Verification of smoking abstinence was determined by comparing the cotinine results (positive or negative) with the most recently submitted smoking self-report on the same day the sample was collected. Participants met the correspondence criteria when both the cotinine test and the smoking self-report indicated tobacco abstinence or tobacco use. The percentage of corresponding results across all participants and time points was reported.

Treatment Acceptability

The Treatment Acceptability Questionnaire was a 38-item survey developed to assess the perceived effectiveness of the intervention, gameplay feedback, and a comparison of how Inspired was viewed relative to other cessation strategies. Statements were rated on an 11-point scale, with 0 meaning "definitely not" to 10 meaning "yes, absolutely." Participants were also asked to rank 10 features of the game from most to least valuable (1 being "most valuable" to 10 being "least valuable"). This questionnaire was administered at week 7.

Results

Participants

A total of 48 participants were randomized (n=24, 50% per group), and a summary of their characteristics can be found in Table 1. Of those participants, 27 (56%) were female, 4 (8%) were Hispanic, and 37 (77%) were White, and they had an average age of 39.8 (SD 10.7) years. A third of the sample (n=17, 35%) had never been married and most either reached high school graduation (n=15, 31%) or completed some college (n=19, 40%). Approximately half of the participants reported being employed (n=27, 56%), earning <US $40,000 a year (n=26, 54%), and renting a home (as opposed to living in a home they or someone else owned; n=26, 54%). Geographically, 14 (29%) participants lived in nonurban areas (eg, rural or suburban) [32].

[c]Although gender would have been the more appropriate metric, participants were asked to indicate their sex as opposed to gender at the time of assessment.

Detailed smoking history of the participants is presented in Table 2. All participants reported currently smoking and 38% (18/48) of the participants said they also currently smoke other substances (including cannabis). On the Fagerström Test for Nicotine Dependence, participants scored an average of 6.5 (SD 1.5), indicating moderate nicotine dependence. Participants endorsed playing games (on any device, including their mobile phone) for an average of 27.1 (SD 25.4) hours per week at baseline.

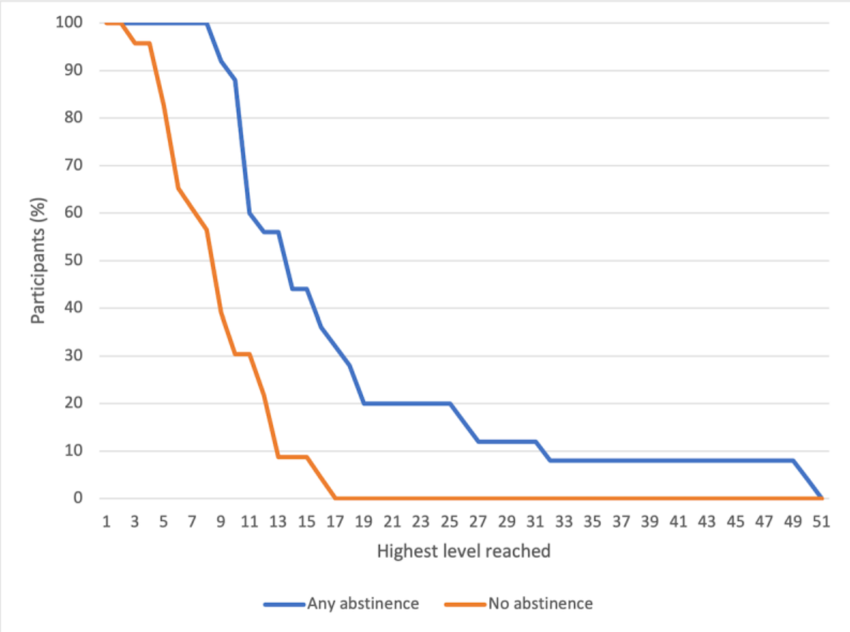
Study Phases

Most participants completed the baseline (45/48, 94%) and tapering phases of the study (26/48, 75%). Of the total 48 participants, 20 (42%) continued to submit smoking self-reports through the end of the abstinence phase at week 4. Very few participants (n=7, 15%) submitted smoking self-reports by the end of the thinning phase (week 7). A survival curve of the highest level achieved by any abstinence reported in the abstinence phase is presented in Figure 3.

Figure 3. Survival curve of the highest level achieved by any abstinence reported in the abstinence phase.



Gameplay

The participants played the game for an average of 20.6 (SD 15.3) days over the 7 weeks of the study. They scored an average of 30,187.5 (SD 33,662.6; range 0-220,925) points and earned an average of 35.6 (SD 34.4) stars from level completions. The mean highest level reached in the game was 10.7 (SD 8.4). In the metasystem, players either built or upgraded an average of 16.4 (SD 17.6) structures. The average video game addiction score (on a scale from 9 to 45) remained stable, with scores of 14.6 (SD 4.5) at baseline versus 14.0 (SD 3.9) at week 7. Game use results are presented in Table 3.

Table 3. Game use.

[b]SC: submission contingent.

Smoking Self-Reports

A detailed summary of the smoking self-report results is presented in Table 4. Of the 98 total possible report submissions over the 7 weeks of the study, participants submitted an average of 34.7 (SD 29.1; 34.7/98, 35%) reports. Participants reported smoking abstinence on 28.7 (SD 32.5; 28.7/98, 29%) reports of all 98 smoking self-reports submitted over the entirety of the intervention and on 13 (SD 38.2; 13/42, 31%) reports of all 42 reports submitted in the abstinence phase only. During the abstinence phase, 25 (52%) of the 48 participants submitted at least 1 abstinent report, meaning that nearly half of the participants did not have any abstinent reports during this phase. On average, participants reported 5.4 (SD 9.8) consecutive abstinent smoke reports.

Table 4. Smoke report summary.

	Total sample (n=48), mean (SD)	AC[a] group (n=24), mean (SD)	SC[b] group (n=24), mean (SD)	*P* value
Longest abstinence streak	5.4 (9.8)	5.3 (8.3)	5.5 (11.2)	.94
Percent smoke report submitted	34.7 (29.1)	31.5 (30.3)	37.8 (28.0)	.46
Percentage of abstinent smoke reports (out of all smoke report submissions across all phases)	28.7 (32.5)	26.9 (31.3)	30.5 (24.3)	.70
Percentage of abstinent smoke report (out of all smoke report submissions in the abstinence phase only)	31.4 (38.2)	34.1 (41.7)	28.6 (34.9)	.63

[a]AC: abstinence contingent.

[b]SC: submission contingent.

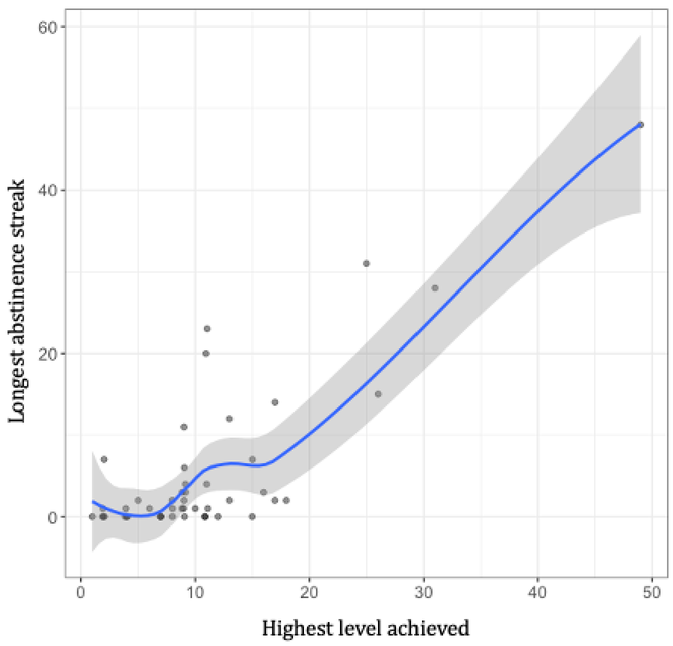
The main outcome of this examination was the 7-day smoking point prevalence at the 30-day follow-up. Of the 30 participants (across both groups) who completed the follow-up survey 30 days after the end of the intervention, 11 (37%) had not taken a puff of a cigarette in the previous 7 days and 15 (50%) said they spent at least 24 hours without smoking in the prior 2 weeks. Overall, 15 (50%) participants reported not smoking for 24 hours in the previous two weeks (AC=4, 36%; SC=11, 58%; *P*=.45) and 11 (37%) participants reported not taking a single puff from a cigarette in the previous 7-days (AC=4, 36%; SC=7, 37%; *P*=.65).

When individuals who did not respond to the survey were conservatively considered not abstinent from smoking, 11 (23%) of the 48 participants had not taken a puff of a cigarette in the previous 7 days and 15 (31%) said they spent at least 24 hours without smoking in the prior 2 weeks. Fifteen (31%) of participants reported not smoking for 24 hours in the previous 2 weeks (AC=4, 17%; SC=11, 46%; *P*=.06) and 11 (23%) reported not taking a single puff from a cigarette in the previous 7-days (AC=4, 20%; SC=7, 29%; *P*=.49).

Game Use on Smoking Abstinence

A total of 2 generalized linear models were conducted, first examining the impact of total game score and the highest level achieved on the percentage of abstinent submissions during the abstinence phase and the second examining the impact of total game score and the highest level achieved on the longest duration of continuous abstinence. Both models favored the exclusion of the interaction term, so only the individual contributions of the total game score and the highest level achieved were considered. Every 1 SD increase in total game score was associated with an 11% decrease in the percentage of abstinent submissions, whereas every 1 SD increase in the highest level achieved was associated with a 27% increase in the percentage of abstinent submissions. Similarly, an increase by 1 SD in the total score was associated with a 51% decrease in the longest abstinence streak, whereas an increase by 1 SD in the highest level achieved was associated with a 405% increase in the longest duration of continuous abstinence. In sum, the highest level achieved, but not the total game score, was positively related to both the percentage of abstinent submissions and the longest abstinence streak, with the stronger effect demonstrated between the highest level achieved and the longest duration of continuous abstinence (Figure 4).

Figure 4. The highest level achieved by the longest abstinence streak. The longest abstinence streak is calculated by determining the maximum number of continuously reported abstinent submissions over the course of the study.



Cotinine Testing

Throughout the study, 20 cotinine samples were collected across all participants and at all time points. These 20 samples were compared with the number of cigarettes smoked as self-reported by the participants, 7 (35%) of whom reported tobacco abstinence. There was a 95% (19/20) correspondence between self-reported tobacco use and biologically verified cotinine results across all samples and a 100% (20/20) correspondence for the 7 abstinent reports.

Treatment Acceptability

On an 11-point scale, ranging from 0 (“definitely not”) to 10 (“yes, absolutely”), participants rated the intervention moderately favorably. Specifically, they said that if they had to do it over again, they would use Inspired to help them quit smoking (mean 6.4, SD 3.4), that Inspired was helpful in their current attempt to quit (mean 5.3, SD 3.6), and that they would recommend Inspired to a friend (mean 6.5, SD 3.2). Participants felt the game was moderately fun to play (mean 6.7, SD 3.3), found the in-game rewards as motivating for them to submit tobacco-free smoke reports (mean 7.0, SD 3.6), and felt that the connection between in-game rewards and meeting smoking cessation goals was clear (mean 6.1, SD 3.9). More detailed results are presented in Table 5. Of the 10 game elements listed in the questionnaire, participants rated having specific-colored gems, being able to upgrade buildings to fight darkness, having waves at the end of the level that killed all remaining darkness, and being able to upgrade buildings to produce good health as the most valuable features. Apart from an open-ended “other” category, participants reported that the least valuable elements were silver to customize their village and the silver multiplier earned with consecutive tobacco-abstinent submissions.

Table 5. Treatment acceptability[a] (n=30).

	Total sample (n=30), mean (SD)	AC[b] group (n=11), mean (SD)	SC[c] group (n=19), mean (SD)	*P* value
If you had to do it over again, would you use Inspired to help you quit smoking?	6.4 (3.4)	7.1 (3.8)	6.1 (3.3)	.44
Was Inspired helpful to you in your attempt to quit smoking?	5.4 (3.6)	5.5 (3.6)	5.3 (3.6)	.92
Do you think the Inspired game is fun to play?	6.7 (3.3)	7.3 (3.8)	6.4 (3.0)	.47
Would you recommend Inspired to a friend?	6.5 (3.2)	7.5 (3.1)	6.0 (3.2)	.22
I felt motivated to submit clean samples in order to obtain cessation points[d]	7.0 (3.6)	7.6 (3.2)	6.6 (3.9)	.45
It was clear to me how I could use the rewards I earned from meeting my goals	6.1 (3.9)	6.4 (4.3)	6.0 (3.8)	.81

[a]Scored on an 11-point scale, with 0 meaning "definitely not" to 10 meaning "yes, absolutely."

[b]AC: abstinence contingent.

[c]SC: submission contingent.

[d]Although "abstinent" samples would be a more appropriate way to refer to these smoke reports, participants were asked to indicate their motivation to submit "clean" samples at the time of assessment.

Discussion

Principal Findings

The study results supported the preliminary treatment acceptability for the use of the Inspired mobile game as a smoking cessation intervention. Treatment dropout was high, and both game engagement and tobacco abstinence were highly variable, decreasing feasibility. Half of the participants (25/48, 52%) submitted at least 1 abstinent report during the abstinence phase, and game scores had a large range, suggesting that some participants may have been more receptive to the intervention than others. The main outcome, the 7-day smoking point prevalence at the 30-day follow-up, found that one-quarter (11/48, 23%) of all participants had not taken a puff of a cigarette in the prior week and a third (15/48, 31%) had spent at least 24 hours without a cigarette in the prior 2 weeks. However, it is important to note that during testing, we discovered that the game was imbalanced, and there were remaining bugs (discussed more later in the Limitations section), all of which likely prohibited game progression and led to premature dropout. These bugs likely made the in-game rewards earned through submitting smoke reports less valuable and, therefore, less likely to function as a reinforcer to facilitate smoking abstinence. Overall, participants played an average of almost 11 levels over 20 days of gameplay, and their video game addiction scores remained steady. One-third (31.4%, SD 38.2%) of submissions during the abstinence phase indicated tobacco abstinence, and participants averaged 5.4 (SD 9.8) submissions of continuous abstinence.

Of note, the AC and SC groups did not differ on gameplay and smoking cessation. It is possible that the SC group erroneously believed that they would earn in-game rewards through meeting the smoking goal requirement rather than submission of smoking reports alone. It is also possible the in-game rewards (gem prisms and silver multipliers) did not function as reinforcers. Gem prisms and silver multipliers were not required for playing the game, and their utility was most apparent for later, more challenging levels, which many participants did not reach. Participants ranked the silver multiplier among the least valuable game features in the Treatment Acceptability Questionnaire, though the helpfulness of gem prisms was not directly assessed. In addition, we do not have the data on earning and using the gem prisms and silver multipliers to determine whether the participants made contact with these rewards. Participants indicated, on the Treatment Acceptability Questionnaire, that they had a reasonably clear understanding of how the rewards in the game could motivate their smoking cessation, but participants were not asked about how they earned in-game rewards, what those rewards were, and how they could be valuable for their gameplay. Therefore, it is unclear whether the game-based incentives impacted participants' reports of smoking.

The generalized linear models found that the highest level achieved was positively associated with the percentage of abstinent submissions and the longest abstinence streak, which suggests promise for the potential efficacy of the game to support smoking abstinence. However, the total game score was not associated with reported abstinence. Participants unlocked levels through smoking self-report submissions only and not through gameplay, whereas participants increased their score by completing levels in a sequential fashion and replaying levels, which could be done independently of submitting smoking self-reports or meeting smoking abstinence goals. In addition, the total game score had a high range and a large SD, meaning that some participants scored very little, whereas some scored very high. It is possible that the highest-scoring individuals engaged with the game more due to finding it fun or challenging rather than being related to their efforts to achieve smoking abstinence.

It is also important to note that most participants (28/48, 58%) stopped submitting smoking reports by the thinning phase. This decrease in engagement aligns with the lack of continued engagement across app-based smoking cessation interventions more broadly, which continues to be a concern in the field [33]. High dropout likely contributed to the low percentage of smoking reports submitted out of the total possible reports, at around one-third (34.7%, SD 29.1%). Finding strategies to increase and maintain engagement will be critical for future video game–based smoking cessation interventions.

The 30 participants who completed the Treatment Acceptability Questionnaire at week 7 found the game to be relatively helpful, fun, and motivating to help them quit smoking. It should be noted that participants who dropped out of the study before week 7 or who otherwise did not complete the survey may have had different opinions of the treatment, particularly if those opinions contributed to their dropout. Those who did complete the survey (30/48, 63%) highly valued the more active gameplay elements (eg, colored gems and defensive buildings) as opposed to the optional village customization that was part of the metasystem.

Limitations

These results should be considered in the context of the study's limitations. Due to technical difficulties, CO collection could not be performed, and smoking abstinence was determined primarily from smoking self-report. It is possible that participants falsely reported abstinence for social desirability or to gain access to in-game rewards. Although not ideal, self-reporting is common in smoking cessation studies and has aligned closely with biologically verified smoking measures in prior research [25,34,35]. We were only able to collect 20 cotinine samples; however, these demonstrated a high level of agreement with self-reported tobacco use among both abstinent and nonabstinent individuals.

The difficulties with CO collection also hindered the final sample size. The power was originally calculated for a sample size of 114 as opposed to the final sample of 48, and these analyses were based on group membership as an independent variable and the 7-day smoking point prevalence as an outcome. The study was underpowered to detect group differences in the outcome. The 2 groups were also not found to systematically differ in demographics, smoking history, game use, or self-reported abstinence. These developments informed the choice to focus on feasibility and acceptability in these analyses.

In addition, as noted earlier, participants encountered a number of bugs in the gameplay because Inspired was still in an early phase of testing. Study staff worked closely to collect this information from participants and helped troubleshoot difficulties. The high level of dropout seen throughout the study may have been due to participants returning to smoking or due to frustrations with the bugs they encountered in the game. For example, we know that level 9 of the core game was unbalanced, and many participants (9/48, 19%) stopped engaging at this level because it was too difficult to complete. Limited information was collected on exact actions during gameplay, such as the number of attempts on each level, which prevented a more granular analysis. Future examinations should focus on the playability of the game and the reasons for discontinuation. Finally, the duration of follow-up was short (30 days), preventing the examination of the intervention's impact over a longer period.

Strengths

This study had many strengths. Participants were relatively diverse in terms of age, education, employment, and annual income. In addition, the game was designed to deliver rewards that were only valuable in the context of the game, which, if effective, could greatly reduce the costs associated with delivering interventions that typically rely on financial incentives to promote abstinence (ie, contingency management) [36]. Although Inspired was ineffective in promoting abstinence for most participants for several potential reasons already noted, if it could be improved to promote greater levels of abstinence, it could be expanded to reach many people. Scaling up a game-based intervention that could be used by thousands of users over an extended period would add little additional cost, especially when compared to monetary-based contingency management, where each successful quit attempt, as well as longer periods of sustained abstinence, increases costs [37].

A major strength of Inspired was its flexibility. Participants were able use their mobile phone to access the game at any time of day and from any location, maximizing convenience. Using participants' existing mobile phones made this intervention scalable and sustainable, requiring no additional hardware. Although some disparities do continue to exist concerning access to smartphones, especially among lower-income populations who are also more likely to smoke, this gap has been steadily closing, and approximately 76% of people living in households making ≤US $30,000 have access to smartphones [38]. Although participants were required to submit smoke reports twice per day, they were able to incorporate them into their existing schedule and play the game when they wished. The core game was intentionally designed to take approximately 5 minutes to complete (ie, casual game), which is about the duration of a craving arc and approximates how long it might take to smoke a cigarette, serving as a competitor to smoking [39-41]. Furthermore, common barriers to in-person smoking cessation treatment include high cost, lack of access to health care settings, and lack of cessation support from health care providers, with those of low socioeconomic status and those belonging to underrepresented groups being particularly vulnerable to disparities in care [42,43]. A mobile smartphone game such as Inspired could provide a cessation intervention regardless of the health care status or the ability to pay for treatment. The flexibility of a smartphone game–based intervention could allow for low-cost access to cessation services for a wider range of individuals.

Conclusions

Taken together, these results showed promise for Inspired as an acceptable video game–based smoking cessation intervention. Participants were highly motivated to quit but had unsuccessfully tried to do so an average of 5.4 (SD 5.5) times before enrolling in the study. Although engagement and abstinence were variable, a subset of the participants (11/48, 23%) appeared to respond well to this approach having not taken a puff of cigarette in the previous 7 days at the 30-day follow up, which may make the difference in their smoking cessation quit attempts. Inspired used the principles of contingency management, delivering incentives, the value of which only existed within the context of the game and did not require additional monetary resources to implement [44].

Although Inspired provides an exciting alternative to traditional, in-person smoking cessation interventions, much needs to be done to ensure feasibility and scalability. The bugs in the gameplay limited the potential reinforcing value of the in-game rewards. Future examinations of Inspired and other such interventions should work to ensure that the gameplay is easy to learn and enjoyable so that achieving abstinence goals results in immediate, meaningful rewards.

The incentives offered through Inspired did not have value outside of the game, but participants may have been motivated to conceal their smoking anyway. To be in alignment with the science of contingency management, objective measures of smoking abstinence are needed. The iCO portable breath CO detector and NicAlert cotinine test strips that we attempted to use in this study were flawed [24]. Other objective measures of smoking abstinence could be explored, such as Alere rapid oral cotinine tests, which we successfully used in another study, or changes in resting heart rate that can be measured from smartphone cameras or smart watches [45,46]. The limitations of this study can inform future video game–based smoking cessation interventions, helping them fulfill the promise of using contingency management as a scalable and fun way to enact behavior change. Such low-cost and accessible interventions could be the key to achieving a healthier, smoke-free life.

Acknowledgments

The authors would like to thank Connor Burrows for helping with early-stage testing and data management, Caitlyn Upton for helping to collect cotinine data, Dan Scherlis for helping with early-stage game conceptualizing, Nicolas Fortugno for game design and overseeing game development, and John Hewitt for helping with coding the game and database.

Conflicts of Interest

DR is in conflict because he has the potential to benefit from sales of the final Inspired game.

Abstract

Background: Exercise offers substantial health benefits but can induce oxidative stress and inflammation, especially in high-intensity formats such as high-intensity interval exercise (HIIE). Exergaming has become an effective, enjoyable fitness tool for all ages, particularly older adults. Enzyme supplements may enhance exercise performance by improving lactate metabolism and reducing oxidative stress.

Objective: This study investigates the efficacy of fruit and vegetable enzyme supplementation in modulating fatigue and enhancing aerobic capacity in older adults following HIIE through exergaming.

Methods: The study recruited 16 older adult female participants and allocated them into 2 distinct groups (enzyme and placebo) based on their pretest lactate levels. This division used pairwise grouping to guarantee comparability between the groups, ensuring the integrity of the results. They engaged in HIIE using Nintendo Switch Ring Fit Adventure, performing 8 sets of 20 seconds of maximum effort exercise interspersed with 30 seconds of rest, totaling 370 seconds of exercise. Key metrics assessed included blood lactate levels, heart rate, rating of perceived exertion, and training impulse. Participants in the enzyme group were administered a fruit and vegetable enzyme supplement at a dosage of 30 mL twice daily over a period of 14 days.

Results: The enzyme group showed significantly lower blood lactate levels compared to the placebo group, notably after the fourth (mean 4.29, SD 0.67 vs mean 6.34, SD 1.17 mmol/L; *P*=.001) and eighth (mean 5.84, SD 0.63 vs mean 8.20, SD 1.15 mmol/L; *P*<.001) exercise sessions. This trend continued at 5 minutes (mean 6.85, SD 0.82 vs mean 8.60, SD 1.13 mmol/L; *P*=.003) and 10 minutes (mean 5.91, SD 1.16 vs mean 8.21, SD 1.27 mmol/L; *P*=.002) after exercise. Although both groups exceeded 85% of their estimated maximum heart rate during the exercise, enzyme supplementation did not markedly affect the perceived intensity or effort.

Conclusions: The study indicates that fruit and vegetable enzyme supplementation can significantly reduce blood lactate levels in older adults following HIIE through exergaming. This suggests a potential role for these enzymes in modulating lactate production or clearance during and after high-intensity exercise. These findings have implications for developing targeted interventions to enhance exercise tolerance and recovery in older adults.

Introduction

Exercise represents a paradoxical element in health management, offering substantial benefits yet posing potential risks if not properly moderated [1,2]. High-intensity exercise, although efficacious in improving various health parameters, can lead to oxidative stress, muscle damage, and inflammation [3,4]. The oxidative stress primarily arises from increased reactive oxygen species production during intensive physical activities [5]. Moreover, exercise-induced fatigue serves as a protective mechanism against overexertion and consequent injuries [6,7]. In contemporary fitness regimes, high-intensity interval exercise (HIIE), particularly the Tabata training method, has gained prominence for its effectiveness in enhancing aerobic power, fat oxidation, and muscular endurance [8-10]. These attributes are especially crucial for the older adult population, a demographic that significantly benefits from regular physical activity [11-13].

Exergaming, an innovative blend of physical exercise and interactive gaming, has emerged as a transformative approach to fitness, especially in engaging diverse age groups in regular physical activity. Its efficacy in enhancing key fitness parameters such as aerobic capacity, agility, and coordination, coupled with its ability to make exercise more enjoyable, has been well documented [14-16]. This fusion of technology and exercise not only caters to the digital age but also opens avenues for personalized fitness experiences, which are adaptable to various demographic needs [17,18]. Although exergaming has been effective across a range of ages, its application in older adult populations presents unique opportunities and challenges. As the older adult population seeks safe, engaging, and effective exercise methods, exergaming could offer a solution that aligns with these requirements. However, integrating HIIE concepts into exergaming for older adults remains a relatively uncharted territory. HIIE, known for its efficiency in improving cardiovascular health and metabolic function, could significantly benefit older adults, particularly in terms of enhancing functional capacity and overall quality of life [12,19].

The potential of HIIE within exergaming for older adults hinges on the balance between intensity and safety. Although HIIE is beneficial, it is crucial to adapt its intensity to suit the physiological capabilities and limitations of older individuals. Research indicates that tailored HIIE programs can be both feasible and beneficial for older adults, leading to improvements in cardiovascular health, muscle strength, and metabolic function [20,21]. Integrating these concepts into exergaming could further enhance adherence and enjoyment, which are crucial factors in maintaining regular exercise habits in this demographic. Furthermore, the interactive and immersive nature of exergaming can address common barriers to exercise among older adults, such as the lack of motivation or fear of injury. By providing a safe, controlled environment for engaging in HIIE, exergaming can potentially transform the perception and experience of high-intensity workouts for older adults. This is particularly pertinent given the increasing need for innovative exercise interventions that cater to the aging global population [11].

Nutritional supplementation, especially with natural fruit and vegetable enzymes, presents a promising avenue in augmenting exercise performance through their antioxidant, anti-inflammatory, and metabolic benefits [21-28]. Such supplementation could potentially optimize lactate metabolism and enhance muscle function during exercise. Recent advancements in nutritional science have highlighted the substantial role of natural fruit and vegetable enzymes in enhancing exercise performance. These enzymes are increasingly recognized for their multifaceted health benefits, including their antioxidant, anti-inflammatory, and metabolism-enhancing properties [21,22]. Notably, their potential impact on exercise physiology, particularly in the context of high-intensity workouts, offers a new perspective on improving athletic performance and recovery.

One of the critical areas where these enzymes show promise is in the modulation of lactate metabolism. Lactate, often produced in higher quantities during intense physical activity, can lead to fatigue and decreased muscle efficiency. The traditional view of lactate as merely a byproduct of anaerobic metabolism has evolved, with current research acknowledging its role as a valuable energy source during prolonged exercise [23]. This shift in understanding opens up new avenues for using enzyme supplementation to optimize lactate use. Enzymes such as bromelain and papain, found in pineapples and papayas, respectively, have been studied for their potential in improving lactate metabolism. These enzymes are known to facilitate faster clearance of lactate from the bloodstream, thereby enhancing recovery and reducing fatigue [26,28]. Furthermore, the antioxidant properties of these enzymes play a crucial role in combating oxidative stress, which is often elevated during intense exercise regimens [24,25]. This reduction in oxidative stress is not only beneficial for immediate recovery but also contributes to long-term muscle health and function. Moreover, the anti-inflammatory actions of these natural enzymes can mitigate the inflammatory response often triggered by high-intensity exercise [27]. By reducing inflammation, these enzymes may enhance muscle recovery and function, thus allowing for more efficient and prolonged exercise performance. This aspect is particularly relevant in training regimens where recovery is as crucial as the exercise itself.

The primary aim of this feasibility study is to examine the effects of fruit and vegetable enzyme supplementation on aerobic capacity and blood lactate response in older adults engaged in HIIE through an exergaming framework. This study is dual faceted, focusing on (1) the physiological responses and feasibility of an exergaming HIIE regimen tailored for older adults and (2) the impact of enzyme supplementation on enhancing these exercise outcomes.

Methods

Sample Size

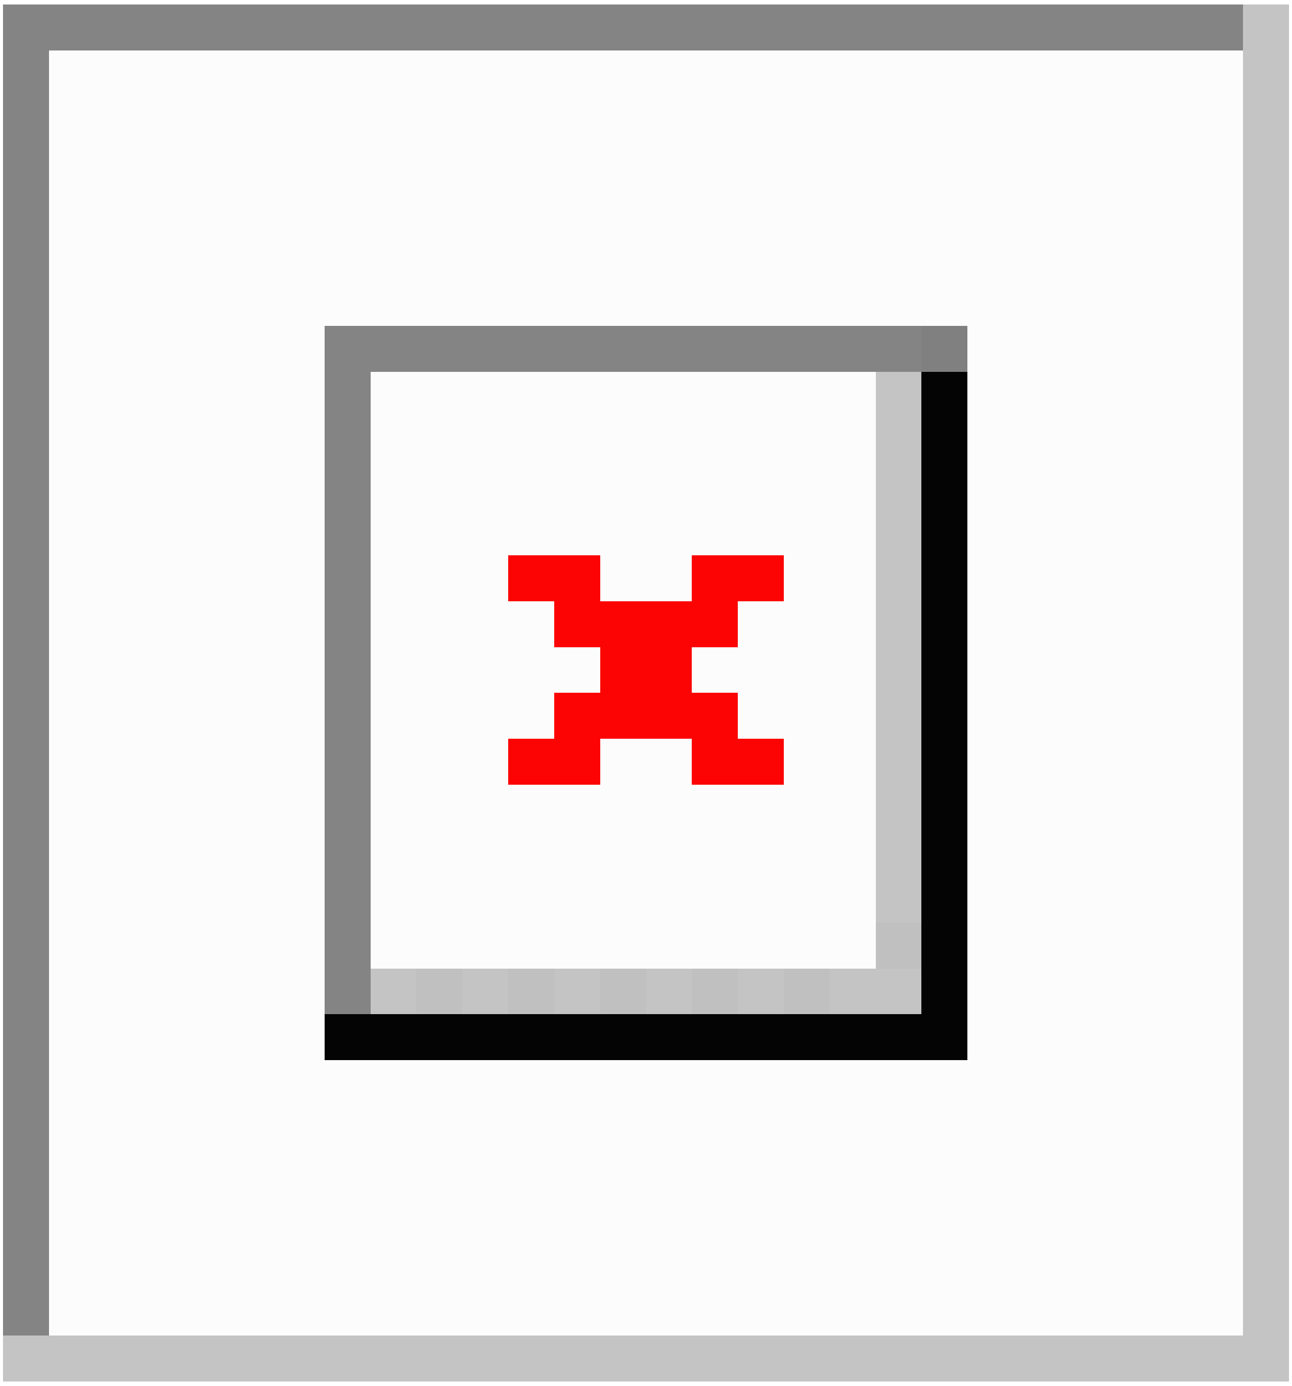
The sample size computation was based on the study by Flanagan and Jakeman [29]. Based on a statistical power analysis, a total sample size of 16 participants (8 per group) was needed to achieve a statistical power of 0.8 to detect a large effect size (ES) for supplement-time interaction at an α level of .05 [30].

Participants and Experimental Design

After recruiting a total of 30 healthy older adult participants, the study proceeded with screenings and initial explanations. Subsequently, 12 individuals were excluded as they did not meet the inclusion criteria, and 2 declined to participate. Ultimately, 16 female older adult participants were enrolled in the study. These participants were then divided into 2 distinct groups (enzyme and placebo) based on their pretest lactate levels. Pairwise grouping was used to ensure comparability between the groups, thereby preserving the integrity of the results. All participants reported a regular exercise habit (3 times per week within the past year). They also completed the Physical Activity Readiness Questionnaire and confirmed no history of upper-limb skeletal muscle injury or major injury. Participants were instructed to avoid strenuous activities and the intake of caffeine or muscle-enhancing supplements for 24 hours prior to the experiment. Before the study commenced, all participants provided personal information, completed health questionnaires, disclosed personal medical history, and signed informed consent forms.

The 16 participants underwent the exergaming HIIE test as an initial assessment (pretest). Participants engaged in a 5-minute warm-up on a stationary bike, followed by HIIE using Nintendo Switch Ring Fit Adventure. The training method was adapted from previous research [8,9] and consisted of 8 sets of 20 seconds of maximum effort exercise with 30 seconds of complete rest between each set, resulting in a total exercise time of 370 seconds. The HIIE design incorporated training modes targeting the deltoid, pectoralis major, latissimus dorsi, and quadricep muscles in Nintendo Switch Ring Fit Adventure. Blood lactate levels, heart rate (HR), and ratings of perceived exertion (RPE) were recorded before, during, and after exercise, and training load was quantified using training impulse (TRIMP). Participants were matched and divided into 2 groups, the enzyme group and the placebo group, based on their blood lactate levels during HIIE. Each group comprised 8 individuals. Supplementation with vegetable and fruit enzymes or maltodextrin commenced 3 days after the pretest and lasted for a total of 14 days. On the 14th day, following the completion of supplementation, the participants underwent the exergaming HIIE test as a posttest (Figure 1). This study was not preregistered as it was considered a feasibility study.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) and experimental procedure diagram. HIIE: high-intensity interval exercise; HR: heart rate; RPE: rating of perceived exertion.



Ethical Considerations

The human research ethics committee of the local university approved this study, which was also approved by the human research ethics committee of the National Cheng Kung University, Taiwan (approval NCKU HREC-E-112-419-2). Users volunteered for this study and agreed to participate by signing an informed consent form. To protect the personal data of participants, all participant information has been anonymized and assigned identification numbers. Participation was voluntary following recruitment, and participants were given a small gift at the conclusion as a token of appreciation.

Supplementation Protocol

After the pretest, the enzyme group consumed 30 mL of vegetable and fruit enzymes (the contents included needle-leaf cherries, cherries, apples, cranberries, blackberries, black currants, blueberries, beets, broccoli, cabbage, carrots, Concord grapes, cranberries, elderberries, kale, oranges, peaches, papayas, parsley, pineapples, raspberries, red currants, spinach, and tomatoes, etc; Enzyme Village) mixed with 150 mL of water twice a day (at breakfast and dinner) for 14 consecutive days. The placebo group followed the same protocol but consumed malt syrup (Amazon) instead until the end of the study. Participants returned to the laboratory each morning to receive the daily supplement, which was administered on site.

Following supplementation, participants reported their dinner intake to the researchers, ensuring compliance with the prescribed supplementation regimen.

Exergaming HIIE Test: Combination of Exergaming and HIIE

Participants in this experiment engaged in HIIE using the Nintendo Switch Ring-Con within a laboratory environment. All participants completed pre- and posttest assessments on the same day. The exergame used in this study was Nintendo Switch Fitness Adventure, which ingeniously blends exercise with an adventure narrative to deliver both physical workouts and gaming enjoyment concurrently. This game is noted for its intuitive, user-friendly interface that accommodates players of all ages. It incorporates a specialized fitness ring—a smart accessory that connects to the Nintendo Switch console. The sensor system used 2 Nintendo controllers: 1 mounted on the exercise ring and the other secured to the participant's thigh to enhance gameplay interaction. Through the Ring-Con, participants engaged in diverse physical activities such as weightlifting, yoga, and aerobic exercises. The fitness ring sensor accurately captures and integrates players' movements into the game. The gameplay involves unlocking levels and engaging in fitness challenges that are achieved through actual physical activities. It offers a wide range of exercise routines targeting various muscle groups and provides engaging gaming challenges. The exercise protocol included 8 sets of 20-second, high-effort exercises, interspersed with 30-second rest intervals, totaling 370 seconds of active exercise time. Specifically, the fitness game mode used was the Adventure Mode in Ring Fit Adventure, comprising exercises targeting the pectoralis major, latissimus dorsi, deltoid, and quadricep muscles (Figures 2 and 3).

Figure 2. Experimental flowchart. * indicates lactate test. # indicates tests for heart rate and rating of perceived exertion. Ex-: bouts of HIIE; HIIE: high-intensity interval exercise; post–5 min: after 5 minutes of HIIE; post–10 min: after 10 minutes of HIIE.

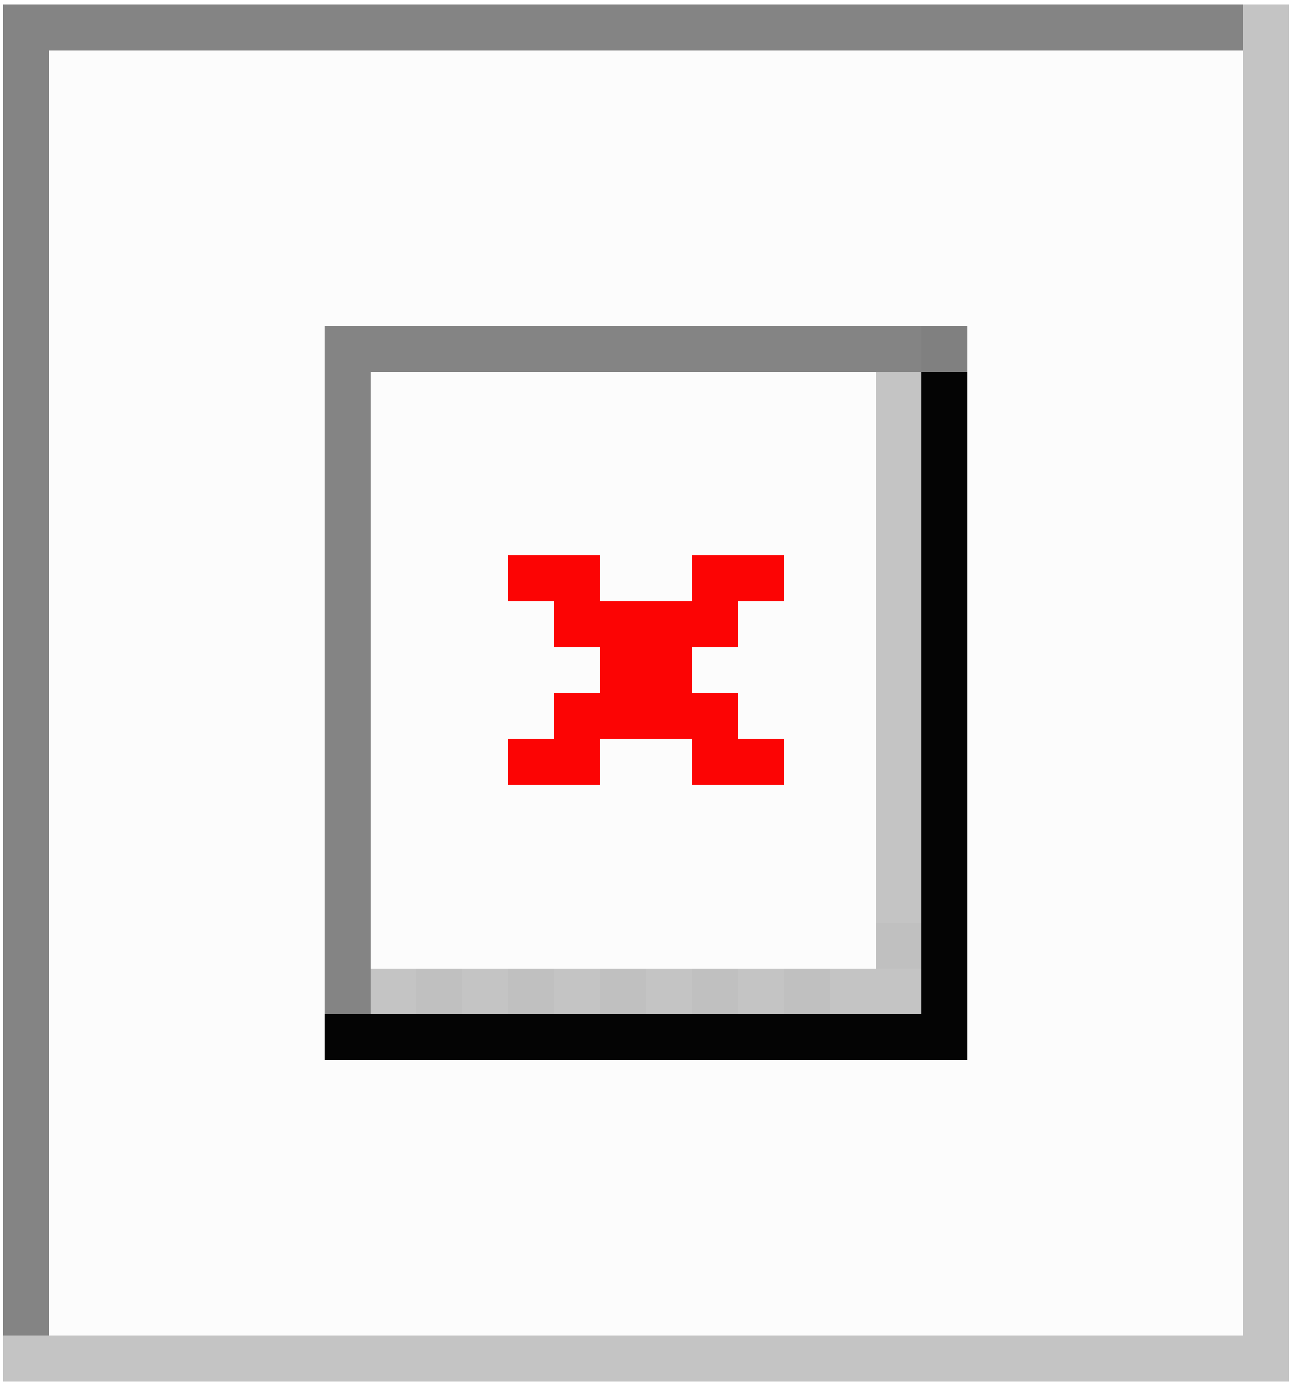


Figure 3. Exercise training model: (A) pectoralis major, (B) deltoid, (C) latissimus dorsi, and (D) quadricep muscles. The images represent the 4 exercises used in this study. (A) shows pressing the fitness ring inward; (B) and (C) depict pulling the fitness ring outward; and (D) illustrates mounting the sensor device on the thigh, which should be raised to approximately 90°.

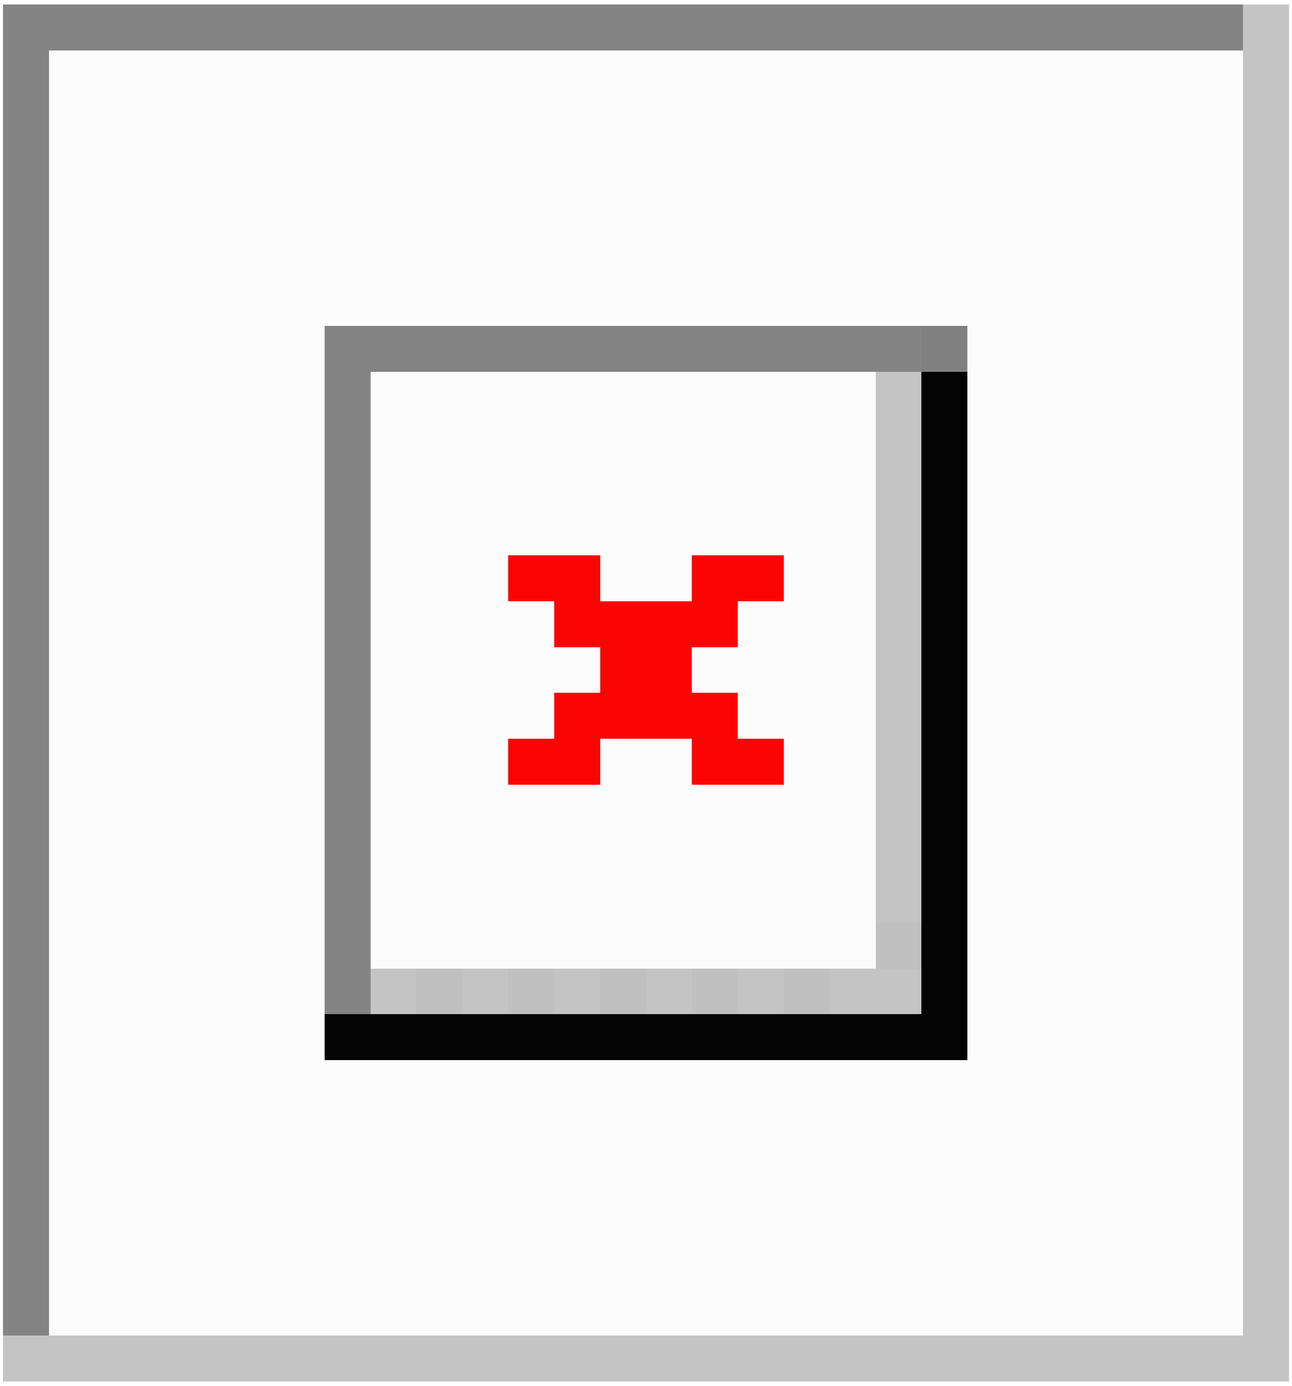


Blood Lactate Test

Blood lactate was measured at 5 time points: before exercise, after the fourth and eighth bouts of exercise, and at 5 and 10 minutes after exercise. Blood lactate was analyzed using a Biosen Cline blood analysis system (EKF-diagnostic). Capillary blood samples of 10 μL were collected, added to red blood cell lysis reagent, and stored at low temperature until analyzed. Prior to analysis, instrument standardization and test calibration were performed, and the coefficient of variation was determined to be ≤1.5%. The detection range for blood lactate was 0.5-40 mM [31].

Exercise Load (TRIMP)

Overview

In this study, the exercise load was represented by the TRIMP [32], which was calculated as the product of exercise intensity and duration. To accommodate the convenience of the experiment, 2 different TRIMP calculation methods were used, including % maximum HR (HRmax; objective) and RPE (subjective). At the end of each exercise bout (8 bouts in total) and during the recovery period before the next bout (7 bouts in total), participants were asked to report their RPE, and their HR was recorded. This process was repeated 8 times.

% HRmax Calculation Method

During the entire HIIE, the participant's HR was recorded every 5 seconds using a HR monitor (iHeart Polar) to calculate % HRmax. The block TRIMP method developed by Edwards [33] was used, which divides the exercise intensity into 5 blocks with corresponding weighting factors (Table 1). The weighted score of each block was multiplied by the exercise time (min) and then summed to obtain the exercise load (arbitrary unit [AU]). The calculation formula was as follows: *Exercise load = (Z1 exercise time × 1) + (Z2 exercise time × 2) + (Z3 exercise time × 3) + (Z4 exercise time × 4) + (Z5 exercise time × 5).*

Table . The Edwards [33] block training intensity calculation method.

