual choices, such as just focusing on medical therapy for depression and analyzing the influence from different perspectives (time and cost). At the same time, our experimental results could promote VR technology for the treatment of depression and provide reference and guidance for individuals and hospitals that are willing to use VR treatment.

Our study's results showed that individuals prefer VR technology as a psychological intervention method for treating psychological disorders (such as depression) and easing their anxiety. There are several studies that might support our findings [30,31,64,65]. First, an article suggested that a virtual and peaceful environment with relaxing music could make the participants feel like they are in a realistic soothing environment [64]. Second, the research done by Ioannou et al [65] stated that VR could effectively reduce these symptoms in different contexts and with regard to different diseases, including cancer. Another paper suggested that VR has good clinical potential to reduce the severity of depression [30]. A study conducted by Schleider et al [31] revealed that immersive technology, such as VR headsets, may be an efficient strategy for reducing adolescent depressive symptoms. According to the aforementioned studies, the comfortable feeling that VR technology can provide and its effectiveness in treating depression may explain the participants' preference for using VR technology in treating psychological disorders.

Indeed, most other VR depression experiments are focused on the methodology and VR content making more than the university students' depression therapy. By contrast, participants' preferences in our results, such as "Probability of adverse events" and "Treatment modality" from the DCE, could help doctors adopt some new strategies with VR headsets for depression therapy. Besides, in the university environment, the mental health treatment center and psychological counseling room in the school could use VR applications to prevent depression and anxiety for students. Another similar study used VR to enhance employees' mental health and work performance [66].

Limitation

There are some limitations to this study. First, the new high technocracies that involve VR may influence university students' preferences. In addition, participants with knowledge of drugs (antidepressants), such as selective serotonin reuptake inhibitors and serotonin and norepinephrine reuptake inhibitors, may cause bias in the preferred choice in the questionnaire [67]. All of these factors will cause the experimental process to become more complex. We will continue to perform a variety of mixed treatment experiments in the future to further accurately analyze the effects of different combinations of treatment methods for depression. At the same time, we will also focus on more parameters, such as gender, major, and age, in depression therapy. For example, medical students will have some bias in depression treatment compared with other students.

Conclusion

People placed significant preference on VR technology's psychological intervention methods, which indicates that VR may have a potential market for treating psychological problems, especially for university students. However, most participants were concerned about the side effects and treatment modality of the VR technology, and these 2 attributes need to be considered when designing treatment plans for individuals. This study can guide policies relevant to the development of the application of VR technology in the field of psychological pressure and depression treatment. At the same time, doctors can consider adopting multiple methods, such as VR plus counseling, in clinical applications.