Zone	Intensity (% HRmax[a]), range	Weighted score
Z1	50-60	1
Z2	60-70	2
Z3	70-80	3
Z4	80-90	4
Z5	90-100	5

[a]HRmax: maximum heart rate.

RPE Calculation Method

The TRIMP calculation method of Foster et al [34,35] was used to calculate the exercise load, by multiplying the RPE value of each exercise segment by the exercise time and summing them up. The RPE scale used in this method was the CR-10 version modified by Foster et al [35] based on Borg et al [36] (Table 2). The calculation formula was as follows: *Exercise load (AU) = Borg CR-10 RPE score × exercise time (min).*

Table . Borg CR-10 rating of perceived exertion (RPE).

Borg CR-10 RPE score	Level of exertion
0	Rest
1	Very, very easy
2	Easy
3	Moderate
4	Somewhat hard
5	Hard
6	Hard
7	Very hard
8	Very hard
9	Very hard
10	Maximal

Statistical Analysis

All the data were analyzed by SPSS for Windows 20.0 (IBM Corp). Data are expressed as mean (SD) and 95% CI. A mixed design 2-way ANOVA (group×time) was used to compare the variables of lactate response, HR, and TRIMP between 2 groups before and after the 14 days of supplementation. Graphs were generated using GraphPad Prism 8.0 (GraphPad Software). Cohen conventions for ES (Cohen *d*) were calculated by the G*Power 3.1 software program (Heinrich-Heine-Universität), where the ESs of 0.2, 0.5, and 0.8 are considered small, medium, and large, respectively. Statistical significance was set as $P<.05$.

Results

Overview

Table 3 outlines the baseline characteristics of participants in the study, divided into the enzyme and placebo groups. The average age of participants was slightly higher in the placebo group (66.50, SD 1.31 y) than the enzyme group (65.75, SD 0.88 y). Heights were similar across both groups, with the enzyme group averaging 160.50 (SD 2.67) cm and the placebo group averaging 160.13 (SD 2.75) cm. The enzyme group members were slightly heavier (mean 56.75, SD 4.27 kg) than those in the placebo group (mean 53.5, SD 3.42 kg), which was also reflected in a higher average BMI (22.02, SD 1.41 kg/m² in the enzyme group vs 20.89, SD 1.71 kg/m² in the placebo group). Regarding exercise habits, both groups engaged in regular physical activity, with the enzyme group exercising on average 3.75 (SD 0.71) days per week and the placebo group exercising slightly more at 4.00 (SD 0.76) days per week. The daily exercise duration was comparable between groups, with the enzyme group averaging 76.25 (SD 41.04) minutes and the placebo group averaging 78.75 (SD 31.82) minutes.

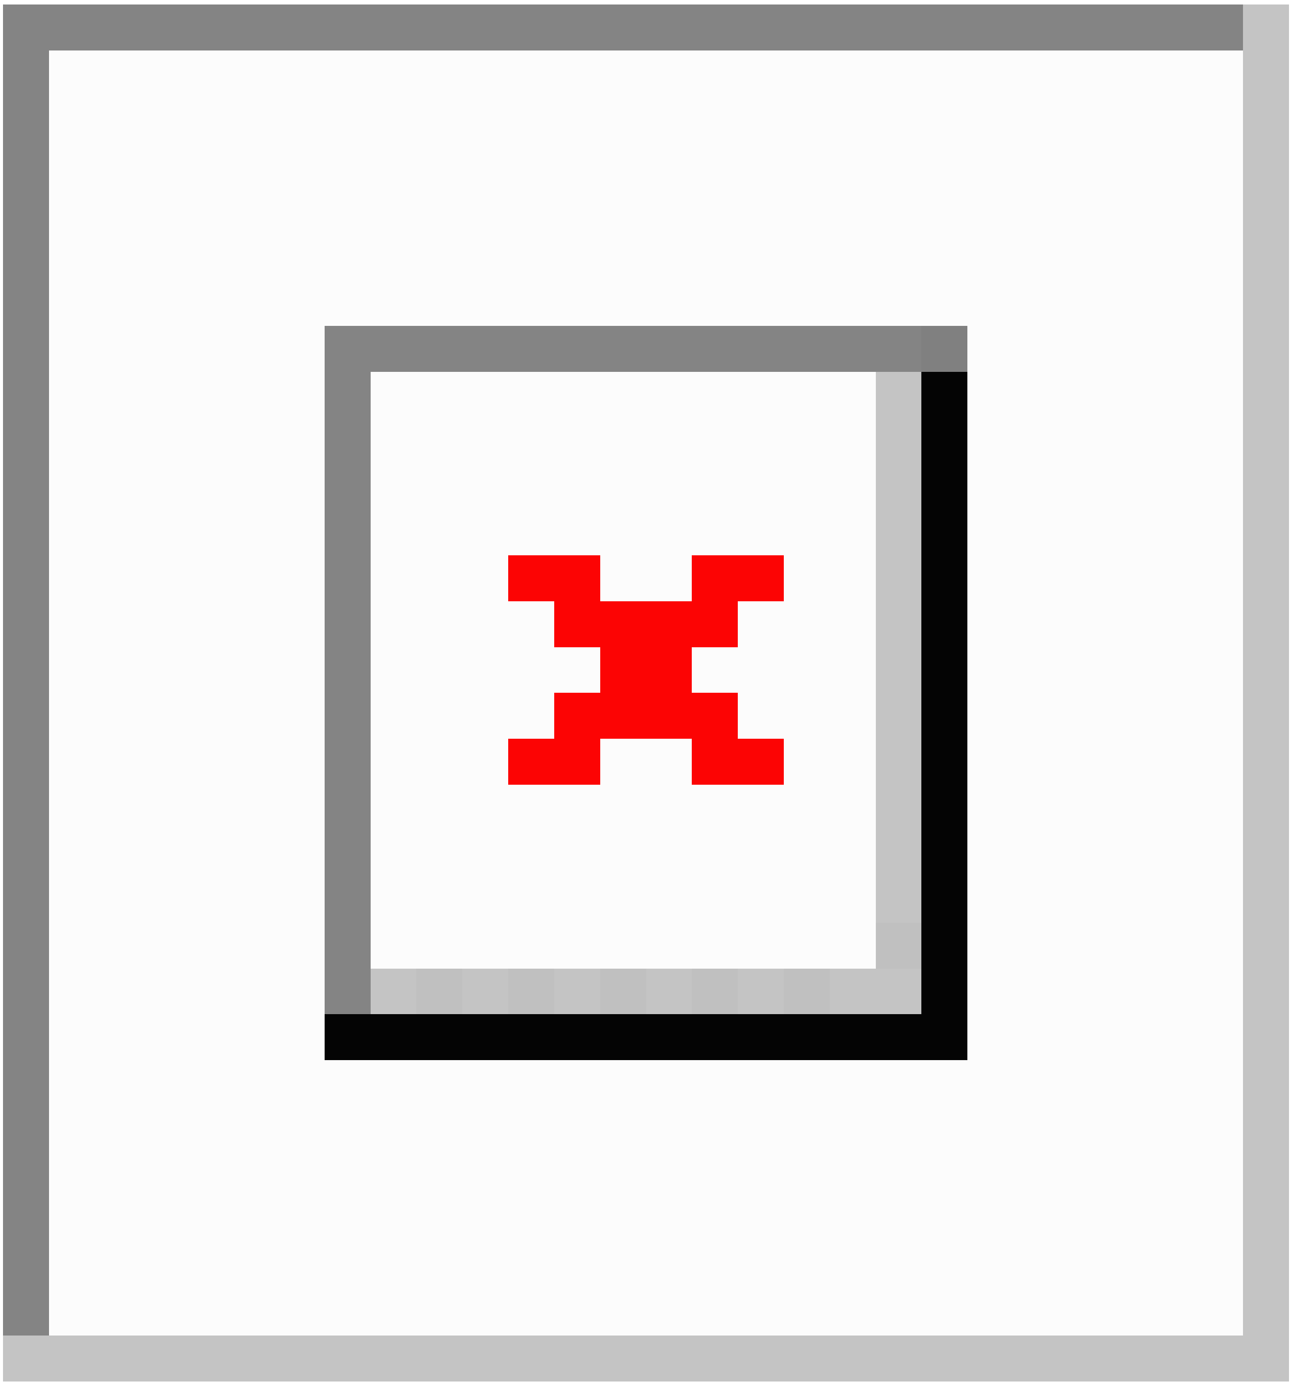
Table . Participants' baseline characteristics.

Characteristics	Enzyme group, mean (SD)	Placebo group, mean (SD)
Age (y)	65.75 (0.88)	66.50 (1.31)
Height (cm)	160.50 (2.67)	160.13 (2.75)
Weight (kg)	56.75 (4.27)	53.5 (3.42)
BMI (kg/m^2)	22.02 (1.41)	20.89 (1.71)
Frequency of regular exercise habits (d/wk within the past year)	3.75 (0.71)	4.00 (0.76)
Daily exercise duration (min)	76.25 (41.04)	78.75 (31.82)

Enzyme Supplementation's Impact on Lactate Response in Exergaming Combined With HIIE

The results demonstrated that blood lactate levels surpassed 4 mmol/L after the fourth exercise bout, indicating the presence of high-intensity exercise. Additionally, the study examined the effects of 14 days of enzyme or placebo supplementation on blood lactate levels ($F_{1,14}$=6.99; *P*=.001). The enzyme group exhibited significantly lower blood lactate levels than the placebo group after the fourth (mean 4.29, SD 0.67; 95% CI 3.56-5.01 vs mean 6.34, SD 1.17; 95% CI 5.61-7.06 mmol/L; ES=−2.14; *P*=.001) and eighth (mean 5.84, SD 0.63; 95% CI 5.14-6.54 vs mean 8.20, SD 1.15; 95% CI 7.50-8.90 mmol/L; ES=−2.56; *P*=.001) exercise bouts, as well as at 5 minutes (mean 6.85, SD 0.82; 95% CI 6.10-7.60 vs mean 8.60, SD 1.13; 95% CI 7.85-9.35 mmol/L; ES=−1.78; *P*=.003) and 10 minutes (mean 5.91, SD 1.16; 95% CI 4.99-6.84 vs mean 8.21, SD 1.27; 95% CI 7.29-9.14 mmol/L; ES=−1.89; *P*=.002) after exercise (Figure 4). These findings suggest that the combination of HIIE and exergaming can lead to high-intensity exercise, and enzyme supplementation can contribute to a reduction in lactate levels.

Figure 4. Blood lactate response (A) before and (B) after 14 days of enzyme or placebo supplementation. Data are presented as mean (SD). * indicates a significant difference (*P*<.05) from the pre-exercise value within the group. # indicates a significant difference (*P*<.05) between the groups. Ex-4: fourth bout of HIIE; Ex-8: eighth bout of HIIE; HIIE: high-intensity interval exercise; post–5 min: after 5 minutes of HIIE; post–10 min: after 10 minutes of HIIE.

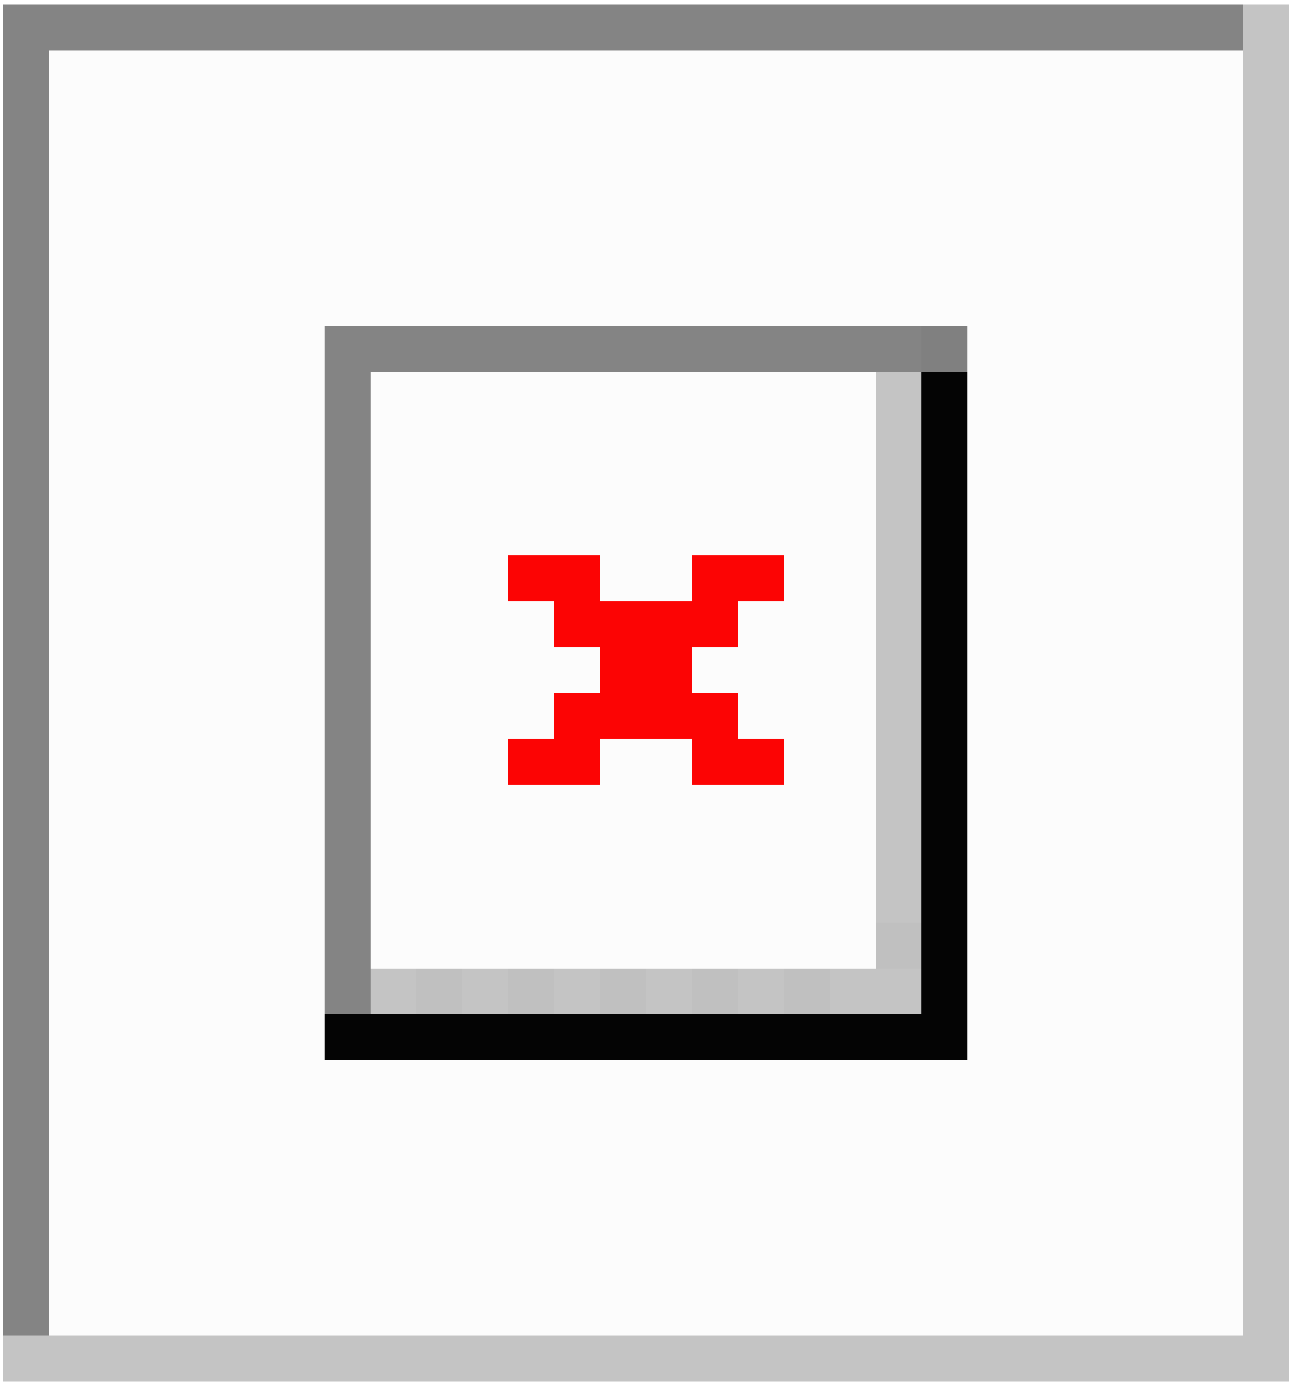


Enzyme Supplementation’s Impact on HR in Exergaming Combined With HIIE

The results demonstrated that during exergaming combined with HIIE, older adult participants experienced a significant increase in HR compared with before exercise (*P*<.05). The estimated HRmax (*220 – age, SD 10*) for older adults was 155 (SD 10) beats per minute (bpm), and the observed HRs during exercise exceeded 85% of the estimated HRmax for both groups. However, there was no significant difference in the average HR of the older adults between the enzyme and placebo groups before and after supplementation. Before supplementation, there was no significant difference in the HRs of the older adult participants between the enzyme and placebo groups during the first (mean 104.63, SD 24.71; 95% CI 86.77-122.48 vs mean 104.63, SD 22.32; 95% CI 86.77-122.48 bpm; ES=0; *P*>.99), second (mean 116.13, SD 21.81; 95% CI 101.54-141.72 vs mean 114.38, SD 16.26; 95% CI 99.79-128.96 bpm; ES=0.09; *P*=.86), third (mean 126.13, SD 24.30; 95% CI 110.53-141.72 vs mean 118.38, SD 15.96; 95% CI 102.78-133.97 bpm; ES=0.38; *P*=.46), fourth (mean 130.13, SD 21.97; 95% CI 114.63-145.62 vs mean 121.38, SD 18.77; 95% CI 105.88-136.87 bpm; ES=0.43; *P*=.41), fifth (mean 124.63, SD 20.49; 95% CI 109.37-139.88 vs mean 125.63, SD 19.73; 95%

CI 110.37-140.88 bpm; ES=−0.05; *P*=.92), sixth (mean 128.88, SD 23.34; 95% CI 112.71-145.04 vs mean 127.38, SD 19.06; 95% CI 111.21-143.54 bpm; ES=0.07; *P*=.89), seventh (mean 131.63, SD 22.01; 95% CI 116.56-146.69 vs mean 129.75, SD 17.45; 95% CI 114.69-144.81 bpm; ES=0.09; *P*=.85), and eighth (mean 137.75, SD 23.60; 95% CI 121.78-153.73 vs mean 135.63, SD 18.19; 95% CI 119.65-151.60 bpm; ES=0.10; *P*=.84) sets (Figure 2). Similarly, after supplementation, there was no significant difference in the HRs of the enzyme and placebo groups during the first (mean 102.13, SD 21.21; 95% CI 88.87-115.67 vs mean 109.88, SD 13.64; 95% CI 96.33-123.42 bpm; ES=−0.43; *P*=.40), second (mean 111.13, SD 18.04; 95% CI 98.32-123.93 vs mean 114.88, SD 15.63; 95% CI 102.07-127.68 bpm; ES=−0.22; *P*=.66), third (mean 121.13, SD 19.38; 95% CI 108.63-133.62 vs mean 115.38, SD 12.95; 95% CI 102.88-127.87 bpm; ES=0.35; *P*=.50), fourth (mean 128.25, SD 18.75; 95% CI 116.57-139.93 vs mean 118.5, SD 11.10; 95% CI 106.82-130.18 bpm; ES=0.63; *P*=.23), fifth (mean 129.25, SD 18.12; 95% CI 115.29-143.21 vs mean 128.75, SD 18.68; 95% CI 114.79-142.71 bpm; ES=0.03; *P*=.96), sixth (mean 132.00, SD 19.79; 95% CI 118.70-145.30 vs mean 125.50, SD 14.95; 95% CI 112.20-138.80 bpm; ES=0.37; *P*=.47), seventh (mean 133.88, SD 20.84; 95% CI 120.50-147.25 vs mean 127.63, SD 13.70; 95% CI 114.25-141.00 bpm; ES=0.35; *P*=.49), and eighth (mean 137.75, SD 21.18; 95% CI 124.42-151.08 vs mean 134.63, SD 13.02; 95% CI 121.30-147.95 bpm; ES=0.18; *P*=.73) sets (Figure 5). In summary, the findings indicate that exergaming combined with HIIE leads to a significant increase in HR among older adults. However, there was no significant difference in HR between the enzyme and placebo groups before and after supplementation.

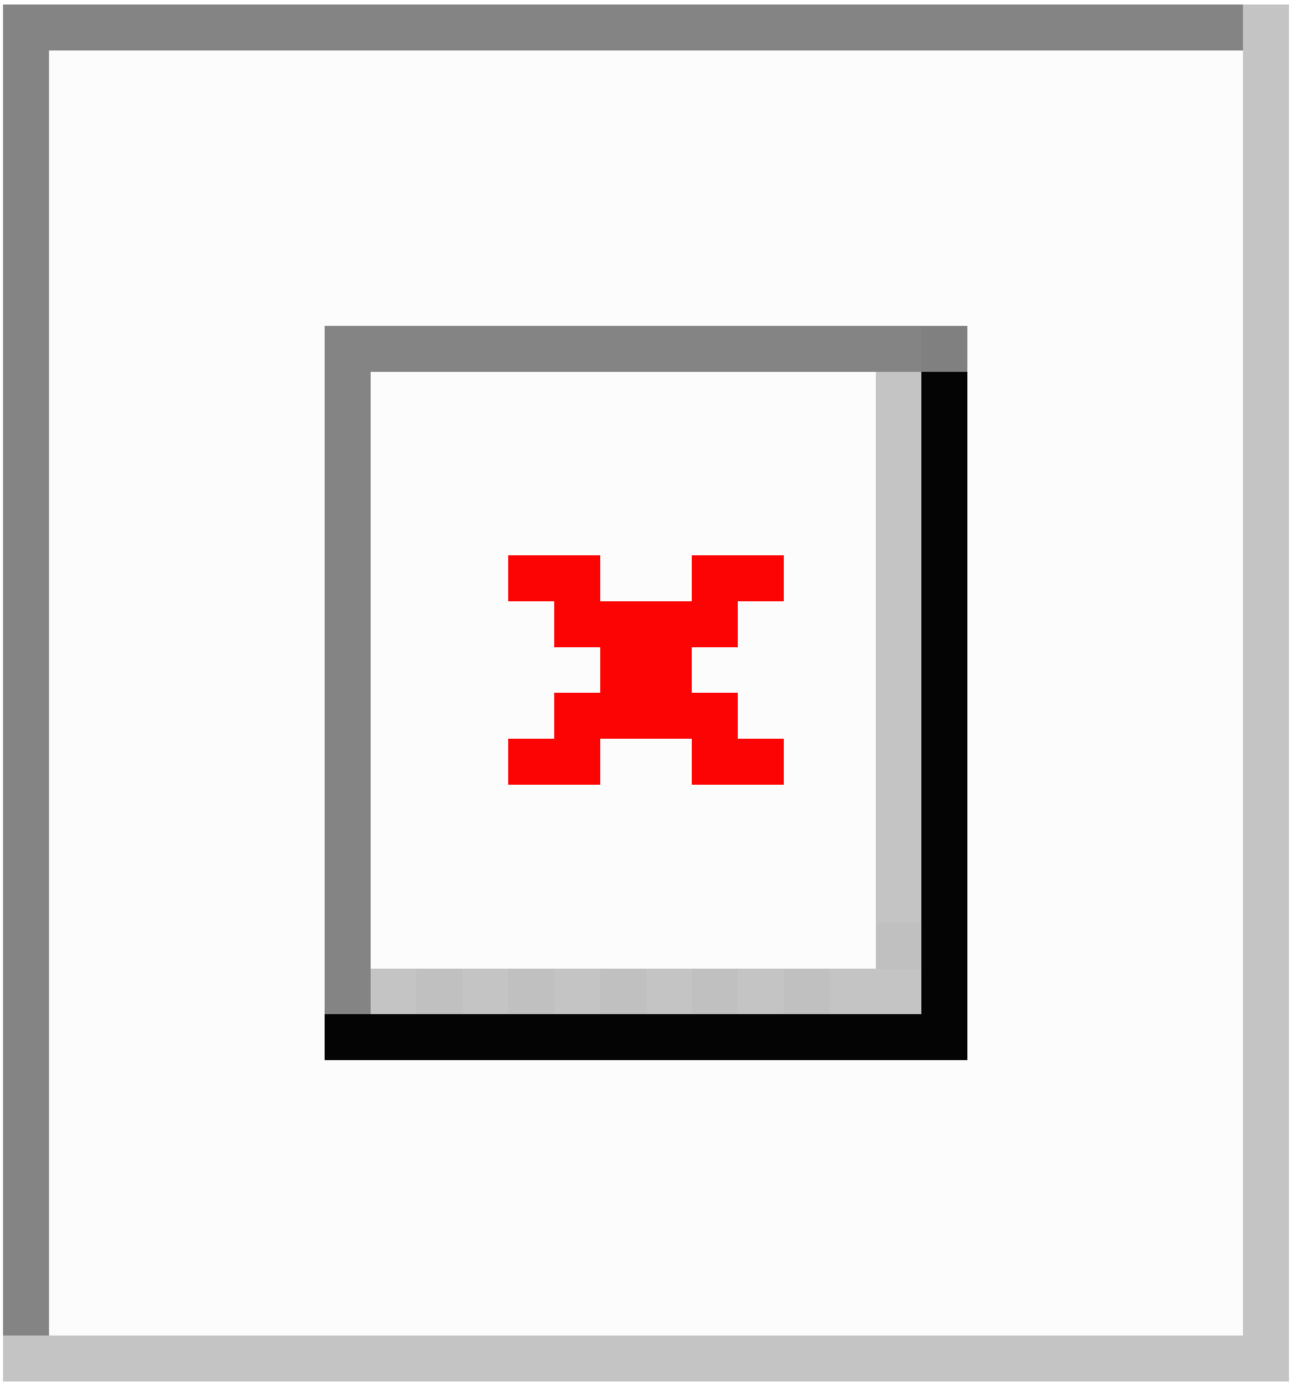
Figure 5. Heat rate response (A) before and (B) after 14 days of enzyme or placebo supplementation. Data are presented as mean (SD). * indicates a significant difference (*P*<.05) from the pre-exercise value within the group. Ex-: bouts of HIIE; HIIE: high-intensity interval exercise; post–5 min: after 5 minutes of HIIE; post–10 min: after 10 minutes of HIIE.



TRIMP in Enzyme Versus Placebo Groups After Supplementation in Exergaming Combined With HIIE

The TRIMP, representing both objective and subjective training loads, was compared between the enzyme and placebo groups after supplementation. Analysis revealed no significant differences in either the objective (mean 542.5, SD 172.19 vs mean 531.25, SD 123.34 AU; ES=0.08; *P*=.88) or subjective training loads (mean 895, SD 143.73 vs mean 847.50, SD 223.46 AU; ES=0.25; *P*=.62) between the groups (Figure 6). This suggests that the supplementation did not significantly alter the perceived intensity or effort of the HIIE when combined with exergaming.

Figure 6. Comparison of (A) objective and (B) subjective training impulse (TRIMP) between the enzyme and placebo groups after supplementation during HIIE with exergaming. Data are presented as mean (SD). AU: arbitrary unit; Ex-: bout of HIIE; HIIE: high-intensity interval exercise; HRmax: maximum heart rate; RPE: rating of perceived exertion.



Discussion

Principal Findings

The study investigated the effects of enzyme supplementation on lactate response and HR in older adult individuals engaging in a combination of exergaming and HIIE. The results indicated that enzyme supplementation significantly reduced blood lactate levels after exercise, particularly after the fourth (*P*=.001) and eighth (*P*<.001) exercise bouts, demonstrating the potential of enzymes to mitigate exercise-induced lactate accumulation. Despite a notable increase in HR during the exercise sessions, which surpassed 85% of the estimated HRmax for older adult participants, there was no discernible difference in HR responses between the enzyme and placebo groups, either before or after supplementation. Furthermore, the analysis of TRIMP, encompassing both objective and subjective measures of training load, revealed no significant differences between the enzyme and placebo groups after supplementation. This suggests that although enzyme supplementation may aid in lactate management, it does not significantly impact the overall perceived intensity or cardiovascular demand of HIIE combined with exergaming in older adult individuals.

Lactate Response in Exergaming

This study contributes valuable insights into the efficacy of fruit and vegetable enzyme supplementation in optimizing exercise outcomes for older adults, particularly when combined with HIIE and exergaming. The notable finding that blood lactate levels surpassed the 4 mmol/L threshold after the fourth exercise bout underlines the high intensity and physiological rigor of the exercise protocol. This study's emphasis on enzyme supplementation's impact on blood lactate levels is especially pertinent. Enzyme supplementation significantly lowered blood lactate levels after exercise, as compared to the placebo, after both the fourth (P=.001) and eighth (P<.001) exercise bouts and at 5 and 10 minutes after exercise (P=.003 and P=.002, respectively). This observation suggests a potential role of enzyme supplementation in enhancing lactate metabolism, either through its reduction or improved clearance during and after high-intensity exercise. The metabolism-enhancing attributes of fruit and vegetable enzymes, such as bromelain and papain, may facilitate this reduction in lactate accumulation [22,37]. Furthermore, their antioxidant and anti-inflammatory properties could lead to enhanced muscle function, thereby contributing to lower lactate production [38].

Exergaming, when integrated with HIIE, presents an innovative and engaging exercise modality, particularly for older adults. It has been established as an effective and enjoyable exercise option, capable of achieving intensities comparable to traditional exercise forms [16]. This study reinforces the feasibility of exergaming combined with HIIE as a viable strategy for older adults, achieving substantial exercise intensity as evidenced by elevated lactate levels. However, the study is not without limitations. The relatively small sample size and focus on a specific demographic and exercise protocol may restrict the broader applicability of the findings. Further research with larger, more diverse populations is necessary to validate and extend these preliminary results.

HR Response in Exergaming

Interestingly, although exergaming combined with HIIE effectively elevated physiological parameters such as HR and lactate levels, no significant difference in HR response was observed between the enzyme and placebo groups. This suggests that the subjective perception of effort might not accurately reflect the actual physiological demands of the exercise, echoing previous research [32,33]. In summary, this study illustrates that enzyme supplementation can potentially reduce blood lactate levels during and after high-intensity exercise in an older adult cohort engaged in HIIE combined with exergaming. These findings underscore the value of enzyme supplementation in enhancing metabolic responses and optimizing exercise outcomes. Future research should aim to unravel the underlying mechanisms and investigate the long-term impacts of enzyme supplementation across diverse populations. A deeper understanding of the interplay between nutritional supplementation, exercise modality, and physiological responses is crucial in tailoring effective interventions for optimal exercise performance and overall health promotion.

TRIMP Response in Exergaming

An additional focal point of our study was the evaluation of TRIMP in relation to enzyme supplementation during HIIE combined with exergaming. TRIMP is a quantifiable measure of training load, incorporating both objective and subjective elements of exercise intensity [32]. In our study, the analysis revealed no significant differences in TRIMP between the enzyme and placebo groups after supplementation. This outcome suggests that enzyme supplementation does not significantly alter the perceived intensity or exertion levels during HIIE with exergaming. This finding aligns with previous studies that have explored the multifaceted nature of TRIMP. For instance, research by Laursen and Jenkins [39] highlighted the complexity of accurately measuring training load, emphasizing the need to consider both physiological and psychological factors. The lack of significant difference in TRIMP in our study could be attributed to the stable physiological responses (HRs and lactate levels) observed across both groups. This observation is consistent with the work of Manzi et al [40], who noted the importance of physiological markers in determining training load, particularly in endurance sports.

Furthermore, the subjective component of TRIMP, which relates to athletes' perceived exertion, is a crucial aspect of training load assessment [35]. Our study's findings, where the subjective perception of effort did not significantly differ between the enzyme and placebo groups, resonate with the notion that perceived exertion is a complex interplay of physical and psychological factors [33]. This complexity might explain why enzyme supplementation, primarily impacting physiological responses, did not significantly alter the subjective experience of the training load. The implication of these results is substantial for designing exercise programs for older adults. As suggested by Bethancourt et al [41], understanding and managing training load is crucial in preventing overtraining and optimizing exercise benefits, especially in older adults. The lack of difference in TRIMP between the groups in our study indicates that enzyme supplementation, although beneficial in reducing lactate levels, does not necessarily impact the overall training load as perceived by the participants. This insight is vital for practitioners and researchers in tailoring exercise regimens that are both physiologically effective and psychologically manageable for older adults.

In conclusion, our study contributes to the growing body of knowledge on TRIMP and its applications in exercise science. Although enzyme supplementation shows promise in reducing lactate levels, its impact on the overall training load, as measured by TRIMP, appears to be minimal. Future research should continue to explore this area, considering both physiological and psychological aspects of exercise, to develop comprehensive training strategies for various populations, including older adults.

Conclusions

This study aimed to evaluate the impact of fruit and vegetable enzyme supplementation on aerobic capacity and blood lactate response in older adults participating in HIIE combined with exergaming. The results demonstrate that enzyme supplementation significantly reduced blood lactate levels after exercise compared to a placebo. This finding is indicative of the potential role of such supplementation in enhancing lactate metabolism during and after high-intensity exercise. Additionally, the integration of HIIE with exergaming has proven to be a novel and effective approach to exercise for older adults, achieving significant physiological intensities while maintaining engagement and enjoyment. However, enzyme supplementation did not exhibit a noticeable effect on HR response or the overall perceived training load, as measured by TRIMP. This suggests that although enzyme supplementation may influence specific physiological responses, such as lactate production and clearance, it does not significantly alter the overall perceived exertion or exercise experience for participants.

These findings contribute to the growing body of literature on the synergistic effects of nutritional supplementation and innovative exercise modalities such as exergaming in the older adult population. They highlight the potential of enzyme supplementation in optimizing exercise outcomes, particularly in reducing lactate accumulation, which is a crucial aspect of high-intensity exercise tolerance. Moreover, the study underscores the feasibility and effectiveness of exergaming combined with HIIE as a strategy to enhance physical activity levels in older adults. The study's implications extend beyond exercise physiology, offering practical insights for health practitioners, fitness professionals, and researchers in the development of targeted, effective, and enjoyable exercise interventions for older adults. Future research should aim to further elucidate the mechanisms behind enzyme supplementation's impact on exercise performance and explore the long-term effects of such interventions in a wider demographic.

In summary, this research supports the notion that carefully tailored nutritional and exercise interventions, such as enzyme supplementation combined with HIIE and exergaming, can significantly enhance exercise outcomes in older adults. These interventions hold promise for improving overall health and well-being in this demographic, contributing to the growing field of serious games and their application in health and fitness.

Acknowledgments

We thank all members of our research team for their contributions to this study and all participants for taking part in this study. Financial support was provided by the Taiwan Ministry of Education's 'Industry Academy Program' and a grant from the Tainan University of Technology. We also extend our gratitude to Taiwan Enzyme Village Co., Ltd. for participating in the industry-academia collaboration, which facilitated the successful completion of the experiment.

Authors' Contributions

SCL carried out the laboratory experiments, analyzed the data, interpreted the results, prepared figures and tables, and prepared the manuscript. CYW, THH, CCW, and HCC assisted in the data collection and the discussion of the literature. CCW designed the study, supervised the experimental procedure, and reviewed the entire preparation of the manuscript.

Conflicts of Interest

None declared.

Editorial Notice

This randomized study was only retrospectively registered. It was not prospectively registered as the authors considered it to be a feasibility study. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials, because the risk of bias appears low and the study was considered formative. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: One of the main contemporary forms of physical activity (PA) involves exercises and games in an immersive virtual reality (VR) environment, which allows the user to practice various forms of PA in a small space. Unfortunately, most of the currently available VR games and workout applications are mostly based on upper body movements, especially the arms, which do not guarantee sufficiently high exercise intensity and health benefits. Therefore, it is worth seeking solutions to help increase the exercise load during PA in VR.

Objective: The main aim of this study was to evaluate the effect of elastic arm resistance in the form of latex resistance bands of different elasticity levels on the intensity of students' PA while playing the BoxVR game. We further assessed the satisfaction of this form of exercise and its associations with PA intensity.

Methods: A total of 21 healthy and physically fit men (mean age 22.5, SD 2.0 years) were included in the study. The tests consisted of 3 10-minute games. One game was run with no load and the other two were run with 1.5-meter latex resistance bands (low and high resistance). The order of the tests was randomized and the participants rested for 20 minutes after each exercise. Exercise intensity was estimated using objective (heart rate monitoring) and subjective (Borg scale) methods. The Physical Activity Enjoyment Scale was used to assess satisfaction with the PA. The effect of elastic resistance on exercise intensity and user enjoyment was estimated using ANOVA for repeated measures.

Results: The ANOVA results indicated that incorporation of elastic resistance caused a significant change ($F_{2,40}$=20.235, P<.001; $\eta^2 p$=0.503) in the intensity of PA in VR, which was low while playing without resistance and then increased to a moderate level with additional resistance. The use of elastic bands also changed participants' perceptions of the enjoyment of exercise in VR ($F_{2,40}$=9.259, P<.001; $\eta^2 p$=0.316). The students rated their satisfaction with PA in VR on a 7-point scale highly and similarly when exercising without an upper limb load (mean 6.19, SD 0.61) and with slight elastic resistance (mean 6.17, SD 0.66), whereas their satisfaction declined significantly (mean 5.66, SD 0.94) when incorporating a higher load.

Conclusions: The intensity of PA among students playing the BoxVR game is at a relatively low level. With the added resistance of elastic bands attached to the upper limbs, the intensity of the exercise increased to a moderate level, as recommended for obtaining health benefits. Participants rated the enjoyment of PA in VR highly. The use of slight elastic resistance did not negatively affect satisfaction with the BoxVR game, although user satisfaction declined with a higher load. Further research should be undertaken to increase the effectiveness of exercise in VR so that regular users can enjoy the health benefits.

Introduction

The past few years have seen a rapid development of technologies related to immersive virtual reality (VR). With immersive VR, the user is cut off from the visual and auditory stimuli of the surrounding reality and instead receives artificially produced images, sounds, and even tactile sensations using information technology, which is finding increasing applications in various areas of human life. In particular, VR is increasingly used for physical activity (PA) and in the development and diagnosis of physical fitness parameters. VR applications are being developed to shape and assess motor skills [1-5], research on motion analysis in VR is now actively carried out [6,7], and active virtual reality games (AVRGs) are becoming increasingly popular [8]. Feedback from users indicates the attractiveness of AVRGs, making them competitive with conventional forms of PA [9-11]. Some reports have also shown that VR can offer greater flow for PA than a similar form of exercise in the real world [12]. The great potential of AVRGs is also linked to the fact that these types of applications enable practicing different forms of exercise in a small space at home. However, one of the main limitations of VR technology in the context of its use for PA is that most of the exercises performed in the virtual environment are primarily based on movements of the upper body as the sensors placed in the VR headsets allow for tracking movements of the head and possibly the torso, while the movement sensors located in the controllers allow for tracking arm movements. Although some trainers currently work with VR headsets, such as virtual treadmills, flight simulators, and cycle ergometers, these are relatively expensive and take up space in living areas. Since PA performed in VR is mainly based on upper limb movements, there is a concern that this type of exercise may be characterized by relatively low intensity. Consequently, physical efforts practiced in a virtual environment may not be effective in terms of potential health benefits. According to World Health Organization (WHO) recommendations, PA should be characterized by moderate to high intensity to obtain health benefits [13]. Therefore, solutions should be sought to increase the body's workload when practicing PA in VR.

The first related studies are already being carried out. One of the proposals to increase the intensity of physical exercise in VR is to use an additional load in the form of handheld weights (HHWs). Based on the experiments carried out to date, this type of solution can be effective [10]. An alternative solution to Velcro-fastened weights could be elastic resistance in the form of rubber bands attached to the distal parts of the upper limbs. Indeed, resistance bands have been widely used in fitness classes and various sports to improve the effectiveness of training [14-17]. Such a solution may be used provided there is effective stretching of the elastic bands during arm movements in VR. Applications that meet this condition include the popular AVRGs based on boxing techniques. With appropriately fastened straps, boxing movements can be performed with elastic resistance, which should potentially increase the intensity of this type of PA. However, the specific amount of resistance that should be applied to increase the effectiveness of the exercise while not causing discomfort due to the excessive load remains unclear, as this could negatively affect the attractiveness of PA perceived by users.

Therefore, the main aim of this study was to evaluate the effect of elastic resistance in the form of latex resistance bands with different elastic properties on exercise intensity in young and physically fit adults while playing the popular AVRG game BoxVR [18]. The results obtained were related to the WHO health recommendations for PA. This study further assessed the attractiveness of such a form of exercise and the relationships between the use of elastic resistance and user satisfaction. It was hypothesized that the use of resistance bands would significantly increase the participants' exercise intensity and would not significantly affect their assessment of satisfaction with playing the AVRG.

Methods

Participants

The study involved 21 healthy and physically fit men studying at the Academy of Physical Education in Katowice, Poland (mean age 22.5, SD 2.0 years; mean body height 181.6, SD 7.3 centimeters; mean body weight 79.5, SD 11.0 kilograms). People with motion sickness, sensitivity to flashing lights, epileptic seizures, and balance disorders were excluded from the study. The research was carried out at the Jerzy Kukuczka Academy of Physical Education in Katowice, Poland, at a certified Laboratory of Research on Pro-Health Physical Activity (PN-EN ISO 9001:2015, certificate validity: 7.12.2021 - 16.12.2024).

Ethical Considerations

The study was conducted according to the guidelines of the Declaration of Helsinki, and was reviewed and approved by the Research Ethics Committee of the Jerzy Kukuczka Academy of Physical Education in Katowice (protocols: 9/2018; KB/27/2022). All participants took part in the study voluntarily and could discontinue their participation at any time. All participants were familiarized in detail with the purpose of the study, safety rules, the use of the VR equipment, and the course of the study. In addition, a written informed consent form was provided to all eligible study participants. The test results were secured in accordance with the security procedures in force at the Laboratory of Research on Pro-Health Physical Activity.

Research Tools and Procedures

An HTC Vive (HTC Corporation, New Taipei, Taiwan) kit was used for immersive VR, consisting of a headset, two base stations, two controllers, and a computer. The HTC Vive set is one of the popular VR systems on the market, which is characterized by high visual quality and allows for realistic VR experiences. This system was selected for this research since the motion-tracking system in HTC Vive is very precise and accurate, which allows the user to move smoothly and naturally in the virtual environment. Owing to a set of sensors and controllers, users can freely explore the virtual world. The BoxVR application was used with several training programs of varying difficulty. These programs involve boxing routines combined with music, reminiscent of shadow boxing. The game is based on basic boxing punches (ie, straight, hook, and undercut), which are performed on virtual objects coming from the depths of the room to the rhythm of the music in various combinations. There are also shapes the user has to avoid or block. The user hits targets with their hands, which they perceive in the virtual environment as boxing gloves in two colors: blue (left hand) and pink (right hand). An illustration of the playing environment is provided in Figure 1. To obtain a high score in the game, the user has to execute the punches correctly and hit the targets moving toward them that correspond to the appropriate glove color. The user scores points for every correct response. In the case of a series of several or more accurate hits, the score is further multiplied by an appropriate multiplier.

Information on the number of points scored and the duration of the game is displayed on virtual screens in front of the user.

The systsem has a panel that allows the user to select game modes with different durations, levels of difficulty, and nature of exercise. For the purposes of the study, mode “seventeen” was selected lasting 10 minutes, set at medium difficulty and with the no squat option. This mode was considered to be optimal for physically fit young adults. The squat option was disabled because the aim of the study was to assess the impact of the elastic resistance of the arms on the intensity of physical exercise; therefore, additional lower limb exercises would be a factor that could complicate the interpretation of the study results. It should be noted that many active video games (AVGs) are based solely on arm and torso movements. Before the study, participants were familiarized with the use of the application and took part in a short (2-minute) no-load trial.

The tests consisted of 3 10-minute games. One game was run with no load and the other two were run with 1.5-meter latex resistance bands, including green (low resistance) and silver (high resistance) bands. The elasticity characteristics of the resistance bands provided by the manufacturer (Thera-Band) are presented in Table 1. The bands were attached to the ground on one side and to tactical gloves (M-Tac) on the other. When starting the exercise with the bands, users held their hands in a guard position and were positioned at an appropriate distance from the point of attachment ensuring that the bands were taut but not stretched. When the punches were performed, the bands stretched, causing resistance (Figure 2). The order of the tests was randomized, and the participant rested for 20 minutes after each exercise before starting the next game.

While playing the VR game, participants’ heart rates were monitored using a Vantage V heart rate monitor (Polar Electro Oy, Kempele, Finland) coupled with a chest strap (Polar H10). Based on the average exercise heart rate (HR_{ave}), the PA intensity was estimated as the average percentage of maximum heart rate (% HR_{max}). The HR_{max} value was first estimated from the formula 208 – 0.7 × age (years) [19]. The results obtained were compared to the PA intensity standards recommended by the American College of Sports Medicine [20]. According to this classification, it is assumed that during low-intensity exercises, HR_{ave}<64% of HR_{max}, high-intensity PA occurs when HR_{ave}≥77% of HR_{max}, and moderate exercise is defined in the condition of HR_{ave}≥64% of HR_{max} with less than 77% of HR_{max}. Furthermore, the average absolute duration of PA (in seconds) was estimated for the following exercise intensity zones: 0, less than 50% HR_{max}; 1, 50% - 59% HR_{max}; 2, 60% - 69% HR_{max}; 3, 70% - 79% HR_{max}; 4, 80% - 89% HR_{max}; and 5, ≥90% HR_{max}. These intensity zones were selected because they are used to report the results in the software of the heart rate monitor (Vantage V) used in the study.

At the end of each test, the participants also self-assessed their perceived exertion using the Borg Rating of Perceived Exertion (RPE), which ranges from 6 to 20 [21,22]. According to this scale, a score of 10-11 indicates low-intensity exercise, a score of 12-13 indicates moderate-intensity exercise, and a score of 14 - 16 indicates high-intensity exercise [23]. The RPE scores were compared with the objective measurements to determine the correlation of PA intensity with the subjective perceptions of the participants.

Subsequently, the participants assessed their satisfaction with PA in VR using the long version of the Physical Activity Enjoyment Scale (PACES), consisting of 18 items [24], which were answered after each test on a 7-point Likert scale. The average calculated from all responses was used for analysis.

Figure 1. Screenshot showing a view of the BoxVR game environment from the user's perspective.

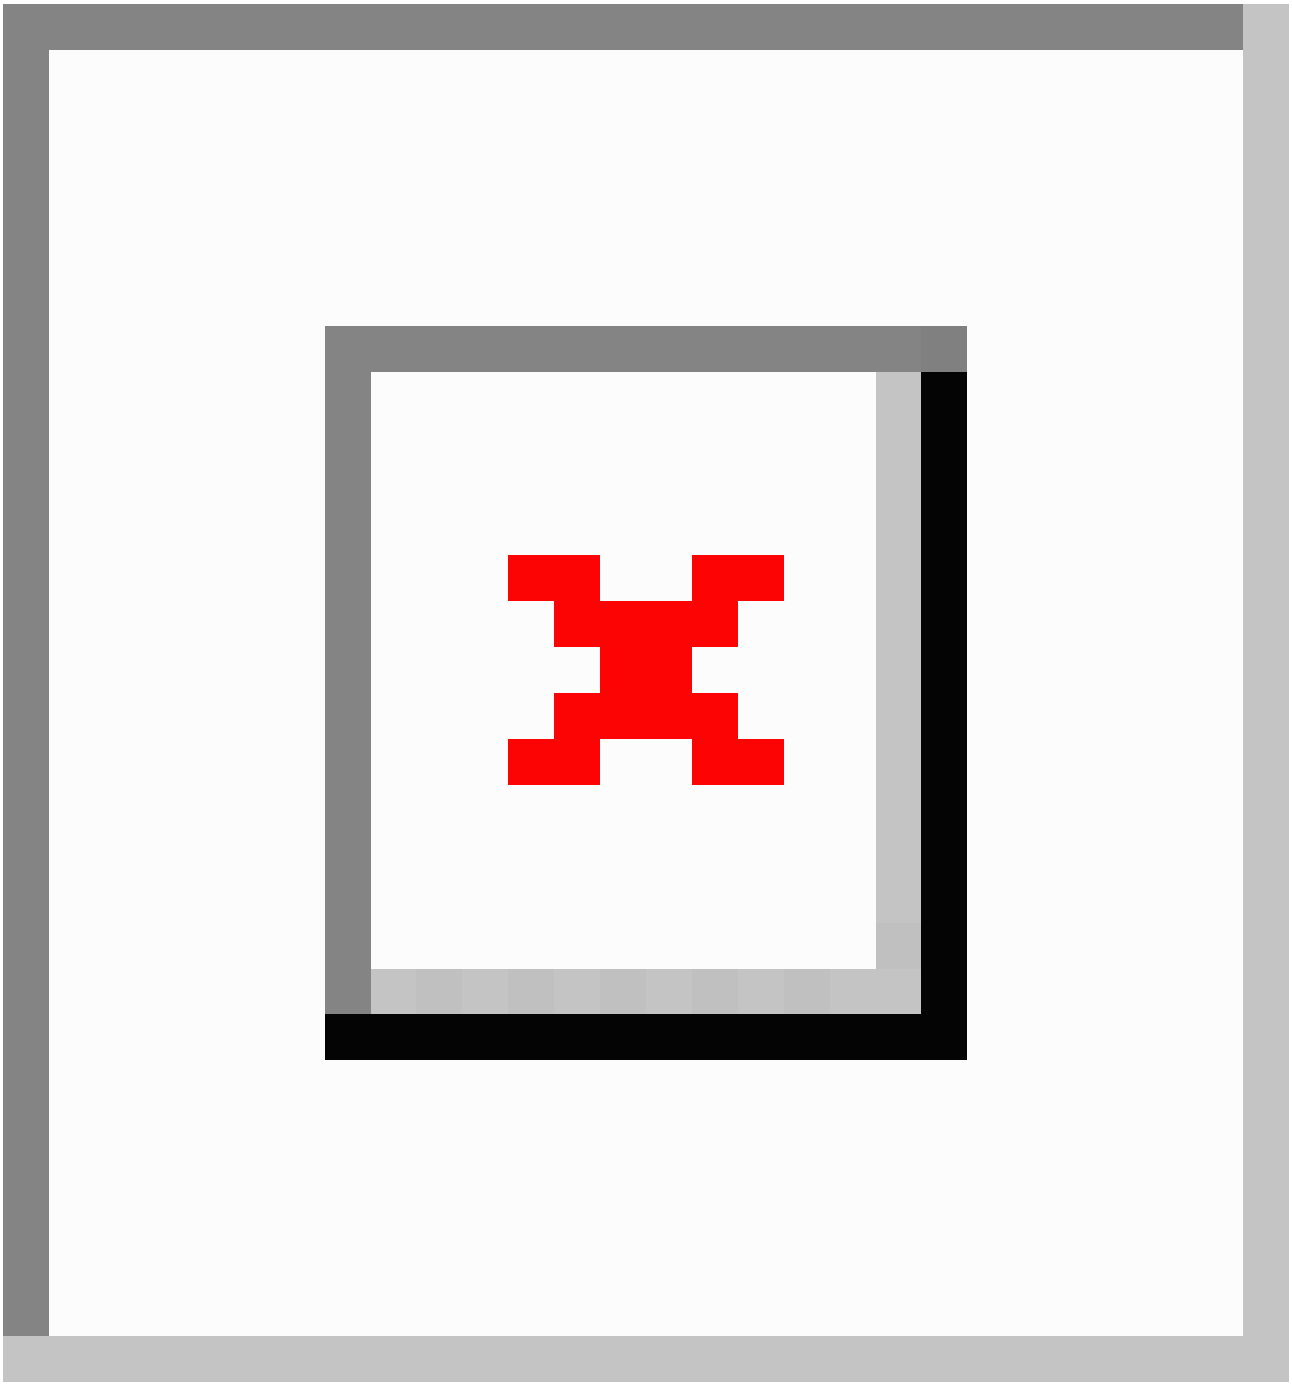

Table . Specifications of the elastic bands (Thera-Band) used during testing.

Stretch, %	Resistance, kilograms	
	Green band	Silver band
25	0.9	2.3
50	1.5	3.9
75	1.9	5.0
100	2.3	6.0
125	2.6	6.9
150	3.0	7.8
175	3.3	8.6
200	3.6	9.5
225	4.0	10.5
250	4.4	11.5

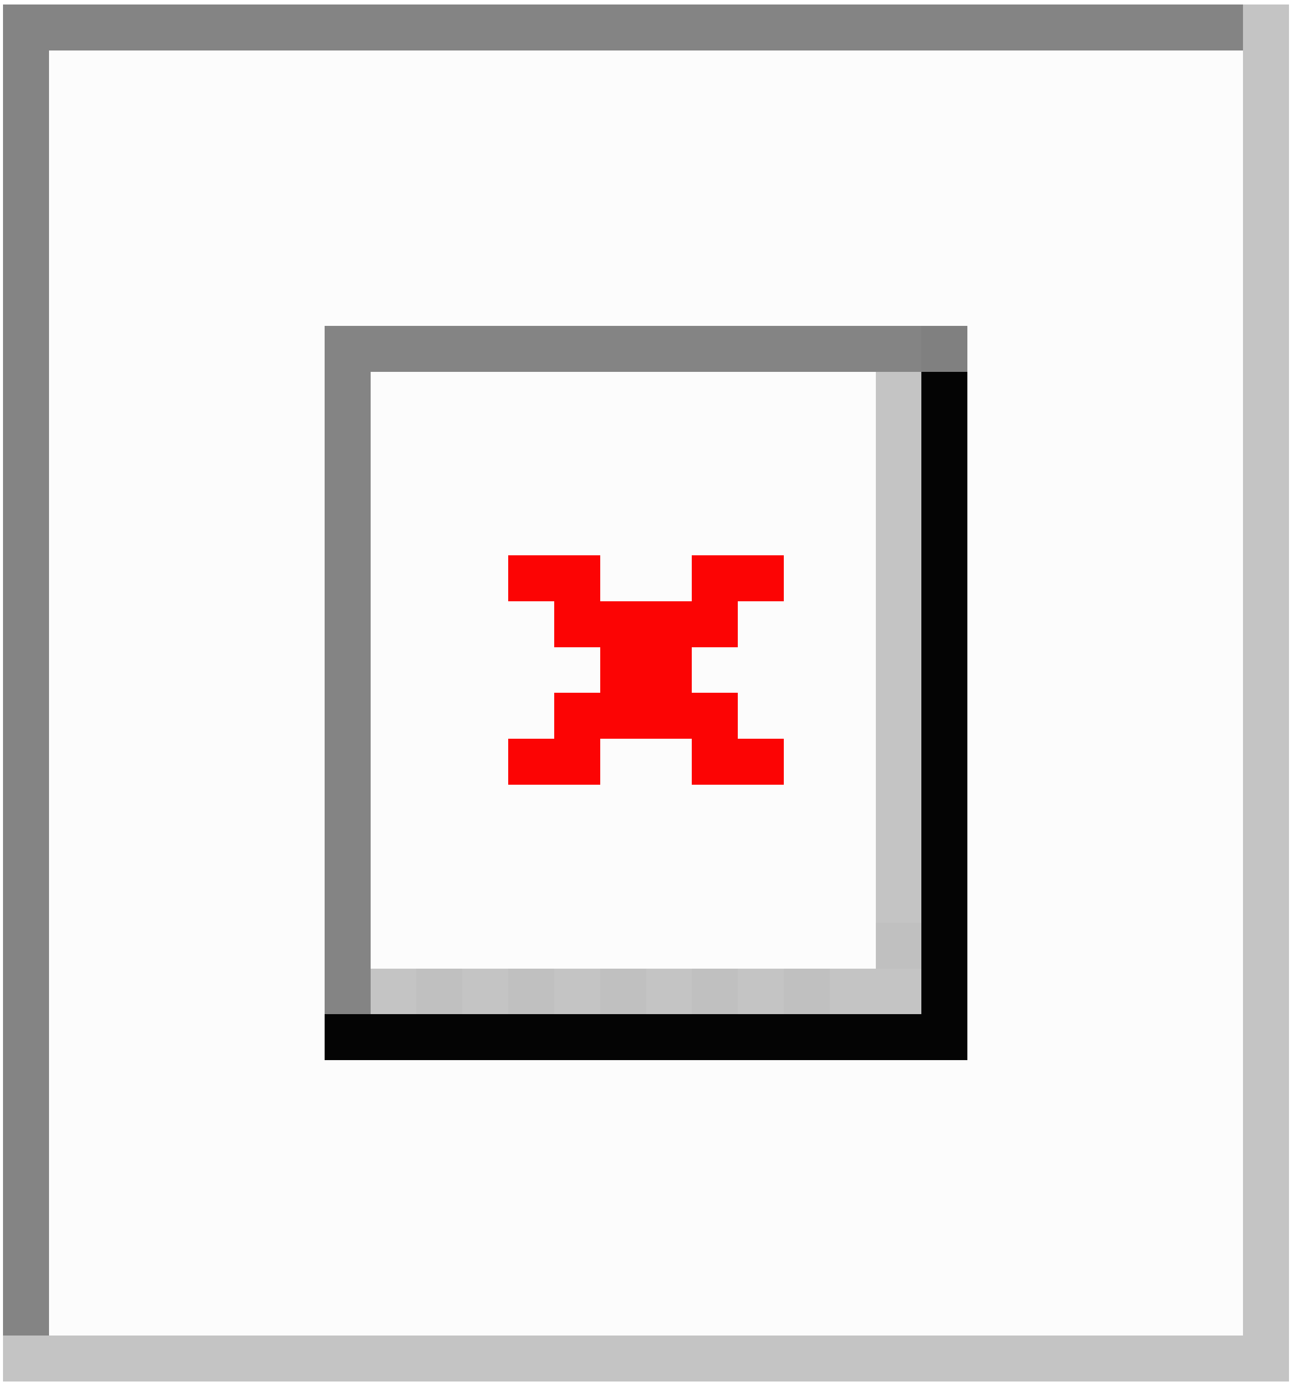

Figure 2. A participant during a resistance exercise with the green band.

Statistical Analysis

Basic descriptive statistics (arithmetic means and SDs) were calculated. The Shapiro-Wilk test was used to assess whether the data followed a normal distribution, whereas sphericity was assessed using the Mauchley test. The effect of elastic resistance on exercise intensity was estimated using ANOVA for repeated measures or Friedman ANOVA, depending on the distribution of the data. The repeated-measures ANOVA was supplemented with Tukey posthoc tests, whereas Friedman ANOVA was followed by the Dunn posthoc test. The level of statistical significance was set at α=.05. The effect size was estimated using η^2p or the Kendall coefficient (*W*). The Spearman rank correlation coefficient (r_S) was used as a measure of the relationship between objective and subjective intensity measures. Statistical analyses were performed using Statistica v.13 (TIBCO Software Inc) and Jamovi v. 2.2.3.0 software.

Results

Exercise Intensity in VR Without Upper Limb Loading and With Elastic Resistance

Repeated-measures ANOVA showed that elastic resistance significantly affected the participants' heart rate ($F_{2,40}$=20.151, *P*<.001; η^2p=0.503). When playing without external resistance, the heart rate was the lowest, with a mean of 117.33 (SD 21.21) beats per minute (bpm). The heart rate increased to a mean of 124.43 (SD 20.62) bpm during play with the green elastic band

and increased further to a mean of 134.90 (SD 20.33) bpm during exercise with the silver band. Posthoc tests showed statistically significant differences between the results of all measurements taken according to the level of resistance applied (Figure 3).

Elastic resistance also resulted in a significant change ($F_{2,40}$=20.235, P<.001; η²p=0.503) in exercise intensity as expressed by the mean %HR_{max}. While playing without resistance, the intensity of physical effort was low, with a mean %HR_{max} of 61.27% (SD 11.21%). With elastic resistance, physical effort (%HR_{max}) increased to a moderate level, as recommended for health benefits, for both the green (mean 64.97%, SD 10.86%) and silver (mean 70.43%, SD 10.68%) bands. Posthoc tests revealed statistically significant differences between the results of all tests according to varying levels of resistance (Figure 4).

Under conditions of no external load, the participants' heart rates lasted the longest in zone 1 (50% - 59% of HR_{max}), whereas in both cases of exercise with elastic bands, the heart rates remained in zone 2 (60% - 69% of HR_{max}). The Friedman ANOVA showed significant variation in results for zones: 0 (χ^2_2=14.711, P<.001; W=0.350), 3 (χ^2_2=8.954, P=.01; W=0.213), and 5 (χ^2_2=9.333, P=.009; W=0.222). No significant effect of arm loading on PA intensity was found for the other zones: 1 (χ^2_2=3.610; P=.17; W=0.086), 2 (χ^2_2=2.913; P=.33; W=0.052), and 4 (χ^2_2=3.360; P=.19; W=0.080) (Figure 5).

We further analyzed the exertion perceived by the users after each test based on the RPE scale (6-20). Friedman ANOVA demonstrated that elastic resistance loading significantly (χ^2_2=36.861, P<.001; W=0.878) altered users' perceptions of exertion. The lowest fatigue was declared by those exercising without additional load. The exercise intensity in this case was rated a mean of 11.19 (SD 2.54) points. In contrast, significantly more exertion was reported for PA with elastic resistance. The mean scores for the intensity of exercise were 13.67 (SD 2.15) for the green band and 16.62 (SD 1.72) for the silver band. Posthoc tests for the pairwise comparisons of the results revealed statistically significant differences (Figure 6).

Spearman correlation analysis between subjective and objective measures of exercise intensity showed a statistically significant positive relationship between intensity evaluated based on %HR_{max} and the Borg RPE scale (6-20) for PA in VR without load (r_S=0.504, P=.02) and with green elastic band resistance (r_S=0.45, P=.04). No significant correlation was found for physical exercise with the silver band (r_S=0.356, P=.11).

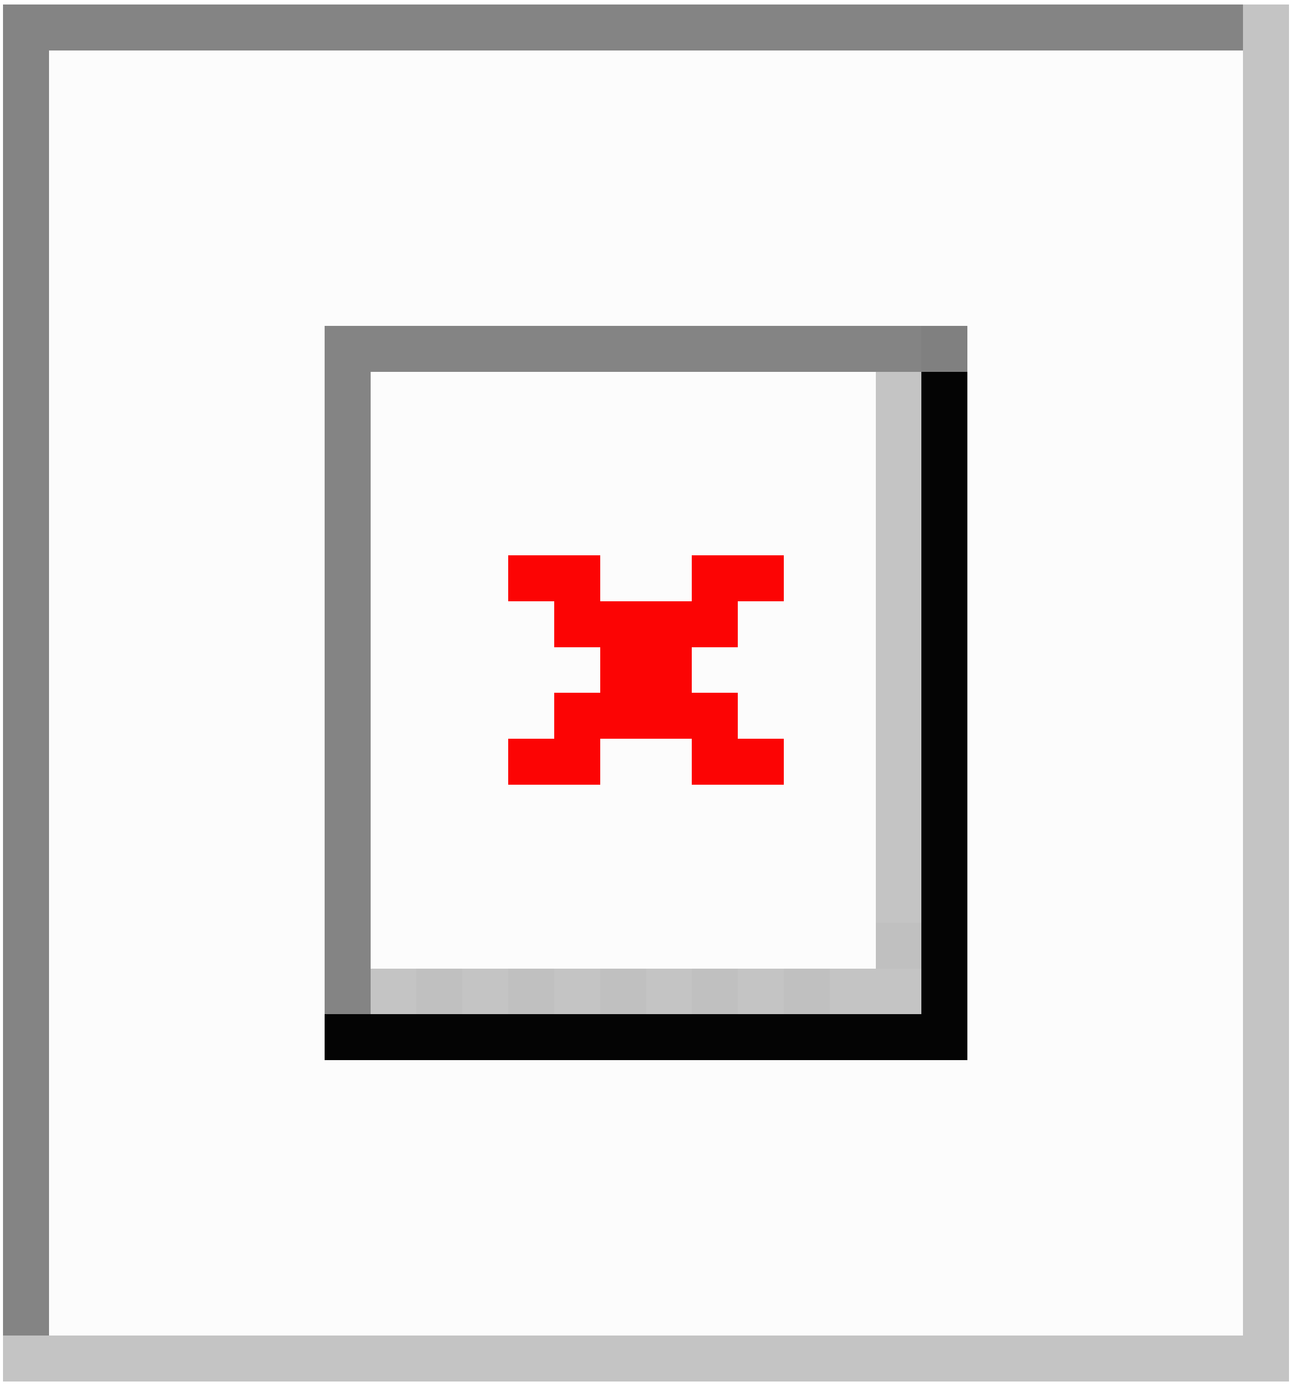

Figure 5. Average time spent in different heart rate zones by participants depending on upper limb load while playing BoxVR; HR_{max}: maximum heart rate.

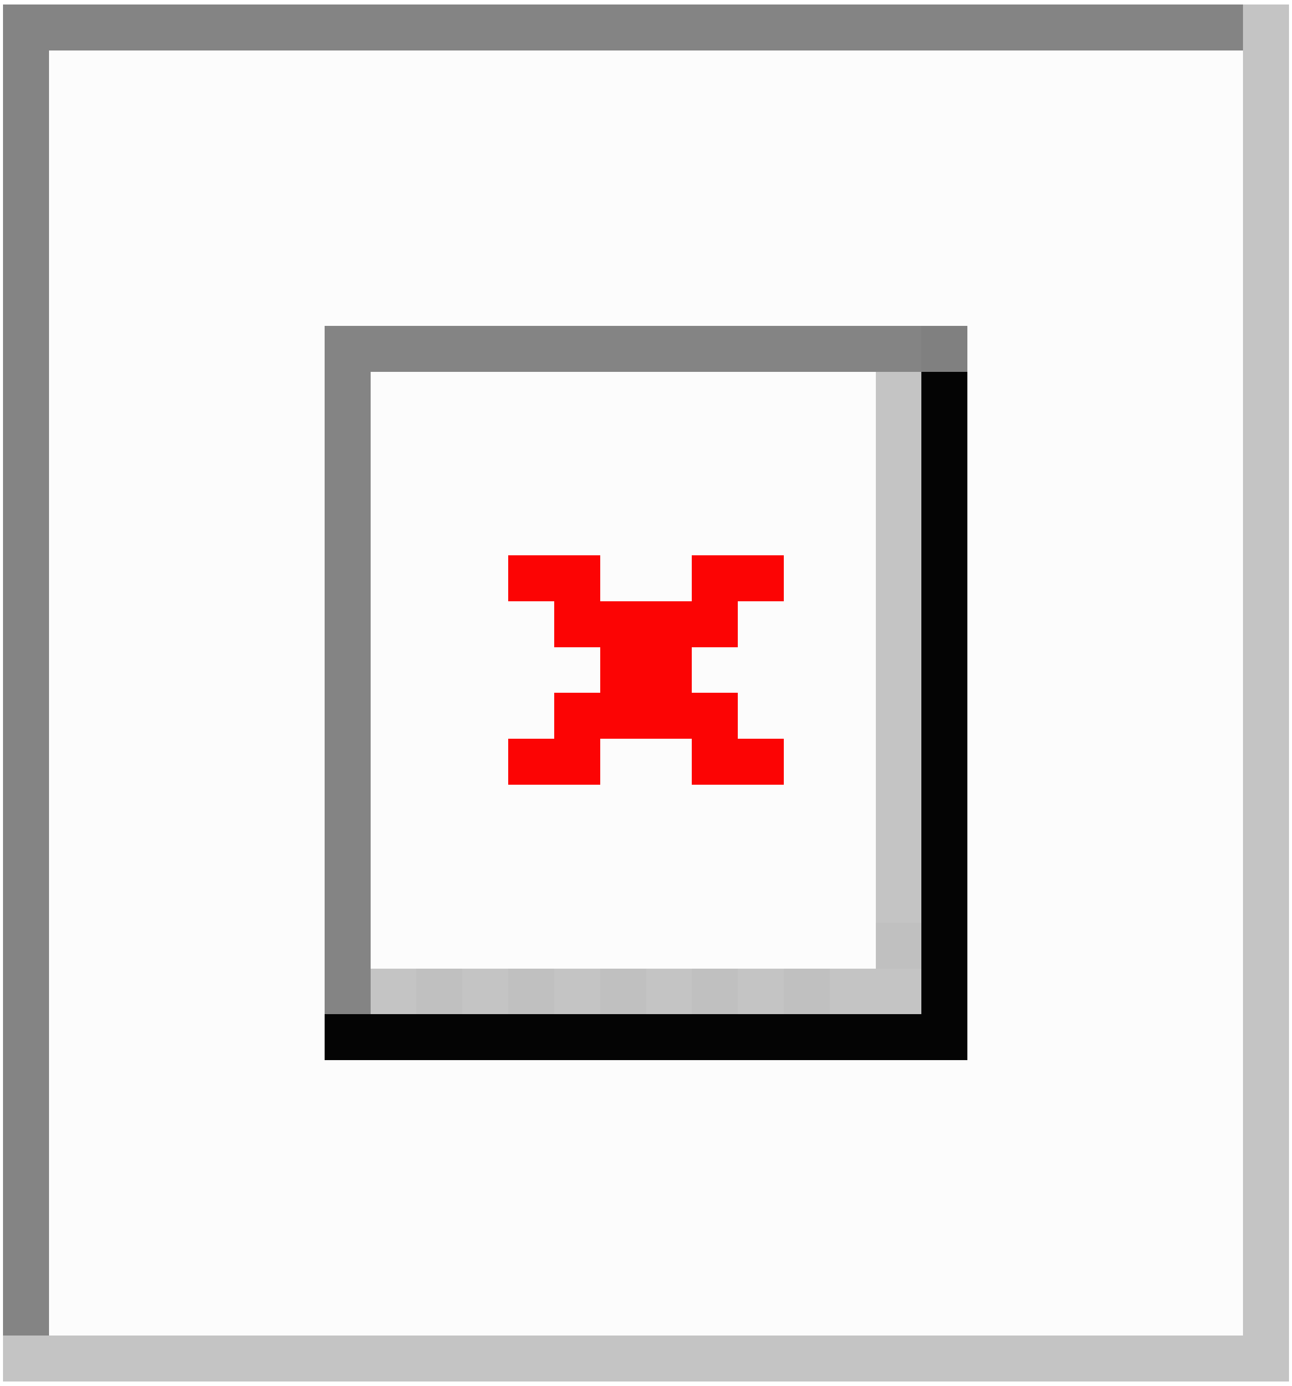

Figure 6. Rating of Perceived Exertion (RPE) scale versus upper limb load while playing BoxVR.

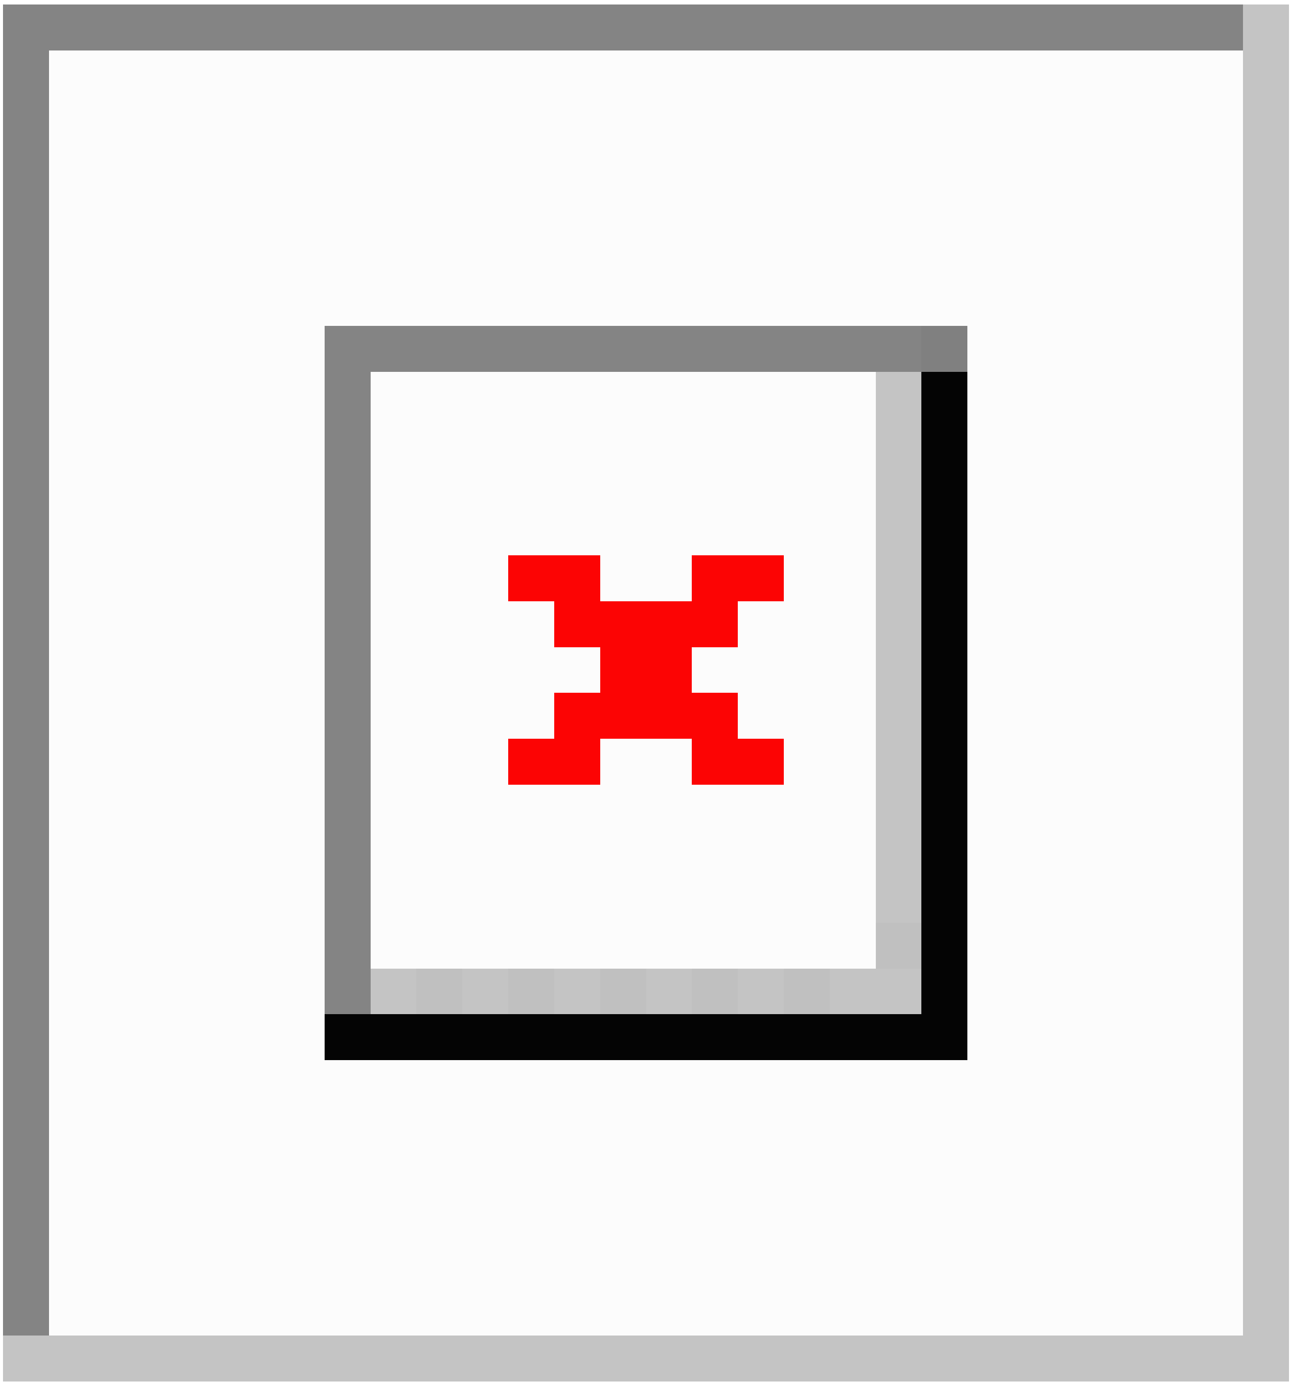

Satisfaction of Study Participants With Exercise in VR

The ANOVA of the PACES questionnaire results showed that additional elastic resistance significantly ($F_{2,40}$=9.259, P<.001; η^2p=0.316) influenced participants' perceptions of the attractiveness of exercise in VR. Study participants rated their satisfaction with PA in VR very similarly and highly for exercise without an upper limb load (mean 6.19, SD 0.61 points) and with elastic resistance in the form of a green band (mean 6.17, SD 0.66 points). The differences between these scores were minimal and statistically insignificant. Study participants were by far the least satisfied with PA in VR with the silver band (mean 5.66, SD 0.94 points). Therefore, statistically significant differences were found between the results of the assessment of exercises without additional resistance and with the silver band (P<.001) and between the assessment of exercises with the green and silver bands *(P*=.002) (Figure 7).

Discussion

Principal Findings

This study found that the use of elastic bands while playing the AVRG BoxVR had a significant effect on exercise intensity, as shown by objective measurements and manifested by an increase in the heart rate. Furthermore, PA accompanying boxing exercises in VR, which was classified as low-intensity exercise, became moderately intense with additional resistance, and therefore became an exercise program that is considered beneficial for health according to WHO recommendations [13]. The heart rates remained in the high zones for a longer period of time during the resistance band exercises. Therefore, this type of shoulder loading during PA in VR appears to be an effective solution for increasing the intensity of physical exercise based on arm work.

The method presented in our study to increase PA intensity in VR by using resistance bands represents a novel solution. To date, weights attached to the distal part of the limbs have been used for this purpose. A recent study showed that the use of 0.5-kilogram Velcro-fastened HHWs placed on the wrists increased the intensity of PA in VR [10]. The authors found that under such upper limb loading, the PA intensity while playing the popular AVRG Beat Saber increased from low to moderate, thus becoming a healthy exercise. Similar studies were carried out using 2-kilogram ankle weights while playing an AVRG based on locomotor movements and practiced on an Omni omnidirectional treadmill (Virtuix) [11]. In this case, the additional load on the lower limbs was found to significantly increase physical exertion during virtual active entertainment. Recently, manufacturers of VR accessories have begun to view additional limb loading as a way to improve the effectiveness of exercise in a virtual environment. More recently, special controller overlays in the form of small discs have been offered for sale for users of the Oculus Quest 2 headset, which, when placed on the controllers, cause an increase in their weight to increase the intensity of exercise while using the application. As the use of resistance bands promotes increased PA intensity in arm-based VR, the use of elastic resistance offers an alternative to HHW or controller-mounted weights. However, there is currently a lack of such dedicated solutions for VR users.

The effect of elastic arm resistance on the intensity of physical exertion of users while playing BoxVR was also evidenced by the participant-reported RPE scores, which increased significantly after the use of elastic bands. Comparison of RPE reported by the participants with the objective classification of PA intensity [23] revealed that the students rated the PA without external loading as light and that with the green elastic band as moderate, which was similar to the objective assessment based on the heart rate monitor. In contrast, physical exercise performed with the silver band was rated as vigorous by the participants, indicating that the students overestimated its intensity in relation to objective measurements. This overestimation may be confirmed by the correlation analysis between subjective and objective measures of exercise intensity, showing a statistically significant relationship between RPE and $\%HR_{max}$ for PA in VR without a load and with the green elastic band resistance, while no significant relationship was found for exercise with the silver band. The exaggerated level of the subjective rating of PA during exercise in VR is somewhat puzzling, as previous studies have demonstrated that being in a VR environment reduces the intensity of perception of various stimuli (eg, pain) because VR, by stimulating different senses, distracts the immersed person from the problem [25-28]. During exercise in VR, this phenomenon, known as cognitive distraction, can alleviate the discomfort associated with hard training. The few studies on this topic published to date suggest that VR may be useful in distracting from unpleasant bodily sensations occurring during aerobic PA in children with overweight and obesity [9] and in reducing negative sensations associated with the performance of isometric exercises [29].

According to the PACES survey, study participants highly rated their satisfaction with PA in a virtual environment while playing BoxVR. Scores exceeded 6 on a 7-point scale for two measurements. Although the ANOVA of the PACES questionnaire results revealed that additional elastic resistance significantly affects the participants' perceptions of the attractiveness of exercise in VR, study participants rated their satisfaction with PA in VR very similarly for exercise without upper limb loading and with green resistance bands; the differences found were minimal and statistically insignificant. This may indicate that the low external load on the arms does not bother users and does not cause discomfort that could reduce the enjoyment of the exercises performed in VR. This was also confirmed by the aforementioned studies using a 0.5-kilogram HHW and a 2-kilogram ankle weight [10,11]. However, our results suggest that as the elastic external load on the arms increases, there may be a reduction in user satisfaction with PA in VR. Participants in this study were the least satisfied with playing BoxVR while having to overcome the resistance of the silver band, although a score of 5.66 still seems to be relatively high. The attractiveness of PA in VR has also been assessed in other contexts [10-12,30-36], and most of these studies have indicated a high level of user satisfaction with such exercises. Because those studies assessed other forms of PA or the attractiveness of physical exercise was measured with different tools, it is difficult to compare their results with those obtained in our study. Due to the rapid development of AVRGs and training applications used in a virtual environment, further research is warranted to identify the determinants of satisfaction of people participating in PA in VR. This will help guide the further development of this new form of exercise. Notably, satisfaction is an important motivation for undertaking regular healthy PA, and how people feel when they exercise determines their future training engagement [37]. Therefore, identifying user preferences for different forms of PA in VR can increase the likelihood of the regular active use of modern technology, which should translate into health benefits.

Limitations and Prospects

Despite these promising results, the solution we have presented has some limitations. Namely, for the user to perform the exercise with the resistance band attached to the ground, they must be looking forward and cannot move freely. Consequently, the use of such a solution is only possible for certain AVRGs. However, there is a way to address this limitation. There are wearable resistance band (WRB) systems (eg, WearBands or MASS Suit), using specially designed belts, socks, gloves, and other items of clothing to anchor elastic resistance bands connecting two or more body segments. WRB training is a new entry to the field of resistance training. With WRBs, the exerciser can move freely while performing movements with elastic resistance [38]. Despite the lack of research on exercise with WRB, it appears that this type of training system may be useful for increasing the intensity and effectiveness of exercise in VR. Testing this assumption may provide objectives for further empirical research. Currently, elastic resistance is being used in AVGs in nonimmersive VR. An example is the original pointing device created by Nintendo called Ring Fit, which works with the Ring Fit Adventure app. This is an elastic ring that can be squeezed, stretched, and moved in space, which enable controlling the movements of the virtual avatar. The few studies conducted to date have shown that Ring Fit exercises have a beneficial effect on students' physical fitness [39], reduce lower back pain in adults [40], improve balance in older people [41], and may be a useful form of PA for children with overweight and obesity by increasing their daily energy expenditure [42].

Conclusions

The intensity of PA among students playing the BoxVR game is at a relatively low level. With the added resistance of elastic bands attached to the upper limbs of the participants, the intensity of the exercise increased to a moderate level, as recommended for obtaining health benefits. Participants in this study highly rated the attractiveness of PA in VR. The use of slight elastic resistance did not negatively affect the satisfaction of study participants with the BoxVR game, although the satisfaction declined with a higher load.

Due to the rapid development of VR, the great popularity of games and training programs in a virtual environment, and their attractiveness to users, it is expected that more and more people will enjoy active entertainment in VR. Therefore, research should be undertaken to assess user preferences and seek solutions to increase the usefulness and effectiveness of this newly developed form of PA so that regular users can improve their physical fitness and reap the health benefits. Our study may provide guidance to VR equipment manufacturers on how to make exercise more effective while playing AVRGs based on upper limb movements. However, the validity of the considerations outlined above should be confirmed in further research using applications that allow various forms of PA to be practiced in an immersive VR environment.

Abstract

Background: Currently, the fusion of technology and sports is inevitable. The integration of various systems and devices has brought about significant transformations in established sports practices, impacting not only the rules but also physiological, biomechanical, and even psychological aspects.

Objective: The purpose of this study was to analyze the effect of an attention intervention through a video game on young soccer players.

Methods: Twelve young male soccer players (age: mean 8.5, SD 1 years) were divided into 2 groups: a control group (CG; n=10) and an experimental group (EG; n=10). During the 6-week training program, the EG received attention training through a video game twice a week for 15 minutes per session. Pre- and postintervention measurements included a specific decision-making soccer test and interviews with coaching staff. Additionally, success in the video game, muscular activity, and sweat levels were monitored.

Results: The EG demonstrated a significant improvement in video game success following the intervention program, as indicated by the achieved level (*P*<.001). However, no significant differences were found between groups regarding electromyographic (EMG) activity (*P*=.21) and sweating (*P*=.20). Prior to implementing the attention training program, both groups exhibited similar data for variables related to decision-making and execution mechanisms (≤10%). Only 2 decision-making variables exceeded 10% but remained below 15% (Shot_D=13.35%; Marking_with_Ball_D=−12.64%). Furthermore, changes in attacking action variables were more pronounced in execution-related variables, except for dribbling and fixing. Conversely, in defensive action variables, changes were greater in decision-related variables, except for marking with the ball and marking without the ball.

Conclusions: Our findings reveal that incorporating a specific attentional video game into a soccer training program enhances decision-making compared to a program without the video game. Therefore, it is advisable for practitioners to consider using this tool due to its high efficiency in terms of economic and temporal costs, particularly in improving a key psychological variable.

Introduction

Currently, technology use is inseparable from sports. The integration of various systems and devices has brought about significant transformations in established sports practices, impacting not only the rules but also physiological, biomechanical, and even psychological aspects. This revolution is particularly evident in soccer, where the implementation of technology has primarily concentrated on the professional sphere. From a physiological perspective, technology has facilitated notable advancements in the understanding and control of physical demands during elite soccer matches. Tools such as the GPS [1,2], accelerometry, and specialized match analysis programs [2] have made it possible for coaches to design training tasks on the basis of data obtained from actual games. Optical tracking systems and GPS devices were compared in professional soccer, revealing no significant differences in analyzed variables such as total distance, distance per minute, average speed, and maximum speed [3]. However, limitations were identified, such as the ineffectiveness of the GPS in indoor sports and the inability of optical tracking systems to access internal variables. Nevertheless, researchers concluded that both technologies were suitable for monitoring the physiological demands of soccer players [3].

Technological applications in soccer have also shed light on performance mechanisms in areas such as jumping [4] and the minimization of lower limb injuries [5]. Usually, these technologies rely on 3D movement analysis, muscle activation assessment, and force production evaluation. Nonetheless, the high economic cost and specialized expertise required for their use pose significant challenges, making it difficult to implement them in the daily lives of athletes. Another way to harness the use of technology with a better cost-benefit relationship is through the use of video games; in particular, those with a clear aim to improve performance and learning, known as serious games [6]. Games have been used to introduce challenging concepts or develop skills in different areas such as surgery [7] and rehabilitation [8] or to enhance team coordination via cooperative training—the latter being called “small side games” [9,10]. All manner of play seeks to achieve improvements in skill acquisition in a more attractive way over and above traditional forms [11,12]; in particular, among pediatric populations with special attention and motivation characteristics [13,14]. Playful forms of intervention have improved affective responses in children compared to traditional teaching methodologies [15], having achieved benefits with the use of video games that optimize performance in variables as attention and executive control [16] and other psychological variables [17]. Serious games are emerging as valuable tools with positive impacts on cognitive aspects, providing specific value to their users. A pertinent study demonstrated that the implementation of a serious game based on chess, titled “The Secret Trail of Moon,” led to notable increases in emotional control levels and a reduction in attention deficits among participants [18]. In the sports domain, literature also highlights benefits, with a serious virtual reality game showing a significant improvement in players’ concentration during skiing tasks [13]. These findings underscore the potential positive impact of serious games on diverse cognitive and sports-related domains. Studies have increasingly focused on the psychological and cognitive aspects of athletes over the years [19,20], having highlighted attention, memory, and motivation as crucial psychological variables for athletes [21,22]. While the relationship among technology, games, and the psychological behavior of athletes has been explored, research specifically focusing on technology training in soccer remains scarce compared with other areas of knowledge. A notable study [23] revealed that young soccer players who trained with a computerized attention training system called Rejilla (version 1.0) [24] experienced significant improvements in their attention. However, these improvements were not directly linked to on-field performance variables. The literature has primarily centered around elite soccer, with limited attention given to youth soccer. Providing information to youth soccer coaches regarding how technology can impact the psychological and cognitive variables of their athletes will help optimize performance and achieve long-term success.

Methods

Participants

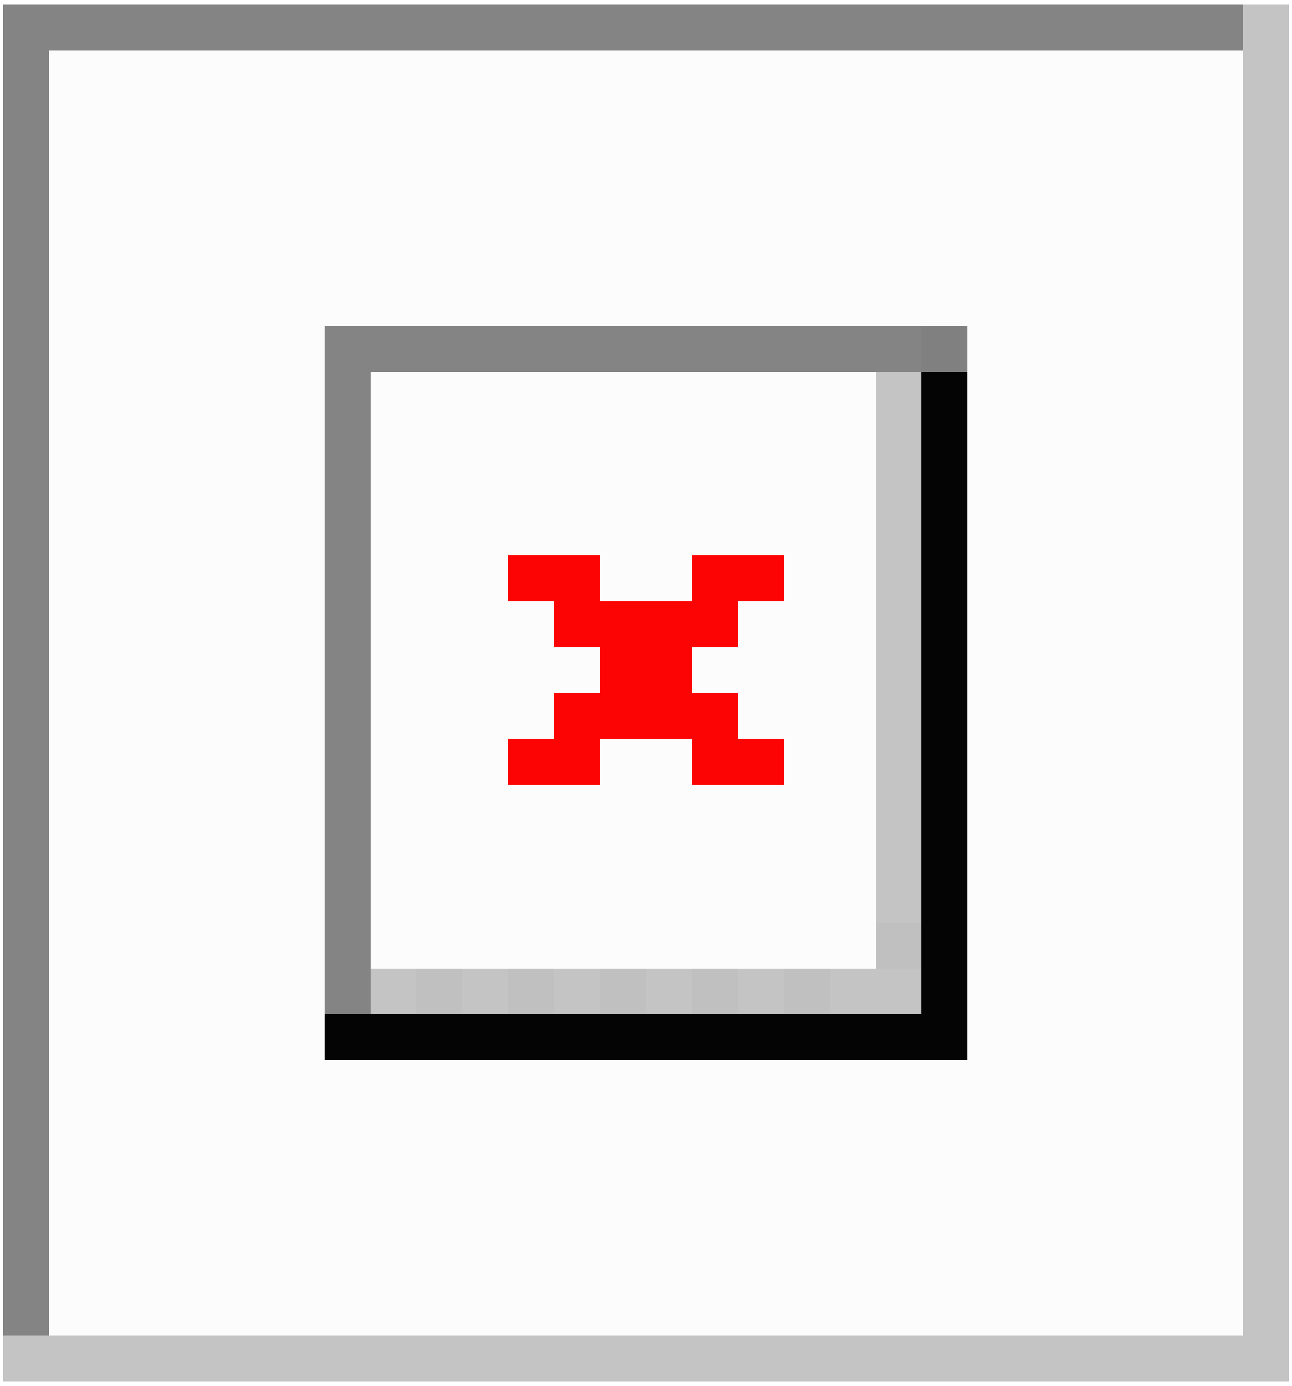
The study involved 12 young male soccer players aged between 8 and 9 years from a club in Seville, Spain. The participants underwent training sessions 3 days a week, each lasting approximately 120 minutes. The sample was divided into 2 groups: a control group (CG) and an experimental group (EG). Both groups were informed about their participation in a program aimed at enhancing their soccer skills. For the CG, the training involved watching videos of goals scored by the first team in previous seasons, followed by researchers posing questions to elicit responses. In search of a placebo effect, the EG was informed that the activity they were engaging in was attention training. This involved the visualization of videos showcasing goals scored by the first team in past seasons. After the video session, participants were required to answer questions related to the content (eg, “how many goals did the player with the number 9 score?”). Alternatively, the EG engaged in attention training using a video game.

Sample size calculation was convenience-based. For this, the study participants were players from a youth team belonging to a top-tier club in the Spanish Professional Football League. As an inclusion criterion, participants had to be 8 or 9 years old. Additionally, they should have been free from injuries that would have prevented them from participating in training or competitions. Their required training frequency was 3 times per week. During the 6 weeks, if any player reduced their training frequency to once a week, they were withdrawn from the study. Finally, a simple randomization method was chosen to randomize the groups, using the toss of a coin.

Procedure

The study spanned a duration of 6 weeks (Figure 1). Initially, all players underwent an evaluation of their decision-making skills in relation to soccer performance using the Game Performance Evaluation Tool (GPET) test [25]. The GPET is a tool to assess performance in invasion sports, specifically in soccer. Subsequently, both groups were assessed on the basis of their success in the video game, electromyographic (EMG) activity during the test, and sweat level. Throughout the study, all participants maintained their regular training routine, consisting of 3 sessions per week and a competitive game. The intervention varied, in that, on the one hand, the CG attended a room session twice a week where videos showcasing goals scored by the first team in past seasons were shown during 15 minutes, and after each video, the investigators posed a question to elicit a response; on the other hand, the EG attended a room session where attention training was conducted using a video game, with sessions lasting 15 minutes and taking place twice a week. Upon completion of the 6-week intervention, all players were reassessed regarding their decision-making abilities in relation to soccer performance using the GPET, as well as their performance in the video game, EMG activity, and sweat level during video game practice. Finally, an interview was conducted with the coaching staff to gauge the subjective attention levels of each soccer player, assigning them a score ranging from 1 (very low attentional level) to 3 (optimal attentional level) in relation to competitive situations.

Figure 1. Study design. Left to right: participants were randomized into 2 groups. Subsequently, all soccer players were assessed using the Game Performance Evaluation Tool (GPET), in addition to being evaluated for success in the video game, electromyographic (EMG) activity, and sweating levels. Afterward, the intervention proceeded for 6 weeks. Thereafter, both groups were evaluated again with the GPET, EMG activity, and sweating levels. Finally, the coaching staff was interviewed.



Instruments

The Video Game: BallApp

The video game used in the study involved the task of memorizing a ball with a distinct color among others displayed on the screen. After a period of 5 seconds, all the balls would change to the same color and move randomly across the screen. The participants were then required to identify the ball that initially had a different color. Accomplishments in the video game were measured in both groups, with the criterion being the ability to advance to the next level 3 consecutive times to mitigate the influence of luck. As the levels progressed, the speed of the balls, the number of selectable balls, and the presence of distractors such as noise increased. To replicate the environment of competitive soccer matches, specific background noise recordings from the soccer players' actual matches were provided.

The attention game for soccer players, BallApp, is designed to enhance their attention processes, aiming for a positive impact on attentional mechanisms when playing soccer. The game has been developed as an application using various technologies, including HTML for structural aspects, JavaScript for functionality, and Material Design for Bootstrap for design. The game is tailored for young soccer players and has been designed for individual play, although multiple players can participate on multiple screens.

The game involves selecting a ball of a different color than the others, and after a few seconds, all the balls turn into the same color and move randomly across the screen. The speed of movement, number of balls, depth of movement, and added noise vary as the difficulty levels progress. For example, in level 1, three balls appeared (one of them being of a different color), and the task was to choose 1 ball. All the balls moved without depth, and the speed was low. As levels increased, the difficulty level also increased on the basis of the number of balls on the screen. In subsequent levels, such as level 3, four balls appeared (one of them being of a different color), and the task was to choose 1 ball. The balls moved without depth, at a low speed, and without added noise. In total, the maximum number of programmed levels in the game was 8.

Level 4 onward, an ambient sound replicating those in real-world soccer matches was introduced. The aggressiveness of the noise increased with an increase in the difficulty level (Table 1). The aggressiveness of the noise was described on the basis of whether it was a murmur (low noise), cheering noise (medium noise), cheering noise with chants (moderate noise), noise with chants where specific phrases from a fan stood out (aggressive noise), or noise with chants and synchronized disturbances in the form of complaints or disgust toward plays (very aggressive noise).

Table . Overview of the characteristics of each level of the game.

Level	Number of balls on the display	Number of eligible balls	Depth of the movement	Speed of the balls	Sound
1	3	1	No depth	Low	Noiseless
2	3	1	With depth	Low	Noiseless
3	4	1	No depth	Low	Noiseless
4	5	1	No depth	Moderate	Slight noise
5	6	2	No depth	Moderate	Medium noise
6	6	2	With depth	Moderate	Moderate noise
7	7	2	No depth	High	Loud noise
8	8	2	With depth	High	Very loud noise

Regardless, to progress to a higher level, the player had to win the played level 3 times consecutively, eliminating luck as a factor for level progression. If the player correctly identified the balls of a different color in each level, they were awarded a score. This score depended on not only accuracy but also the time taken to make their choice.

The game has a configuration for individual use, although competitions can also be held with other players. Thus, it provides players with a leaderboard that compares scores among players, and this ranking changes on the basis of the following variables: the number of games played, the number of points achieved per game, and the number of levels surpassed by the player.

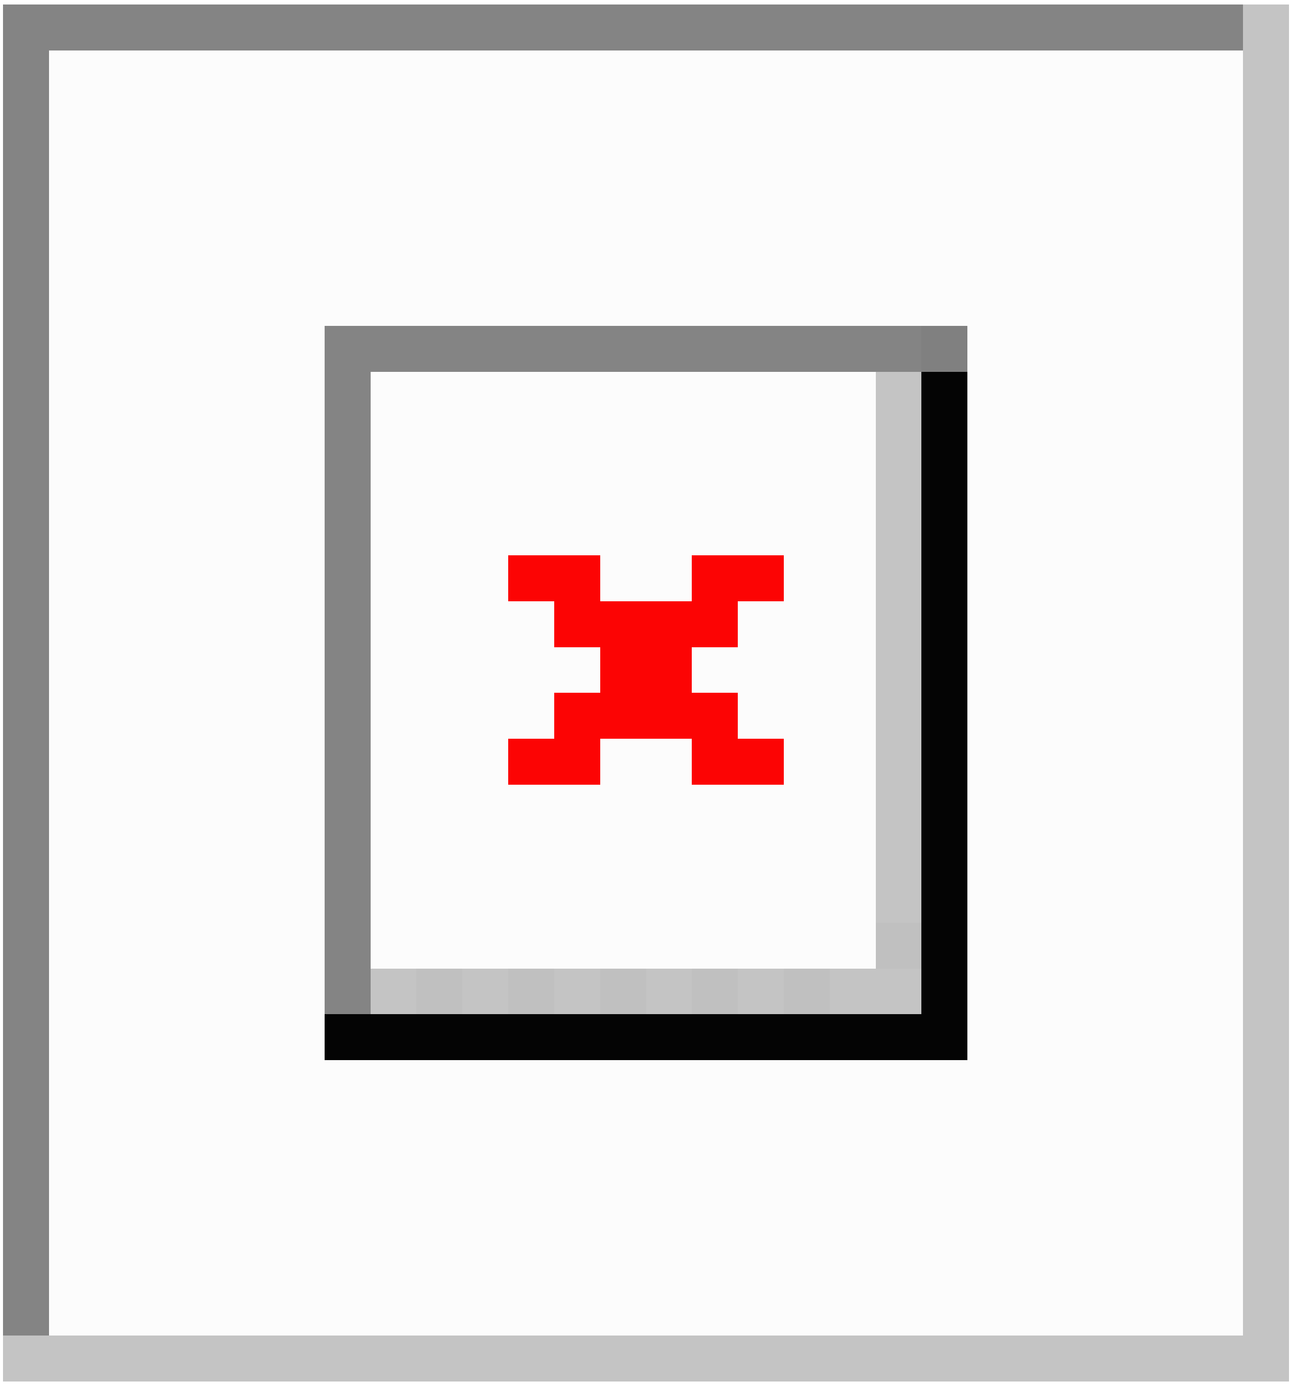
The selection of this particular video game for implementation is predicated on its consistent engagement of the attentional mechanism. This mechanism holds substantial implications in the developmental processes of young soccer players and, consequently, may yield positive effects on targeted soccer-related tasks.

EMG and Skin Conductance

EMG activity and electrodermal activity (EDA) were assessed on the basis of skin resistance and sweat production (bioPLUX). The EMG activity and EDA of the dominant hand's extensor muscle were evaluated in all participants. Electrodes were applied to the dominant hand, and these variables were analyzed before and after the intervention program during video game practice. These variables were examined from a somatic perspective, allowing for the monitoring of psychophysiological indicators during an attention-demanding task such as playing a video game (Figure 2).

The assessment of somatic variables of anxiety using biofeedback devices appears to be an excellent tool for controlling anxiety during different tests and among different populations [26], specifically in the analysis of EMG activity [27] and EDA variables [28], as specific control of somatic responses seems to be a good indicator of psychological states. Alterations in these variables could indicate somatic states and anxiogenic responses that would hinder the individuals' task performance [29]. Our study monitored these 2 responses while participants played the video game.

Figure 2. Evaluation of electromyographic activity (**A**) and electrodermal activity (**B**) during video game practice.



GPET

The GPET assessment tool was used to evaluate decision-making in relation to soccer performance. This instrument differentiates the cognitive-decisional aspect of performance from execution. The playing field has dimensions of 20×10 m^2, with delimited areas of 3×4 m^2 and goals measuring 0.95×0.70 m^2. The ball used is an A-7 soccer ball, with a circumference ranging between 0.635 and 0.66 m. The players engage in the task in teams consisting of 2 players each, with two 4-minute halves and a 3-minute break between them. The timer remains active throughout, and there are assistants designated to retrieve the ball. The variables captured by the test are assessed in both attacking and defensive situations, both with and without the ball (as outlined in Table 2). The test is recorded using a video camera for subsequent analysis. Using an observation sheet, successful actions are coded on the basis of the predefined roles into 4 options: appropriate decision (coded as 1), inappropriate decision (coded as 2), successful execution (coded as 1), and unsuccessful execution (coded as 2).

Table . Description of variables evaluated using the Game Performance Evaluation Tool.

	With the ball	Without the ball
Attack	• Control • Pass • Dribbling • Shot	• Losing one's defender • Fixing
Defense	• Marking with the ball • Defensive blocking • Tackle • Clearing with the ball	• Marking without the ball • Interception • Clearing without the ball

Outcome Measures

All variables evaluated using the GPET are described below and are classified in accordance with two criteria (Table 2): (1) whether the action is carried out with or without the ball and (2) if the actions are those wherein the decisional or execution mechanism predominates. For this purpose, all acronyms used have been "_with_ball" for variables with the ball, "_without_ball" for variables without the ball, "_D" for variables where the decisional mechanism predominates, and "_E" where the execution mechanism predominates. Thus, the variables are the following: (1) control: this refers to situations where the player keeps the ball under control; (2) pass: this is the action where the player successfully makes a pass to another teammate; (3) dribbling: this is an action where the player gets away from his opponent, eliminating any possibility of the ball being taken away from him; (4) shot: the player takes a shot at goal with the aim of scoring; (5) Losing_one's_defender: the player, by means of an attacking action, unmasks themself from their defender; (6) fixing: the player, in an attacking action, fixes the defender, forcing the latter to occupy a specific position on the field; (7) Marking_with_ball: in a defensive action, the player marks the player who has the ball; (8) Defensive_blockin: in a defensive action, the player tackles the player with the ball but does not fall to the floor; (9) tackle: in a defensive action, the player falls to the ground to snatch the ball from the opponent; (10) Clearing_with_Ball: in a defensive action, the player clears the player with the ball, using a free space; (11) Making_without_ball: in a defensive action, the player marks another player of the opposing team who is not in possession of the ball; (12) interception: in a defensive action, the player cuts off a play, preventing the ball from reaching its receiver; and (13) Clearing_without_ball: in a defensive action, the player makes a clearance to the player who does not have the ball, using a free space.

Interview

Traditionally, the coach's role as a key element in understanding the athlete has proven to be crucial [30]. Specifically, the athletes' psychological factors have been tested using various procedures, with the coach playing a pivotal role as a key to understanding the athlete's psychological status [31,32]. Thus, the qualitative insights obtained from interviews with coaches regarding the psychological variables of athletes can be a crucial element that significantly enhances the understanding of these psychological variables, aiding in decision-making about athletes [33].

An individual interview was conducted with the coach to subjectively assess the level of attention concerning decision-making and athletic performance for each soccer player. The coach was asked to rate, using a scale from 1 to 10, the level of attention exhibited by the soccer player in making optimal decisions that contribute to enhanced athletic performance. The coach provided a numerical rating, which was duly recorded by the evaluation team.

Statistical Analysis

A statistical analysis was conducted on the data obtained for each variable. Initially, a parametricity analysis was performed for each variable using the Shapiro-Wilk test. Subsequently, the mean and SD of each variable were assessed. To compare the means between groups, an independent samples *t* test was used, with a significance level set at 95% confidence ($P \leq .05$). Moreover, the effect size for the variables was determined using a 95% confidence limit. To qualitatively evaluate the potential quantitative changes observed after the program, the following categories were used [34]: highly improbable (<1%), very unlikely (1%-5%), unlikely (5%-25%), possible (25%-75%), likely (75%-95%), highly likely (95%-99%), and virtually certain (>99%).

Ethical Considerations

This study received ethical approval from the Ethics Committee of the Center for University Studies affiliated with the University of Seville (20190215) on February 5, 2019. This study complied with the ethical guarantees and requirements for experimentation on human beings and animals and the requirements established in Spanish legislation in the field of biomedical research, protection of personal data, and bioethics, and adhered to the fundamental principles of the Declaration of Helsinki and the European Convention on Human Rights. Informed consent was obtained from the responsible tutors of the players.

Results

The aim of this investigation is to assess the impact of an attention intervention among soccer players, using a video game. To assess the video game's impact on the athletic performance of these players, an analysis of various variables was conducted, categorized into 3 main groups: the first group focused on the video game itself, examining the success rate in the game, EMG activity, and EDA; the second group encompassed decision-making variables related to the athletic performance component in soccer players; and in the third group, a subjective evaluation of each soccer player's level of attention was obtained from their coach.

Regarding the variables analyzed in the video game, a significant improvement in the success rate of the soccer task was observed in the EG following the intervention program, as indicated by the level achieved. Both groups exhibited no differences in terms of success rate before undergoing training using the video game. However, after the 6-week duration, the EG demonstrated a substantial increase in the obtained score compared to the CG (Table 3).

Our findings indicate that there were no significant differences in EMG activity and assessed sweat between the 2 groups (Table 4).

Regarding the set of variables assessed using the GPET tool, both groups underwent evaluation before and after the implementation of the attention training program using the video game. The variables were categorized as successful or failed actions based on the prevailing decision or execution mechanism, and they were further classified as attacking or defensive actions. All data were analyzed and are presented as percentages. Furthermore, the change in percentages for each variable was calculated by subtracting the values to determine both inter- and intragroup differences, and these differences were evaluated. See Figures 3 and 4.

Regarding the mean score, a significant difference was observed between the EG and CG after the intervention period (pre-CG mean 46.2, SD 12.5; pre-EG mean 46.9, SD 13.8; P=.95; Cohen d=−0.01; post-CG mean 40.7, SD 13.7; post-EG mean 59.7, SD 17.3; P=.01; Cohen d=−1.73). As indicated, before the application of the attention training program using the video game, both groups showed relatively similar variables in which the decision mechanism predominated, as well as in those in which the execution mechanism predominated, the differences between both groups being less than 10%. Only 2 decision mechanism variables had values above 10% but never exceeding 15% (Shot_D=13/100, 13%; Marking_with_Ball_D=12/100, −12%).

Regarding the EG, following a 6-week intervention, all variables underwent some degree of modification, with minor changes below 15%. The variables that experienced the most substantial changes were Fixing_D (27/100, −27%), Fixing_E (37/100, −37%), Defensive_blocking_D (28/100, −28%), Marking_with_Ball_D (22/100, −22%), and Interception_D (18/100, −18%). The minus sign in these changes indicates that the percentage for each variable decreased after the intervention period. In the case of the CG, 9 variables showed changes exceeding 15%, with 5 of them surpassing 30%. On comparing the percentage changes between the 2 groups after the intervention, all variables had higher values in the EG than in the CG. The only variable that had higher values in the CG was the shot, on evaluation of both the decision mechanism (Shot_D=−1.43) and the execution mechanism (Shot_E=−1.69). However, the differences observed in both cases did not exceed 2 units.

Table . Comparison of success in the video game between groups before and after the intervention.

Variable	Before[a]		After[b]	
	CG[c]	EG[d]	CG	EG
Success, mean (SD)	1.66 (0.51)	1.5 (0.54)	1.83 (0.40)	4.16 (0.75)

[a]P=.61.
[b]P<.001.
[c]GC: control group.
[d]EG: experimental group.

Table . Comparison of EMG[a] activity and EDA[b] between groups before and after the intervention.

Variable	Before			After		
	CG[c]	EG[d]	P value[e]	CG	EG	P value
EMG activity (μV), RMS[f] (SD)	1.66 (0.10)	1.71 (0.09)	.50	1.78 (0.12)	1.72 (0.05)	.21
EDA (μΩ), RMS, (SD)	25.11 (0.07)	25.81 (0.88)	.08	25.51 (0.48)	25.01 (0.85)	.20

[a]EMG: electromyographic.
[b]EDA: electrodermal activity.
[c]CG: control group.
[d]EG: experimental group.
[e]P≤.05 was considered significant.
[f]RMS: root-mean-square.

Figure 3. Comparison between the groups before the training period. CG: control group; EG: experimental group; GPET: Game Performance Evaluation Tool.

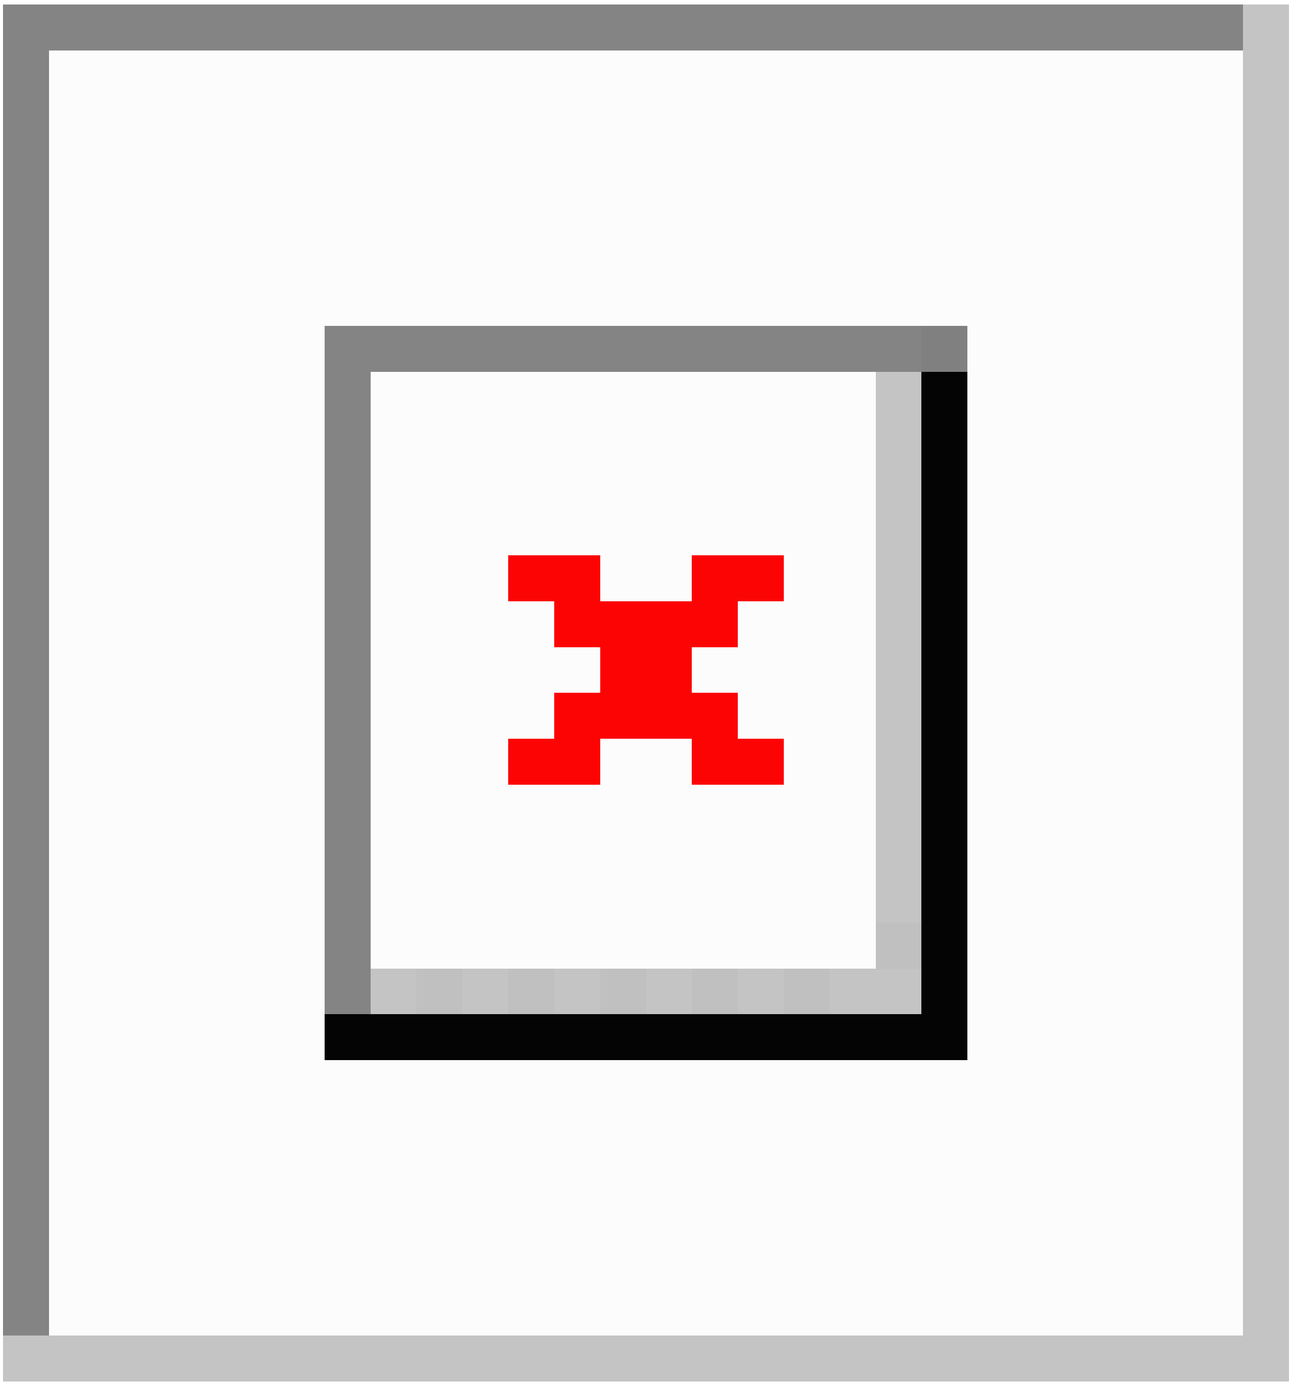


Figure 4. Comparison between groups after the training period. CG: control group; EG: experimental group; GPET: Game Performance Evaluation Tool.

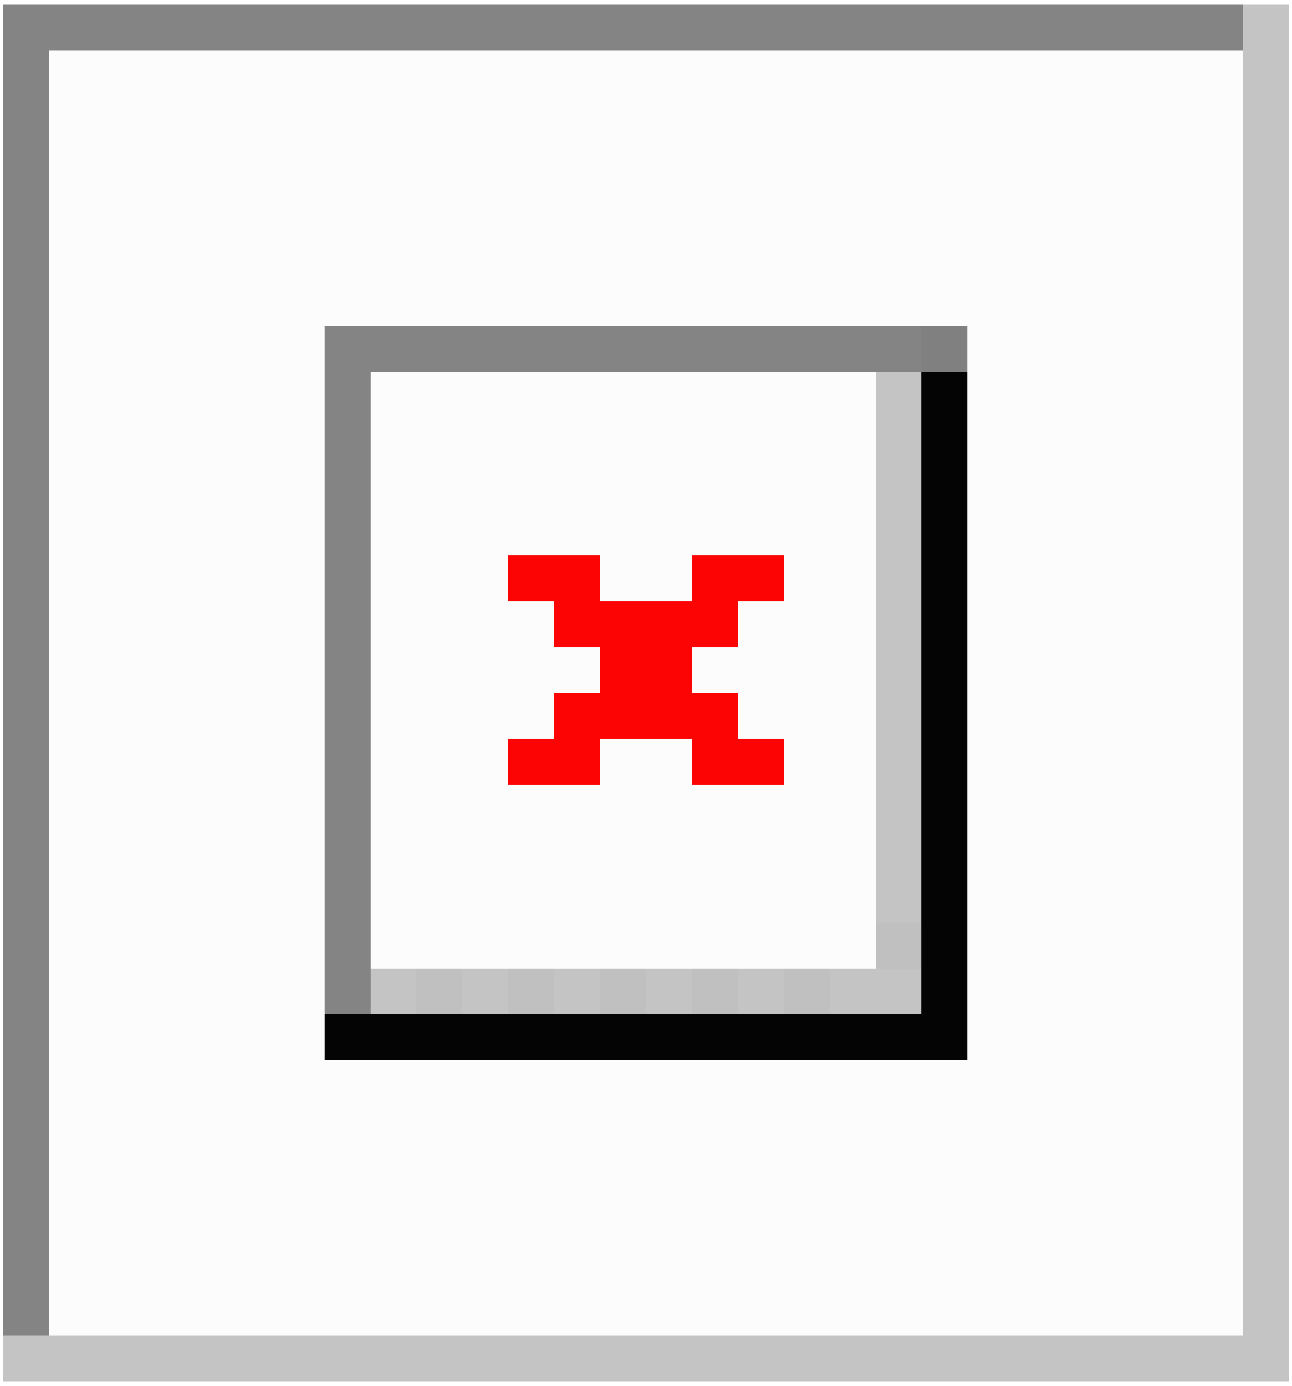

Furthermore, it is evident that in the set of variables related to attack actions, the changes are more pronounced in variables associated with the execution mechanism than with those associated with the decision mechanism, except for dribbling and fixing. Conversely, in the set of variables related to defensive actions, the changes were more significant in the decision variables than in the execution variables, except for the variables of marking with the ball and marking without the ball.

Finally, the results obtained from the interview-based subjective evaluation of the soccer players' attention levels are presented in Table 5.

Table . Subjective levels of attention evaluated by the coach.

Variable	Control group, mean (SD)	Experimental group, mean (SD)	*P* value[a]
Subjective level of attention	4.83 (1.47)	5.83 (1.16)	.22

[a]*P*≤.05 was considered significant.

Discussion

Principal Findings

The primary aim of this study was to develop a video game targeted at enhancing the attentional skills of young soccer players. By providing coaches with a tool for training the psychological aspect of attention, positive effects on various performance variables in soccer players could be observed. Following the intervention program, the EG demonstrated improvements in video game performance, indicating significant progress in overcoming the challenges presented by the game. These findings are consistent with those of a previous study [23] that reported improvements in attention execution through software interventions and considered using video games as an interesting tool for improve cognitive variables [35] in this population [36]. While our study did not use a specific attention assessment such as the D2 Attention Test [37] used by Reigal et al [23]x, one of our key findings is that alongside attention training through the video game, we evaluated decision-making related to soccer performance.

To monitor somatic factors such as muscle activity and skin conductance, we used EMG activity and EDA measurements for all participants. Research suggests that cognitive control and management of the somatic aspects of anxiety could impact attention levels [38]. In our study, we specifically collected EMG activity data from the hand extensor muscles. Our evaluation methodology aligned with that developed by Palkowski and Redlarski [39], who assessed EMG activity during various hand gestures. Our results revealed similar EMG activity patterns during hand opening actions, comparable to the postures observed when our sample participants placed their nondominant hand on the table while using the dominant hand to operate the computer mouse.

However, our analysis of EDA did not reveal any significant differences between the groups. This lack of divergence in the somatic response to anxiety suggests potential heightened control over the outward display of anxiety during the test. Surprisingly, both the CG and the EG obtained similar results. One possible explanation for this finding could be the presence of the play component, as both EMG activity and EDA evaluations were conducted during the practice of the video game. These results are aligned with the findings of Pop-Jordanova and Pop-Jordanov [40], who observed similar skin resistance outcomes when assessing individuals using biofeedback in static and calm situations. However, it appears that the video game may not be an effective tool for regulating somatic anxiety.

The evaluation of performance-related variables in soccer players with the GPET confirms the perceptual improvements in decision-making and execution observed in the EG after engaging in the intervention program with the video game. This suggests that enhancing attention through video game practice has a positive impact on decision-making in relation to soccer performance. These findings are aligned with those of González-Víllora et al [41], who assessed decision-making and execution in soccer situations using the same tool and observed significant differences between groups. Thus, our results further support the notion that the video game can serve as a valuable tool for enhancing the psychological aspect of attention in young soccer players, yielding positive effects on various performance variables in soccer.

Regarding shooting decisions, the CG demonstrated higher results than the EG. One possible explanation for this is that the EG developed attentional skills through the video game intervention, leading to improved decision-making during soccer and consequently reducing the frequency of shooting attempts. While no significant differences were observed between the 2 groups in the coach's subjective evaluation of their players' attentional mechanisms, it is evident that the video game serves as an effective tool for decision-making training. Moreover, it shows promise as a tool for detecting attentional impairments or abnormalities, highlighting its potential beyond its training benefits.

Limitations

Despite our study reporting that this video game shows promise in improving attention in young soccer players, there are clear limitations that should be explained. Among the most important limitations of this study is that the sample size was small. This study comprised 12 soccer players, all members of a youth team of a first-level soccer team of the Spanish League. Although they comprised 100% of the team and effectively represented that team, our findings cannot be generalized; hence, it would be interesting to increase the sample size to verify our data.

The duration of the intervention was 6 weeks. Future studies could evaluate the effect of the intervention over a greater period, verifying if the effect on the improvement of some attentional processes assessed using the GPET was positive. In addition, the timing of the season where this attentional training program was integrated through the video game may also have been a limitation. Future studies could evaluate what happens at different times of the season.

Furthermore, somatic variables such as EDA and EMG activity were evaluated. Undoubtedly, the complexity underlying their evaluation is an important limitation in terms of reproducibility. Nevertheless, these variables were analyzed with the aim of determining whether there were any somatic issues that prevented the soccer players from being able to play the video game and obtain the best possible results.

Finally, there is a contextual limitation regarding the analysis of attention in real soccer situations. Although the ecological nature of the GPET has been proven, it is still a test that evaluates only the attention mechanism and the decision mechanism in soccer situations. This limitation could be overcome if future studies investigate what happens during a real match after attention training using the video game. Nevertheless, this evaluation was performed using the GPET to standardize the procedure so that all participants were evaluated in the same way and under the same conditions.

Acknowledgments

Sevilla FC (Football Club) deserves our heartfelt gratitude for generously granting us the opportunity to conduct this study. Their commitment to advancing knowledge and contributing to the sports community is truly commendable, and we are honored to have had their involvement in this endeavor.

We are very grateful to Enrique Arroyo for the fundamental work he has done in this study. His dedication is a symbol of effort and serves as a mirror for those of us who love sport.

Editorial Notice

This randomized study was only retrospectively registered. The editor granted an exception from ICMJE (International Committee of Medical Journal Editors) rules mandating prospective registration of randomized trials. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: New interventions based on motor learning principles and neural plasticity have been tested among patients with ataxia and hemiparesis. Therapies of pedaling exercises have also shown their potential to induce improvements in muscle activity, strength, and balance. Virtual reality (VR) has been demonstrated as an effective tool for improving the adherence to physical therapy, but it is still undetermined if it promotes greater improvements than conventional therapy.

Objective: Our objective was to compare the effect on lower limb range of motion (ROM) when using VR technology for cycling exercise versus not using VR technology.

Methods: A randomized controlled trial with 20 patients with ataxia and hemiparesis was carried out. The participants were divided into 2 groups: the experimental group (n=10, 50%) performed pedaling exercises using the VR system and the control group (n=10, 50%) performed pedaling exercises without using VR. Measurements of the active and passive ROM of the hip and knee joint were taken before and after a cycling intervention, which consisted of 3 sessions of the same duration but with progressively increasing speeds (4, 5, and 6 km/h). Repeated measures ANOVAs were conducted to compare the preintervention (T_i) and postintervention (T_e) assessments within each group. Additionally, the improvement effect of using the VR system was analyzed by comparing the variation coefficient ($\Delta = 1 - [T_e / T_i]$) between the preintervention and postintervention assessments for each group. Group comparisons were made using independent 1-tailed *t* tests.

Results: Significant improvements were shown in active left hip flexion (*P*=.03) over time, but there was no group-time interaction effect (*P*=.67). Passive left hip flexion (*P*=.93) did not show significant improvements, and similar results were observed for active and passive right hip flexion (*P*=.39 and *P*=.83, respectively). Neither assessments of knee flexion (active left: *P*=.06; passive left: *P*=.76; active right: *P*=.34; passive right: *P*=.06) nor knee extension showed significant changes (active left: *P*=.66; passive left: *P*=.92; active right: *P*=.12; passive right: *P*=.38). However, passive right knee extension (*P*=.04) showed a significant improvement over time. Overall, although active and passive ROM of the knee and hip joints showed a general improvement, no statistically significant differences were found between the groups.

Conclusions: In this study, participants who underwent the cycling intervention using the VR system showed similar improvement in lower limb ROM to the participants who underwent conventional training. Ultimately, the VR system can be used to engage participants in physical activity.

Introduction

Background

Ataxia is an umbrella term for describing deficits in limb movement coordination such as dysmetria, dyspraxia, and dyssynergia [1]. The persistence of these deficits affects an individual's functional ability and poses a health challenge for both patients and clinicians.

Current scientific evidence indicates that the most effective treatment for ataxia should combine balance and coordination retraining and constraint-induced functional movement therapy [2]. However, the scientific literature still lacks a consensus on the details of these interventions and the timing of their implementation to enhance the recovery of the functionality of motor deficits in an individual [3].

On the other hand, in the field of neurophysiology, it is well known that to induce changes in neuroplasticity to achieve the functional recovery of motor deficits, the application of therapies based on the repetition of movements is required [4]. Some studies point out that the principles of motor learning are directly related to the regeneration of structures and the reorganization of neuronal function [5,6]. Moreover, the amount of practice is a key factor in motor learning, as well as the feedback provided during practice [7]. In fact, physical therapists must consider both the error feedback and activity guidance as 2 fundamental components of patient interaction during therapy to promote neuromotor learning [8]. Thus, interventions that promote normal function rather than the compensation of deficits are more recommended and should be applied to generate a physical activity plan based on the principles of motor learning and neural plasticity for patients with ataxic hemiparesis.

Prior Work

The scientific literature in the field of neurorehabilitation shows that pedaling exercises have the potential to induce improvements in muscle activity, strength, and balance [9]. This is mainly due to the fact that pedaling exercises based on the use of a cycloergometer provide a high number of flexion and extension repetitions [10] in the lower extremities for considerable periods of time. Because pedaling and walking are cyclical locomotor tasks that require the lower limb to alternate between flexion and extension [11,12], both share similar locomotor patterns of alternating muscle activation of antagonists [10,13]. Thus, cycling exercises are found to be useful for strengthening the lower limb muscles while acting as a pseudowalking task-oriented exercise. Some studies eluded that those biomechanical functions may be altered by the muscle groups involved in the pedaling tasks [14-16]. In fact, it was found that the degradation of pedaling performance in adults with hemiparesis was related to abnormalities in the execution of specific biomechanical functions [15]. Subsequently, it has been proven that human walking and cycling shared similar muscle synergies [16]. This evidence is the basis for rehabilitation treatments based on pedaling movements with potential positive outcomes for walking [16].

The ergometer is an equipment designed to perform cardiovascular work based on the alternative circular movement of the lower limb. Its use is advantageous for a muscle coordination study because balance is not an applicable factor in this kinematically constrained task [13]. In fact, applying an ergometer-based cycling routine could be useful because it requires no balance. Moreover, the exercise intensity of the ergometer-based cycling can be adapted to the user by adjusting the resistance of the pedal or the target speed. The ability to personalize the intensity of the exercise is a relevant factor for the patient's rehabilitation process. For these reasons, regular ergometer-based cycling is found to be a safer unsupervised exercise that is recommended for lower limb rehabilitation. Nevertheless, cycling exercise is also a static and repetitive form of exercise that leads to boredom and listlessness in patients. To deal with this discouragement factor, emerging technologies have been applied to elicit intrinsic motivation for rehabilitation patients [17]. Several studies pointed out the usefulness of gaming elements and virtual environments as assistive technology [18,19] and their potential effectiveness in physical therapies as opposed to conventional therapies [20].

Quite a few studies have focused on the analysis of functional metrics in virtual pedaling. A recent study evaluated the functionality of a virtual reality (VR) cycling training program that was applied to 10 patients with stroke [21]. It assessed the improvement of the bilateral asymmetry between the experimental group and the control group after the VR cycling intervention program. To evaluate this index, they equipped the ergometer pedals with force plates to determine the effect of the VR cycling training on each limb. The improvement of bilateral strength and standing balance was significantly different between VR cycling training and traditional physical training. Similarly, a previous study compared the effects of a cycling training program with extrinsic biofeedback and a nonimmersive interface versus traditional physical training on lower limb functional recovery in patients with stroke [22]. The results showed that improvements in walking endurance, walking speed, and muscle spasticity of the group using VR were significantly better than the group who underwent traditional physical training.

Objectives

The main objective of this study was to evaluate 2 different interventions: pedaling with VR and pedaling without VR. This study focused on comparing the improvements in lower limb range of motion (ROM) in pedaling activity between the group using VR and the group not using VR. To this end, a randomized controlled trial was carried out with patients with ataxia and hemiparesis. Hip and knee ROMs were measured before and after the cycling intervention. The overall aim of these analyses was to determine the effects of the 2 different interventions on short-term improvement of lower limb function and ROM.

Methods

VR System

The VR system implements extrinsic feedback strategies, gamification by levels, and personalization of the sessions with the aim of achieving greater adherence to pedaling exercise sessions. Its immersive nature means an increase in the sense of "presence," promoting the active involvement of the user.

The VR system is based on the transmission of the cycling kinematic data captured by the inertial sensors to the Oculus Quest 2 (Meta) head-mounted display (HMD) via Bluetooth. Therefore, the virtual application estimates the pedaling cycles, cadence, and distance during the exercise activity. The VR scenarios generated for this therapy consist of mapping the cycling cadence to the vehicle speed. Thus, the patient is placed inside a vehicle and visualizes the session data on the control panel while moving at the speed of the pedaling motion.

The design of the VR experience has been technically validated computationally to ensure low latency in motion analysis and visual representation of motion [23], thus preserving the embodiment effect and the sense of presence. Subsequently, the platform has also been validated from the point of view of satisfaction and ease of use of the system [24]. Additionally, considering that it is a stationary experience with an HMD that simulates a displacement, we evaluated to which extent the VR experience generates the type of motion sickness that causes fatigue, nausea, disorientation, postural instability, or visual fatigue [25]. Indeed, we verified that the platform does not generate adverse effects due to cybersickness [24].

Recruitment

The participants were patients of both sexes between 18 and 90 years of age, recruited at the Lescer Clinic applying the inclusion and exclusion criteria. Inclusion criteria were as follows: individuals were eligible if they (1) had been prescribed pedaling exercise as treatment for lower limb rehabilitation and (2) were able to perform a pedaling session with VR technology. Exclusion criteria were as follows: (1) an insufficient cognitive state, (2) an unbound bone fracture, (3) severe disorders of vision or audition (inability to perceive visual or auditory information coming from VR), and (4) any incompatibility with the use of a VR system according to the clinical record. A sample of 22 participants (n=13, 59% male and n=7, 32% female; mean age 59.90, SD 13.56 y) volunteered to participate in this pilot randomized controlled trial (Table 1). Of this 22-person cohort, 1 participant dropped out of the study and 1 participant did not complete the study (Figure 1). The cohort was randomly divided into the experimental group (EG; 9/10, 90% male and 1/10, 10% female; mean age 60.80, SD 12.26 y) with VR cycling exercises or the control group (CG; 4/10, 40% male and 6/10, 60% female; mean age 59.00, SD 14.69 y) with traditional cycling exercises.

Table . Clinical and epidemiological features of the experimental group (EG) and control group (CG) participants.

Group and participant number	Sex	Age (y)	Etiology	Condition
EG				
1	Male	57	Ischemic stroke	Hemiparesis
2	Male	71	Hemorrhagic stroke	Ataxia
3	Male	53	Hemorrhagic stroke	Ataxia
4	Male	72	MCA[a] stroke	Hemiparesis
5	Male	53	MCA stroke	Hemiparesis
6	Male	62	Ischemic stroke	Hemiparesis
7	Male	59	Hemorrhagic stroke	Ataxia
8	Male	56	Progressive multifocal leukoencephalopathy	Ataxia
9	Female	86	Hemorrhagic stroke	Hemiparesis
10	Male	39	Ischemic stroke	Hemiparesis
CG				
1	Male	45	MCA stroke	Hemiparesis
2	Female	64	Hemorrhagic stroke	Ataxia
3	Male	58	Guillain-Barré syndrome	Hemiparesis
4	Female	41	Hemorrhagic stroke	Ataxia
5	Female	49	Ischemic stroke	Ataxia
6	Male	83	Ischemic stroke	Ataxia
7	Female	80	Hemorrhagic stroke	Hemiparesis
8	Female	72	Traumatic brain injury	Hemiparesis
9	Male	57	Ischemic stroke	Hemiparesis
10	Female	41	Guillain-Barré syndrome	Ataxia

Ethical Considerations

Ethical approval was obtained from the Research Ethics Committee of the San Pablo CEU University (550/21/51). This study has been registered at ClinicalTrials.gov (NCT05162040). All the participants were given written information in accordance with the Research Ethics Committee. The informed consent and the ability for participants to opt out was provided. Additionally, participants were informed that the data collected in this study can only be used for this study, not for secondary studies. The approval of the Research Ethics Committee of San Pablo CEU University only covers this study and does not cover a secondary analysis without additional consent. However, no additional analysis had been carried out.

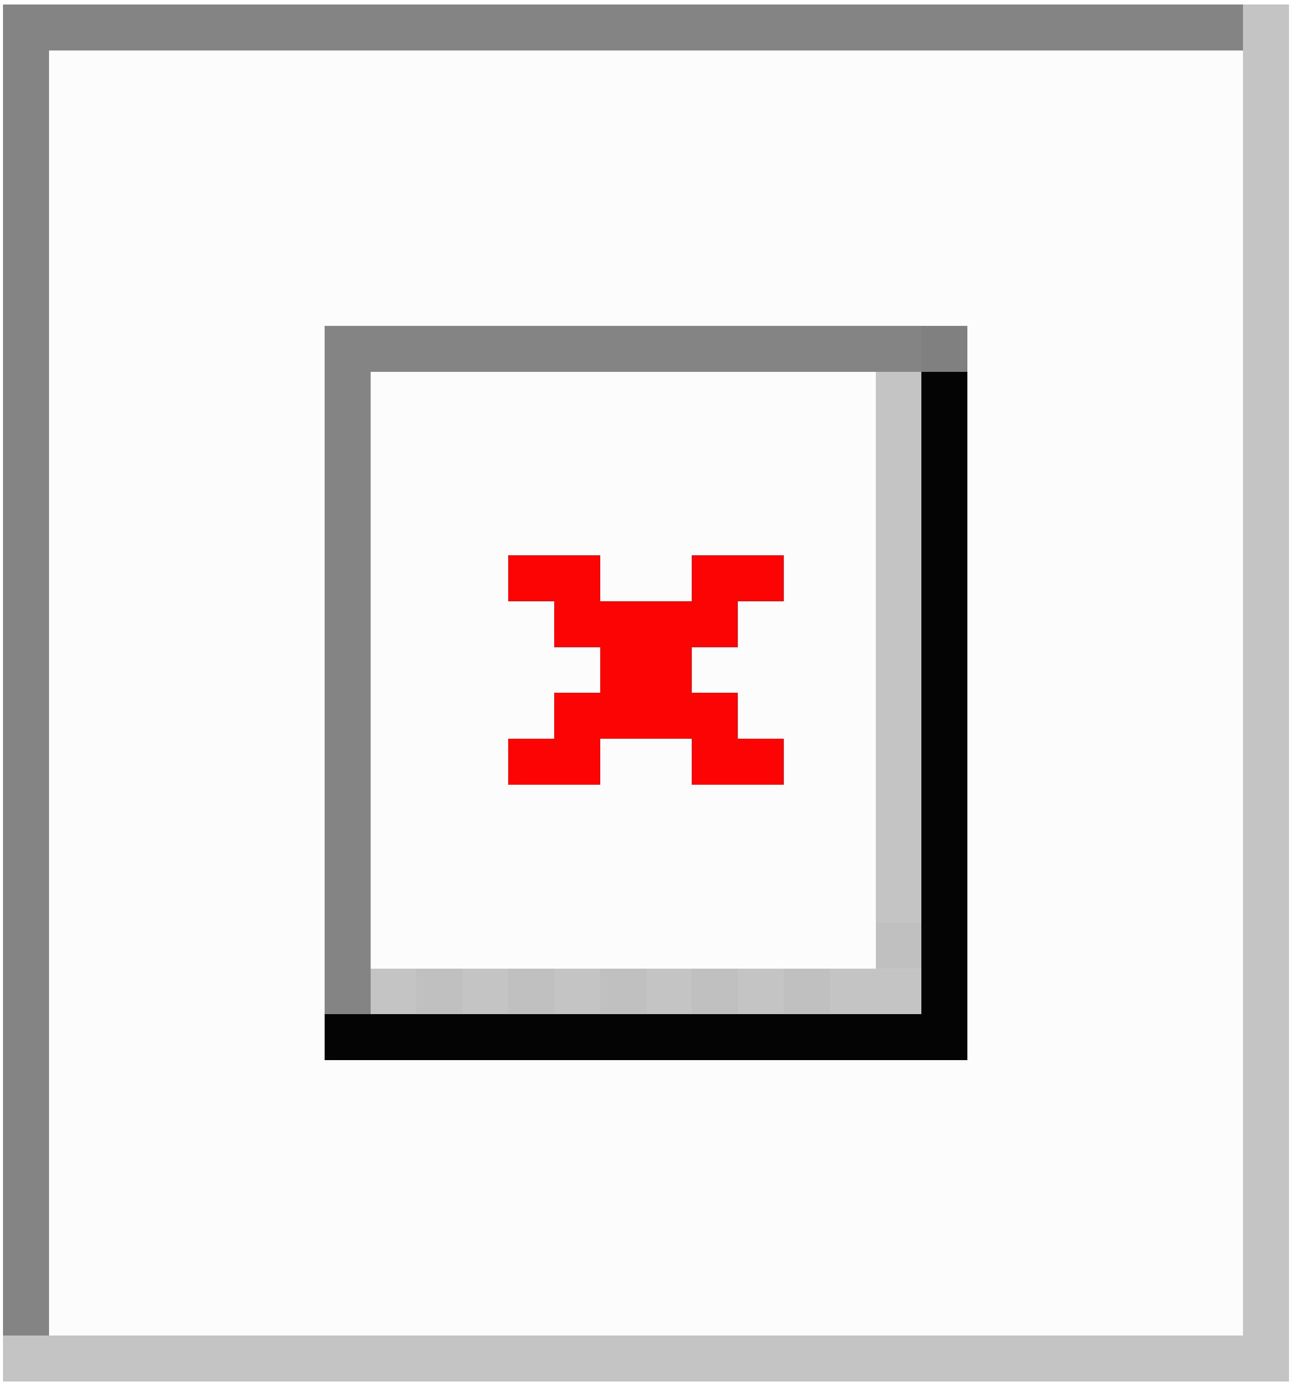
To ensure privacy and confidentiality, data are collected by employees of the agencies participating in the study. Each participant is assigned a unique code along with personal sociodemographic data and informed consent. These files remain in the custody of the principal investigator in charge of the project, while the assigned number is the one that identifies the anonymized data that was later analyzed. Finally, the participation in this study is completely voluntary; no compensation of any nature is offered to the human participants.

Intervention

This study was designed as a randomized controlled trial with 20 participants divided into 2 groups, following a block randomization method. The participants of the EG (n=10) performed pedaling exercises while using the VR system, whereas the participants of the CG (n=10) performed pedaling exercises without using the VR system. Before and after completing the exercise program, measurements of gait function metrics and joint ranges were performed to assess the effect of using VR stimulus during the cycling exercises.

The participants completed the cycling intervention simultaneously with their rehabilitation sessions. Afterward, for each participant, 3 cycling sessions were scheduled over 1 week with a maximum of 48 hours between sessions. Each session consisted of 2 sets of a 5-minute pedaling exercise spaced with a 2-minute break (to rest). Similar studies [19,26] have tested robotic unicycles in pedaling sessions at a cadence of 60 revolutions per minute. In our case, the pedaling speed of 1 cycle per second is equivalent to a target speed of 6 km/h. For this reason, it was decided to set this speed as the maximum speed and to start the first session with a slightly more comfortable speed (4 km/h) and increase it progressively (Figure 2). The participants of both groups performed the exercise following a set pedaling speed so that they received visual feedback according to the set target speed of 4-6 km/h for each session. The EG participants received visual feedback through the immersive VR application, whereas the CG participants received visual feedback on the ergometer display. All participants were instructed to maintain a constant pedaling speed throughout the session at the target cadence.

Figure 2. Summary of the intervention program for experimental and control group participants. VR: virtual reality.



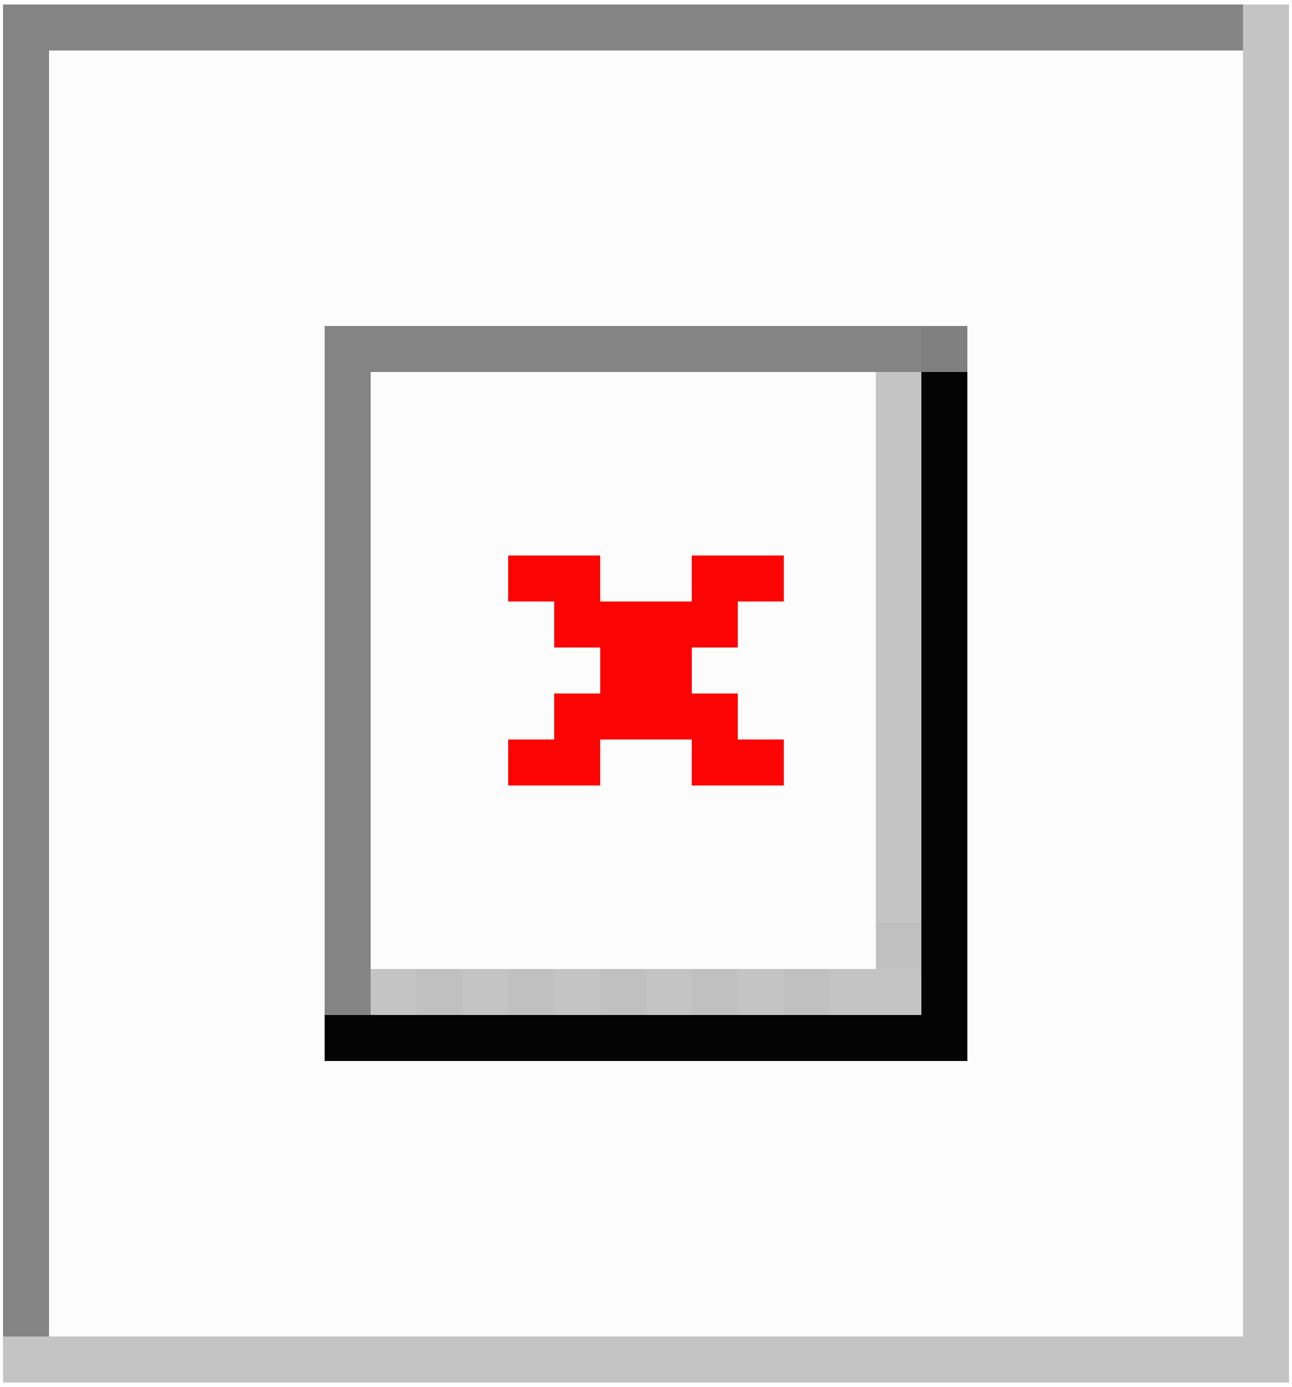
Physical Assessment

For the assessment of active and passive ROM of the hip and knee joint, a specifical ROM assessment tool was used. Measurements were extracted from biomechanical analysis using an inertial motion capture system (Werium; Werium Solutions) consisting of 2 inertial sensors: 1 placed in the distal part of the extremity (moving sensor) and the other in the proximal part (fixed sensor). Both sensors send their measurements via Bluetooth to a PC that runs the data acquisition software, Pro Motion Capture (Werium Solutions). This software computes the relative angle from both angle measurements (avoiding compensations) with an accuracy of 1 degree.

Protocol

The cycling sessions for both groups consisted of the use of a leg ergometer that allows training of the lower limb. Additionally, the EG used an inertial sensor placed on the right thigh and the Oculus Quest 2 HMD (Figure 3).

Figure 3. Cycling session of a participant in the experimental group using the virtual cycling platform.



The EG underwent the following procedure each session:

- The clinician connected the inertial sensor to the Oculus Quest 2 HMD.
- The patient was seated in a nonmovable chair (with no armrests) in front of the pedaling station during the entire session. The inertial sensor was placed on the right thigh

of the patient by adjusting an elastic band, and the sensor was turned on.

- The clinician fitted the Oculus Quest 2 HMD comfortably on the patient and guided him or her through the selection of the game scene. Once the game environment was entered, the clinician indicated the number of minutes of exercise and the target speed of the session so that the patient could configure these parameters on the interactive settings panel.
- Finally, the user performed 2 sets of a 5-minute cycling exercise with a 2-minute break between the sets.

Similarly, the CG underwent the following procedure each session:

- The patient was seated in a nonmovable chair (with no armrests) in front of the pedaling station during the entire session.
- The clinician turned on the ergometer's display and entered the number of minutes of exercise and the target speed of the session.
- Finally, the user performed 2 sets of a 5-minute cycling exercise with a 2-minute break between the sets.

Statistical Analysis

The data analysis model is the repeated measures model between 2 groups and the analysis of the longitudinal effect in increments of the measurements. Multifactor ANOVA analysis (with $P<.05$) were computed with SPSS Statistics (version 27.0; IBM Corp). The sample size was calculated using the software tool G*Power (version 3.1.9.7; Heinrich Heine Universität Düsseldorf). Ideally, assuming an effect size of 0.7, a minimum sample of 20 participants was required for the study to provide consistent statistical results. Since the effect size shows the strength of the relationships, it represents a minimum clinically meaningful difference. Of the many different types of effect sizes, the G*Power software uses Cohen *d* to characterize effect size by relating the mean difference to variability. Therefore, his study standardized the effect size to 0.7 for sample size calculation and power analysis.

Results

To identify the underlying differences between the preintervention (T_i) and postintervention (T_e) assessments in each group, repeated measures ANOVAs were conducted with time ($T_i – T_e$) as the dependent variable and group as the main within-subjects factor. When the ANOVA was significant, the Bonferroni post hoc test was used. To ensure that the error variance of the dependent variables is equal across groups, the Levene test was applied beforehand for all the metrics.

In addition, to identify the improvement effect due to the use or nonuse of the VR system, the variation coefficient between the preintervention and postintervention assessments was analyzed for each group as follows: $\Delta = 1 – (T_e / T_i)$. The variation coefficient outcomes were compared between groups by the independent 1-tailed *t* test. The mean and SD of the ROM outcomes for the hip and knee of each group are shown in Table 2. The mean increase Δ for each measurement is shown in Figures 4 and 5.

Table . Hip and knee range-of-motion outcomes.

Outcome	Experimental group, mean (SD)			Control group, mean (SD)		
	Preintervention (°)	Postintervention (°)	Variation coefficient (%)	Preintervention (°)	Postintervention (°)	Variation coefficient (%)

Figure 4. Summary of increments in active and passive hip ROM parameters with SD bars. The vertical axis represents the percentage of postintervention increase or decrease of each hip ROM parameter. ALHF: active left hip flexion; ARHF: active right hip flexion; PLHF: passive left hip flexion; PRHF: passive right hip flexion; ROM: range of motion.

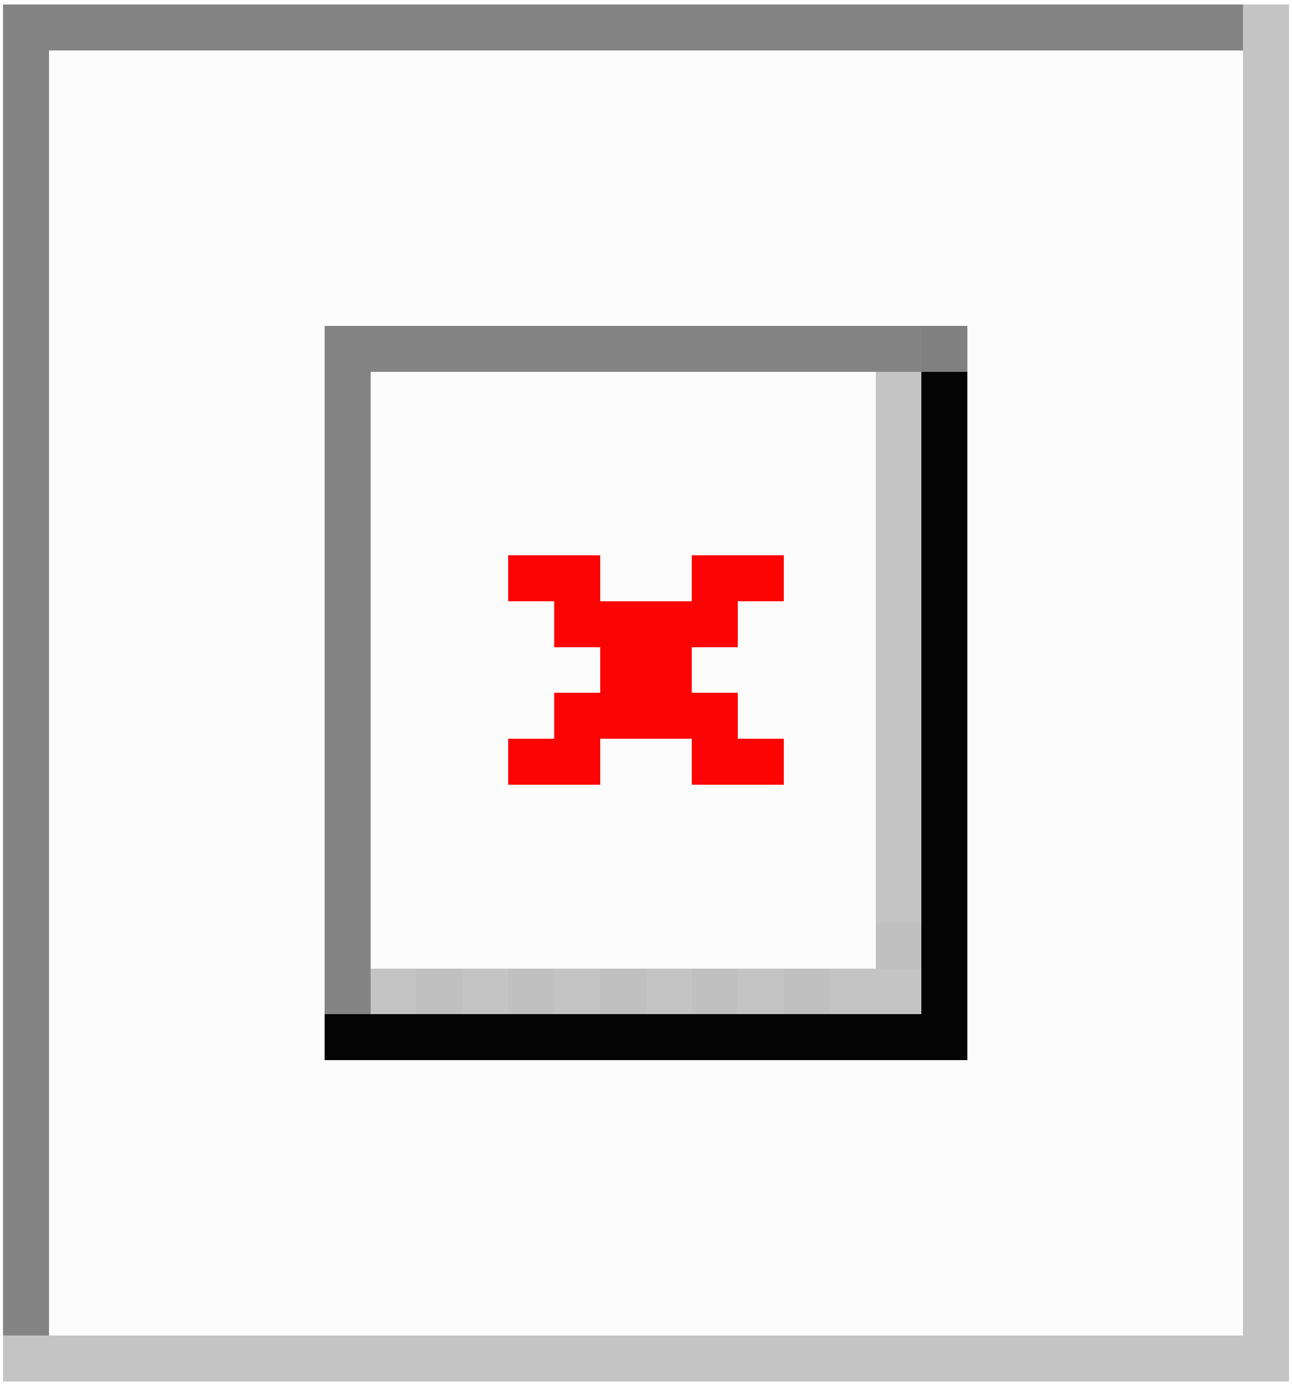

Figure 5. Summary of increments in active and passive knee ROM parameters with SD bars. The vertical axis represents the percentage of postintervention increase or decrease of each knee ROM parameter. ALKE: active left knee extension; ALKF: active left knee flexion; ARKE: active right knee extension; ARKF: active right knee flexion; PLKE: passive left knee extension; PLKF: passive left knee flexion; PRKE: passive right knee extension; PRKF: passive right knee flexion; ROM: range of motion.

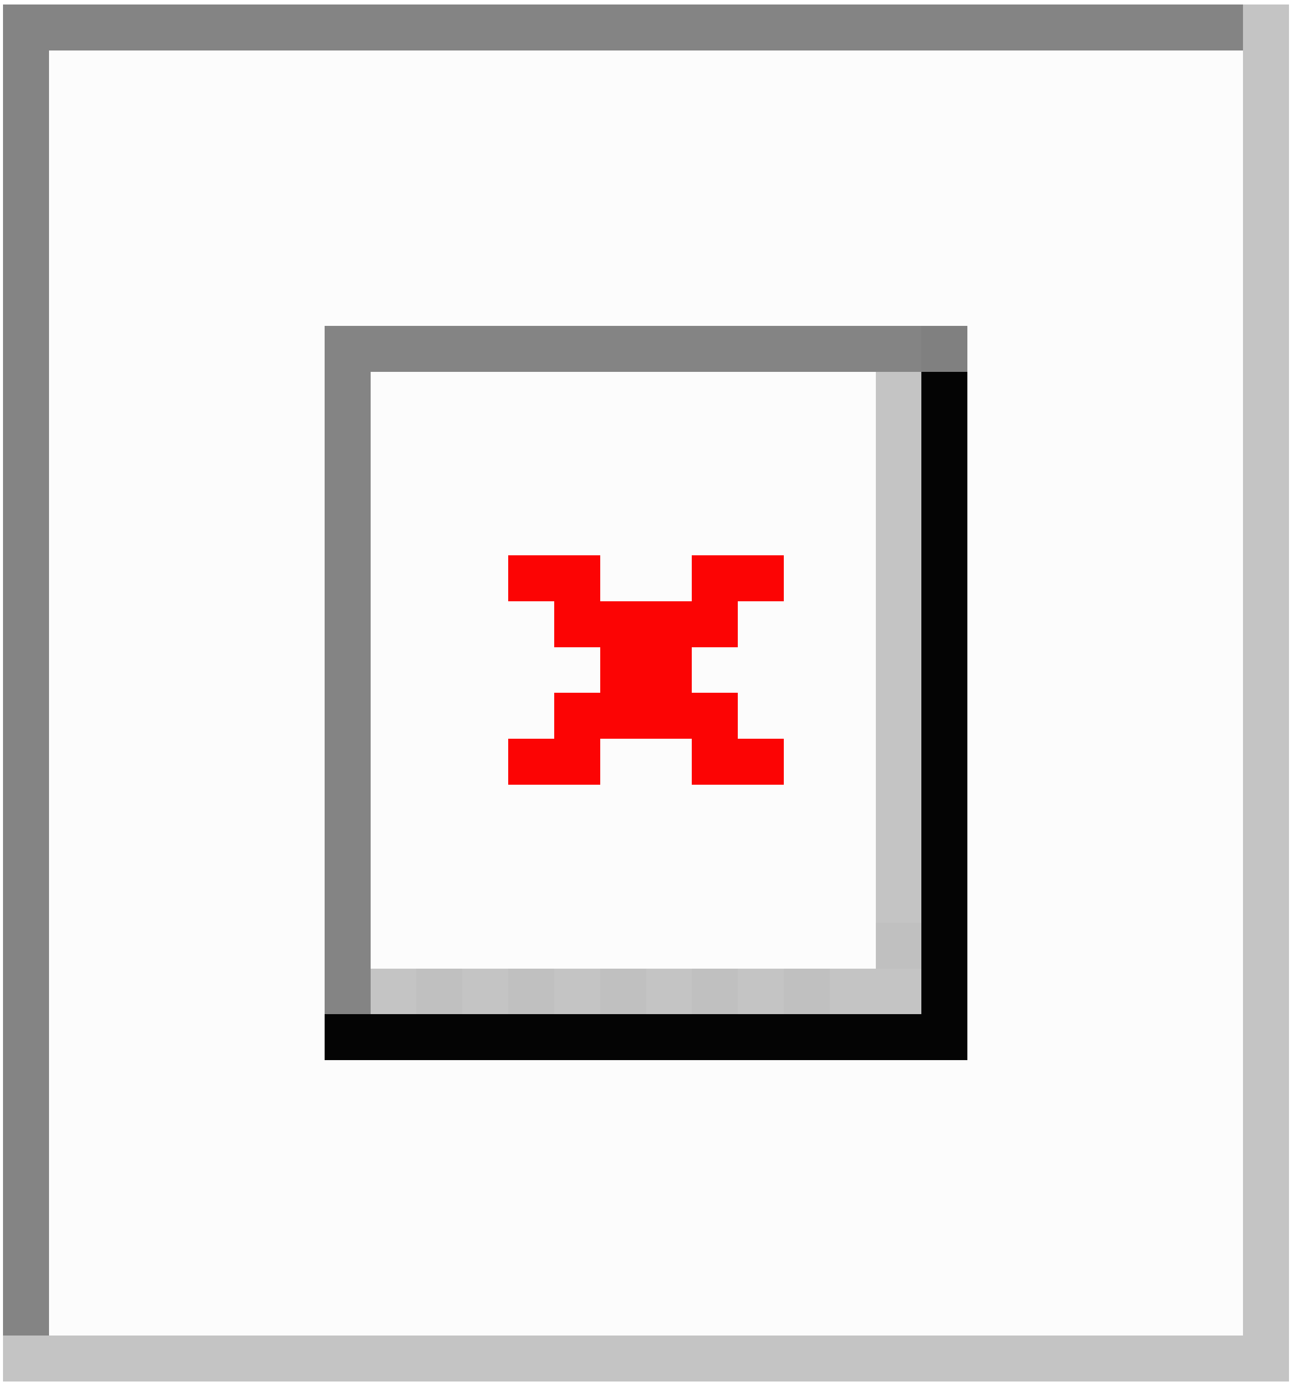

With regard to the hip flexion outcomes, the active left hip flexion results were significant by ANOVA (*P*=.03), with no significance observed for the between-subjects effects test (*P*=.67). However, the within-subjects effects test was significant for the time factor (*P*=.03), but no significant group-time interaction effect was found (*P*=.08). Despite the opposing results showing passive left hip flexion improvements for each group, there was no significance difference by ANOVA (*P*=.93) and no statistically significant result was obtained by the between-subjects effects test. Passive left hip flexion was statistically significant in the within-subjects effects test for the time factor (*P*=.008). The active and passive right hip flexion results were not significant by ANOVA (*P*=.39 and *P*=.83, respectively). In both cases, no significant results were obtained for the between- and within-subjects effects tests.

For the knee ROM measurements, when analyzing the left knee assessments, the active and passive left knee flexion outcomes were not significant by ANOVA (*P*=.06 and *P*=.76, respectively). No statistically significant results were obtained by the between- and within-subjects effects tests in both cases. Similar results were obtained for the active left knee extension outcomes. Although reasonable differences in the active and passive left knee extension increases between groups can be observed in Figure 5, neither active nor passive left knee extension were significant by ANOVA (*P*=.66 and *P*=.92, respectively). No statistically significant results were obtained by the between- and within-subjects effects tests in both cases.

Regarding the right knee assessments outcomes, all outcomes were not significant by ANOVA (active flexion: *P*=.34; passive flexion: *P*=.06; active extension: *P*=.12; passive extension: *P*=.38). No statistically significant results were obtained by the between- and within-subjects effects tests for all cases, except for passive right knee extension, which was statistically significant for the time factor (*P*=.04) by the within-subjects effects test.

Discussion

Principal Findings

The aim of this study was to test the short-term effects of 2 different interventions on short-term improvement of lower limb function and ROM. For this purpose, a randomized controlled trial was carried out with participants with ataxia and hemiparesis.

In this study, the improvement outcomes of active and passive knee and hip joint ROMs due to the use of VR technology were inconclusive. Likewise, no statistically significant differences in the results between groups can be indicated. Even so, all the active ROMs measured—that is, performed by the patients—showed an increase with respect to the initial values. A greater disparity was observed in the passive measurements, although this may be attributed to the different passive mobilizations performed at each time by different physiotherapists. In this case, the active measurement is of special relevance in clinical terms because it indicates a ROM that the patient is able to achieve autonomously. On the other hand, large SDs in outcome variables clearly indicate that the improvements in the functional gait outcomes are not entirely consistent or represent a group effect. We observe that no significant effect can be attributed to VR intervention based on the statistical analysis of the immediate effects on gait function and joint ROM.

However, considering this similarity between groups, it can be pointed out that the use of VR has similar positive effects as the use of the conventional pedaling treatment. Thus, this immediate observation of effects leads us to conclude that the use of VR during pedaling exercise has similar effects to non-VR exercise training. Therefore, given that the use of VR technology does not worsen the improvement of lower limb ROM, and in line with the scientific literature [17-20], it may be advantageous to use it to maintain the patient's motivation.

Strengths and Limitations

A limitation of this study is the short-term nature of the intervention program. It is arguable that a longer intervention program would have shown more notable effects on functional improvement. However, assuming that it is precisely the treatment time that is one of the main causes of progress in physical improvement, the motivational impact of VR technology over time would need to be assessed. Therefore, further studies on the motivational impact of VR cycling versus conventional cycling on long-term physical activity remain to be addressed. Regarding these future studies, we suggest that cohort studies should be conducted among a population with more homogeneous neurological conditions. This recommendation is based on the limitations encountered in this study, where the difficulty of drawing conclusions about group changes or improvements with such wide SDs is presumably a reflection of the heterogeneity of the group.

Another factor to consider is that different physiotherapists were involved in taking the ROM measurements of the participants, although the measurement system was the same. This fact could be considered in future studies to evaluate interrater effects.

Future Directions

We consider it relevant to analyze, in future studies, whether these improvements in active and passive ROM are accompanied by greater muscle activation, in particular, the hamstrings, rectus femoris, gastrocnemius, and tibialis anterior muscles, as suggested by scientific literature [27].

Conclusions

The results of this trial demonstrate that pedaling exercises coordinated with VR technology works as successfully as conventional training for patients with lower limb disorders such as ataxia and hemiparesis. In this study, it was found that participants who performed the pedaling exercise program using the VR system showed similar results to the participants who performed the exercise activity without using VR technology. Overall, VR technologies can be a useful tool to help patients with ataxia and hemiparesis engage in lower limb exercise therapies.

Acknowledgments

The authors would like to thank all the participants who collaborated in this study, as well as the therapists and health care professionals from Centro Lescer for their participation in this study. The financial support for the industrial doctorate project "Desarrollo y estudio de una plataforma interactiva y un sistema electrónico de pedaleo para rehabilitación funcional de personas mayores" of the Autonomous Community of Madrid (IND2019/TIC17090) toward this research is hereby acknowledged. Abstract

Background: There is ample evidence that most children do not perform enough physical activity (PA). To address this major public health problem, the French government implemented 30 minutes of daily PA (DPA) at schools but did not provide any supplemental resources or concrete guidance. Considering both children's interest in video games and the need for teachers to complete their curriculum, the use of a learning-based exergame that combines PA and learning appears particularly relevant.

Objective: The first objective of this study was to evaluate the feasibility of implementing 30 minutes of DPA through exergaming among school-age children. The second objective was to examine the effects of an exergaming program on physical literacy, academic learning, and soft skills (motivation, self-efficacy, and concentration).

Methods: This interventional study had a pre-post design and used the Play LÜ exergame platform. The study included 79 children with a mean age of 8.9 (SD 1.2) years from grade 2 (7 years old) to grade 5 (11 years old). Play LÜ requires players to throw balls against a wall to reach a target or to activate an object and provides an interactive game area for educational activities linked to specific learning themes. After a 4-session familiarization phase during which the teachers chose to prioritize mathematics learning in 30-minute DPA sessions, students took part in DPA sessions over a period of 3 weeks with Play LÜ and a motor skills circuit behind the LÜ setup to keep them continuously active. All sessions were carried out by PA specialists. Each session started with a warm-up using the Grööve application, continued with main activities promoting mathematics learning adapted to each grade level, and ended with a 3-minute meditation for returning to a calm and serene state using the Gaïa application. Before (T0) and after (T1) the program, students completed a self-evaluation booklet to assess their levels of physical literacy, academic performance, and soft skills.

Results: The implementation of this exergaming program was welcomed by the school's administration, teaching staff, and parents. After the program, we observed increased scores for physical literacy (difference +2.6, percentage change +3.6%; W=933.0; P=.002; r_{rb}=−0.39, 95% CI −0.58 to −0.16) and motivation in mathematics (+0.7, +9.8%; W=381.5; P=.005; r_{rb}=−0.44, 95% CI −0.66 to −0.16). In addition, it is important to note that some measures progressed differently across learning levels and age groups.

Conclusions: The study results indicate positive impacts of learning-based exergaming on physical literacy and motivation in mathematics among school-age children.

Introduction

Background

Regular exercise and physical activity (PA) have been shown to benefit children's physical and social health, as well as their academic performance [1-3]. For children, the World Health Organization (WHO) recommends a minimum PA practice of 60 minutes of daily moderate-to-vigorous PA [4]. Yet, in France, only 41.8% of children reach these recommendations [5]. In other words, nearly 6 out of 10 children are physically inactive. In this context, the French national health strategy [6] has set as a major objective the implementation of a comprehensive policy of prevention and health promotion. As a result, since September 2022, primary schools have been required to provide 30 minutes of daily PA (DPA) to promote PA and encourage the development of children's motor skills and physical abilities. Distinct from the teaching of physical education (PE), the 30 minutes of DPA can take a variety of forms, adapted to the context of each school. They can be split up and combined over the various school and extra-curricular periods. This was extended to all elementary schools after 2 years of testing in 11,000 volunteer schools [7].

Given the significant amount of time children spend in school throughout their childhood, schools represent an ideal setting to achieve maximum impact with regard to improving PA levels [8,9]. Furthermore, several studies have suggested that combining PA with academic activities can improve children's health and cognitive functioning, which could subsequently lead to an improvement in children's academic performance [10-12]. Attention, in particular, which is a prerequisite for learning, is often targeted during classroom-based PA [13]. However, other variables, such as motivation and self-efficacy (referring to the child's perception of his or her capabilities), are well known to influence children's school performance and acquisition [14-17] and could be influenced by a more entertaining approach to learning via exergaming.

Despite all the benefits of implementing regular PA at school, in a systematic review, Nathan et al [18] highlighted several barriers, such as environmental context and resources with "a lack of time in the curriculum;" goals with "competing curriculum demands of other subjects" or "physical activity considered a lower priority than other subjects;" and beliefs about capabilities, such as a lack of teacher expertise and confidence in delivering PA, and intentions with "a lack of teacher motivation to implement PA" [18]. By contrast, the authors also mentioned several facilitators. Among them, the knowledge domain was indicated to play a facilitating role, for example, "sufficient knowledge about PA and health to effectively conduct PA" [18]. This dimension could be explored through the notion of physical literacy (PL), which corresponds to "the motivation, confidence, physical competence, knowledge, and understanding to value and take responsibility for engagement in physical activities for life" [19]. Indeed, PL is particularly important in early childhood, a crucial period for the development of fundamental movement skills [20] and the adoption of PA habits. Physically literate individuals are more physically active, spend more time playing sports, and are less sedentary. PL is a multi-level concept that is increasingly taken into consideration in the field of public health as it is a key determinant of PA habits across the lifespan [21].

One of the factors behind children's low levels of PA and high levels of sedentary behaviors is screen time use. Indeed, 71.7% of French boys and 58.5% of French girls aged 6 to 10 years have more than 2 hours a day of screen time [5]. Children aged between 8 and 12 years have 1.5 hours of daily screen time attributable to video games [22]. Over the last decades, video games have emerged as one of the most popular forms of global entertainment. Given children's keen interest in video games, it seems particularly appropriate to use gamification to encourage PA. For staying active while enjoying the pleasures of video games, a worthwhile alternative is exergaming. Indeed, exergaming or active video gaming requires bodily movements to play the game and encourages PA, with a focus on children's interest in the game's dynamics and stimulation. Our approach to exergaming takes into account a health dimension and can be associated with the conceptualization proposed by Oh and Yang [23], defining an exergame as "a video game that promotes (either via using or requiring) players' physical movements (exertion) that is generally more than sedentary and includes strength, balance, and flexibility activities."

Given that children spend most of their time at school, that they have a particular appeal for video games, and that exergaming seems to have beneficial effects on school learning [24], the use of exergaming at school appears to be an ideal solution for promoting PA, PL [25-27], and learning [28]. Furthermore, it appears that the use of a technology-based learning environment at school can increase soft skills, such as motivation and concentration on academic tasks [29]. Similarly, it has been shown that incorporating technology into an instructional intervention can improve students' sense of self-efficacy [30], which is a key variable for academic learning. Exergames, in particular, have been found to promote cognitive functions, motor skill training, enjoyment, and motivation to play among school-age children [31], and improve self-efficacy over traditional exercises [32]. Supporting this idea, it has been shown that exergaming (eg, Nintendo Wii Games [33]) incorporated into PE classes combined with health messages has a higher potential to enhance PA-related attitudes and behaviors than regular PE classes, especially in elementary school children [27]. An interesting exergaming tool for reconciling learning and DPA is the Play LÜ exergame platform (LÜ Interactive Playground) [34]. This technology can be used to change the traditional sports-school atmosphere into an interactive learning environment through interactive wall projection and a synchronized sound system. LÜ Playground activities are designed to improve the learning of children and adolescents by allowing them to respond to questions in specific fields (eg, mathematics, history, and natural sciences) by throwing balls against an interactive wall. This tool would therefore allow the practice of PA within non-PE curricula and thus ensure the 30 minutes of DPA among primary school children. Moreover, given the associations among cognitive functioning, soft skills, learning, and PA demonstrated in the literature, it appears essential to assess whether an exergaming program can improve these different variables.

Objectives, Research Questions, and Hypotheses

The first objective was to study the feasibility of implementing 30 minutes of DPA through exergaming. Given that exergaming combines the interests of children (for video games) and teachers (for learning and respecting the curriculum) while promoting PA, we hypothesized that it will enable effective implementation of the 30 minutes of DPA in schools.

The second objective of this study was to evaluate the effects of an exergaming program on PL, academic learning, and soft skills (motivation, self-efficacy, and concentration). We hypothesized that implementing a DPA program involving exergaming on a specific academic course combined with information on health-promoting behaviors daily could increase children's PL (hypothesis 1) and increase academic performance (hypothesis 2). Indirectly, allowing students to work on an academic subject more entertainingly through exergaming could improve students' motivation in the academic discipline (hypothesis 3), their sense of self-efficacy in the subject (hypothesis 4), and their concentration in class and the academic subject (hypothesis 5).

Methods

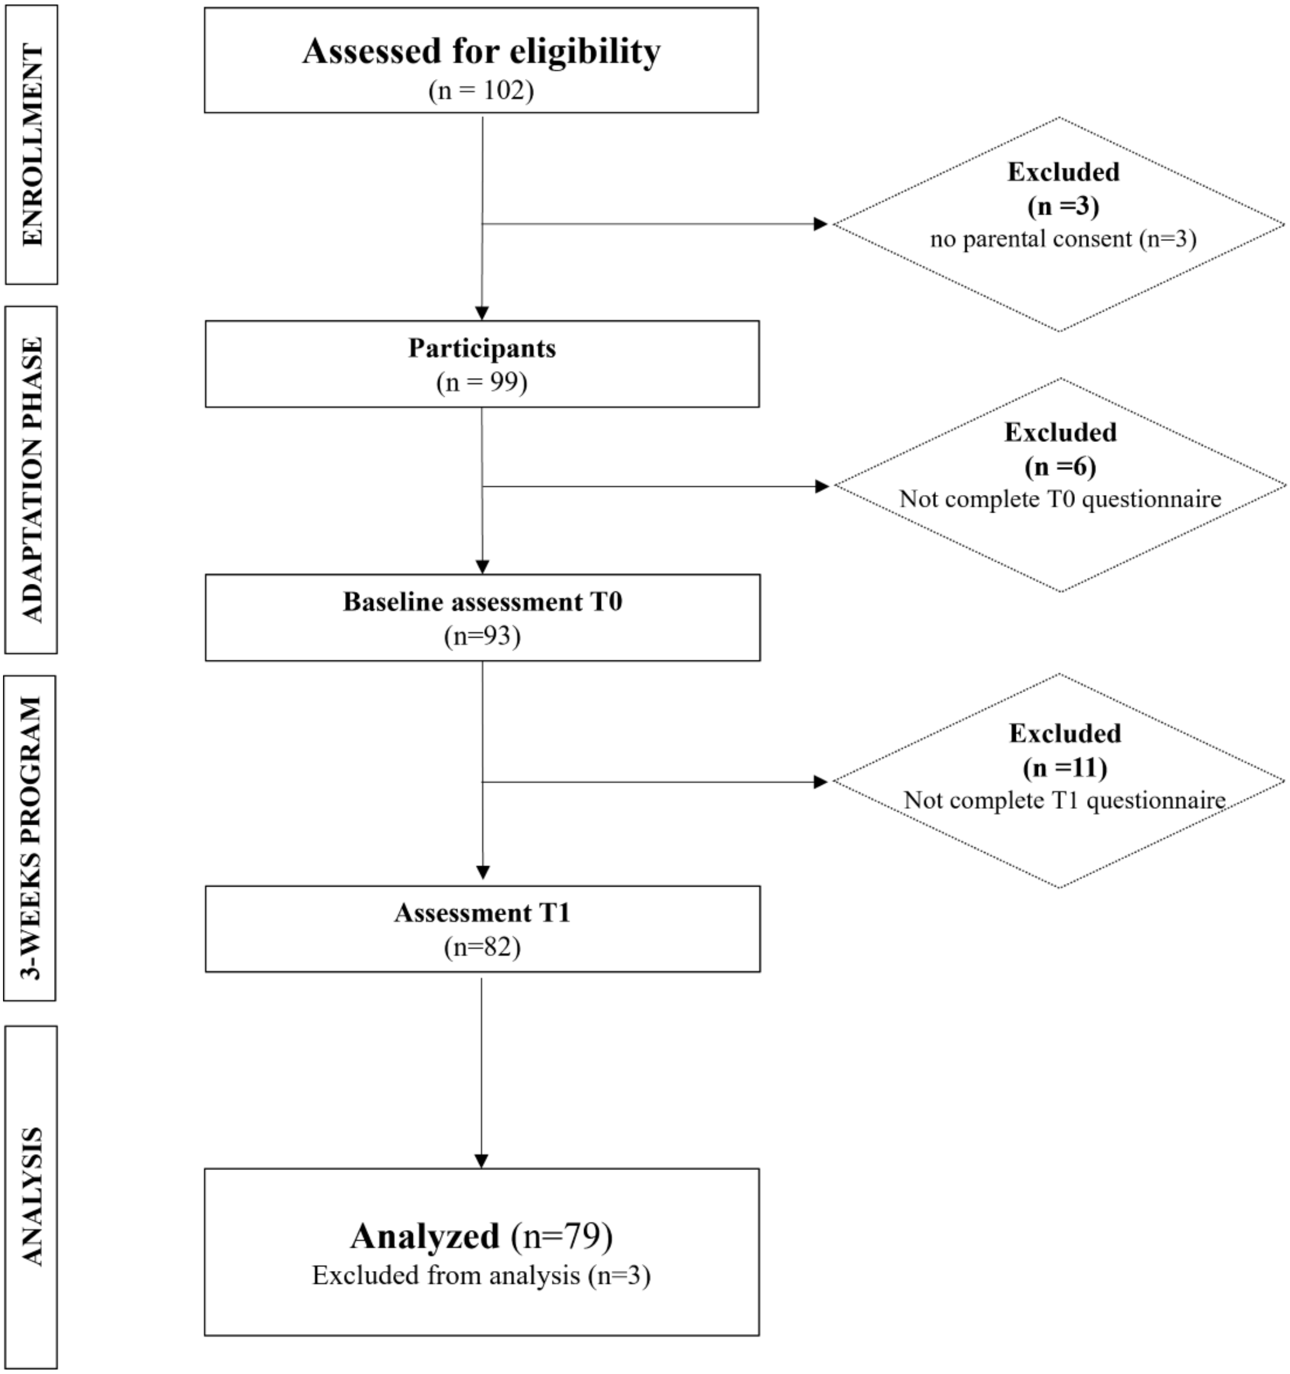
Population

This study was conducted with children aged 7 to 11 years as part of the implementation of the 30 minutes of DPA policy. The study was designed as an interventional study with a pre-post design. It included children from grade 2 (7 years old) to grade 5 (11 years old) in a mid-sized city school in the southern part of France, who had never benefited from any intervention in the field of exergaming. Before the project, the study and objectives of this research were presented to the school administration and then to the teachers. This pilot study took place in a small school with 1 class per level and 1 teacher per grade, with each of them (n=4) having no experience of exergaming and volunteering to take part in the research protocol. This school was selected for its pre-existing collaboration with the research team and middle-school students (8th grade), as well as for the availability of a space that could be used to install the LÜ mobile setup over a period of several weeks.

Subsequently, the parents of the children in the classes concerned were informed that their children would be part of a research protocol on 30 minutes of DPA during school time. A request for parental consent was sent via the school administration to each parent. In the event of parental refusal (only 3 parents refused), the children's data were not analyzed. A habituation phase was then proposed, and the teachers were able to learn about the various potentialities of the LÜ tool, as well as the implementation of the 30 minutes of DPA by the project team. The intervention then began and lasted 3 weeks, and preintervention (T0) and postintervention (T1) assessments were conducted.

During the enrollment period, 102 children were eligible (Figure 1). However, owing to the absence of parental consent (n=3) or the absence of children at evaluation time 0 (n=6) or time 1 (n=11), the analyses were carried out on 79 children. This final sample was made up of 34 girls and 45 boys, with a mean age of 8.9 (SD 1.2) years.

Figure 1. Study flow chart.



Class Measures

All the teachers expressed the wish to work on mathematics (geometry and arithmetic). A planning schedule was drawn up with the classes concerned so that the sessions could be scheduled during mathematics lessons.

Teacher Measures

At the end of the program, teachers were asked the following questions: On a scale from 0 to 10, how would you rate (1) your students' motivation for mathematics before the program? (2) your students' concentration for mathematics before the program? (3) your students' motivation for physical activity before the program? (4) your students' motivation for mathematics today? (5) your students' concentration for mathematics today? (6) your students' motivation for physical activity today?

Child Measures

At T0 and T1, students completed a questionnaire consisting mainly of analog visualization scales or checkboxes on different variables of interest (PL, motivation, self-efficacy, and concentration), which are described in the following sections. In addition, exercises adapted according to grade level were proposed in the target subject (mathematics) and a control subject (French).

Physical Literacy

PL was assessed using the Physical Literacy Assessment for Youth Self (PLAYself), designed for children aged 7 years or older, to explore children's perceptions of their PL [35]. PLAYself demonstrated robust psychometric properties, with good fit statistics, internal reliability, and a lack of item bias and problematic local dependency [36]. For a better understanding of the different dimensions of PL in the PLAYself questionnaire, the forms are available in English [37] and French [38] versions. The adaptation of this form within the evaluation booklet of this pilot project is available in Multimedia Appendix 1.

PLAYself consists of 22 questions divided into the following four subsections: (1) *Fitness*, which involves children's perceived fitness level with "disagree" and "agree" response categories for a single item; (2) *Environment*, which involves measures of 6 different environments in which children can do sports and activities (eg, "How good are you at doing sports and activities in the gym?") on a 5-point Likert scale ranging from 1 ("never tried") to 5 ("excellent"); (3) *Physical literacy self-description*, which involves 12 statements about doing sports and activities based on cognitive and affective factors (eg, "It doesn't take me long to learn new skills, sports, or activities"), where the children are asked to rank how well they agree on a 4-point Likert scale ranging from 1 ("not true at all") to 4 ("very true"); and (4) *Relative ranking of literacies*, which involves children's ranking of the importance of literacies in school, at home with family, and with friends (eg, "Math and numbers are very important in school") on a 4-point Likert scale ranging from 1 ("strongly disagree") to 4 ("strongly agree").

The first section is informative, while in the other 3 subsections, a separate score can be calculated and a total score can be obtained for PLAYself. The total PLAYself score is the average across the scores of each subsection, excluding the fitness question. A higher score (range 0-100) indicates a higher self-perceived PL.

Academic Achievement

To measure academic achievement, exercises in French and mathematics were retrieved from the national program by level following teacher school year progression. The test evaluated students' academic knowledge and skills related to specific subject areas, including French and mathematics. The test was grade-specific; did not contain any bias regarding age, gender, or ethnicity; and was scored as a percentage of achievement in French on one side and mathematics on the other.

Motivation, Self-efficacy, and Concentration

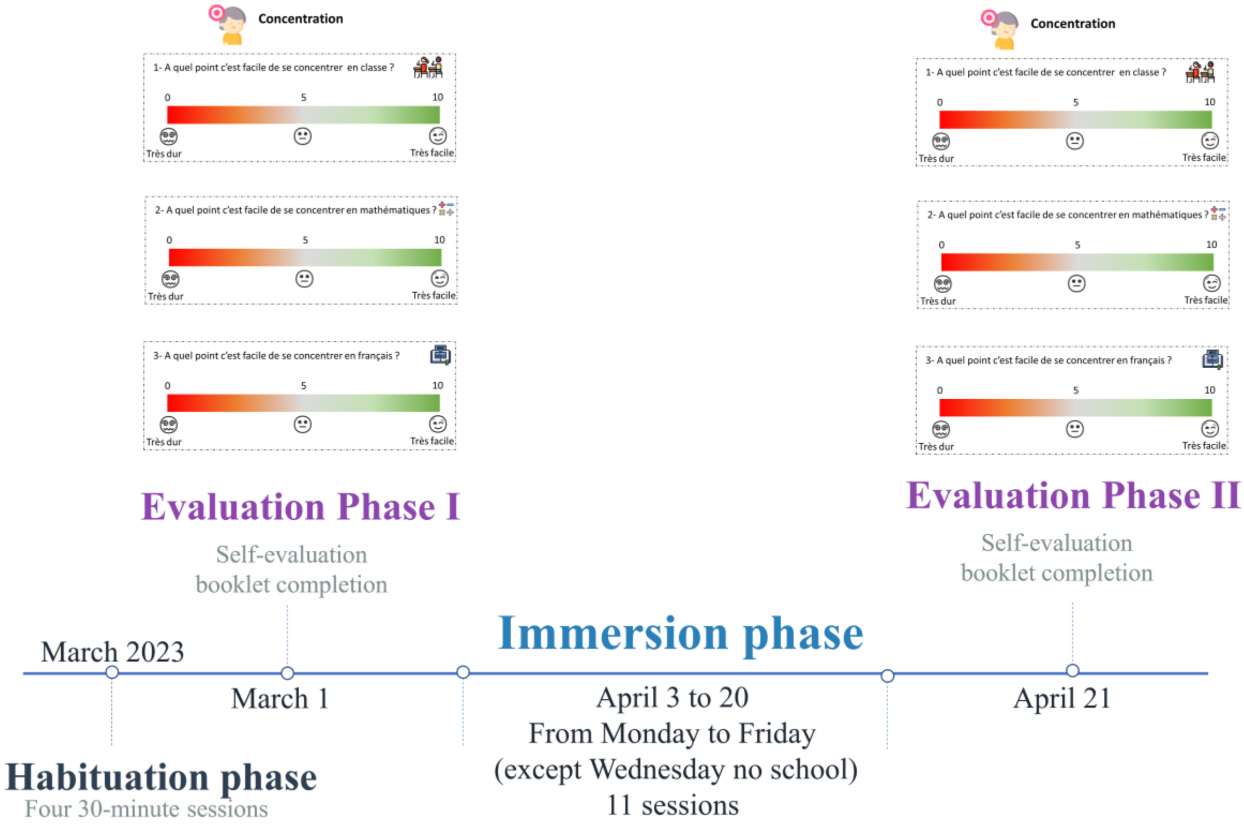
Motivation and self-efficacy were assessed by 2 items each, one for mathematics and the other for French. For motivation, children were asked: "How much do you enjoy doing [mathematics/French] exercises?" For self-efficacy, children were asked: "How well do you think you did on the [mathematics/French] exercises?" Concentration was assessed by 3 items, one for mathematics, one for French, and a more general one targeting concentration in class. For this variable, children were asked: "How easy is it to concentrate in [class/mathematics/French]?" We used a simple question per variable to reduce the time needed to complete the entire protocol. The items were formulated as clearly as possible to be adapted to the children's age and to ensure that they measure the core component of each variable. For all items, children were asked to respond using a 10-cm–long visual analog scale representing their feelings and marked by extreme labels at 0 cm (eg, very hard) and 10 cm (eg, very easy), which appeared as reliable response options in children's questionnaires [39].

Procedure

Habituation Phase

On Thursdays in March 2023, students had 4 LÜ 30-minute habituation sessions, spaced 1 week apart, enabling them to familiarize themselves with the interactive gymnasium. Activities linked to the academic development of the LÜ catalog were proposed, targeting language (ie, Minewörd), mathematics (ie, Wäk, Newton, Constello, and SphYnX), science and technology (ie, Brüsh and Grüb), history (ie, Störia), and arts (ie, Pixël). With mathematics accounting for one-fifth of the school program in each grade and the LÜ catalog offering more mathematics-related applications (except PE, which was not at the center of the project), the 4 teachers wanted to work on mathematics during the 3-week DPA immersion phase (Figure 2).

Figure 2. Timeline of the project.



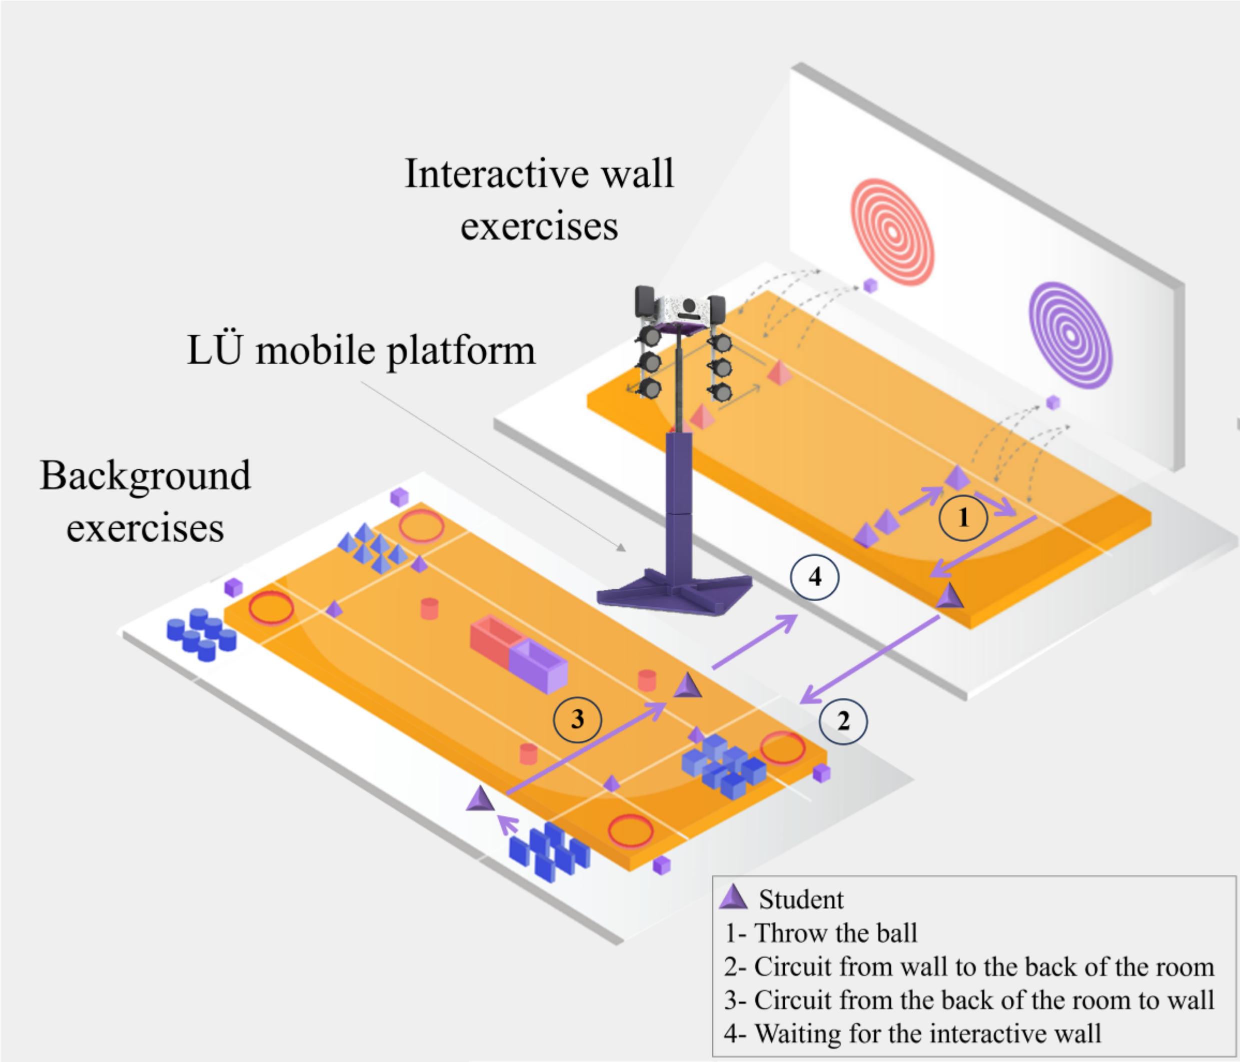
Immersion Phase

After the habituation phase, students took part in 30-minute DPA sessions using the Play LÜ exergame platform and worked on a single subject selected by the teacher (Figure 2).

Exergame Setting

For this research protocol, the LÜ mobile equipment owned by the research team was made available to the school for this pilot project and was installed in a designated space for the duration of the project. The Play LÜ exergame platform (LÜ Interactive Playground) has the potential to overcome the limitations of a physical room. With Play LÜ, the participants are immersed in the games displayed on a giant projection wall (6×3 m). The principal mechanism of Play LÜ requires the players to throw balls against the wall (eg, to reach a target or to activate an object; Step 1 in Figure 3). In addition, this mobile platform offers an interactive game area for educational activities linked to specific learning themes (calculations, puzzles, etc). For this research protocol, a work area with a daily changing activity circuit was implemented behind the LÜ mobile setup (without the interactive wall). With class compositions ranging from 26 to 30 students, this "with" and "without" interactive wall configuration was essential to keep students active during the 30-minute session. Once the ball was sent to the interactive wall (Step 1), the student was required to go behind the LÜ mobile setup toward the back of the room (Step 2) to carry out various exercises to promote different motor skills (eg, jumping, throwing, and balancing) and perform other exercises on the way back (Step 3). At the end of the circuit behind the LÜ setup (Steps 2 and 3), the student waited for his or her turn in front of the interactive wall (Step 4).

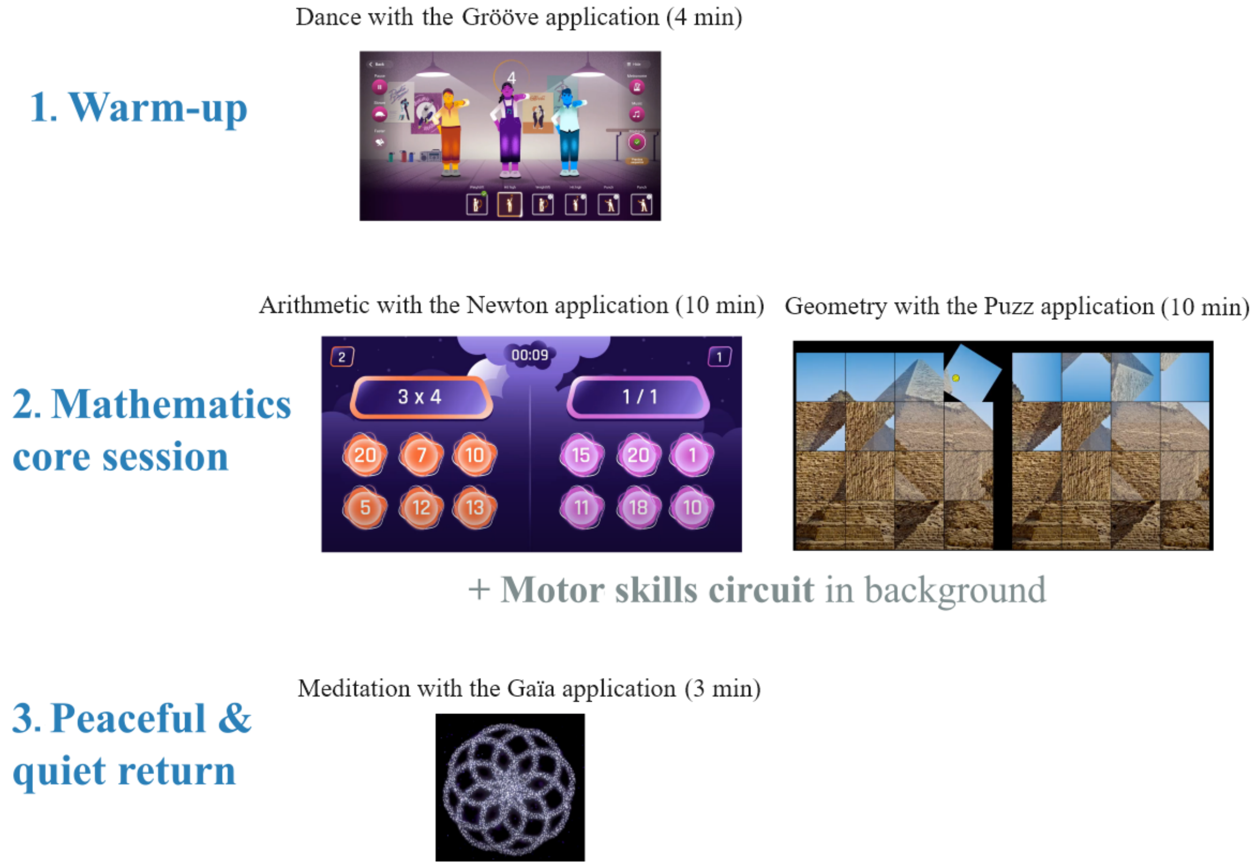
Figure 3. Practice environment implementation.



Daily Session Exercises With Play LÜ

During the 3-week immersion phase, sessions were structured in the same way, with a warm-up using the Grööve application at the beginning (Figure 4), which can be assimilated with the active video game Just Dance (Nintendo) [40], and then a core session promoting mathematics learning adapted to each grade, involving a section in front of the interactive wall with the Newton application for arithmetic and Puzz application for geometry (ie, with picture geometric forms or rules), and a section without the interactive wall consisting of a motor skills circuit (eg, throwing, jumping, and balancing) that enabled the child to be as active as possible (Figure 4). During break times (mainly while waiting for their turn on the interactive wall), the children had access to posters presenting active health behaviors with their favorite heroes according to age (ie, The Minions, Miraculous, and a successful French singer or Youtuber, depending on student age). The session ended with a 3-minute meditation for a return to peace and quiet, using the Gaïa application (Figure 4).

Figure 4. Daily physical activity core session details.



Focus on LÜ Applications

The Play LÜ exergame platform allows the use of applications (with or without customization) that can be used to meet general or specific learning objectives. The applications used during the immersion phase and their pedagogical benefits are summarized in Table 1.

Table 1. Play LÜ applications.

Application	Duration (min)	Description	Learning objectives		
			Academic development	Physical and motor development	Sociocognitive development
Grööve	4	This is a perfect warm-up and allows the development of gross motor skills.	• Movement • Dance	• Coordination • Cardiovascular endurance	• Cognitive flexibility • Inhibition
Newton	10	Newton is a fun way to combine physical activity and mathematics with the customization of equations by grade.	• Arithmetic	• Manipulation (throw the ball and aim at the target)	• Inhibition
Puzz	10	Throw the ball at a piece of the puzzle to rotate it and allow it to create an active knowledge competition.	• Puzzle created with geometry-related images • Spatial orientation	• Manipulation (throw the ball and aim at the target)	• Task engagement
Gaïa	3-5	This application helps students cool down after they have been active.	• Health and healthy habits	• Proprioception	• Emotional regulation

The customization of pre-existing games in LÜ was carried out on the Newton and Puzz applications for mathematics learning. For the Newton application, the difficulty of the operations proposed depended on each grade (eg, addition and subtraction calculations for grades 2 and 3, and multiplication calculations for grades 4 and 5). For the Puzz application, the images to be assembled were linked to the geometry program (eg, polygons and nonpolygons for grades 2 and 3, and complex polygons for grades 4 and 5).

Evaluation Phase

Before (T0) and after (T1) the 3 weeks of DPA (Figure 2), students completed a self-evaluation booklet to assess their levels of PL, academic performance, and soft skills that could be impacted by the program (eg, motivation, concentration, and self-efficacy).

At the end of the 3-week immersion phase, the students retook the same questionnaire, with only minor changes to the exercises (eg, 12+18 replaced by 14+15), but with the same instructions and level of difficulty. Following this, a short interview was conducted with the teachers, asking them to assess the changes observed in their classrooms.

All DPA sessions were carried out by sports science students specializing in adapted PA and health, under the supervision of a qualified teacher of adapted PA and health.

Statistical Analysis

Power analyses were conducted using G*Power (Heinrich-Heine-Universität Düsseldorf). For a pre-post comparison, with a medium effect size (0.50), an alpha error probability of .05, and a power of 0.95, we obtained a total sample size of 45. We then adjusted according to the number of participants available in the school, which allowed us to reach the sample size of 45.

As our data did not follow a normal distribution and given the characteristics of our sample, the intervention impact was tested with nonparametric within-group comparisons (T0 vs T1; Wilcoxon test, bilateral *P* values) for all participants and then by school-grade grouping. Effect sizes were expressed as the rank biserial correlation (r_{rb}) and its 95% CI. We also provided the score differences between T1 and T0, and expressed them as a percentage of improvement. Data were analyzed using JASP software (version 0.17.2.1; JASP Team).

Ethical Considerations

This pilot study involved an experiment in human and social sciences in the field of health. As mentioned in article R1121-1 section II subsection D of the French Public Health Code, this type of experimentation in human and social sciences does not require the authorization of the Committee for the Protection of Persons. Before the start of the study, a favorable opinion was obtained from the president of the University of Nîmes ethics committee. This individual verified that the study was conducted in accordance with institutional and national ethical standards, as well as the Declaration of Helsinki (2008). Moreover, this study was integrated into the school's activities and projects, and the protocol was validated by the school administration.

Consent to Participate

Concerning consent and information, the study was first presented to the school's teaching staff and administration who gave their approval to take part. Next, an online information notice and online informed consent form with the names and university affiliations of the experimenters were provided to the parents of all children in the classes involved in the study before initiation. Finally, the information and informed consent of the children and their teachers were collected face-to-face. Recruitment was based on voluntary participation, with no compensation for participants. Participants were informed that they could withdraw their consent at any time, whether at the request of the child, parent, or teacher.

Specific Measures Taken

To assure safety and security, all activities took place during class hours, under the supervision of the teacher, and the exercises were led by an associate professor specializing in public health and PA and two 3rd-year students in adapted PA from the University of Nimes. The expertise of the 3 animators enabled them to adapt the PA to the children's abilities in order to prevent any risk of injury. Moreover, the number of animators made it possible to provide individual support when needed. Finally, to guarantee the security of the data, they were stored on a secure university computer, and the printed versions of the data were kept in a secure cupboard in a university office.

Results

Feasibility of DPA and Exergaming

With regard to our first objective, which was to study the feasibility of implementing 30 minutes of DPA through exergaming, our results showed that implementing exergaming during school time is entirely feasible. First, regarding the parents, all but 3 were in favor of their children taking part in the project. Second, regarding the teachers, all agreed to take part in the project. Third, all scheduled sessions (n=11) were carried out, with no sessions canceled. External constraints, such as educational visits or other activities, could have led to cancellations, but the teachers expressed a desire not to miss any sessions and agreed to exchange schedules with other classes when constraints arose, demonstrating their interest.

Effects of the Exergaming Program

Effects on the Entire Cohort

With regard to our second objective for the whole cohort, the 3-week intervention of DPA led to increased scores in PL (in accordance with hypothesis 1) and motivation in mathematics, which was the subject covered in the intervention (in accordance with hypothesis 3). There was a general improvement regarding concentration in class, and we expected (hypothesis 5) this increase to be observed for mathematics as well (Table 2). In addition, contrary to our assumptions, we did not observe any changes in academic performance (hypothesis 2) or feelings of self-efficacy (hypothesis 4) in mathematics. Surprisingly, the intervention also favored French learning, which was not covered in the intervention, with academic performance, concentration, and self-efficacy in French being higher after the intervention.

Table 2. Descriptive analyses of variables of interest before (T0) vs after (T1) the 3 weeks of daily physical activity in the whole cohort (N=79).

Variable	Score before the program (T0), mean (SD)	Score after the program (T1), mean (SD)	Difference (T1-T0), value (% change)	*W*	*P* value	r_{rb}[a], value (95% CI)
Physical literacy	70.8 (13.6)	73.4 (13.3)	+2.6 (+3.6%)	933.0	.002[b]	−0.39 (−0.58 to −0.16)
Academic achievement						
Mathematics	63.6 (32.5)	60.8 (31.0)	−2.8 (−4.4%)	1440.0	.35	0.12 (−0.13 to 0.37)
French	59.3 (26.2)	65.0 (27.9)	+5.7 (+9.6%)	858.0	.05[b]	−0.26 (−0.50 to 0.00)
Motivation						
Mathematics	7.1 (3.6)	7.8 (3.0)	+0.7 (+9.8%)	381.5	.005[b]	−0.44 (−0.66 to −0.16)
French	5.3 (3.2)	5.6 (2.9)	+0.3 (+5.6%)	1222.0	.48	−0.09 (−0.34 to 0.16)
Concentration						
Classroom (general)	5.5 (3.0)	6.0 (2.7)	+0.5 (+9.0%)	934.5	.07	−0.24 (−0.48 to 0.01)
Mathematics	7.0 (3.2)	7.2 (2.8)	+0.2 (+2.8%)	580.0	.16	−0.21 (−0.48 to 0.08)
French	5.6 (2.7)	6.4 (2.8)	+0.8 (+14.2%)	838.0	.01[b]	−0.34 (−0.55 to −0.09)
Self-efficacy						
Mathematics	6.8 (2.8)	7.2 (3.1)	+0.4 (+5.8%)	887.5	.30	−0.14 (−0.40 to 0.13)
French	6.1 (3.1)	6.7 (2.8)	+0.6 (+9.8%)	728.5	.02[b]	−0.32 (−0.54 to −0.05)

Effects on Grade 5 Participants

Focusing specifically on each grade (see Multimedia Appendix 2 for full details), participants in grade 5 were those most affected by the intervention.

After the intervention, grade 5 participants showed an increase in PL (difference +5.6, percentage change +7.9%; *W*=9.0; *P*<.001; r_{rb}=−0.91, 95% CI −0.96 to −0.78; hypothesis 1), mathematics motivation (+1.1, +20.0%; *W*=15.5; *P*=.007; r_{rb}=−0.77, 95% CI −0.91 to −0.43; hypothesis 3), and mathematics concentration (+0.8, +12.7%; *W*=21.5; *P*=.01; r_{rb}=−0.68, 95% CI −0.88 to −0.27; hypothesis 5) scores. Regarding French classes (even though they were not targeted by the intervention), grade 5 participants demonstrated an increase in motivation (+0.8, +17.7%; *W*=60.0; *P*=.05; r_{rb}=−0.48, 95% CI −0.76 to −0.03) and self-efficacy (+1.5, +29.4%; *W*=45.0; *P*=.02; r_{rb}=−0.57, 95% CI −0.81 to −0.14) scores after the intervention. They also tended to show an increase in academic achievement scores in French after the intervention (+7.3, +11.4%; *W*=53.0; *P*=.09; r_{rb}=−0.44, 95% CI −0.75 to −0.03). Contrary to hypothesis 1, grade 5 participants showed a decrease in academic achievement scores in mathematics after the intervention (−10.7, −13.6%; *W*=192.0; *P*=.006; r_{rb}=0.66, 95% CI 0.29 to 0.85).

Effects on Grade 2 to 4 Participants

The other grades also benefited from the intervention but to a lesser extent. After the intervention, grade 2 participants showed an increase in PL scores (difference +5.2, percentage change +7.1%; *W*=28.0; *P*=.03; r_{rb}=−0.58, 95% CI −0.84 to −0.11; hypothesis 1) and a marginal increase in academic performance in mathematics (+15.1, +33.7%; *W*=18.5; *P*=.06; r_{rb}=−0.59, 95% CI −0.86 to −0.06; hypothesis 2). Grade 3 participants showed an increase in mathematics concentration (+0.5, +7.5%; *W*=50.5; *P*=.04; r_{rb}=−0.51, 95% CI −0.79 to −0.07; hypothesis 5) after the intervention. Regarding French classes, grade 2 participants showed a marginal increase in self-efficacy scores (+1.0, +14.4%; *W*=24.0; *P*=.07; r_{rb}=−0.54, 95% CI −0.83 to −0.01), grade 3 participants showed a significant increase in academic performance (+16.8, +40.1%; *W*=68.0; *P*=.01; r_{rb}=−0.58, 95% CI −0.80 to −0.21), and grade 4 participants showed a marginal increase in concentration (+1.1, +20.7%; *W*=25.0; *P*=.09; r_{rb}=−0.52, 95% CI −0.82 to 0.01) after the intervention. Grade 4 participants showed a decrease in academic performance in French after the intervention (−15.0, −19.8%; *W*=103.5; *P*=.01; r_{rb}=0.72, 95% CI 0.33 to 0.90).

Effects on Teachers' Perceptions

Concerning the results obtained from teachers, 3 out of 4 teachers observed an improvement in their students' motivation for mathematics after the program (grade 2, T0=5.5 vs T1=7.5; grade 3, T0=7.0 vs T1=7.5; grade 5, T0=8.0 vs T1=8.5), and 1 teacher observed no change (grade 4, T0=6.0 vs T1=6.0). In addition, 2 out of 4 teachers observed an improvement in their students' concentration for mathematics after the program (grade 2, T0=6.0 vs T1=6.5; grade 4, T0=3.0 vs T1=5.0), and the other 2 teachers observed no change (grade 3, T0=6.0 vs T1=6.0; grade 5, T0=6.5 vs T1=6.5). Finally, regarding students' motivation for PA, only 1 teacher observed an increase (grade 2, T0=8.0 vs T1=9.0). It should be noted that 2 of the teachers who observed no change (grades 4 and 5) had already identified the maximum motivation score before the start of the program. The last teacher rated the students' motivation at 9.0 before and after the program.

Discussion

Principal Findings

Since September 2022, primary schools have been required to provide 30 minutes of DPA. In this pilot study, the implementation of an exergaming program as part of the 30 minutes of DPA policy was welcomed by the school's administration, parents, and teachers, with an increase in perceived motivation for mathematics.

After the program, we observed that children showed increased scores in PL and motivation in mathematics following 11 learning-based exergaming sessions.

Exergaming Implementation

Although this PA reform is recent in France, it has already been introduced in other countries several years ago. Indeed, the DPA school policy has been implemented since 2005 in Canada to promote active lifestyles for children in school settings [41], and in the province of Ontario, all elementary school children perform DPA during instructional time [42]. Yet, 10 years later (in 2015), it was revealed that only half of Ontario teachers were meeting this expectation [43], and this number dropped to 23% 5 years later in the report by Martyn et al [44]. The Canadian experience underscores the need to explore effective and sustainable methods for implementing the 30 minutes of DPA in schools. Consequently, this pilot study shows that exergaming can be used as a valuable tool in the deployment of DPA at schools.

Efficiency and Usefulness of Exergaming

Our second objective was to find out whether an exergaming intervention could be effective and useful. We hypothesized that implementing a DPA program involving exergaming on a specific academic course could have an impact on different aspects of a child's experience. First, in line with hypothesis 1, our results showed a significant increase in the PL of the entire cohort, with significant increases of over 7% for both grades 2 and 5. This result is all the more important as it has been highlighted that elevated PL leads to greater PA participation, resulting in positive physiological, social, and psychosocial adaptations, and thus improved physical, mental, and social health [45]. In other words, PL could play a role across the lifespan in promoting positive health. Therefore, exergaming seems to be an effective and useful instrument to promote PL. This observation is in line with the review by Sun [46], which highlighted that active video gaming could contribute to enhancing children's PL, in particular on the motivational aspect of exergaming, making it possible to provide a variety of opportunities to develop or reinforce basic motor skills among children.

Second, concerning motivational aspects, in line with hypothesis 3, our results showed an overall positive effect on students' motivation toward the discipline. Indeed, we found an increase in motivation for mathematics (target subject), with a significant increase of almost 10% for the total cohort, while motivation for French (control subject) was not impacted. It seems that allowing students to work on mathematics more entertainingly (ie, by throwing balls onto calculation operations) helps to increase their appeal in this course.

Third, contrary to hypotheses 2, 4, and 5, our results showed no increase in academic performance, motivation, and sense of efficacy in mathematics, but they showed an increase in these variables in French, even though this subject was not directly targeted in the sessions. Although the interpretation is limited without a control group that did not benefit from the intervention, it is conceivable that the participants benefited from additional motivational resources provided by the 30 minutes of DPA toward learning at school, in accordance with the results of Vazou et al [16] regarding motivation and self-efficacy. An argument in support of this explanation may be the marginal increase in general concentration in class for the total cohort, as has been observed in the review by Taras [47], which noted an immediate increase in concentration in students after PA. This overall concentration may have benefited all subjects, especially those frequently considered less difficult than mathematics (ie, French).

Finally, it is important to note that the positive effects of the intervention were found in all school grades, even if a greater benefit was observed in grade 5. As the ability to apply skills or knowledge learned during one activity to another activity is evidence of a transfer process, older children are likely to be more sensitive to it [48]. Indeed, in this study's intervention, the children were learning with different tasks and objectives (in DPA exergaming and their normal lessons). The transfer of skills from one to the other was therefore not obvious (even if the "mathematics" cue was common to both) and remains a particularly demanding cognitive process for which the children need to be motivated. Decreases in academic performance in French and mathematics (grades 4 and 5) may be explained by constraints in the classrooms, as the teachers were rotated during the semester and the last data collection took place the day before the vacation (the participants were less involved overall in the academic exercises required). However, the marginal increase in mathematics performance in grade 2 and the increase in French performance (overall cohort and grade 3) demonstrate the importance of continuing to test this intervention.

Practical Implications in the Educational Context

Learning-based exergames can be powerful allies in the implementation of the DPA policy at schools. For schools and educational teams, the first obstacle could be the associated cost. In France, the Ministry of Education has launched a call for projects entitled, "Pour un socle numérique dans les écoles élémentaires" ("for a digital base in elementary schools") [49] to equip the schools of tomorrow. In this context, it is necessary to create links between the worlds of research and education. Researchers need to present teachers with the advantages (ie, academic performance, self-efficacy, motivation, PL, PA, and sedentary behavior) and constraints (ie, update, group management, and security) of this type of practice to make the teachers as efficient as possible in different teaching situations. Indeed, as part of the 30 minutes of DPA policy in elementary schools, one of the major difficulties is sustaining the actions and motivation of teachers, as presented in the Canadian study [43,44]. Once the equipment has been acquired and installed in a fixed position (ceiling-mounted model), one of the solutions for maintaining motivation among teaching teams would be to integrate PA professionals into the internship framework. This option enables teachers to not only benefit from the specific skills of the trainees but also position themselves as observers of the class, to be able to work on specific notions during PE teaching [18].

Limitations

In the context of this pilot study, which focused mainly on implementation feasibility and learning, it would have been interesting to consider the children's physical fitness (ie, muscular strength, agility, and cardiorespiratory fitness) and general state of health. Indeed, a French longitudinal study with a 3-year follow-up of children aged 7.7 years at the start of the study showed that the physical fitness of French youth decreased between childhood and early adolescence [50].

It would also have been interesting to compare the effects of this program with a control group. For example, it would have been worthwhile to compare the scores of the experimental group involving exergaming and targeted school exercises to 2 control groups: the first one with no PA and no school exercises, and the second one with no PA but with school exercises identical to the experimental group (eg, on a tablet computer). To verify the validity of the results, it would also have been necessary to vary the targeted school exercises (eg, mathematics and French; randomizing their inclusion in the intervention to ensure that the most difficult material is not the only one tested). Moreover, this study was carried out in a single school with a single class per level. It would be worthwhile to increase the size of the cohort by increasing the number of classes per level in different schools. Furthermore, our program had a limited duration (3 weeks), and a longer program (at least 1 trimester) with more DPA sessions would undoubtedly have increased the effects we observed and allowed additional benefits to be observed. In future studies, it would be interesting to compare the effects of a short program like ours with those of a longer program, and this could shed light on the duration of effects through time (in particular, following longer interventions).

Perspectives

Future studies could explore the possible diffusion effects of enhanced DPA interventions with or without exergaming on various PA indicators (eg, physical fitness, increased mobility by accelerometry, sedentary time and breaks, and increased implication in PE curricula at school). It would also be useful to conduct a longitudinal study to measure the impact of exergaming on not only PA and fitness levels but also the evolution of overweight and obesity in children.

Furthermore, in future studies, it could be relevant to assess intervention effects on students' academic performance, motivation, and self-efficacy in specific academic courses during interventions, or general attitudes and performances in different courses. Finally, specifying various student profiles concerning these measures (eg, depending on the initial levels of PL and PA, and depending on age or grade) could provide information on the subgroups of children benefiting the most from such exergaming interventions. In addition to student characteristics, it might be useful to consider teacher characteristics (eg, attitudes toward exergaming) to better understand the individual and environmental factors likely to moderate the effects of such interventions.

Conclusions

As part of the 30-minute implementation of DPA, the use of learning-based exergaming showed very interesting results in increasing PL as well as student motivation toward mathematics. Furthermore, supporting pedagogical teams with qualified teachers in PA has been proven to be beneficial for both students and staff.

With this encouraging pilot study, it is necessary to continue investigations by increasing the number of students per grade and to carry out research over a longer school period with a control group to confirm these results regarding the use of learning-based exergaming with Play LÜ within the framework of DPA.

Acknowledgments

We would like to thank the school (administration and teaching staff) for allowing us to carry out this pilot study.

Authors' Contributions

AG conceptualized and supervised the project, and contributed to the data collection and processing, project administration, and writing of the original draft. FL, GB, EVC, and EC conceptualized and supervised the project and were involved in reviewing and editing the manuscript. FL contributed to the statistical analysis. AP was involved in daily physical activity implementation supervision and physical literacy during the session. ED and NAB were students in adapted physical activity who carried out the daily physical activity sessions as part of their end-of-year internship.

Abstract

Background: Many senior adults are at risk of mental and physical disorders due to a lack of sufficient exercise. Therefore, adherent exercise should be urgently promoted to improve senior adults' muscle strength, preventing falls and conditions caused by physical and cognitive decline. However, off-the-shelf exercise games, so-called exergames, are mainly targeted at the younger generation or children, while senior adults are neglected, when this age group strongly needs exercise. Exergames could serve as a health intervention for promoting exercise.

Objective: This study aimed to investigate senior adults' experience, perceptions, and acceptance of game technology to promote exercise in order to suggest game design guidelines.

Methods: In this usability study, participants engaged in playing Nintendo Switch and Xbox Kinect games, after which semistructured interviews were conducted. Before the gameplay, the participants provided their background information, exercise habits, and use of technology products. Next, all participants completed a workshop including 3 activities (brief instructions on how to play the games: 20 minutes; playing the selected exergames: 80 minutes; semistructured interviews: 20 minutes) for 2 hours a day for 3 days each. The participants played the latest Nintendo Switch games (eg, Just Dance, Boxing, Ring Fit Adventure) and Xbox Kinect games (eg, Kinect Adventures!, Mini Games). Just Dance, Zumba, and Boxing were played in activity 1; Ring Fit Adventure and Mini Games in activity 2; and Kinect Adventures! in activity 3. Reflexive thematic analysis was applied to identify the relative themes generated from the interviews.

Results: In total, 22 participants (mean age 70.4, SD 6.1 years) were enrolled in the workshop in May 2021. The results of the generated themes included incomprehension of game instructions, psychological perception of game technology, and game art preferences. The subthemes generated from game art preferences included favorite game genres, characters, and scenes.

Conclusions: There is a significant need for customized game tutorials considering senior adults' cognitive and physical aging. Furthermore, the adventure game genre is preferable to other games. Humanlike game characters are preferable, especially those with a fit and healthy body shape. Nature scenes are more enjoyable than indoor stages or rooms. Furthermore, the game intensity design and playing time should be carefully planned to meet the World Health Organization's criteria for physical activity in older adults. Intelligent recommendation systems might be helpful to support older adults with various health conditions. The guidelines suggested in this study might be beneficial for game design, exercise training, and game technology adoption of exergames for older adults to improve health.

KEYWORDS

exergame; senior user experience; senior technology acceptance; game technology; psychological perception; serious games; exercise; aging; older adults; physical activity

Introduction

Background

The rapid growth of the aging population has drastically increased the need for medical and health care services. The life expectancy is increasing; however, the average life in a state of good health, the so-called healthy life expectancy, is almost 8-10 years less than the life expectancy [1,2]. It is important to increase the healthy life expectancy for active aging and reduce the financial burden on health systems caused by incapacitation, bedridden patients, and chronic physical or mental health conditions. The World Health Organization (WHO) [3] has suggested that adults 65 years and older perform 150-300 minutes of moderate-intensity or 75-150 minutes of strenuous-intensity aerobic physical activity in a week in order to improve physical and functional health and lower the risk of noninfectious chronic illness and mental health conditions. However, it has been reported that in Taiwan, 33.8% of older adults in the age group of 65-74 years and about 36% of 55-64-year-old "graying" adults do not exercise at all [4]. Many "graying" adults in Taiwan are at risk of mental and physical disorders due to a lack of sufficient exercise. Therefore, providing preventive health care and promoting adherent exercise are urgent issues to be considered in order to improve senior adults' muscle strength and physical fitness to prevent falls and conditions caused by physical and cognitive decline.

Studies on Exergames for Health

Several studies have highlighted the benefits and positive impact of exercise games, so-called exergames, on overall health. The term "exergame" is most frequently used by health-related researchers to refer to video games that use strength training, balance, or flexibility [5]. Exergaming has gained public and commercial interest due to its combination of fun and fitness together and is particularly popular for obesity-related interventions [6]. Furthermore, it is regarded as the future of fitness to maintain regular activity as it is a healthy, appealing alternative to other physical activities, as seen especially during the COVID-19 quarantine [7]. In addition to increasing physical exercise, exergaming could also be beneficial for psychological, cognitive, or psychosocial issues [8]. Exergames have been gradually applied in psychological treatment or physical rehabilitation for senior adults. For example, some studies have adopted exergames in psychological treatment for cognition [9], dementia [10], and depression [11]. Exergames have also been adapted for physical treatment to improve physical skills or fitness [12,13], balance [14,15], fall prevention [16], and rehabilitation [17-19]. Although many studies have applied off-the-shelf exergames for mental and physical health, with proof of their benefits and effectiveness, older adults' perceptions, experiences, and expectations are rarely discussed. Therefore, it is important to investigate older adults' experiences and expectations of playing exergames as a preventive approach to promote exercise habits.

Exergame Technology

Exergames require players to interact with the virtual gameplay by means of their physical movements and gestures in the real world [20]. Exergames generally use motion-sensing technology, which tracks and monitors players' movements while they perform game tasks using sensory devices, such as Nintendo's Joy-Con or Microsoft's Xbox Kinect. Motion-sensing technology differs between Nintendo and Xbox consoles. The Joy-Con contains an accelerometer and a gyroscope built into the device to track a player's motion. Additionally, the Joy-Con also contains 3D touch technology, which provides subtle vibration feedback to the player. In contrast, Xbox Kinect, which is a camera-based and infrared depth-scanning-approach device, enables a player to interact with the game with body movements. Various types of game consoles with different underlying body motion technologies offer different user experiences, but the amount of physical effort and energy required to play exergames remain similar [21]. Accessibility and entertainability are the 2 distinguishing factors of exergames in promoting exercise and activity [22]. This study explored which interactive technology is preferred by older adults.

Technology Acceptance of Older Adults

For decades, many studies have researched how people adopt technology [23-26]. Davis [23] first developed the technology acceptance model to explain user behavior and the intention to use technology. Chen and Chan [26] further modified the technology acceptance model, calling their modified version the senior technology acceptance model, to learn about senior users' adoption of technology. The term "older adults" generally refers to people whose chronological age is 60 years or older [27]. Researchers suggest that older adults' attitude toward using and their intention to use technology are particularly affected by their self-efficacy, anxiety, health conditions, cognitive ability, social relationships, attitude toward life and satisfaction, physical functioning, and the support of technology use they receive around them. The senior technology acceptance model has been applied to understand older adults' behavior with regard to technology in Hong Kong [26], Sweden [28], and Taiwan [29].

According to a statistic survey by the American Association of Retired Persons (AARP), in 2019, in the United States, 44% of older adults enjoyed playing video games compared to 38% in 2016 [30]. The growing population of older adults in the game market shows that their needs should be considered in game design. However, many older adults may not have had much experience playing video games during their childhood, as computer-based video games became popular around the 1980s [31]. The target users of these exergames are mostly younger adults or children. The aging population is neglected in the market, when this age group strongly needs exercise. Therefore, this study investigated older adults' experience, perceptions, and acceptance of game technology to promote routine exercise.

Methods

Study Design and Recruitment

The workshop was conducted in a spacious classroom that was transformed to accommodate exergame testing. The classroom was large enough to ensure there were no obstacles to the participants performing their movements and gestures while playing the games. Four Sanlux 55-inch 4K Ultra HD televisions with Nintendo consoles and Xbox Kinect consoles were set up in the classroom, and each television equipped with the consoles was shared by 2 participants while playing the selected exergames. The participants had sufficient space to move around and had full range of motion with the whole body. The classroom accommodated 6-8 participants in each workshop, and 3 workshops were conducted in total.

The inclusion criteria for the workshop and interview were participants aged 60 years and older who could exercise and understand the instructions provided. A total of 22 senior adults (≥60 years old) were enrolled in this study.

Gameplay

Each of the 3 workshops included 3 activities (Figure 1). Every activity was conducted for 2 hours a day for 3 days. Before playing the games, a questionnaire was administered, in which the participants provided their background information, exercise habits, and use of technology products. The following games were selected for this study: the latest Nintendo Switch games *Just Dance*, *Boxing*, *Mini-Games*, and *Ring Fit Adventure* and the Xbox Kinect game *KinectAdventures!* Before each activity, the participants were provided with brief instructions for 20 minutes on how to play the games. Next, they played the selected exergames for 80 minutes, and finally, a 20-minute semistructured interview was conducted. The participants played *Just Dance* and *Boxing* in activity 1, *Ring Fit Adventure* and *Mini-Games* in activity 2, and *Kinect Adventures!* in activity 3.

Figure 1. Participants played Boxing (left) and Ring Fit Adventure (right).

Data Analysis

Data were collected from the semistructured interviews using audio recordings and transcribed verbatim. Qualitative data were analyzed using thematic analysis, a qualitative data analytics method proposed by Braun and Clarke [32,33] and further clarified and defined as reflexive thematic analysis. Reflexive thematic analysis is a common approach to identify, analyze, and report themes from qualitative data sets in content analysis and grounded theory [34]. Braun and Clarke [35] have provided a 6-phase process of thematic analysis for researchers to conduct qualitative studies: (1) familiarizing with the data, (2) generating initial codes, (3) searching for themes, (4) reviewing potential themes, (5) defining and naming themes, and (6) producing a report. The 6-phase process is not linear but an iteratively developing process that is flexible enough to be tailored for qualitative data [36]:

- Phase 1 (familiarizing with the data): In phase 1, the researcher read and reread the data and made notes on a manual transcript. The researcher also identified connections between participants, data, and existing studies.
- Phase 2 (generating initial codes): The interview transcript was systematically analyzed through coding. Some codes matched the participants’ concepts, while others had to be interpreted by the researcher.
- Phase 3 (searching for themes): All the coded data were identified and clustered into broader topics or themes based on their similarities and overlaps.
- Phase 4 (reviewing potential themes): All the generated themes were reviewed to check whether they worked meaningfully and relevantly with the coded data.
- Phase 5 (defining and naming themes): After reviewing possible themes, the identified themes were subsequently defined and labeled.
- Phase 6 (producing a report): The generated themes answered the research questions about senior adults’ experience, perceptions, and acceptance of adopting exergames for exercise.

Ethical Considerations

This study was approved by the Central Regional Research Ethics Committee China Medical University Taiwan (review number: CRREC-109-090). All participants were informed of the procedures involved in the study. They agreed to participate in the study and signed the consent form. The data in this study is anonymized. This study offered non-monetary incentives to participants as compensation.

Results

Participant Details

In total, 22 participants (n=16, 73% female; n=6, 27% male) were enrolled in the study. Their ages ranged from 60 to 82 years (Table 1).

Table 1. Participants' general information (N=22).

Characteristics	Value
Age (years), mean (SD)	70.4 (6.1)
Male	68.7 (5.4)
Female	71.0 (6.4)
Sex, n (%)	
Male	6 (27)
Female	16 (73)
Education (years), mean (SD)	11.5 (4.5)
BMI (kg/m^2), mean (SD)	
Male	23.3 (4.5)
Female	22.4 (2.8)
Exercise routine, n (%)[a]	
Everyday	6 (27)
3-5 days a week	12 (55)
1-2 days a week	3 (14)
1-3 days a month	1 (5)
Exercise time (minutes/day), n (%)	
>30	16 (73)
20-30	4 (18)
10-20	1 (5)
<10	1 (5)
Exercise intensity, n (%)	
Barely there	11 (50)
Moderate	10 (46)
Harder	1 (5)
Technology products use habits (possession of smartphones/tablets/computers), n (%)	
I do not have any of them.	1 (5)
I have 1 of them.	8 (36)
I feel comfortable using them.	13 (59)
Frequency of using the technology products, n (%)	
Never	1 (5)
1 time a week	3 (14)
2-3 times a week	0 (0)
Many times a week	1 (5)
1 time a day	2 (9)
Many times a day	15 (68)
Experience of playing videogames/digital games (arcade, home console, handheld game console, computer game, or online game), n (%)	12 (55)

[a]The percentages might add up to more than 100 because of rounding.

The background information of the 22 participants showed that only 7 (32%) met the WHO criteria for weekly exercise. The participants were familiar with phone technology and often used it for social media, photography, Google searching, or online shopping. Some of them had previous experience of playing video games. These results showed that the participants were less active and were comfortable using technology products.

Most participants performed regular or mild light-intensity exercise; however, only a few participants met the WHO criteria for senior adult exercise. WHO recommends multicomponent physical activity at a moderate or high intensity [3]; however, the results showed that the exercise intensity of older adults and the time they spend are not enough.

Thematic Analysis

The semistructured interviews raised topics relating to user experience, psychological perceptions, and the adoption of game technology. In phase 2 of the thematic analysis, the manual transcript was systematically analyzed through coding. For example, "The tutorials in the game were not clear and not easy to understand. It is better to have instructors to teach me how to operate the game" was coded as the game tutorials not being supportive, being difficult to understand, and causing the participant to lose the motivation to play. In phase 3, the coded data was grouped into larger themes based on how they were connected. For example, coded data such as "do not know how to play," "not understanding," and "forgot tutorials" were clustered into "incomprehension of game instructions." In phase 4, the identified themes were carefully reviewed to ensure they accurately and meaningfully represented the coded data. In phase 5, the themes were defined and named as (1) incomprehension of game instructions, (2) confusion caused by a complicated interface, (3) frustration caused by the fast game speed, (4) a sense of control and freedom, (5) psychological perception of game technology, (6) social interaction, and (7) preference of game art. These 7 themes could answer the research questions about older adults' experience, perceptions, and acceptance of exergaming. The first 6 themes and the participants' feedback are shown in Table 2.

Table 2. Themes 1-6 generated from the interviews.

Theme and example quotes	Sex (male/female), age (years), game experience (yes/no)
1. Incomprehension of game instructions (n=8, 36%)	
“It is very critical that someone could guide us before playing games [*Just Dance*]. Knowing how to play motivates me to play the game.”	Female, 74, no
“I need someone next to me and tell me how to play.	Female, 67, yes
“I don’t know how to play the game because I don’t understand the game mechanics and rules.”	Male, 68, yes
“I need a detailed game tutorial of the game to support me when playing the game.”	Female, 75, no
“The tutorial in the game is not clear and not easy to understand. It is better to have instructors to teach me how to operate the game [*Ring Fit Adventure*].”	Male, 62, yes
“By the game instructions, I cannot fully understand what it means and how to play. I prefer someone (instructors) to teach me for better understanding.”	Male, 72, yes
“I can't remember things well. So, I forgot tutorials while playing. I might remember how to play after many times gameplay.”	Female, 79, yes
“I need more practice to remember how to play.”	Male, 76, yes
2. Confusion caused by a complicated interface (n=5, 23%)	
“At the beginning, it was difficult to understand the game interface, but after practicing, I got used to controlling it.”	Female, 66, no
“I don’t know the meanings of the icons in the game interface.”	Female, 74, no; male, 76, yes
“There is too much information on the screen; I don’t know what to look at while playing [*Ring Fit Adventure*].”	Female, 75, no
“The game interface was very complicated and difficult to use. I guess it is also difficult to control machines for most of the older adults [*Just Dance*].”	Female, 63, no
3. Frustration caused by the fast game speed (n=8, 36%)	
“I would give up and feel frustrated when I cannot keep up with the speed of the games.”	Female, 82, yes
“I wish I could control the speed of the game from slow to fast so that I could participate in the game, not be excluded since the very beginning.”	Female, 63, no
“I was too slow in the response in the playing. For example, I wanted to jump and get the golden coin, but when I jumped, the golden coin disappeared [*Kinect Adventures!*].”	Female, 78, yes; female, 75, no
“It is very difficult and complicated to do more than 2 actions at the same time. I have to avoid getting bombed and to get golden coins [*Ring Fit Adventure*].”	Female, 74, no
“I feel I am not as agile as I was. The game should provide different levels of difficulty for different ages.”	Female, 79, yes
“After seeing the boxing icon showing up from the bottom of the screen, I need to punch at the right tempo. But I was always too late to react. I need some time to think and then do the action [*Boxing*].”	Female, 66, no
“The speed in the game was too fast for me. I think the game should provide different levels of difficulty or provide different levels according to different age groups [*Boxing*].”	Female, 79, yes
4. A sense of control and freedom (n=4, 18%)	
“I like to use joystick to control games because of the tactile responses, although I feel free when I don’t need to hold anything to control the game. However, I don’t receive tactile sensation feedback to know whether I did the correct movement or not [*Kinect Adventures!*].”	Female, 60, yes
“I like to use my body motion to control the game because I don’t like to hold anything on hands. I don’t know how to use joystick, and I feel it is quite complicated. It is easy, free, and intuitive to control the game by my body.”	Female, 63, no
“I prefer the realistic feeling of pressing and dragging the Ring-Con. It gives me real feedback and is easy to use.”	Male, 71, no
“The vibration of the joystick gives me feedback of correct movement, and I like to receive the feedback [*Boxing*].”	Female, 74, no
5. Psychological perception of game technology (n=9, 41%)	
“Playing the games could make me keep focus, train my brain and coordination.”	Female, 66, no

Theme and example quotes	Sex (male/female), age (years), game experience (yes/no)
"It is so much fun to do exercise by playing games. I didn't expect myself to enjoy doing exercises [*Boxing*, *Kinect Adventures!*]."	Male, 68, yes
"I prefer to play *Boxing* game because it is very challenging."	Male, 62, yes
"I feel it is fashionable to play state-of-the-art games, which could connect me and the younger generations."	Female, 82, yes
"I feel I am keeping up with trends because I can operate game technology device and share with my grandchildren."	Female, 74, no
"I didn't know games could so charming and interesting. It is a fresh experience, and it is quite fashion and trendy to play games for me."	Female, 79, yes
"I would like to try new things, and I wish I could keep up with the times."	Female, 74, no
"I was afraid of new technology in general. I don't know how to use them. But if I have a chance to approach it and someone could teach me, I will be happy to learn."	Female, 60, yes
I feel video games are not for us; it is for the youth.	Female, 82, yes
6. Social interaction (n=5, 23%)	
"It has become a common interest between me and my grandchildren. We can play together, and we have common topics to talk about."	Female, 75, no
"Collaborating with other players is very fun, and it attracts me to continue using exergames."	Female, 69, yes
"I am feeling that I don't want to lose against my friends. I will make every effort to win."	Male, 68, yes
"I felt lonely when I did exercise alone, so I like exergames, which allow me to do exercise with people."	Female, 68, no
"I enjoyed playing with friends who are the same age as me. It's much more fun to play games or do exercise with friends than by myself."	Male, 63, yes

Additionally, the subthemes of game art preference were generated from the "preference of game art" theme. The qualitative data related to game art were collated and coded into game genres, characters, and scenes (Table 3). In the interviews, participants talked about their favorite games from among *Just Dance*, *Zumba*, *Boxing*, *Kinect Adventures!*, *Mini Games*, and *Ring Fit Adventure*. Adventure games were constantly mentioned as participants' favorite games (n=16, 73%, participants): 11 (69%) participants preferred *Kinect Adventures!*, and 5 (31%) participants liked *Ring Fit Adventure*. Only 3 (14%) participants liked the *Zumba* dance game and 3 (14%) liked *Boxing*. Thus, most participants were fond of the adventure game genre compared to the sports genre, such boxing or dance. Most participants (n=13, 59%) preferred true-to-scale 3D human models as game characters instead of cartoons. Some participants (n=8, 36%) preferred to see a real man on the screen to lead them in exercise, that is, the participants preferred the game characters to be real-scale humans or virtual models. Nearly all participants (n=21, 95%) mentioned that they enjoyed and immersed themselves in outdoor or natural scenes in the games, while only 1 (5%) participant preferred a static virtual stage.

Table 3. Subthemes generated from theme 7 (preference of game art; n=8, 36%, participants).

Subtheme and example quotes	Sex (male/female), age (years), game experience (yes/no)
7.1. Favorite game genre	
“My favorite game is adventure games. It made me focus and immersed myself in the gameplay. The adventure game is very exciting, which could also train my brain and improve my coordination. I don’t usually have the experience in my daily life [*Kinect Adventures!*].”	Female, 74, no
“The *Ring Fit Adventure* provides a more intense and challenging exercise for me. I love to take the challenge.”	Male, 76, yes
7.2. Preference of game character	
“I like the game character is made by 3D humanlike model with a realistic ratio, such as the character in *Ring Fit Adventure*. The character looks fit, muscular, and powerful.”	Female, 75, no
“I prefer a real man in the game, such as the coaches in *Zumba*. They are real people, who make it easier to understand and learn their dancing.”	Female, 69, yes
7.3. Preference of game scene	
“I like the game with outdoor natural scenes. I feel like I was doing exercise outdoor rather than in an indoor room.”	Female, 69, yes
“I was very excited and fully immersed in the game with a natural scene, such as *Xbox Adventure!* or *Ring Fit Adventure*.”	Male, 63, yes
“The natural background made me feel comfortable, and I wanted to go forward to see what shows up next. It also keeps me focus on the gameplay [*Kinect Adventures!*].”	Female, 69, yes
“I prefer static stages in the background because then I can focus on my game tasks [*Boxing*].”	Female, 60, yes

Themes Generated From the Interviews

A total of 7 themes were generated from the semistructured interviews. Of these themes, 3 (43%; themes 1, 5, and 7) were initially identified in the study. The remaining 4 themes (57%; themes 2, 3, 4, and 6) aligned with prior research findings and are discussed in the *Comparison With Prior Work* section.

Theme 1: Incomprehension of Game Instructions

Lacking gaming experience in their youth might result in senior adults not understanding the game mechanics, the meaning of visual effects or reward icons, health points (HPs), or experience points (EPs). The instructions in the gameplay were not easy to understand, so most of the participants perceived them negatively. Moreover, although some participants had game experience, it did not seem to support their learning in exergames. They still needed appropriate instructions for gameplay learning.

As the game instructions were not helpful to the participants, they needed instructors to explain and teach them again to learn how to play. However, although the participants were taught how to play before the gameplay, they forgot how to play when playing. It was not easy for some participants to understand and memorize the given information. These findings showed that age-related visual and hearing loss might also contribute to increasing the barriers to understanding the gameplay. Thus, repetitive and real-time tutorials in games might be helpful to support memory, learning, and thinking. Therefore, simple visual instructions and oral guidance using plain language might support senior adults’ game learning.

Theme 2: Confusion Caused by a Complicated Interface

In general, younger adults tend to find game interfaces more intuitive and user friendly compared to senior adults with regard to playing digital games. Senior adults often encounter significant challenges when attempting to engage with game interfaces. For instance, *Ring Fit Adventure* integrates a diverse range of physical tasks within its exercise regimen. Players are required to perform actions such as pressing or dragging the ring with their hands while simultaneously engaging in activities such as jumping, squatting, or running with their feet. The information and tasks presented in the game interface pose a complexity that senior adults may find challenging to comprehend. For instance, 1 (5%) participant (female, age 75 years, nonexperienced player) said:

> *There is too much information on the screen, I do not know what to look at while playing.*

Another participant (female, age 63 years, nonexperienced player) said:

> *The game interface is very complicated and difficult to use.*

Furthermore, senior adults often struggle to grasp the meaning of icons or virtual objects displayed in the game interface. For instance, they may not be aware that collecting golden coins in *Ring Fit Adventure* can lead to earning additional points. Two participants expressed:

> *I do not know the meanings of the icons in the game interface.*

Theme 3: Frustration Caused by the Fast Game Speed

One participant expressed frustration and a sense of exclusion when unable to keep up with the game’s pace. They desired the ability to control the game's speed, allowing for a more inclusive gaming experience. The participant (female, age 66 years, nonexperienced player) playing *Boxing* noted that her ability to perform actions effectively was affected by slower response times. She explained:

> *After seeing the boxing icon showing up from the bottom of the screen, I need to punch at the right tempo. But I was always too late to react. I need some time to think and then do the action.*

Another participant (female, age 82 years, experienced player) said:

> *I would give up and feel frustrated when I cannot keep up with the speed of the games.*

In addition, participants perceived a decrease in agility compared to their previous exercise experiences, which could be attributed to the natural decline associated with aging. Thus, an inappropriate game speed could result in senior adults feeling frustrated and avoiding playing exergames.

The American College of Sports Medicine [37] has classified the characteristics of physical fitness into health-related and skill-related components. The skill-related components of physical fitness include agility, coordination, balance, power, reaction time, and speed, which can be adjusted in-game to meet individual conditions. The results in this study showed that game speed levels should be adjustable according to given skill-related health conditions. Senior adults need more time to understand what is going on and how to react accordingly. Therefore, games should provide a range of difficulty levels specifically designed to accommodate different age groups, thereby ensuring an enjoyable gaming experience for senior adult players.

Theme 4: A Sense of Control and Freedom

Participants shared diverse preferences regarding their choice of gaming controls. Some appreciated the tactile responses provided by a joystick (n=3, 14%) or the Ring-Con (n=7, 32%), while others found freedom in not having to hold anything when controlling the game, such as Kinect motion-sensing interaction (n=12, 55%). Alongside their appreciation for the sense of freedom, 7 (32%) participants favored the Ring-Con because it resembles holding a steering wheel, thus enhancing their perception of control.

However, the absence of tactile feedback in some games left participants uncertain about the accuracy of their movements. For example, 1 (5%) participant said:

> *Although I feel free when I do not need to hold anything to control the game...I do not receive tactile sensation feedback to know whether I did the correct movement or not.*

Theme 5: Psychological Perception of Game Technology

Playing exergames was perceived to relate to enjoyment, socializing, achievement, frustration, defeat, and keeping up with trends. Generally, participants enjoyed playing and socializing with people. In addition, playing exergames and operating technological devices made them feel trendy.

> *I feel I am keeping up with trends because I can operate [a] game technology device and share with my grandchildren.* [Female, 74 years]

Some participants felt frustrated when they could not follow the game speed or obtained lower scores due to their longer reaction time and lack of coordination.

> *I want to have a feeling of achievement, rather than being defeated.*

Therefore, the game design should consider senior adults' psychological perceptions to meet their emotional needs.

Theme 6: Social Interaction

The use of exergames fostered a sense of connection and engagement, both within the family and among peers.

> *I enjoyed playing with friends.* [Male, age 63 years, experienced player]
>
> *I like to play with my family, and it is the biggest motivation to play.*

Some participants enjoyed the collaboration and competition with team players. For instance, 1 (5%) participant (female, age 69 years, experienced player) expressed:

> *Collaborating with other players is fun, and it attracts me to continue using exergames.*

These findings showed that playing exergames serves as a common interest that allows for enjoyable collaborative experiences, providing shared topics for discussion, and enhancing the motivation to continue using exergames.

Theme 7: Preference of Game Art

The game preference for game art and game genres was investigated. The exergames in the workshop included the latest Nintendo Switch games, such as *Just Dance* and *Ring Fit Adventure*, and Xbox Kinect games, such as *Kinect Adventures!* Among these games, 16 (73%) participants were fond of adventure games, including *Ring Fit Adventure* and *Kinect Adventures!* Interestingly, the results showed that younger senior adults (6/16, 37.5%, participants; average age 65.8, SD 5.7 years) preferred *Ring Fit Adventure*, which is a resistance exercise and a high-intensity training game, more than older senior adults (10/16, 62.5%, participants; average age 71.4, SD 5.3 years). Other participants (n=6, 27%) preferred less intensive exercise games, such as *Boxing* and *Zumba*. Of these 6 participants, 5 (83%) had no previous game experience, and the average age was 73.2 (SD 6.2) years. Therefore, younger senior adults might prefer a more intensive resistance exercise, while older senior adults might prefer a gentle exercise with less leg work.

For game characters, most of the participants preferred a human or humanlike character because it was easier to understand their movements. The participants also could reflect themselves as the avatar if the game character looked like a human. Of the 22 participants, 21 (96%) preferred human or humanlike characters, of which 13 (62%) participants preferred a humanlike game character and 8 (38%) preferred real humans as game characters. One participant did not show her preference. These findings showed that among the cute animal characters and human (humanlike) characters, senior adults prefer human or humanlike avatars, which allows them to easily reflect themselves in games and observe exercise movements more clearly.

For game scenes, outdoor nature scenes were the most preferable, such as scenes in *Kinect Adventures!* and *Ring Fit Adventure*. Of the 22 participants, 20 (91%) preferred nature scenes, followed by static scenes. The participants felt the nature scenes made them feel comfortable and helped them focus. Two participants preferred simple and clean colored indoor scenes rather than a sophisticated background, which allowed them to focus on the game mission and not be distracted by the background.

Therefore, adventure games, humanlike characters, and nature scenes could create a sense of reality and players might be more easily immersed in the gameplay.

Discussion

Principal Findings

In this study, most of the participants had no or little experience of playing exergames. However, after playing exergames in the workshop, they found them interesting and appealing. The results of this study reflect factors of the senior technology acceptance model [26]. Most of the participants referenced a positive attitude, perceived usefulness, and social relationships regarding using game technology. However, the participants provided negative feedback for the perceived ease of use and support of technology use. Lacking experience of playing video games might have also resulted in the participants not having the knowledge and skills needed to adopt game technology.

The supports for technology use, such as understandable tutorials or game mechanics, to help senior adult players are not sufficient. Thus, there is a significant need for customized instructions for senior adults. Overall, the reasons the participants did not have the intention to play could be because they thought video games are for younger people, not for them. Therefore, exergames should also meet senior adults' psychological needs to increase their adoption of game technology.

The results of this study present older adults' experience, perceptions, and acceptance of commercial exergames. In total, 7 themes were generated from the semistructured interviews; 4 of these are in line with previous studies, but 3 were identified in this study.

Three distinguished themes generated from this study are incomprehension of game instructions, psychological perception of game technology, and preferences of game art. These themes have rarely been discussed in prior studies. The psychological perception toward exergames that the participants expressed was that it is fashionable and trendy to play the latest digital games, which belong to the youth. They also enjoyed the gameplay by collaborating and competing with their peers. Among the exergames, the participants preferred adventure games much more than other genres. In this study, the adventure games were *Kinect Adventures!* and *Ring-Fit Adventure*, both of which focus on players' action tasks. These types of games typically emphasize storytelling and character development, as players assume the role of a principal character who must overcome various challenges and obstacles to reach their objectives. The exciting experience of outdoor sports motivated them to continue to play, and the virtual environment provided a safe place to perform thrilling activities.

The game characters and scenes are also critical visual elements to immerse senior adult players in games. In this study, senior adults preferred humanlike characters who looked healthy, fit, and muscular. The game character with a healthy outlook inspired senior adult players to reflect themselves as energetic people exercising in the gameplay. The nature scenes in the game also gave the senior adult players feelings of comfort and relaxation during the gameplay. WHO recommends that adjustable intensity and game levels should be carefully designed to support senior adults perform a sufficient amount of physical activity.

However, if senior adults cannot understand how to play a game or react in time, they feel defeated and frustrated. They may give up playing straight away. Therefore, there is a significant need for game tutorials that are easy to understand for senior adults and game levels that are suitable for their mobile ability.

Comparison With Prior Work

Four themes generated from the qualitative data demonstrated similar issues as in previous studies. First, "confusion caused by a complicated interface" (theme 2) and "frustration caused by the fast game speed" (theme 3) are in line with the results of Aarhus et al [38], who found that simultaneously increasing information, speed, and colors would more likely increase cognitive challenges. Although Aarhus et al [38] adopted Nintendo Wii in a physical rehabilitation context, the issue remains in the current Nintendo Switch. Second, the game speed was too fast to follow for most of the participants, which is in line with the results of Brox et al [39]. From the cognitive ability perspective, an age-related decrease in working memory causes a reduction in the amount and speed of information processing [35]. Third, the participants in this study highlighted "a sense of control and freedom" (theme 4) in the gameplay, similar to the results of Thin et al [21], who found that the game experience of motion-sensing games is preferrable due to its greater freedom and holistic movement experience. Fourth, "social interaction" (theme 6) is a prominent motivation for senior adults to adopt exergames, which is in line with previous studies [38]. Therefore, social interactions with peers, friends, the family, and society formed through playing exergames are appreciated.

Previous studies have also discussed the aforementioned themes, although most of the commercial games tested in previous studies were Nintendo Wii, Wii Fit, Wii Balance Board, and Wii Sports. Compared to prior studies, this study adopted the latest Nintendo Switch and Xbox Kinect to investigate the player experience. However, obstacles, such as game speed, interface, and tasks, remained, indicating that the latest games still do not consider the needs of senior adults.

Evaluation of This Study

According to the criteria for scientific rigor (credibility, dependability, confirmability, and transferability), in the qualitative research proposed by Lincoln and Guba [40], consistent outcomes are expected when replicating the research process within the same setting. To enhance credibility in this study, continuous interaction was maintained with each participant throughout the data collection process. Furthermore, the participants were encouraged to provide examples while discussing their gaming behavior and experiences, with the interviewer posing follow-up questions. This approach facilitated the participants' familiarity with both the research setting and the content, thereby ensuring an accurate interpretation of their original perspectives. Regarding transferability, which pertains to applicability, the researcher provided detailed descriptive data, such as participants' demographics, exercise characteristics, technology use habits, inclusion criteria of recruitment, workshop and interview procedures, and the iterative research process. The information helped the researcher explain the participants' behavior and experience within a gaming context, potentially making them meaningful and transferable to an external observer. To ensure dependability, which is related to consistency, a detailed analysis process was used throughout this study [41], thereby establishing the potential for reproducing the outcomes across similar participant cohorts and settings. Given the constraints, concerning confirmability, which relates to maintaining neutrality, although the absence of an external review was recognized, diligent steps were taken to compensate for this limitation by implementing a rigorous process of self-evaluation and critical reflection on the research process and outcomes. This included a careful examination of the data, consistent cross-referencing with established literature, and self-awareness regarding potential biases.

Strengths and Limitations

This study makes a noteworthy contribution by emphasizing the importance of game tutorials, preferences of game art and genres, and the perception of trendiness in the game design for older adults. However, the study does have limitations. First, it is essential to acknowledge that the sample size was restricted to 22 participants, consequently impacting the precision of estimates for main outcomes. Second, evaluating the qualitative study's confirmability would ideally involve external researchers. The advantage of having a single researcher code the content is that it ensures consistency and stability in the use of codes; however, confirmation bias can be manifest during various stages of the research process, such as data coding or interpretation [42]. As previously stated, a single researcher may hold preconceived ideas or preferences about the outcomes they anticipate or desire, and these biases can inadvertently impact their scholarly work. Although this study was conducted by a single author, the inherent limitations associated with solo authorship are recognized. The absence of external researchers in this study could limit the diversity of perspectives during data coding and interpretation. This limitation may result in a narrower scope of interpretation and analysis, potentially overlooking valuable insights. By acknowledging potential biases and preconceptions, steps have been taken to minimize their impact on the study's findings. Although collaborative research may not have been feasible in this study, the research process involved continuous cross-referencing with established literature and a sustained awareness of potential biases. It is hoped that this study will contribute valuable insights to the field of digital exergames for senior adults, despite its single authorship limitations. Additionally, it is anticipated that future research will build upon the study's findings to further enhance our understanding of senior adults' experiences in engaging with exergames.

Conclusion

Exergames could serve as an engaging approach to promote exercise and a healthy life among senior adults. Most of the prior studies have focused on usability and facilities, but senior adults' psychological perception toward the exergame experience is highlighted in this study. The findings of this study have some important practical and research implications for adoption of game technology, as well as for research with senior adults' gameplay experience for future work. First, tailored game tutorials for senior adults could be beneficial for increasing the adoption of exergames to promote physical health. Because of insufficient game experience in their youth and cognitive decline due to aging, there is a significant need for understandable and age-friendly tutorials of exergames to equip senior adults with affordable information and skills to get into the game scenario and mechanics. Second, preferences of game art and genres reveal that adventure games are the most favorable game genre and humanlike avatars in nature scenes are most liked among senior adults. Moreover, evidence from this study and the literature shows that the exercise time and intensity of senior adults in Taiwan are clearly not sufficient according to WHO criteria. Thus, game design should plan appropriate game times and intensities for senior adults, which could support them in gradually performing moderate- or high-intensity exercise to promote their health. In addition to game intensity, the game speed of current off-the-shelf exergames is still not suitable for senior adults. Therefore, intelligent recommended systems of game intensity, speed, or difficulty might be helpful for senior adults with various health conditions. Finally, senior adults also want to be fashionable and keep up with trends, not to be excluded by the market, so exergame developers may consider including senior adults' physical and psychological needs to create age-friendly exergames that are more accessible. Future research could focus on investigating age-friendly game tutorials, developing approachable adventure games, creating adjustable game intensity levels, and designing game artwork for senior adults to enhance their exercise for better health.

Acknowledgments

This research was funded under National Sci-Tech Programs by the Ministry of Science and Technology (ROC; MOST 109-2410-H-025-005).

Data Availability

All data generated and analyzed during this study are included in this published paper.

Authors' Contributions

YHW is the sole author of this manuscript, responsible for conducting the research, analyses, and data verifications. She successfully secured research funding from the Ministry of Science and Technology. Her contributions encompass interpreting the results and approving the latest version of the manuscript.

Abstract

Background: The effectiveness of virtual reality (VR) fitness games as a form of moderate to vigorous physical activity has yet to be thoroughly quantified through gold standard energy expenditure measures.

Objective: The purpose of this study was to examine the energy expenditure of 2 medium-intensity modes ("Flow and "Boxing") of a VR fitness game, Supernatural, using indirect calorimetry.

Methods: Indirect calorimetry was used to examine relative and objective maximal oxygen consumption (VO_2 max), metabolic equivalents of task (METs), and calories burned during medium-intensity bouts of both Flow and Boxing gameplay modes in young (mean age 25.42, SD 3.25 years), active individuals (n=12 female and n=11 male). METs and calories were also compared using a triaxial waist-worn accelerometer, an Apple smartwatch, and a VR headset. Mood states were assessed pre- and postbout using the shortened Profile of Mood States Questionnaire. Paired 2-tailed *t* tests were used to examine differences in game modes, between sexes, and pre-post exercise sessions.

Results: Objective and relative VO_2 max averaged 1.93 (SD 0.44) L/min and 27.61 (SD 5.60) mL/kg/min, respectively, between modes. Flow (mean 8.2, SD 1.54 METs) and Boxing (mean 7.6, SD 1.66 METs) are both classified as high energy expenditure, vigorous activities. Calorie expenditure data of the accelerometer and VR headset differed significantly from the metabolic cart. Mood changes pre- to post exercise were consistent with expected values for moderate- to vigorous-intensity physical activity, with participants reporting that they felt more "active," "full of pep," "vigorous," and "lively" ($P<.05$) following bouts. Male individuals reported higher objective oxygen consumption (VO_2) for both Flow and Boxing modes; no other sex-specific differences were observed.

Conclusions: Both Flow and Boxing gameplay modes of Supernatural classify as vigorous physical activity and demonstrate the potential to promote mental and physical health benefits. Supernatural may be an effective exercise modality in a VO_2 training program.

energy expenditure; exergaming; indirect calorimetry; virtual reality; VR; VR fitness; VR gaming

Introduction

Regular physical activity (PA), described as a movement-driven increase in energy expenditure [1], is an important health behavior that has well-established mental and physical benefits [2]. Evidence suggests that individuals who partake in regular PA of 150 minutes of moderate-intensity PA or 75-150 minutes of moderate- to vigorous-intensity PA (MVPA) each week [3] have a lower risk of cancer, type 2 diabetes mellitus, ischemic heart disease, and ischemic stroke [4].

While there are diverse modes in which individuals can engage in regular PA, at-home exercise options have increased in popularity recently [5]. Before the COVID-19 pandemic, at-home PA may have been chosen due to the ease of access, high levels of autonomy in modifying both workouts and equipment, and the increased feeling of comfort provided by exercising in a familiar environment [6]. Due to COVID-19–related shutdowns of traditionally frequented centers for PA (eg, gyms, recreation centers, and organized sports leagues), individuals had to develop new routines to stay active. Many turned to home fitness workouts and exergames, including virtual reality (VR) fitness options, to maintain their PA levels [7,8]. Even beyond the pandemic, home workout options, such as VR gaming and internet-based fitness workouts, continue to appeal to individuals, in part due to their convenience and accessibility.

VR can be described as a head-mounted amalgamation of the human perception of sensation into an interactive virtual environment [9]. Contemporary iterations of VR, specifically immersive VR (such as the Oculus Quest 2 or HTC Vive), involve a head-mounted device inlaid with cameras that track the wearer's environment, in order to project a virtual environment within the headset. VR gaming (also known as VR exercising, VR game exercising, or active VR games) refers to the use of a VR headset (and often handheld controllers) to engage in a single immersive, digital fitness experience consisting of both video game and exercise elements [10]. VR gaming differs from traditional exergaming (eg, Wii Fit and Just Dance) in that the gaming environment is visually immersive and interactive, rather than having visuals confined to a screen and movements or interactivity restricted by the fidelity of an external camera. These limitations of exergaming may contribute to their variability in energy expenditure [11]. Popular VR games include Beat Saber (Beat Games), Fruit Ninja VR (Halfbrick Studios), HOLOFIT (Holodia Holofit), Dance Central (Harmonix Music Systems), and BOXVR (FitXR). VR fitness demonstrated both mental and physical health during the COVID-19 lockdown [12]. Thus, VR fitness continues to remain popular as we emerge from the era of COVID-19 lockdowns, in part due to its enjoyable, flexible, and motivating nature [13].

While VR is gaining in popularity as a form of PA, there are, unfortunately, several factors that currently limit our understanding of whether it can serve as an effective means of achieving MVPA intensity. There is a tremendous amount of variance in the equipment involved within a VR gaming setup. Many studies use specialized equipment (eg, cycle ergometer [14], bespoke machinery [15], or sport-specific VR setups [16]), which would be unrealistic or inaccessible for most users to acquire or comfortably use. Among studies that examined a "regular" VR gaming setup, other confounding factors may also be at play. For example, some studies examine the use of additional accessories to existing VR setups, such as hand weights [17], which further obfuscate the energy expenditure of VR games.

Even in previous research that has used more consumer-friendly VR (eg, Oculus Quest and HTC Vive), the VR games themselves are quite variable in what they demand from the user. For example, Beat Saber, a popular VR rhythm game, requires users to hit targets in a virtual space with either one or both of their handheld controllers. However, the intensity with which these targets must be hit to register as a valid hit can be quite low. Additionally, the movements facilitated by VR games can vary, leading to a change in energy expenditure. Stewart [18] compared the energy expenditure from 3 different VR games, including Beat Saber, and found that each game demonstrated a significantly different energy expenditure for a similar playtime. Given the nature of VR setups and the range of movement they require [19], few studies have used the gold-standard measures of energy expenditure (eg, indirect calorimetry) within VR gaming studies. Furthermore, the presence of sex and gender differences within the field of VR gaming remains a controversial topic, with mixed evidence supporting a higher rate of physical discomfort and symptoms for female individuals [20,21]. Combined with the tendency for male individuals to demonstrate higher maximal oxygen consumption (VO_2 max) values when controlling for age [22], investigating the presence of any sex-specific differences within VR gaming is of importance.

Supernatural is a VR fitness service that is available on the Oculus Quest (Meta) headsets, a popular consumer VR headset. Supernatural was chosen due to its specificity as a fitness service [23]. Other contemporary titles, like Beat Saber and Fruit Ninja VR, play closer to rhythm or arcade games in that the goal of the game is to achieve a high score, which can be done by hitting more targets. Supernatural is similar in that target accuracy is a metric; however, the key difference is that Supernatural records a metric of movement power (ie, power for the "Flow" mode and speed for the "Boxing" mode). In this way, Supernatural provides a means to compare effort, not just accuracy. Hence, limiting our study to just Supernatural was deemed appropriate. Thus, the primary purpose of this study was to examine and compare the energy expenditure of a bout of the VR fitness game Supernatural through indirect calorimetry; specifically, we examined the energy expenditure of both the Flow and Boxing modes, selecting workout durations and intensities (ie, medium intensity) based on the game's average workout data. Comparisons between sexes (ie, male and female) were also examined as part of this primary objective.

The emerging popularity and novelty of VR gaming presents a further point of interest insofar as how accurate traditional PA monitoring devices are when applied to VR contexts. Traditional devices, such as waist-worn accelerometers and wrist-worn accelerometers (eg, smartwatches), demonstrate reasonable validity for capturing walking and running behaviors [24]; however, whether this extends to the more space-restricted, calisthenic-focused movements of VR gaming is unclear [25,26]. The inclusion of an onboard accelerometer in many consumer VR headsets is also a noteworthy activity monitor that is worth comparing to gold-standard energy expenditure measures [23]. Thus, the secondary purpose of this study was to examine the energy expenditure of the VR game as measured by accelerometry, consumer activity monitor (ie, Apple Watch 2), and the built-in accelerometer in the VR headset to provide a comparison to the gold-standard measure of indirect calorimetry.

The tertiary purpose of this study was to examine any changes to mood as a result of engagement in Flow and Boxing, as compared to the contemporary literature on VR exercise and mood [27,28].

Methods

Participants

Inclusion criteria for participants were (1) being 19-40 years of age; (2) self-reporting a minimum of 150 minutes of MPVA per week; (3) self-identifying as not being at increased risk for contracting COVID-19 or being a part of an immunocompromised population; and (4) being considered to have a minimal risk of an exercise-induced adverse outcome. To ensure participants with a broad range of VR experiences were recruited, recruitment documentation described the study as a "digital fitness experience" to avoid confounding any measurements collected. Participants became aware of the use of VR technology upon their receipt of the informed consent documentation before their first visit. Participants were recruited between September 2022 and December 2022 using a combination of social media postings, physical postings on the host university's campus, and word of mouth.

VR Headset and Game

Participants engaged with the VR fitness game Supernatural [29], which was played using the Oculus Quest 2 VR headset [30]. The Oculus Quest 2 uses a head-mounted display and 2 handheld controllers to provide an immersive VR experience for users. For this study, a 5-foot (1.5 m) by 5-foot space was marked onto the floor with tape to calibrate the in-headset play area boundaries (Multimedia Appendix 1). For each participant, the floor level was calibrated, and headset straps were adjusted to fit comfortably.

The Supernatural game has 2 exercise modes: Flow and Boxing. Both modalities cue participants to arm movements with color-coordinated orbs that have directional arrows to indicate movements to participants. There are also horizontal bars and triangles to encourage squatting, lunging, and the dodging of obstacles. During their first session, participants engaged in the workout mode Flow. Flow is an aerobic workout that involves both the upper and lower body and footwork in 360 degrees (Figure 1). Participants wield a virtual bat in each hand, striking targets in a variety of patterns and intensities. Lower-body movements are incorporated into each sequence, requiring participants to squat or lunge to hit some targets. During the second session, participants challenged a Boxing workout. Boxing requires participants to punch, uppercut, or swing through color-coordinated orbs and has horizontal and diagonal bars that participants have to maneuver their head and torso under and around (Figure 2). Note that still captures of Supernatural provide only an approximate impression of the actual, first-person in-app perspective of a Supernatural user on modern Meta Quest hardware.

Figure 1. Supernatural Flow game mode.

Figure 2. Supernatural Boxing game mode.

Experimental Overview

Overview

Interested participants contacted the researcher by email to arrange the initial session. Participants attended 2 sessions at the host institution which occurred a minimum of 24 hours apart. The first visit centered around the Supernatural Flow session, and the second visit was around the Supernatural Boxing session. This order was maintained for all participants. Participants were asked to abstain from engaging in MVPA for 12 hours before each session. During the first study visit, participants signed the informed consent document, completed a Get Active Questionnaire (GAQ [31]), had their anthropometric data collected, and completed a baseline survey assessing previous knowledge and exposure to VR. Before and after each session, participants' mood states using the shortened version of the Profile of Mood States (POMS-SF [32]) were assessed. After initial surveys, participants were fitted with a heart rate (HR) monitor and the Oculus Quest 2 VR headset and then followed a standardized progression up to the measurement intensity workout until meeting the predetermined threshold for competency (see Zones of Competency section). Upon meeting the zone of competency, participants were fitted with the indirect calorimetry mask and headpiece, Apple Watch, and waist-worn accelerometer and completed the measurement session.

VR Game Stage Progression

Following initial surveys at each visit, participants watched a series of tutorial videos for the respective mode of the session (ie, Flow for session 1 and Boxing for session 2) which are available on Supernatural's YouTube page. Participants then engaged in an in-game tutorial (approximately 5 minutes). Participants then proceeded to a low-intensity "Quick Hits" workout and a medium-intensity "Quick Hits" ramp-up workout, both approximately 5 minutes long, to further familiarize them with the mode. Participants who were able to meet the minimum zones of competency for each mode (as detailed in Zones of Competency section) proceeded to the measurement workout. Participants could repeat the "Quick Hits" workouts until the zones of competency were obtained. The measurement session was a medium-intensity workout between 14 and 17 minutes in length. All workouts were selected from a predetermined list of relatively similar-intensity workouts. In correspondence with Supernatural, the makeup of the different workouts within the same intensity is generally similar to one another in the range of motion, target origination, pace, and number of targets delivered. Participants chose the genre of music (eg, pop, rock, hip-hop, and electronic) they preferred, and a researcher would select a workout matching the description.

Zones of Competency

To advance to the measurement session, participants had to meet the predetermined zones of competency for each mode. Flow measures participant competency in accuracy (ie, percentage of targets hit) and power (ie, how fast targets were hit). Participants had to obtain a minimum of 92% accuracy to participate in the measurement session. Power was not used in the determination of participant readiness. Boxing measures participant competency in accuracy (ie, percentage of targets hit) and speed (ie, how fast targets were hit). Participants had to achieve a minimum of 94% accuracy in Boxing to progress to the measurement round. During preliminary testing, it was also determined that a minimum speed goal should be achieved to ensure participants were all working out at a similar intensity. Hence, a minimum score of 70% speed was determined to be sufficient, as this best reflected the lower end of the speed an average user would hit the targets at, according to correspondence with Supernatural.

Instrumentation and Measurement

Primary Outcome: Energy Expenditure (Breath-by-Breath Oxygen Consumption)

A Parvo Medics TrueOne 2400 metabolic cart was used to assess oxygen consumption (VO_2; ie, volume of oxygen) during both measurement sessions [33]. A 2-meter hose and a 3-meter hose were joined together using a polyvinyl chloride elbow joint and hose clamps to allow the hose to reach from the metabolic cart to loop suspended above the participant, then down to the participant to allow VO_2 to be assessed with minimal interference during the testing (Multimedia Appendices 1 and 2). The metabolic cart was calibrated to room air and known gas concentrations before testing, followed by individual setup according to participants' height, weight, age, and sex. Both objective VO_2 max and relative VO_2 max were collected. Relative VO_2 max was also compared to age-predicted VO_2 max. VO_2 averages were recorded in 30-second intervals.

Secondary Outcomes

Energy Expenditure (Metabolic Equivalents and Caloric Expenditure)

Metabolic equivalents of task (METs) and caloric expenditure were assessed using the metabolic cart, an ActiGraph GTX3 triaxial waist-worn accelerometer, a Series 7 Apple Watch, and the built-in accelerometer on board the Oculus Quest 2 headset (as displayed through the Oculus Move in-headset app). Time spent in low-, moderate-, and high-intensity exercise was recorded by the waist-worn accelerometer. The waist-worn accelerometer was calibrated according to each participant's age, height, weight, and sex. The Apple Watch and Oculus Move accounts were calibrated to a reference individual (female, height 181 cm, weight 78 kg) to avoid the need for an individual Apple and Oculus Move account for each participant. The Oculus Quest 2 boundaries were standardized to a 1.5 meter by 1.5 meter square.

Heart Rate

A Polar H10 HR monitor was used to measure average and maximum beats per minute (bpm) and the percentage of time spent in HR zones. Polar classifies HR into 5 zones by both levels of intensity and percentage of age-predicted maximum HR (HRmax). Specifically, these zones are categorized as zone 1: very light, 50%-60% HRmax; zone 2: light, 60%-70% HRmax; zone 3: moderate, 70%-80% HRmax; zone 4: hard, 80%-90% HRmax; and zone 5: maximum, 90%-100% HRmax [34]. The Polar H10 HR monitor was calibrated to a reference individual (female, height 181 cm, weight 78 kg) to avoid the need for an individual Polar account for each participant.

Tertiary Outcomes

Demographics

Participants' age, sex, height, weight, waist circumference, and PA levels were recorded during the initial visit. Age, sex, and PA level were self-reported using a single item. Height, weight, and waist circumference were measured by a researcher.

Mood States

Participants completed surveys at the beginning and end of each session to assess potential changes in mood states, which were assessed with the POMS-SF [32]. Our specific subscales of interest were vigor (ie, lively, active, energetic, full of pep, and vigorous) and fatigue (ie, worn out, fatigued, exhausted, weary, and bushed), as these were thought to be the most receptive to participants' exertion within our acute aerobic intervention and nonclinical sample [35,36]; however, the entire POMS-SF was completed by each participant.

Data Handling and Analysis

Energy Expenditure Outcomes

Energy expenditure outcomes were analyzed descriptively (mean and SD) and assessed for normality. Winsorization [37] of any outliers was planned. An average of the objective VO_2 max and relative VO_2 max for Flow and Boxing sessions was calculated. The relative VO_2 max was also calculated as a percentage of the age-predicted VO_2 max. Accelerometer data were analyzed using the Freedson Adult MV3 cut points [38]. The accelerometer, Apple Watch, and Oculus Move data were compared to the metabolic cart data to determine the percentage difference between the measurement tools. Comparisons between modes (Flow and Boxing) and measurement modalities (ie, metabolic cart, waist-worn accelerometer, Apple Watch, and Oculus Move) were compared for the 21 complete data sets (n=11, 52% male individuals) using paired sample 2-tailed *t* tests using a Bonferroni correction (ie, α=.0125). Missing data were excluded case-wise.

Psychological Outcomes

Changes in mood state (ie, vigor and fatigue subscales) from pre- to postsession for both Flow and Boxing modalities were assessed using paired 2-tailed *t* tests.

Sample Size Determination

To be sufficiently powered to do a sex-specific subanalysis, we aimed to collect at least 20 full data sets (ie, 10 male and 10 female individuals). This number was determined based on an investigation of previous energy expenditure and VR fitness publication recruitment numbers and was deemed appropriate to capture sex-specific differences in energy expenditure outcomes [39-41]. Sex-specific subanalyses were only performed for the energy expenditure outcomes, as the sample was deemed to be too small to capture small-to-medium–sized effects on psychological outcomes.

Ethical Considerations

This prospective, single-group experimental study was approved by the host University of Victoria's research ethics board (22-0213), and all participants provided written, informed consent before their involvement in the study and for inclusion in the publication of any research findings, as indicated by the Declaration of Helsinki.

Results

A CONSORT (Consolidated Standards of Reporting Trials)-eHealth checklist for this study can be found in Multimedia Appendix 3.

Participant Characteristics

A total of 12 male and 12 female individuals who met inclusion criteria and provided informed consent were recruited for this study. One male participant dropped out before beginning the Flow data collection due to issues with the VR environment. Overall, 2 female participants completed the Flow session but not the Boxing session due to factors unrelated to the study. A total of 23 (n=11, 48% male) participants completed the Flow session, and a total of 21 participants (n=11, 52% male) completed the Boxing session.

Participant demographics are presented in Table 1. The average age of participants was 25.42 (SD 3.25) years. Participants reported participating in MVPA 4.71 (SD 1.62) days a week for an average of 72.38 (SD 39.04) minutes per session, classifying our participants as active [3]. Our participant pool was very naive to VR and VR fitness, however, with 96% (n=23) reporting no previous familiarity with VR fitness products before study participation. There were no outliers in the data set.

Table 1. Participant demographics.

Characteristic	Male participants (n=12), mean (SD)	Female participants (n=12), mean (SD)
Age (years)	25.5 (3.1)	25.2 (3.0)
Height (cm)	178.1 (9.9)	166.6 (7.9)
Weight (kg)	76.7 (14.1)	64.36 (7.9)
Waist circumference (cm)	85.5 (6.2)	76.0 (5.1)

Workout Characteristics

The average Flow workout was 15.48 (SD 1.31) minutes in duration and was completed with 94.57% (SD 2.35%) accuracy and 85.52% (SD 5.27%) power. The average Boxing workout was slightly longer than Flow at 16.91 (SD 1.51) minutes in length, with 96.67% (SD 1.77%) accuracy and 78.86% (SD 7.89%) speed.

Energy Expenditure

Oxygen Consumption

Objective VO_2 max, as measured by the metabolic cart, was 1.98 (SD 0.44) L/min for Flow, 1.88 (SD 0.45) L/min for Boxing, and 1.93 (SD 0.44) L/min overall. Relative VO_2 max was 28.52 (SD 5.39) mL/kg/min for Flow, 26.70 (SD 5.79) mL/kg/min for Boxing, and 27.61 (SD 5.60) mL/kg/min overall. There was a significant difference between Flow and Boxing for both objective (mean difference [M_{diff}]=0.14, 95% CI 0.05-0.24; *P*=.006) and relative VO_2 max (M_{diff}=2.05, 95% CI 0.53-3.56; *P*=.01). The percentage of age-predicted VO_2 max was 59.39% (SD 11.75%) for Flow, 55.42% (SD 12.45%) for Boxing, and 57.41% (SD 12.12%) overall. There was no difference between Flow and Boxing with respect to the percentage of age-predicted VO_2 max (M_{diff}=4.20%, 95% CI 1.34%-7.05%; *P*=.006).

With respect to sex-specific differences, a significant difference was observed for objective VO_2, with male individuals demonstrating a significantly higher objective VO_2 for Flow than female individuals (M_{diff}=0.46, 95% CI 0.13-0.78; *P*=.009). Sex differences for objective VO_2 for Boxing were not statistically significant (M_{diff}=0.36, 95% CI –0.02 to 0.74; *P*=.06). No significant differences between sexes were revealed for any other VO_2 outcome (*P*>.05).

Outcomes for METs

METs were collected by both the metabolic cart and the waist-worn accelerometer. The metabolic cart recorded average METs to be 8.15 (SD 1.54) for Flow, 7.63 (SD 1.66) for Boxing, and 7.89 (SD 1.60) overall, while the waist-worn accelerometer recorded averages as 4.31 (SD 0.56) for Flow, 4.78 (SD 0.57) for Boxing, and 4.55 (SD 0.65) overall. For data recorded by the metabolic cart, there was a significant difference between Flow and Boxing modes (M_{diff}=0.58, 95% CI 0.15-1.02; *P*=.01). There was a significant difference between the values recorded by the metabolic cart and the waist-worn accelerometer for both Flow (M_{diff}=3.69, 95% CI 3.12-4.25; *P*<.001) and Boxing (M_{diff}=2.84, 95% CI 2.21-3.47; *P*<.001), with the accelerometer reporting a percent of metabolic cart reading of 45.26% (SD 14.55%) for Flow, 56.03% (SD 13.80%) for Boxing, and 50.64% (SD 15.05%) overall.

With respect to sex-specific differences, no significant differences were revealed for METs as assessed by either the metabolic cart or waist-worn accelerometer (*P*>.05). Oxygen consumption and metabolic equivalent data are given in Table 2.

Table 2. Oxygen consumption (VO2) and metabolic equivalent of task (MET) data.

Energy expenditure outcome	Flow, mean (SD)	Boxing, mean (SD)	Overall, mean (SD)
Objective VO_2 (L/min)	1.98 (0.44)[a]	1.88 (0.45)[a]	1.93 (0.44)
Relative VO_2 (mL/kg/min)	28.52 (5.39)	26.70 (5.79)	27.61 (5.60)
Age-predicted VO_2 max[b] (%)	59.39 (11.75)	55.42 (12.45)	57.41 (12.12)
METs (metabolic cart)	8.15 (1.54)[a]	7.63 (1.66)[a]	7.89 (1.60)
METs (accelerometer)	4.31 (0.56)	4.78 (0.57)	4.55 (0.65)

[a]Values represent a significant difference between modes (ie, Flow and Boxing).

[b]VO_2 max: maximal oxygen consumption.

Calories

The estimated caloric expenditure of the metabolic cart, waist-worn accelerometer, Apple Watch, and Oculus are presented in Table 3. For Flow, both the accelerometer (M_{diff}=79.25, 95% CI 68.30-90.20; *P*<.001) and Oculus Move (M_{diff}=30.79, 95% CI 12.84-48.74; *P*=.002) were found to be significantly different from the metabolic cart, while the Apple Watch (M_{diff}=–4.83, 95% CI –18.30 to 8.66; *P*=.47) was not.

Similarly, for Boxing, both the accelerometer (M_{diff}=70.56, 95% CI 56.59-84.53; *P*<.001) and Oculus Move (M_{diff}=62.89, 95% CI 45.52-80.26; *P*<.001) were found to be significantly different from the metabolic cart, while the Apple Watch (M_{diff}=–14.24, 95% CI –32.22 to 3.73; *P*=.11) was not.

Table 3. Caloric expenditure data.

Device	Flow (kcal)		Boxing (kcal)		Overall (kcal)	
	Mean (SD)	% Metabolic cart	Mean (SD)	% Metabolic cart	Mean (SD)	% Metabolic cart
Metabolic cart	151.22 (35.52)	N/A[a]	159.76 (38.829)	N/A	155.49 (36.95)	N/A
Accelerometer	70.60 (22.34)[b]	45.26[b]	89.20 (28.892)[b]	56.03[b]	79.90 (27.12)[b]	50.46[b]
Apple Watch	155.41 (24.87)	107.56	174.00 (39.607)	112.34	164.71 (33.59)	109.95
Oculus Move	121.27 (21.98)[b]	82.88[b]	102.00 (17.914)[b]	63.75[b]	111.63 (22.06)[b]	73.32[b]

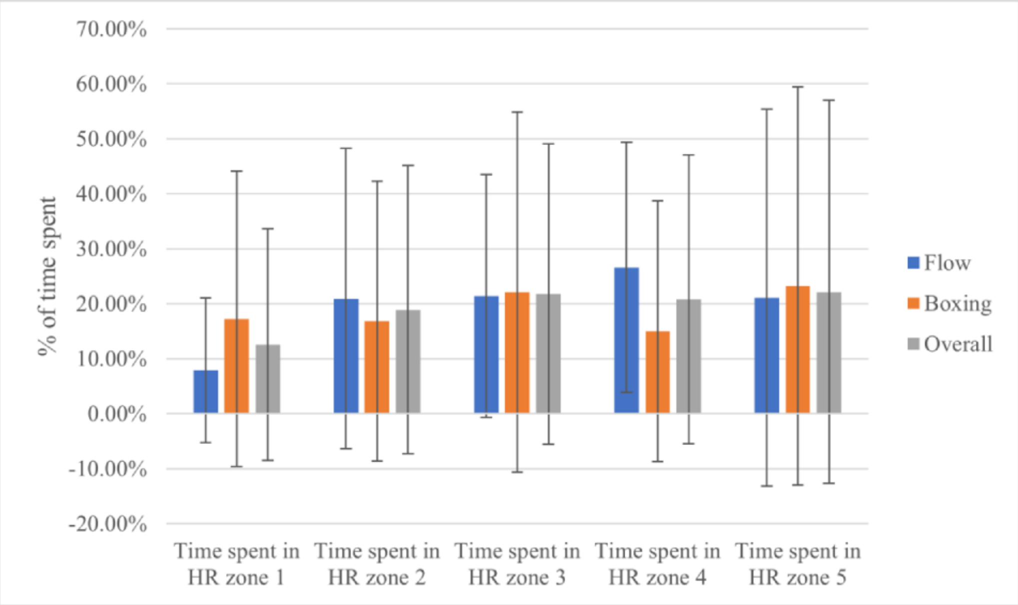
[a]N/A: not applicable.

[b]Values represent a significant difference from the metabolic cart (*P*≤.0125).

Heart Rate

The average HR for Flow was 151.13 (SD 23.12) bpm, and HRmax was 169.39 (SD 20.04) bpm. The average HR for Boxing was 143.29 (SD 26.36) bpm, with an HRmax of 161.43 (SD 26.36) bpm. Flow demonstrated a significantly higher average HR (M_{diff}=8.43, 95% CI 3.45-13.40; *P*=.002) and HRmax (M_{diff}=8.38, 95% CI 3.12-13.64; *P*=.003) when compared to Boxing. The overall average HR across both modalities was 147.21 (SD 23.12) bpm, and the average overall HRmax was 165.41 (SD 20.04). Sex-specific differences in HR were observed for Boxing average HR (M_{diff}=25.61, 95% CI 1.99-49.23; *P*=.04) and HRmax (M_{diff}=25.53, 95% CI 4.04-47.01; *P*=.02), with male individuals demonstrating a higher HR during Boxing. Time spent in HR zones is presented in Figure 3.

Figure 3. Time spent in heart rate zones. Error bars represent the SD. HR: heart rate.



Changes in Mood States

Between baseline and postsession 1, on average, participants reported that they felt more "lively" (M_{diff}=0.46, 95% CI 0.50-0.86; *P*=.03), more "active" (M_{diff}=0.67, 95% CI 0.32-1.07; *P*<.001), more "full of pep" (M_{diff}=0.57, 95% CI 0.14-0.99; *P*=.01), and more "vigorous" (M_{diff}=0.48, 95% CI 0.90-0.87; *P*=.02). Between presession 2 and postsession 2, on average, participants reported feeling more "active" (M_{diff}=0.76, 95% CI 0.36-1.17; *P*<.001), more "full of pep" (M_{diff}=0.38, 95% CI 0.02-0.75; *P*=.04), and more "vigorous" (M_{diff}=0.52, 95% CI 0.18-0.87; *P*=.004). No item on the fatigue subscale of the POMS-SF changed significantly for either session 1 or 2.

Discussion

VR fitness games have seen an increase in popularity as a mode of PA in recent years [7]. However, variability among game demands and objectives, along with difficulties in measuring energy expenditure with gold standard assessments (ie, indirect calorimetry), have limited our understanding of the intensity of these games [19], in turn limiting recommendations involving this mode of PA with respect to MVPA guidelines. Hence, the primary aim of this study was to examine the energy expenditure of one of the most popular VR fitness games, Supernatural. Specifically, we assessed the energy expenditure of a session of medium intensity for both the Flow and Boxing modes of Supernatural using indirect calorimetry. We also examined how other popular measures of energy expenditure compared relative to indirect calorimetry.

For Flow, average relative VO_2 max was 28.52 (SD 5.39) mL/kg/min, which translated to approximately 8.2 (SD 1.54) METs, classifying it as vigorous intensity (ie, >6 METs) [42]. Compared to other forms of PA, Flow was akin to climbing stairs (8.0 METs) or general circuit training (8.0 METs) [43]. Moreover, the percent of age-predicted VO_2 max (mean 59.39%, SD 11.75%) points to the potential use of this mode of Supernatural within a VO_2 training program [44]. Notably, only objective VO_2 was found to be significantly different between male and female participants, which suggests that this mode of PA demonstrates a significant sex difference in objective energy expenditure. This finding is likely due to the body weight nature of the game (ie, movements were relative to participants' own body weight), as this significant difference was not evident when examining the relative VO_2 values or METs (ie, accounting for participants' weight). This is encouraging, suggesting that young, active individuals engaging in a bout of Supernatural Flow should receive a relatively similar aerobic workout, independent of sex. This indicates that during a flow session, participants were averaging a high enough percentage of VO_2 to potentially improve maximum oxygen uptake.

For Boxing, average relative VO_2 max was 26.70 (SD 5.79) mL/kg/min, which translated to approximately 7.6 (SD 1.66) METs, also classifying it as vigorous intensity (ie, >6 METs) [42]. Compared to other modes of PA, Boxing was higher than high-impact aerobics (7.3 METs) and close to sparring while boxing (7.8 METs) [43]. Interestingly, both the Flow and Boxing modes demonstrated a higher energy expenditure than "activity-promoting video or arcade game (eg, Exergaming and Dance Dance Revolution), vigorous effort" (7.2 METs), which further speaks to the heterogeneity in demands among available VR fitness games [45]. For example, the lower average energy expenditure of the Boxing mode may be due to the difference in physical demands between modes, with Flow incorporating more frequent multimuscle group movements (eg, squats and arm swings) than Boxing, which consists primarily of slips and punches. Similar to Flow, there was a trend in objective VO_2 between sexes (P=.06) favoring male individuals but no significant differences in any other VO_2 outcome or METs, for the Boxing session. Furthermore, while the objective VO_2 max and METs were significantly lower for Boxing than Flow, the data suggests that individuals were still exercising at a high enough percentage of VO_2 to improve maximal oxygen uptake [46]. Hence, Boxing also has implications as a candidate for use in aerobic training programs, independent of sex.

Given the lack of research comparing indirect calorimetry to device-based measures when examining VR fitness, we also aimed to compare the findings from the metabolic cart to that of a triaxial waist-worn accelerometer, an Apple Watch, and the Oculus Move. On average, the accelerometers underestimated the energy expenditure of the metabolic cart by approximately 65% (SD 14.55%) for Flow and approximately 45% (SD 13.8%) for Boxing. This discrepancy and variability were somewhat surprising, given the relative reliability and validity of this particular accelerometer in assessing aerobic PA (eg, running and walking) [47]. However, this underestimation is likely due to the placement of the accelerometer (ie, waist-worn), which is unlikely to capture the full range of dynamic upper and lower body movements characteristic of a VR fitness game. Notably, several other studies have used waist-worn accelerometers within VR research [25,26], though these studies have examined time spent in MVPA rather than an energy expenditure outcome (eg, METs). Despite this, an underrepresentation of MVPA as captured by accelerometry still appears to be evident; Sousa et al [26] reported an average of 4.10 (SD 4.93) minutes of MVPA for a 20-minute VR fitness session (approximately 21%), while Giakoni-Ramirez and colleagues [25] reported an average of 3.57 minutes of MVPA for a 9-minute "intermediate" VR fitness session (approximately 40%). Hence, our findings suggest that the use of accelerometers during this form of PA be used cautiously.

Compared to the accelerometer, the Apple Watch was relatively more accurate, estimating approximately 108% (SD 24.88%) and approximately 112% (SD 25.41%) of the metabolic cart for Flow and Boxing, respectively. This may be due to the wrist-worn placement of the Apple Watch, which makes it more sensitive to the movements of the VR fitness games. Notably, there was a considerable degree of variability within the Apple Watch measures, ranging from a 28% underestimation to a 56% overestimation of caloric expenditure. Our findings are consistent with previous validation work using the Apple Watch to measure MVPA and energy expenditure [48]. Work by Bai and colleagues [49] does support the validity of the Apple Watch as a measure of MVPA; importantly, however, their work uses a waist-worn accelerometer as the criterion measure, which limits the interpretability of their findings in a VR fitness context. Hence, while our results support the relative accuracy of the Apple Watch, its usefulness as a precise measure of energy expenditure during VR fitness is limited.

On average, the Oculus Move accelerometer underestimated the energy expenditure of the VR fitness games measured by the metabolic cart by 27% (SD 23.1%) and 44% (SD 12.48%) for Flow and Boxing, respectively. Like the waist-worn accelerometer, the placement of the accelerometer within the Oculus headset may have impacted the accuracy of its measurements. Similar to the other measures of energy expenditure, the use of this outcome as a measure of energy expenditure is limited.

Lastly, preliminary comparisons of pre-post VR fitness measurement session mood states revealed reported changes in mood that are consistent with the beneficial changes we would expect from a bout of moderate-intensity PA [36] and with previous VR exergaming research [28,35]. These changes provide preliminary evidence for the positive mental health benefits of even single sessions of VR fitness, which is encouraging given the relationship between positive affect and adherence to PA [50].

Though our study contained many strengths, such as a gold-standard measure of energy expenditure (ie, indirect calorimetry) and a relatively homogeneous sample, there are limitations to our work. One limitation of this study is that all participants were naive to VR fitness. This may have resulted in a variable amount of energy expended compared to someone who regularly engages in VR fitness. Although we implemented a strict threshold for inclusion in the measurement session, discrepancies in the final accuracy and power scores, along with direct observation of participants, suggest that some participants spent more or less energy adjusting to the difficulty of the measurement session workout. In other words, the final score across participants suggests that some struggled more than others in acclimating to the difficulty of the measurement session. Further, all participants were active individuals (ie, meeting the weekly PA guidelines). As a result, the measured metabolic and cardiorespiratory responses to the measurement session may not be reflective of the average new user.

Both the Flow and Boxing medium-intensity modes of Supernatural demonstrated relatively high energy expenditures (8.2, SD 1.54 METs, and 7.6, SD 1.66 METs, respectively), classifying as vigorous-intensity PA (ie, >6.0 METs) [42]. Device-based measures of energy expenditure varied considerably both between participants and when compared to the metabolic cart results. Hence, caution should be used when using and interpreting device-based measures of energy expenditure within VR fitness games, including Supernatural. This study also provides preliminary evidence to support the physical and mental health benefits of engaging in VR fitness games like Supernatural. These findings are encouraging, given the increasing popularity and accessibility of VR fitness games as a means of achieving MVPA. For individuals who are interested in being physically active at home or are unable to access traditional forms of exercise, VR fitness presents a potential supplement or alternative to achieving the recommended levels of MVPA.

Abstract

Background: Prolonged sedentary behavior, such as sitting or reclining, has consistently been identified as a stand-alone risk factor for heightened cardiometabolic risk and overall mortality. Conversely, interrupting sedentary periods by incorporating short, active microbreaks has been shown to mitigate the negative effects of sedentary behavior. Casual exergames, which mix elements of casual gaming with physical activity, are one prospective intervention to reduce sedentary behavior because they require physical exertion. Casual exergames have shown promise in fostering emotional and physical advantages when played in specific circumstances. However, little research exists on how different types of movement interactions impact the psychological effects as well as the physical exertion of playing casual exergames.

Objective: The primary aim of this work was to explore the psychological effects and physical exertion of playing casual exergames lasting 2 minutes. More precisely, the investigation focused on comparing upper body and full body movement interactions. In addition, the work examined variations in body positions, considering both standing and seated positions during upper body movement interactions.

Methods: Two casual exergames were developed and investigated through 2 quasi-experimental studies. In study 1, we investigated how players' perceptions of control, exertion, and immersion were affected by using upper body as opposed to full body exergame controllers when playing casual exergames. In study 2, we investigated differences in positive affect, performance, enjoyment, and exertion when playing casual exergames with upper body movement interactions in seated and standing positions.

Results: Study 1 showed that perceived control was significantly higher for upper body movement interactions than for full body movement interactions (*P*=.04), but there were no significant differences regarding perceived exertion (*P*=.15) or immersion (*P*=.66). Study 2 showed that positive affect increased significantly for both standing (*P*=.003) and seated (*P*=.001) gameplay. The participants in the standing gameplay group showed slightly higher actual exertion; however, there were no differences between the groups in terms of positive affect, perceived exertion, enjoyment, or performance.

Conclusions: Casual exergames controlled by upper body movement interactions in seated gameplay can produce similar psychological effects and physical exertion as upper body movement interactions in standing gameplay and full body movement interactions. Therefore, upper body and seated casual exergames should not be overlooked as a suitable microbreak activity.

Introduction

Background

High levels of sedentary behavior (such as sitting or lying down) [1] and low levels of moderate to vigorous physical exercise are characteristics of an inactive lifestyle [1,2]. The people most vulnerable to the negative effects of an inactive lifestyle are those who have highly sedentary lives with minimal exercise [3,4]. The advances in domestic and workplace technologies, along with the changes in personal and public transportation, have decreased the necessity for physical activity, leading to increased sedentary lifestyles among populations [5]. The frequency of light-intensity activities (such as walking and performing household chores) in outdoor and nonoffice occupations has decreased in the last few decades [5]. Sedentary behavior is a widespread issue affecting various groups of people (eg, children [6-8], youth [9], and adults [10,11]) across different demographics and settings. While watching television, reading, using a computer, and playing video games are discretionary activities [12], sitting during school [6-8], university [9], or work [10,11] hours is generally nondiscretionary [12]. Therefore, researchers have investigated the impact of sedentary behavior [5]. Numerous studies have demonstrated the connection between excessive sedentary behavior and unfavorable health indicators or results [13-15], regardless of how much time is spent exercising to counteract the sedentary behavior [16]; for instance, when physical activity is taken into account, adults who sit 10 hours a day, as opposed to 1 hour a day, still show a 34% higher risk of increased mortality [17].

Incorporating active microbreaks has demonstrated the potential to mitigate the adverse consequences linked to sedentary behavior [14,18] and improve people's moods [19]; for example, 2- to 3-minute microbreaks with a light activity level every 30 minutes can positively impact mental and physical health [20-22]. Another study showed that over the course of 8 weeks, individuals who were encouraged to stand up and move every 30 minutes for 1 to 2 minutes during the workday significantly decreased their sedentary behavior by approximately 36 minutes per workday [23]. Thus, encouraging frequent, short breaks from sitting could improve health outcomes related to the risk of chronic diseases [23].

Exergames—video games that use movement and physical exertion during gameplay—have been shown to be effective in providing a good psychological experience [24] while also offering advantages for the player's health [25]. Exergames have been created with a variety of health-related goals in mind, including rehabilitation [26] and better mental health [27]. Exergames can increase physical activity [28,29], decrease sedentary behavior [30-33], and promote more active breaks [34-37]. Exergaming has been shown to achieve both moderate [31,38] and vigorous [38] levels of exertion, suggesting that exergames have the potential to serve as an alternative to conventional exercise [39].

Casual exergames are easily learned and quickly accessible exergames with simple rules, designed to motivate players to engage in moderate-intensity exercise during short play sessions [33]. Incorporating active microbreaks using casual exergames has demonstrated the potential to interrupt sedentary behavior [32,37,40]. Playing casual exergames can also induce positive affective states [31,32,41], which can reduce stress levels [42] and enhance overall well-being [43]. Previous studies have demonstrated that casual exergames can be enjoyable and generate appropriate levels of exertion [31,32,40]. However, little research has been conducted on the psychological experience and physical exertion when playing casual exergames [44-73] or on using different types of movement interactions in casual exergames [45].

When developing exergames, it is important to consider both the psychological and physiological aspects of the player's experience [46-48]. According to the dual flow model, the attractiveness of an exergame is determined by balancing the player's skill level with the exergame's challenge level, resulting in a state of psychological flow; and the effectiveness of the exergame is determined by balancing the player's fitness level with the exergame's physical intensity level [35,49]. As the optimal psychological experience and the optimal physiological experience are not necessarily aligned, focusing exclusively on boosting in-game experience may risk reducing health-related advantages [48]. On the basis of the dual flow model, movements with great psychological attractiveness and physiological effectiveness should be used [48]. The psychological and physiological aspects are also connected because the level of enjoyment experienced during playing exergames is correlated with increased exertion levels [44].

One aspect of psychological attractiveness in the exergame experience is immersion, defined in the context of video games as the degree to which the player participates in a game [50] and loses awareness of their surroundings while playing [51]. Immersion is closely related to the concept of flow, which is defined as the psychological state in which one is fully involved in an activity, losing self-consciousness [52]. Immersion impacts the psychological attractiveness of exergames [53] and can be achieved when players have control over the game's actions [50]. While both flow and immersion revolve around player engagement in a game, flow pertains to the general motivation and enjoyment of an activity, while immersion is more directly tied to the user experience and can be seen as a quantifiable aspect of the game experience that relates to both flow and motivation [44]. Movement-based controllers can enhance immersion levels by allowing for natural interaction, leading to increased well-being associated with physical exercise [53]. As control is one of the first stages in creating an immersive experience, it should be considered as a factor that might affect the player's immersive experience and, in turn, the casual exergame's psychological attractiveness [50]. Higher control can also contribute to improved performance, which is positively related to game enjoyment [54-56].

The characteristics of players' movements when exergaming are influenced by the characteristics of the exergame, the difficulty of remaining motivated without sacrificing the quality of the movements, the exergaming experience even when it is of short duration, and the scoring of points [57]. For the physical exertion of playing exergames, the type of movement interaction used in the exergame is an important design decision [47,58]. One decision revolves around using upper body or full body movements. Specifically, for casual exergames designed to target upper body movements, it is worth investigating whether the use of upper body movements can encourage sufficient levels of exertion. To induce positive health-related outcomes, it has previously been stated that casual exergame play should produce a moderate level of exertion [33]. Previous research has shown that upper body movements in exergames have lower potential for increasing exertion compared to full body movements [46,59]. A meta-analysis discovered that lower body and full body exergames produced more energy expenditure than upper body exergames; thus, the authors concluded that upper body exergaming movements are insufficient for achieving adequate energy expenditure [23]. Another study measured movements during gameplay of 3 different exergames using upper body and full body movements and discovered that adequate physical activity required full body movements [58]. However, another meta-analysis showed that exergames with continuous upper body movements have the potential to meet the recommendations for a moderate-intensity activity level [39]; for example, playing Wii boxing exergames with upper body movement interactions has been shown to elicit a moderate-intensity activity level [39,60-63]. On the basis of the mixed results of previous studies, it is worth further investigating whether upper body movements can elicit similar levels of exertion as full body movements for casual exergames as well as how the psychological experience is affected.

Another factor that can affect the psychological and physiological aspects of casual exergames is whether the exergame is designed to be played in a seated or standing position. One study comparing seated and standing gameplay in an exergame for individuals with mobility impairments found that the participants playing seated had higher perceived exertion [64]. However, because the participants chose gameplay mode depending on their abilities instead of being randomly selected for each condition, other factors apart from the seated or standing position could have affected the results. In addition, the psychological effects experienced could have influenced exertion levels because the seated players rated the exergame as more usable than the standing players. By contrast, another study comparing seated with standing positions when playing an adapted game mat exergame showed that participants had lower energy expenditure, perceived exertion, and heart rate when they played seated than when they played standing [65]. This aligns with research outside of the exergame domain that shows that performing an otherwise sedentary activity while standing requires more energy expenditure than performing the same activity while seated [66,67]. However, when we compared upper body movement interactions in seated and standing positions for a casual exergame, we found that there were no significant differences in perceived exertion between seated and standing gameplay [41]. Furthermore, an additional study compared playing 8 to 10 minutes of a boxing exergame in standing and seated positions and found that the seated position resulted in lower energy expenditure than the standing position, while there was no significant difference in perceived exertion [68]. As “Every move counts towards better health” according to the World Health Organization [69], even if exergame activities do not exceed recommended intensity levels, playing exergames is superior to being inactive [39] and might lead to higher exercise adherence [70]. Furthermore, microbreaks with light-intensity exercise every 30 minutes during the day offer both physical and mental health benefits [20]. Therefore, it could be argued that playing upper body casual exergames while seated is better than not playing at all.

In terms of psychological effects, research shows that both standing and seated gameplay generally have the same level of enjoyment [41,64,65,71,72]. However, in 3 of these previous studies [64,65,72], no statistical analysis comparing sitting and standing positions was performed, and in 2 of the studies, different movements were used in the sitting and standing conditions [65,71]. Thus, the generalizability of the results regarding the effect of standing versus sitting positions on enjoyment is limited. On the basis of the limitations of previous studies, we statistically compared 2-minute seated and standing casual exergame play with the same movement interactions in a previous study and found no significant difference between playing seated or standing in terms of positive affect and enjoyment [41].

Objectives

This work is an extension of a conference paper on full body and upper body movement interactions [45]. The aim of this work was to study the psychological effects and physical exertion of playing short-duration casual exergames lasting 2 minutes based on upper body movement interactions designed to promote active microbreaks to interrupt sedentary behavior. Considering the limited research and the mixed results of the psychological effects and physical exertion of different movement interactions in casual exergames, we specifically wanted to explore the psychological effects and physical exertion of upper body compared to full body movement interactions (study 1) and standing compared to seated positions for upper body movement interactions (study 2). The following research questions (RQs) were addressed:

- RQ1: How do casual exergames based on upper body compared to full body movements differ in terms of their psychological effects and physical exertion?
- RQ2: How do upper body casual exergames played in seated positions compared to standing positions differ in terms of their psychological attractiveness and physical exertion levels?

Methods

Overview

To answer the RQs, we conducted 2 studies using distinct in-house–developed casual exergames (Crossing and Beaver) for each study. The casual exergames were developed using the open-source game engine Godot. Each round of play lasts 2 minutes. Both casual exergames can be played on a computer screen equipped with a webcam that captures players’ movements. To enable players to observe their movements in relation to on-screen events, the webcam feed is displayed in the top left corner of the casual exergame interface. The actual time and collected points are displayed in the upper right corner of the interface.

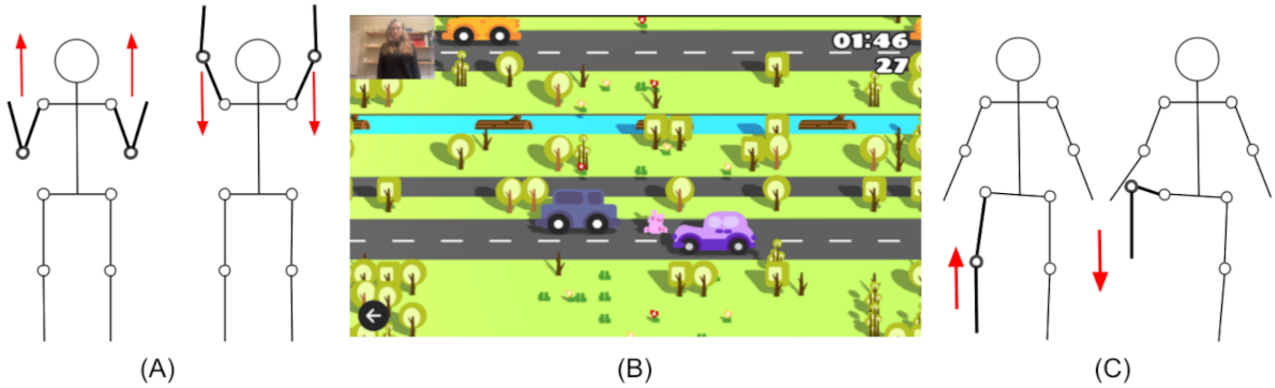
Both studies were performed at a game and cosplay festival. People walking by were asked whether they wanted to participate in a study about exergames. Those interested were provided with detailed information, and if willing to participate, they read through the information materials and signed a consent form. Participants aged <18 years needed their guardian to sign the form on their behalf. By recruiting participants who were naturally interested in games, we aimed to evaluate the impact of exergames on a population that is likely to engage with such interventions in real-world settings. This setting provided a unique opportunity to observe the effects of exergames on individuals already motivated by gaming, which we believe is crucial for understanding the design and immediate effects of these interventions.

Study 1: Upper Body Versus Full Body Movement Interactions

Casual Exergame (Crossing): Design and Interaction

The casual exergame Crossing is based on the classic arcade game Frogger (Figure 1). Using a well-known game genre and basic game mechanics is known to make it easier for players to identify and comprehend the game mechanics [73,74]. In Crossing, players control a rabbit navigating roads, rivers, and rail lines, earning points for forward jumps. Players can also perform sideways jumps, which aid in avoiding obstacles but do not contribute to the accumulation of points. If players collide with vehicles or fall into rivers, the rabbit dies, prompting a 5-second restart. The points acquired before each death are retained, but the waiting period during the restart impacts overall performance.

Figure 1. (A) Demonstration of forward movement for upper body movement interactions for (B) the casual exergame Crossing. (C) Demonstration of forward movement for full body movement interactions. Arrows show the direction of movement.



To support our research, 2 different movement controllers were developed for Crossing: an upper body condition and a full body condition. In the upper body condition, players raise their hands from near their bodies up to their shoulders and above their heads, starting with their arms stretched downward. The rabbit on the screen leaps forward as soon as the hands cross over the head. The player must repeat the movement and extend their arms to the starting position to make the rabbit jump again. In the full body condition, players raise their left or right knee over the hip to make the rabbit jump forward. The rabbit jumps forward when the knee is lifted above the hip. The player must stretch their leg back down to the starting position and repeat the maneuver with either leg to make the rabbit jump once more. To make the rabbit jump to the side in both upper body and full body conditions, players extend a single arm corresponding to the intended direction—raising the right arm for a jump to the right and the left for a jump to the left, unlike extending both arms upward.

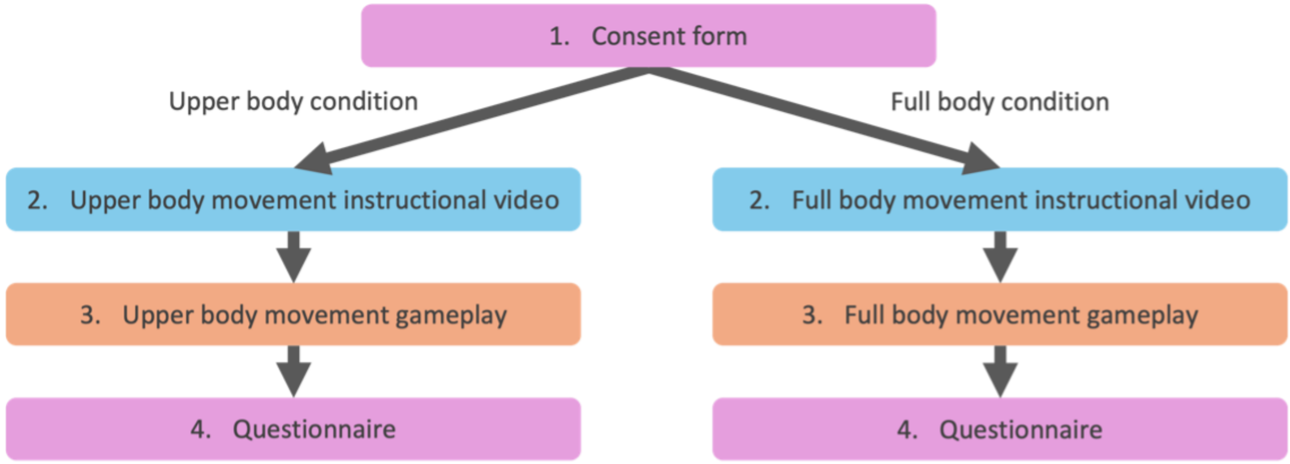
Previous research has indicated the importance of shifting the player's focus away from the physical exertion they are experiencing while playing the exergame [58,73]. When it comes to body focus, Crossing's fast-paced, time-limited gameplay forces players to pay attention to their movements and prevents them becoming self-conscious. The game's obstacles might *kill* players if they remain motionless for an extended period of time, further contributing to the game's fast pace [73].

Participants and Procedure

In all, 80 people participated in the study. The participants' ages ranged from 11 to 54 (mean 25, SD 7) years. Of the 80 participants, 56 (70%) identified as man, 17 (21%) as woman, and 5 (6%) as nonbinary, while 2 (3%) reported that they were unsure about their gender identity. Of the 80 participants, 51 (64%) reported having played exergames multiple times, 25 (31%) reported having played exergames once, and 4 (5%) reported never having played exergames.

After signing the consent form, all participants watched an instructional video about how to play and interact with the exergame. Participants were then asked to stand 1.5 meters away from a computer screen equipped with a webcam. The webcam was adjusted so that the participant was clearly visible, and they were asked to demonstrate the movements they should use. Next, participants played one 2-minute round and then filled out a questionnaire (Figure 2) that included (1) demographic questions, (2) the Borg rating of perceived exertion (RPE) scale [40], and (3) the perceived immersion and control subscales of the Exergame Enjoyment Questionnaire (EEQ) [44]. We alternated between controllers for each new participant, resulting in half the participants (40/80, 50%) playing Crossing in the upper body condition and the other half (40/80, 50%) playing in the full body condition.

Figure 2. Study 1 procedure.



Measures

Physical exertion and psychological effects were the main measures in the study. To measure the physical exertion of playing Crossing, the Borg RPE scale was used to measure perceived exertion [75,76] because it is a valid instrument for measuring exercise intensity [76] and has been used previously to measure perceived exertion when playing casual exergames [33]. The Borg RPE scale ranges from 6 (indicating no exertion at all) to 20 (indicating maximal exertion) [77], with ratings of 11 to 12 corresponding to light intensity, 13 to 14 corresponding to moderate intensity, and 15 to 16 corresponding to hard intensity [78] (Table 1).

Table 1. Correspondence between the Borg rating of perceived exertion (RPE) score and percentage of maximum heart rate [78-80].

Maximum heart rate (%)	Intensity	Borg RPE score
20-39	No exertion at all	6-7
40-59	Very light	8-10
60-69	Light	11-12
70-79	Moderate (somewhat hard)	13-14
80-89	Hard (heavy)	15-16
90-99	Very hard	17-18
100	Maximal	19-20

To measure psychological effects, the perceived immersion and control subscales of the EEQ were used (Table 2) [81]. The EEQ perceived immersion subscale consists of 5 items and measures the degree to which the player is fully engaged and involved in the activity [81]. The EEQ perceived control subscale consists of 4 items and measures the degree to which players can directly affect the outcome of the exergame [81]. All items were measured on a 5-point Likert scale: strongly disagree (score=1), disagree (score=2), neutral (score=3), agree (score=4), and strongly agree (score=5).

Table 2. The Exergame Enjoyment Questionnaire (EEQ) perceived immersion and control items [81].

Item	Scale	Item wording
Immersion 1[a]	EEQ immersion	I did not feel like I wanted to keep playing.
Immersion 2	EEQ immersion	I felt like I lost track of time while playing.
Immersion 3	EEQ immersion	I felt a strong sense of being in the world of the game to the point that I was unaware of my surroundings.
Immersion 4	EEQ immersion	I felt emotionally attached to the game.
Immersion 5	EEQ immersion	I was focused on the game.
Control 1	EEQ control	I felt that it was easy to familiarize myself with the game controls.
Control 2[a]	EEQ control	I felt that it was difficult to understand how the game works.
Control 3	EEQ control	I felt in control over the game.
Control 4	EEQ control	I felt that the game reacted quickly to my movements.

[a]Reversed item.

To provide descriptive data, the number of movements during the play session was measured by counting the number of movements each participant executed while playing the exergame, encompassing both the forward and sideways jumping movements for the rabbit. In addition, each participant's performance was measured by recording their final score.

Statistical Analysis

A between-subjects analysis was conducted for the players in the upper body condition compared to those in the full body condition using SPSS software (version 29.0; IBM Corp). Before the analysis, the items immersion 1 and control 2 were reversed, and internal consistency was measured for the perceived immersion and control subscales of the EEQ using Cronbach α. The Cronbach α value for the 5-item perceived immersion subscale was 0.66, and the Cronbach α value for the 4-item perceived control subscale was 0.68, both close to the satisfactory threshold value of 0.70 [82]. As several of the variables did not meet the assumption of normality and had no significant outliers [83], we chose to use the nonparametric Mann-Whitney *U* test to answer RQ1. The condition was used as the independent variable and perceived control, perceived immersion, and perceived exertion as the dependent variables. Approximate values of the effect size *r* were calculated by dividing the z score for each test by the square root of the number of cases (n=80) [84], following the guidelines of 0.2 corresponding to a small effect size, 0.5 to a medium effect size, and 0.8 to a large effect size [85]. To complement the analysis, a Spearman correlation matrix was produced looking at the correlation between perceived control, perceived immersion, and perceived exertion for both conditions, following the guidelines of ≤0.35 corresponding to a weak correlation, 0.36 to 0.67 corresponding to a moderate correlation, and 0.68 to 1 corresponding to a strong correlation [86].

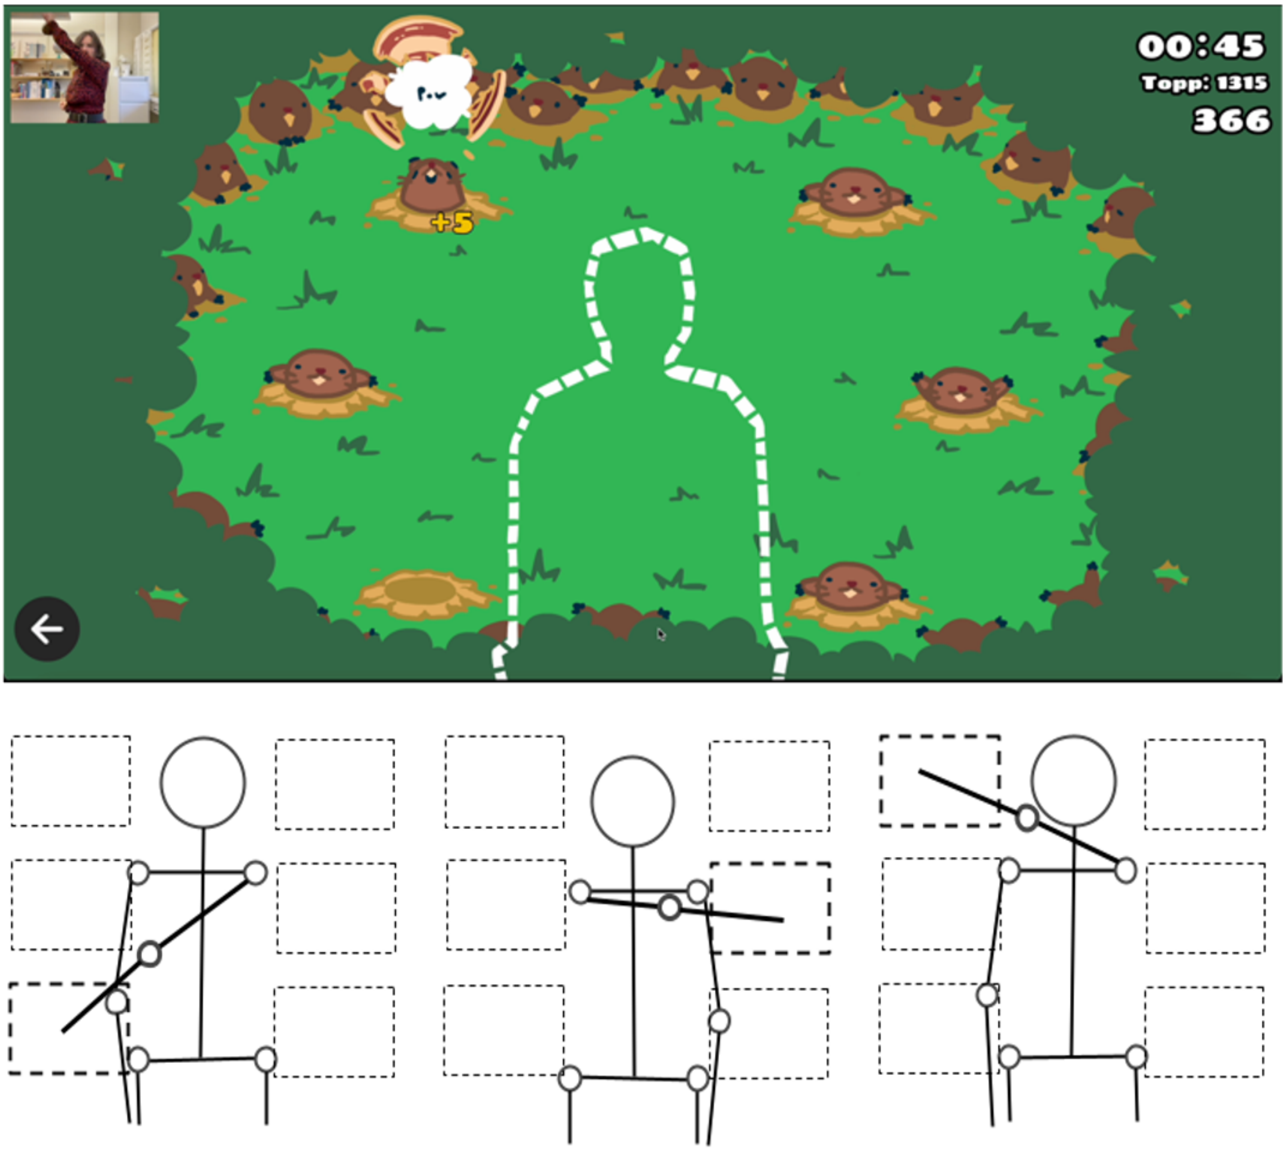
Study 2: Standing Versus Seated Positions for Upper Body Movement Interactions

The second study replicated our previous study on seated and standing exergames [41], using a different casual exergame and with the addition of using the participant's actual heart rate as an objective measure of exertion.

Casual Exergame (Beaver): Design and Interaction

The in-house–developed casual exergame Beaver was used in this study. The goal of Beaver is to hit targets on the screen as fast as possible within the time limit of 2 minutes. In the exergame, beavers holding target boards appear on the screen in 6 different positions according to a specific pattern. The player receives points based on how fast the target is hit (slow hit=1 point, moderately fast hit=3 points, and very fast hit=5 points). The order in which the targets appear follows different patterns but is repeated over 2 rounds, allowing players to learn the current pattern and hit the targets faster in the second round. To hit the targets, the player moves the arm on the opposite side across the body toward the target's position, as shown in Figure 3. Targets alternate between the left and right side of the player's head, shoulders, and hips so that the player keeps hitting the targets across the torso with both arms. This movement is similar to boxing because prior research on boxing exergames has demonstrated that boxing-like movements can result in moderate levels of exertion [39,60-63]. The decision to avoid a boxing game graphics theme was to maintain consistency with the game-like, rather than sport-like, theme and appearance used in the Crossing exergame in study 1.

Figure 3. The casual exergame Beaver with boxing-like upper body movement interactions.

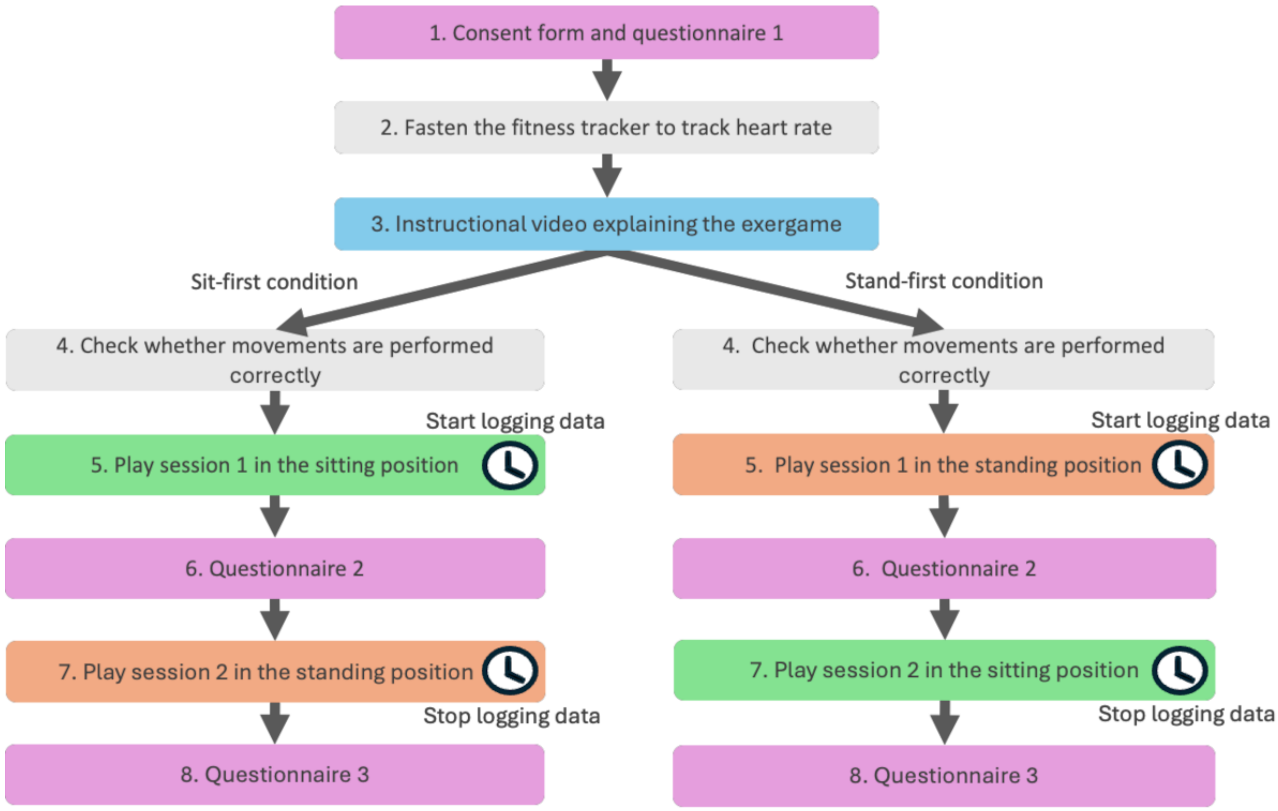


Participants and Procedure

In all, 40 people participated in the study, and their ages ranged from 18 to 47 (mean 25.27, SD 6.357) years. Of the 40 participants, 23 (58%) identified as man, 12 (30%) as woman, and 4 (10%) as nonbinary, while 1 person (2%) reported that they were unsure about their gender identity. Of the 40 participants, 19 (48%) reported as work was their main occupation, 17 (42%) were students, 2 (5%) worked as well as studied, and 2 (5%) had some other main occupation. Of the 40 participants, 4 (10%) had never played an exergame, 17 (42%) had played an exergame at some point, 14 (35%) sometimes played exergames, 4 (10%) played exergames somewhat often, and 1 (2%) often played exergames.

After signing the consent form, participants answered a questionnaire that included (1) demographic questions and (2) the international, shortened version of the Positive and Negative Affect Schedule (PANAS) [87,88]. A Polar Unite fitness tracker was fastened around each participant's wrist to track their heart rate during the play sessions. The participants were then shown an instructional video that explained how to play the exergame. To avoid possible bias, the video was recorded in such a way that it was impossible to tell whether the instructor was sitting or standing. Conditions were alternated for each participant, resulting in half of the participants (20/40, 50%) playing Beaver in the sit-first condition (seated in a chair) and the other half (20/40, 50%) playing in the stand-first condition. Participants were placed 1.5 meters away from a computer screen equipped with a webcam in both conditions. The webcam was then adjusted so that the participant was clearly visible, and the participant was asked to demonstrate the movements they should use. Once the participant had confirmed that they had understood the exergame and movements by demonstrating them correctly, the fitness tracker was set to start logging the heart rate, and the participant started the first game session. The time was also noted to correlate the heart rate data to the questionnaire results. After the session ended, the final score was noted, while the participant filled in the second questionnaire, which included (1) the PANAS [87], (2) the Borg RPE scale [40], and (3) the Physical Activity Enjoyment Scale (PACES) [70,89]. Next, the participant was again guided to sit or stand in front of the computer in the position they had not played before. The webcam was adjusted to the new position, and the participant played a second round of the exergame. The starting time of the second gameplay session was again noted for purposes of later identification in the data. When the gameplay session ended, the heart rate data logging was stopped, and the final score of the second gameplay session was noted while the participant filled out the third and final questionnaire, which included the same scales as the second questionnaire. The entire procedure is shown in Figure 4.

Figure 4. Study 2 procedure.



Measures

Physical exertion of playing exergames can be measured using subjective perception (eg, using the Borg RPE scale [75-77] as in study 1) and objective measures (eg, capturing the actual heart rate) [79]. As there is a strong correlation between heart rate and energy expenditure, heart rate monitors can be used to measure actual exertion in exergames [90]. Borg RPE scores and heart rate measures are positively correlated during exergame play [91]. Thus, integrating both subjective and objective data offers a comprehensive assessment of physical exertion, enhancing accuracy in evaluating exergame physical exertion.

The participant's actual heart rate was measured using a Polar Unite fitness tracker fastened around their wrist during the gameplay sessions, while the perceived exertion was measured using the Borg RPE scale [75-77], which corresponds to the maximum heart rate [75,78] (Table 1). The fitness tracker logs the wearer's heart rate during a recorded training session and displays the heart rate over time in a graph. The highest and average heart rates during the first gameplay session and the second gameplay session were compared to the participant's estimated maximum heart rate (calculated using the following formula: maximum heart rate = 220 – age in years) to obtain a percentage used to determine exercise intensity.

After study 1, some potential issues with measuring immersion in very short exergames were discovered, as described in the Discussion section. Therefore, in study 2, psychological effects were instead measured in terms of affect, enjoyment, and performance. Positive and negative affect before and after playing Beaver were measured using the international, shortened version of the PANAS [88]. The PANAS was selected because of its established reliability and validity in assessing affect [92], its proven efficacy in measuring changes in affect before and after shorter interventions [93], and its frequent use in research on exergames [94]. The shortened PANAS contains 10 validated items—5 for positive affect and 5 for negative affect—and has a total score for both positive and negative affect that ranges from 5 to 25 based on the summation of its items [87]. In this study, only the positive affect scale of the PANAS was analyzed because the negative affect scale exhibited low variation and, as a result, issues with internal consistency, with values close to 0. As the positive and negative affect scales are uncorrelated and independent [88], eliminating the negative affect scale does not impact the findings related to the positive affect scale.

Physical activity enjoyment was measured using the shortened version of the PACES [70,89]. Five of the original 18 statements are included in the shortened version, which has demonstrated strong reliability for exergames across age groups [70]. In the PACES, the player rates how much they agree with each statement using a 7-point Likert scale.

Finally, performance was measured using the participants' final scores. These scores indicated the number of times the participant had successfully jumped forward on the path.

Statistical Analyses

Two main statistical analyses were conducted. First, a within-subjects comparison of the difference in positive affect before and after playing the first round was carried out for both the participants playing the first gameplay session seated and the participants playing the first gameplay session standing. The second analysis was a within-subjects comparison of the differences in heart rate, perceived exertion, affect, enjoyment, and performance between the seated and standing positions for each participant.

For the first analysis, Cronbach α was calculated for positive and negative affect before and after the first gameplay session for participants playing the first gameplay session standing and seated. Internal consistency was acceptable for positive affect before playing for both seated (0.67) and standing (0.75) gameplay, but while negative affect had acceptable consistency for seated (0.70) gameplay, it was low for standing gameplay (0.22). After playing 1 session of the exergame, the internal consistency for positive affect was high for both seated (0.83) and standing (0.86) gameplay, but, once again, the consistency for negative affect was low for standing (0.15) gameplay while remaining high for seated (0.89) gameplay. Because of the low internal consistency for negative affect, only positive affect was analyzed. To evaluate the difference in positive affect after playing 1 session of the exergame, the difference between the positive affect before and after playing the exergame was calculated. The assumption behind the dependent 2-tailed *t* test was checked in terms of outliers and normality. No outliers were found for either sitting or standing gameplay, and the Shapiro-Wilk test statistic showed that the standing group had no significant deviation from normality at a significance of P=.94. However, the seated group deviated from normality with a significance of P=.04, which is less than the threshold of P=.50. Therefore, the nonparametric Wilcoxon signed rank test was run on the positive affect before and after the first seated and standing gameplay sessions. Effect size was calculated using the formula $r = z/\text{sqrt}(N)$ [84].

For the second analysis, the differences between each participant's seated and standing gameplay were calculated. Cronbach α was calculated for the PACES (seated=0.83 and standing=0.83) as well as positive (seated=0.89 and standing=0.88) and negative (seated=0.78 and standing=0.73) affect. As all scales showed high internal consistency, their items were summed. Next, the differences between standing and seated values were calculated for the PACES, positive and negative affect, Borg RPE, percentage of maximum heart rate reached (highest and average), and game score for each participant and analyzed to check assumptions of normality. Negative affect had multiple extreme outliers and was heavily skewed with a Shapiro-Wilk significance of <.001 and was thus excluded from further analysis. No other score showed deviation from normality according to the Shapiro-Wilk test statistic (positive affect=.13, PACES=.50, Borg RPE=.07, highest heart rate percentage=.69, average heart rate percentage=.39, and game score=.50). While the game score had 1 outlier, it was not extreme, and we decided to keep it for analysis due to its being a possible increase in score between gameplay sessions. The dependent *t* test could thus be used to analyze the differences between standing and seated gameplay.

Ethical Considerations

According to the Swedish Ethical Review Act [95], this study did not require ethical review, as it posed no apparent risk of physical or psychological harm to the research subjects, did not involve a physical intervention, and did not involve sensitive personal data. Nonetheless, all procedures adhered to ethical standards outlined in Swedish law (SFS 2003:460). Participants were verbally invited to join the study and were provided with an overview of the project and study procedures. Upon agreeing to participate, individuals received a written information letter and were asked to sign the written consent form. Participants were informed of their right to withdraw from the study at any time without providing a reason. To ensure anonymity, each participant was assigned a unique code that could not be traced back to them. Only the project team had access to these coded data.

Results

Study 1: Upper Body Versus Full Body Movement Interactions

Overall, the participants perceived the exergame as controllable and immersive, with perceived exertion corresponding to a low-intensity activity for both the upper body and full body movement interactions (Table 3). In the upper body condition, participants on average agreed that the casual exergame was controllable (median 4.00, IQR 0.88) and were between being neutral and somewhat agreeing that the casual exergame was immersive (median 3.40, IQR 0.90), with a perceived exertion corresponding to a low-intensity activity (median 11.00, IQR 2.00). In the full body condition, participants perceived the exergame as less controllable (median 3.50, IQR 1.00) than, and as immersive (median 3.40, IQR 1.00) as, the upper body condition, with a perceived exertion corresponding to a moderate-intensity activity (median 13.00, IQR 3.50). The statistical analysis (Table 4) showed that the exergame was perceived as significantly more controllable in the upper body condition than in the full body condition (U=589.00; P=.04), corresponding to a small effect size (0.23). However, there was no statistically significant difference between the conditions regarding perceived immersion (U=754.00; P=.66) and perceived exertion (U=652.00; P=.15).

Table 3. Descriptive statistics for upper body and full body movement interactions.

Measure	Upper body		Full body	
	Mean (SD)	Median (IQR)	Mean (SD)	Median (IQR)
Sideways movements, n	12.88 (6.57)	11.50 (7.50)	9.58 (4.86)	9.00 (8.00)
Forward movements, n	62.30 (13.54)	62.50 (16.00)	56.98 (11.38)	57.50 (16.50)
Performance	58.53 (12.93)	58.50 (16.00)	47.60 (13.98)	46.50 (22.50)
Perceived control	3.78 (0.61)	4.00 (0.88)	3.48 (0.69)	3.50 (1.00)
Perceived immersion	3.24 (0.62)	3.40 (0.90)	3.15 (0.65)	3.40 (1.00)
Perceived exertion	11.47 (2.10)	11.00 (2.00)	12.00 (2.60)	13.00 (3.50)

Table 4. Differences between upper body and full body movement interactions.

Study 2: Standing Versus Seated Positions for Upper Body Movement Interactions

There was an increase in positive affect scores from before (mean 13.90, SD 3.43; median 14.00, IQR 4.50) to after (mean 16.00, SD 4.61; median 15.00, IQR 7.00) playing one 2-minute session of the exergame in the seated position. The Wilcoxon signed rank test showed that this difference was significant (*z*=–3.288; *P*=.001), and the effect size (*r*=0.74) corresponded to a large effect [85]. There was also an increase in positive affect scores from before (mean 13.45, SD 3.69; median 13.50, IQR 5.00) to after (mean 16.00, SD 4.19; median 16.00, IQR 7.00) playing one 2-minute session of the exergame in the standing position. The Wilcoxon signed rank test showed that this was also significant (*z*=–2.947; *P*=.003), and the effect size (*r*=0.66) corresponded to a large effect [85].

The highest percentage of their maximum heart rate that participants reached during standing gameplay (mean 63.29%, SD 7.40%) was slightly higher than that reached during seated gameplay (mean 60.46%, SD 7.38%), which was significant (t_{39}=2.805; *P*=.008), with an effect size (Cohen *d*=0.44) corresponding to a small effect. Similarly, the average heart rate (as a percentage of the estimated maximum heart rate) was also slightly higher in standing gameplay (mean 55.71%, SD

7.78%) than in seated gameplay (mean 52.63%, SD 6.92%). This was again statistically significant (t_{39}=2.542; *P*=.02), with an effect size (Cohen *d*=0.40) corresponding to a small effect.

Standing gameplay also showed slightly higher scores in positive affect, enjoyment, and perceived exertion than seated gameplay, while seated gameplay had slightly higher scores in performance than standing gameplay. However, none of these differences were significant (Table 6).

Table 6. Statistical analysis of seated gameplay compared to standing gameplay.

Measure	Seated gameplay, mean (SD)	Standing gameplay, mean (SD)	Seated gameplay, median (IQR)	Standing gameplay, median (IQR)	*t* test (*df*)	*P* value	Effect size (Cohen *d*)
Positive affect	15.80 (4.85)	16.13 (4.82)	15.00 (8.50)	15.50 (7.00)	1.114 (39)	.27	0.18
Enjoyment	25.38 (5.67)	25.90 (5.66)	25.00 (9.50)	25.50 (8.50)	0.894 (39)	.38	0.14
Perceived exertion	10.60 (2.04)	10.95 (2.40)	11.00 (3.00)	11.00 (3.00)	1.300 (39)	.20	0.21
Average heart rate (%)	52.63 (6.92)	55.71 (7.78)	51.93 (1.74)	55.21 (0.97)	2.542 (39)	.02[a]	0.40
Highest heart rate (%)	60.46 (7.38)	63.29 (7.40)	60.21 (8.44)	62.24 (8.93)	2.805 (39)	.008[a]	0.44
Performance	702.30 (109.52)	695.50 (94.13)	716.50 (154.50)	706.00 (116)	–0.409 (39)	.69	0.07

Discussion

This work aimed to study the psychological effects and physical exertion of playing short-duration casual exergames lasting 2 minutes based on upper body movement interactions designed to promote active microbreaks for people who are sedentary. In the first study, upper body movement interactions were compared to full body movement interactions, and in the second study, seated gameplay was compared to standing gameplay when using upper body movement interactions.

Principal Findings

This work demonstrated that (1) upper body movement interactions in casual exergames can be as effective and appealing as full body movement interactions; and (2) playing upper body casual exergames in standing positions can result in slightly higher effectiveness than, and a similar degree of attractiveness as, playing upper body casual exergames in seated positions.

In terms of the psychological effects of casual exergames, study 1 showed that the upper body casual exergame controller was perceived as more controllable than the full body controller and that the level of immersion was similar for both conditions. As perceived control is seen as a prerequisite to an immersive experience [50] and was found to positively correlate to immersion in this study, longer-duration gameplay could have resulted in the upper body condition being perceived as more immersive over time; for example, 1 study found that short-duration gameplay lasting 3 minutes resulted in less immersion than long-duration gameplay lasting 7 minutes [96]. The short-duration gameplay session lasting 2 minutes in this study could thus have resulted in lower immersion than if the exergame had been played for longer durations. Further research would be needed to investigate whether this holds true. In study 2, the psychological effects were similar for the seated and standing upper body movement conditions, with no significant difference in positive affect, enjoyment, or performance. Furthermore, the results showed that both seated and standing upper body casual exergame movement interactions significantly increased positive affect after participants played a 2-minute session. The result signifies that seated and standing casual exergame play could both be valid movement interaction options for upper body casual exergames.

In terms of physiological effectiveness, study 1 showed that perceived exertion did not differ for the upper body and full body casual exergame conditions. Similarly, in study 2, there was no significant difference between perceived exertion for the standing and seated upper body casual exergame conditions. However, there was a difference in terms of the objective measure of exertion. The standing group had a significantly higher heart rate than the sitting group for both the highest and average heart rates, although the effect size was small for both. As no objective measure of exertion was taken in study 1, a similar pattern could have emerged for the upper body conditions compared to the full body conditions. The upper body movement interactions provided a light level of perceived exertion in both study 1 (mean 11.47, SD 2.10), with the upper body movement corresponding to players lifting their arms, and study 2 (mean 10.60, SD 2.04 for seated gameplay and mean 10.95, SD 2.40 for standing gameplay), with the upper body movement corresponding to boxing-like movements. However, while the highest heart rates reached also showed a light level of exertion (mean 60.46%, SD 7.38% for seated gameplay and mean 63.29%, SD 7.40% for standing gameplay), the average heart rates in study 2 (mean 52.63%, SD 6.92% for seated gameplay and mean 55.71%, SD 7.78% for standing gameplay) only indicate a very light–intensity activity, which might also be the case for study 1. On the basis of previous research claiming that casual exergames should produce at least a moderate level of exertion [33], neither exergame thus reached sufficient levels of exertion. Despite this, both exergames may be considered appropriate tools for microbreaks during the day, considering that every move contributes to better health [69], and microbreaks (2-3 min of light-intensity exercise) during the day (every 30 min) still offer both physical and mental health benefits [20-22]. The higher heart rate averages displayed in study 2 imply that people could gain some benefit from playing upper body casual exergames in standing positions compared to seated positions. However, due to the small difference in effect size and with both measures corresponding to very light activity, playing seated should be seen as a reasonable option for those who prefer to do so. Further research is necessary to ascertain the long-term effects on physical health of playing in seated or standing positions.

Comparison With Prior Work

The importance of considering both the psychological effects and the physical exertion of playing exergames has been highlighted previously [46-48, 73]. This study focused on how the movement interactions used in casual exergames could affect these dimensions.

Previous research has shown that playing exergames in both standing and seated positions produces equivalent levels of enjoyment (psychological attractiveness) [41,64,65,71,72]. The results from this work further support these findings, showing no difference between the seated and standing positions in terms of enjoyment; in addition, they support the notion that the psychological effects are also similar in terms of positive affect and performance [41]. Previous research has also shown that playing casual exergames can induce positive affective states [31,32,41]. The results of this study support this notion, with both the seated and standing positions generating an increase in positive affect. As positive affect can reduce stress levels [42], enhance overall well-being [43], and improve work performance [97], casual exergames could be promising for implementation in a workplace context to promote active microbreaks.

Regarding physiological effectiveness, previous studies have found mixed results when comparing standing and seated exergaming. While some studies have found higher energy expenditure in seated gameplay [64,65], others have found higher energy expenditure in standing gameplay [68,72]. Our results in study 2 support that standing gameplay involves higher objective exertion than seated gameplay, with no difference in subjective measures. The higher exertion in the standing position is likely due to using the leg muscles to stand (although they are not used to play the exergame) because even sedentary activities require more energy when standing instead of sitting [66,67]. When rating perceived exertion, this difference might be small enough that people do not register it because the exertion in their arms is more noticeable after playing, thus leading to similarly rated exertion despite differing heart rates. The results show that the difference in heart rate percentage is only approximately 3% for both the highest and average heart rates, which may feel very similar. As for why the participants rated their exertion higher than their heart rates show, it is possible that the average over the 2 minutes of gameplay does not reflect the exertion level at the end, which is when the participants rated their exertion. When beginning an activity, the heart rate rises gradually. With the short playtimes, this initial increase might affect the average heart rate more than it would in a longer activity. The highest heart rate reached was typically toward the end of the sessions and was also more closely matched to the perceived exertion.

Previous studies have also shown mixed results when comparing upper body to lower body movement interactions. It has been suggested by some studies that upper body exergaming might not be sufficient for achieving adequate energy expenditure [46,59]. Meanwhile, other studies have suggested that certain upper body movements could produce sufficient exertion levels [39,60-63]. This study found no difference in perceived exertion between upper body and full body movement interactions, somewhat supporting the notion that upper body movements could produce sufficient exertion. However, because no objective measures of exertion were recorded in study 1, more research would be needed to validate that this holds true not only for subjective measures of exertion but also for objective measures.

A meta-review shows that upper body movement interactions characterized by continuous movements can result in greater energy expenditures and intensity levels [39]. Previous studies on boxing exergames have shown that boxing-like movements can achieve a moderate intensity of exertion [39,60-63]. However, both the perceived exertion and the heart rate data showed that the exergame in study 2, which involved using boxing-like movements, only reached a light or very light intensity of exertion. A potential explanation for this difference could be the time participants spent playing because a 2-minute exergame session will feel less exerting than the same exergame played for twice as long or more. Another explanation could be that the design of the exergame influenced the amount of physical effort the participants were willing to exert; for example, the exergame in study 2 features short pauses between sets of targets, which could have contributed to participants not reaching moderate levels of exertion. The interplay between gameplay duration, movement design, and exergame design is an interesting avenue for further research.

Limitations

Integrating active microbreaks into the day via casual exergames has shown promising advantages [32,37]. However, both studies took place at a game and cosplay festival at a specific point in time. The 2-minute casual exergames may influence positive affect in distinct ways when experienced in other settings; for example, having an audience of peers sharing an interest in gaming might be experienced as more positive than playing alone. Furthermore, because the number of people observing the players varied throughout the day depending on other activities at the festival, participants may also have had different experiences depending on their reactions to feeling observed. Conducting the studies in a more controlled setting might produce different results. In addition, continuous gameplay might play a role in influencing changes in positive affect over time. Further research should also be undertaken to quantify the findings of these studies by using other casual exergames.

Participants in both studies played the exergames for the first time. Thus, the lack of familiarity may have influenced their impression of the movement interactions in both study 1 (upper body movement interactions compared to full body movement interactions) and study 2 (upper body movement interactions in seated compared to standing positions). Further research should incorporate a phase allowing participants to familiarize themselves with the exergame controllers before the start of the study. This would help determine whether the findings remain applicable when participants have fully mastered the exergame controls. As this study only covered players' initial experience with casual exergames, there is a need for longitudinal studies on the psychological attractiveness and physiological effectiveness of different movement interactions in casual exergames and how they should be constructed to increase the psychological attractiveness and physical effectiveness over time.

The results regarding exertion in study 1 are also limited due to a lack of objective measures of exertion. As seen in study 2, there could be differences in the full body and upper body movement interactions in terms of exertion that are not captured through only perceived exertion. Further research using objective measures (eg, heart rate) should be undertaken to better understand the effectiveness of full body and upper body movement interactions in short casual exergames. Furthermore, both studies could greatly benefit from using more extensive measures of physical activity, such as metabolic equivalents of tasks (METs) and maximal oxygen consumption, to examine the extent of any health benefits of playing short-duration casual exergames in different player modes.

Conclusions

Short-duration casual exergames lasting 2 minutes with upper body movements may hold potential in promoting active microbreaks during sedentary periods. As this study showed, upper body casual exergame play can produce light exertion levels and an increase in positive affect after compared to before playing. Upper body movement interactions may also be more suitable for casual exergames used for microbreaks because they are perceived as easier to control than full body movement interactions, while reaching similar (light) exertion levels and immersion. Playing with upper body movement interactions in standing gameplay could involve slightly higher objective exertion (as measured by the heart rate) than when playing the same exergame in a seated position; however, due to the small difference, seated positions should not be neglected as a viable alternative for players who prefer them. Furthermore, upper body movement interactions in both seated and standing positions elicit comparable psychological effects, resulting in similar levels of enjoyment, positive affect, and performance.

Acknowledgments

The authors would like to thank the users for participating in the study and East Sweden Game for supporting and enabling the data collection. The authors would also like to thank Erik Berglund who developed the exergames used in this research and Izabella Jedel for assisting in the data collection and analysis.

Authors' Contributions

AB and HO contributed to the conception and design of the study. AB contributed to the design of the exergames used in the study. AB and a research assistant, Izabella Jedel, collected the data for study 1. AB and HO collected the data for study 2. HO and a research assistant, Izabella Jedel, performed the statistical analysis. AB wrote the first draft of the manuscript. Both AB and HO then carefully reviewed and edited the manuscript.

Conflicts of Interest

AB is a cofounder and the chief executive officer of Liopep, a spin-off company based on her research projects about exergames that aim to increase physical activity. Liopep is commercializing an app that includes the 2 exergames evaluated in this research. While the authors have taken steps to ensure objectivity, readers should be aware of this affiliation. No revenue was paid (or promised to be paid) to any of the authors or the university for the submission of this work. Transparency and research integrity have been maintained through collaborative efforts and rigorous peer review. AB was excluded from the data analysis phase of both studies to ensure that the conflict of interest did not bias the research process and outcomes. In addition, AB did not collect the data alone; data collection was conducted collaboratively by the entire author team. The study design was also a joint effort by the author team, further ensuring the integrity and impartiality of the research findings. HO declares no conflicts of interest.

Abstract

Background: In the Netherlands, neighborhood sport coaches (NSCs) play an important role as intermediaries in promoting physical activity (PA) in the neighborhood. Gamification is the use of game elements in nongame contexts; it can be implemented with or without technology and holds promise for promoting PA. NSCs infrequently make use of this option.

Objective: This study aims to understand barriers to, and facilitators of, using gamification to promote PA, as perceived by NSCs.

Methods: A total of 25 semistructured interviews were conducted with NSCs in the Netherlands. The interviews were audiotaped, transcribed, and analyzed by means of thematic analysis using ATLAS.ti (version 22; ATLAS.ti Scientific Software Development GmbH) software. The deductive coding was informed by the capability, opportunity, motivation, behavior model and the theoretical domains framework, complemented by inductive coding.

Results: Barriers and facilitators identified as factors influencing the implementation of gamification were related to 7 themes. NSCs required technical, creative, and promotion skills; knowledge about existing gamification tools; and social support from their employer and professional network. Financial costs were identified as a barrier to the successful implementation of gamification. Lack of clarity regarding stakeholders' responsibility to implement gamification could further hamper implementation. In general, NSCs were positive about investing time in implementing gamification and expected positive effects from implementing it.

Conclusions: To overcome identified barriers, a clear overview of tools, best practices, and available subsidies must be created, a gamification network must be established, the responsibility of NSCs must be clarified, and guidance must be offered on the promotion of gamification.

Introduction

Background

Physical activity (PA) supports both physical and mental health. It can prevent noncommunicable diseases, such as cardiovascular diseases, type 2 diabetes, hypertension, and certain types of cancer [1-3], and it reduces the risk of it reduces the risk of becoming overweight or developing obesity [4]. However, worldwide PA prevalence is low, especially in high-income countries [5]. PA guidelines for children recommend daily moderate to vigorous PA for 60 minutes and vigorous activities 3 days per week. PA guidelines for adults recommend at least 150 minutes of moderate-intensity aerobic

PA each week, a minimum of 75 minutes of vigorous-intensity aerobic PA or an equivalent combination of both. Muscle-strengthening activities involving major muscle groups should be performed at least 2 days a week [6]. In the Netherlands, 43% of children (aged 4-11 years), 62% of youths (aged 12-17 years), and 54% (aged 18-64 years) of adults did not meet the PA recommendations in 2022 [7]. Therefore, PA interventions are needed to increase PA levels in all populations.

Intermediaries or health brokers play an important role in offering accessible (ie, geographically close and inexpensive) PA interventions that are tailored to local communities' needs and wishes [8,9]. In the Netherlands, the Dutch Ministry of Health, Welfare, and Sport introduced neighborhood sport coaches (NSCs; in Dutch *buurtsportcoach*) with the aim of connecting the sport sector with other sectors (eg, daycare and welfare) and of promoting PA and sports participation in the neighborhood. NSCs are responsible for supporting local sports clubs, promoting a specific sport (eg, hockey or soccer), or promoting informal PA (eg, physical exertion such as running, jumping, and dancing). These coaches are 40% funded by the state and 60% funded by the municipality or other local organizations. Currently, NSCs are strategically part of the local policy of almost all municipalities in the Netherlands [10]. In each municipality, the NSC's role is unique, thereby allowing municipalities to implement activities in line with local needs and contexts. Examples of activities organized by NSCs include sports clinics, PAs during or after school, and sports tournaments. The latest trend, gamification, is increasingly gaining popularity and interest among NSCs [11,12] and is increasingly applied in PA interventions [13].

Gamification is the use of game elements in nongame contexts [14]. It draws from various theories, with the self-determination theory being the most frequently applied [15], particularly in PA interventions [13]. Self-determination theory supports the proposition that games and gamification can intrinsically motivate individuals to initiate and sustain health behaviors [16] by leveraging people's natural desires for autonomy, competence, and relatedness [17]. Gamification is a set of motivational techniques that can enhance long-term engagement with apps [18], and it offers a promising route for behavioral change [17,19]. It can be implemented either technologically or nontechnologically. Examples of nontechnological gamification include points, badges, challenges, or leaderboards. Technological implementations include, for example, urban dance grounds, digital game walls or playgrounds, or gamified apps. These gamified apps apply gamified elements to enhance user engagement and enjoyment, as seen in popular apps such as Strava (Strava, Inc), Geocaching (Groundspeak, Inc), or Pokémon Go (Niantic, Inc). Gamification is most often applied in PA interventions, and systematic reviews and meta-analyses indicate that it has small to medium effects on various PA outcomes [20-22]. Increased use of gamification elements was associated with greater effectiveness in promoting moderate to vigorous PA [18]. These gamified PA interventions have been shown to affect PA behavior in a broad range of populations, regardless of age or health status [13,18,20], and to be more effective compared with equivalent nongamified interventions [13,18]. Johnson et al [20] identified 7 promises of gamification: enhancing intrinsic motivation, broad accessibility, broad appeal, broad applicability, cost-benefit efficiency, everyday-life fit, and supporting well-being. These benefits of gamification [13,20] align well with NSCs' function of aligning their activities with the local population's needs, ensuring the everyday-life fit of their activities, engaging a wider population, and supporting well-being. Therefore, implementing gamification through NSCs may hold promise.

Despite these benefits and the availability of gamification tools such as interactive (outdoor) play equipment (eg, interactive game walls) or gamified apps (eg, Seppo [Seppo.io]), NSCs' actual use of gamification appears to remain low (Schwarz, AF, unpublished data, December 2022). Insight into factors underlying of implementation of gamification is needed to determine whether gamification aligns with NSCs' intentions and, if so, to better understand how to encourage NSCs to implement gamification. Offering gamification via intermediaries (eg, health professionals, NSCs, and health brokers) has been barely researched [23]. Instead, gamification research has so far focused largely on the development of gamified interventions from end users' perspectives and on the interventions' effectiveness on behavior change in end users [24]. Consequently, knowledge on the strategic implementation of gamified interventions at a systemic level is still lacking, despite this being invaluable for a successful and sustainable uptake of innovations [24].

This Study

Implementation science, which comprises the study of methods to promote the translation and uptake of evidence-based research into practice, has grown as a research field in the last decades. The aim of implementation science is 2-fold. On one hand, it aims to identify barriers to, and facilitators of, uptake. On the other hand, it aims to develop and apply implementation strategies to overcome identified barriers and enhance facilitators in the adoption of innovations [25]. Various implementation frameworks, such as the capability, opportunity, motivation, behavior (COM-B) model and the theoretical domains framework (TDF), have been developed to identify and understand barriers and facilitators [26,27]. Both frameworks can be classified as determinant frameworks that aim to understand influences, including barriers to, and facilitators of, implementation outcomes. This study applied both COM-B and TDF to better understand the perceived barriers to, and facilitators of, intermediaries' gamification implementation, a topic that is barely researched.

Methods

Overview

This research is part of a larger project called mVital@2040 [28], which investigates gamification to promote PA in the neighborhood among youth (aged 10-14 years) living in low-income neighborhoods. In the first step, the project aimed to investigate how NSCs can implement gamification. For this study, we conducted semistructured interviews with NSCs in 5 municipalities in the Netherlands. These 5 municipalities, ranging from small (approximately 55,000 inhabitants) to large

(>250,000 inhabitants), had 56,000; 238,000; 244,000; 368,000; and 918,000 inhabitants, respectively.

Ethical Considerations

All NSCs provided informed consent with the option to opt out, and the study was approved by the Social Sciences Ethics Committee of Wageningen University & Research on March 23, 2022 (2022-45-Schwarz). NSCs did not receive any compensation for their participation, and all personally identifiable information was pseudonymized. Informed consent was obtained by accepting the Microsoft Teams invitation. At the start of each interview, the researcher once again asked for verbal informed consent.

Selection and Study Population

For the purpose of this study, 6 intermediary organizations (eg, youth club and sports club) that employed NSCs were contacted across 5 municipalities in the Netherlands. At each organization, 1 contact person made a preselection of available NSCs, including NSCs both with and without prior experience with gamification or gamified apps to research experienced and expected barriers to, and facilitators of, gamification implementation. All age ranges of NSCs' target group, ranging from young children to older persons, were included. Preselected candidates were invited by email to take part in an interview. A total of 31 NSCs were contacted, and 25 (81%) interviews were held.

Procedure

The interviews were held between April and September 2022. The interviews took place via Microsoft Teams and lasted approximately 1 hour. All interviews were conducted by 1 researcher (AS).

The interview guide can be found in Multimedia Appendix 1. Topics discussed were related to NSCs' function profile, the target group that they aim to reach, their definition of gamification, the role of gamification in their work, inhibiting and promoting factors regarding gamification implementation, and the envisioned future of gamification. The interview guide was informed by the COM-B model [29]. The model proposes that behavior arises from a result of the interaction among 3 components: capability (ie, people must have the knowledge, skills, and strength to perform the behavior), opportunity (ie, the physical and social environment must enable the behavior to occur, by, eg, being accessible, affordable, or acceptable), and motivation (ie, people must be motivated to perform the relevant time). Although best known for its application to understand behavior change in the receivers of health interventions, COM-B has been deemed useful to focus on professionals that incorporate health interventions targeted at a variety of audiences [30-32]. Designing the interview guide based on the COM-B model allowed us to create open questions to identify perceived barriers and facilitators.

Data Analysis

The interviews were audiotaped and transcribed verbatim by an external company. The researcher who conducted the interviews checked the transcripts for accuracy. The transcripts were coded and analyzed using ATLAS.ti (version 22; ATLAS.ti Scientific Software Development GmbH) software. Data were inductively and deductively coded [33] by 1 researcher (AS) and double-coded by a second researcher (KV). Researchers compared the deductive part of the coding until a consensus was reached. In total, 3 (12%) interviews were double-coded.

Deductive coding was based on the COM-B [29] model and TDF [34] (Table 1). Both models allow the identification of barriers and facilitators influencing the uptake and use of gamification. COM-B maps all barriers and facilitators in a simple model of behavior, and TDF complements COM-B with a detailed outline of psychological capability and reflective motivation [34]. TDF contains 14 domains, derived from 33 theories and 128 psychological constructs. These can be mapped onto the components of the COM-B model [29]. The data analysis was based on thematic analysis [35], shifting from codes (TDF) to themes, which are patterns deriving from the large sample of inductive and deductive codes. In the Results section, nonspecific terms of semiquantification (eg, few, several, some, or many) are used to convey general patterns within the data [36].

Table 1. COM-B[a] and TDF[b] as outlined in the study by Michie et al [29].

COM-B component and domains (TDF)	Definition
Physical capability	
Physical skills	An ability or proficiency acquired through practice
Psychological capability	
Knowledge	An awareness of the existence of something
Cognitive and interpersonal skills	An ability or proficiency acquired through practice
Memory, attention, and decision processes	The ability to retain information, focus selectively on aspects of the environment, and choose between ≥2 alternatives
Behavioral regulation	Anything aimed at managing or changing objectively observed or measured actions
Physical opportunity	
Environmental context and resources	Any circumstance in a person's situation or environment that discourages or encourages the development of skills and abilities, independence, social competence, and adaptive behavior
Social opportunity	
Social influences	Those interpersonal processes that can cause individuals to change their thoughts, feelings, or behaviors
Automatic motivation	
Emotions	A complex reaction pattern, involving experiential, behavioral, and physiological elements, by which the individual attempts to deal with a personally significant matter or event
Reinforcement	Increasing the probability of a response by arranging a dependent relationship, or contingency, between the response and a given stimulus
Reflective motivation	
Social and professional role and identity	A coherent set of behaviors and displayed personal qualities of an individual in a social or work setting
Beliefs about capabilities	Acceptance of the truth, reality, or validity of an ability, talent, or facility that a person can put to constructive use
Optimism	The confidence that things will happen for the best or that desired goals will be attained
Intentions	A conscious decision to perform a behavior or a resolve to act in a certain way
Goals	Mental representations of outcomes or end states that an individual wants to achieve
Beliefs about consequences	Acceptance of the truth, reality, or validity of outcomes of a behavior in a given situation

[a]COM-B: capability, opportunity, motivation, behavior.

[b]TDF: theoretical domains framework.

Results

NSCs' Work Profile

We interviewed 25 NSCs from 5 municipalities in the Netherlands. The spread of participants (4, 8, 8, 4, 1) differed depending on the size of the municipality. Of these 25 NSCs, 18 (72%) indicated that they had worked <5 years at their organization, representing the level of work experience. NSC teams typically consisted of 1 coordinating NSC that supervised multiple executive NSCs. The NSCs had predominately an executive role (17/25, 68%), including tasks such as organizing sports activities and events in the neighborhood (eg, at schools or public parks) and recruiting members of the target group for activities and events. The other 8 (32%) NSCs had a coordination role, consisting of project planning, coordinating, and connecting different organizations and parties in the neighborhood, and supporting executive NSCs. Responsible roles and tasks differed between municipalities, and not all municipalities differentiated between executive and coordinating NSCs.

NSCs' Target Groups

Many NSCs focused on a predefined age group (eg, children aged 6-12 years, youth, children and adults, and older persons), which was determined by the responsible municipality or organization. Some, however, indicated that they were responsible for all age groups. NSCs affirmed that they had perceived a shift over the last few years from a focus on younger children (eg, aged 6-12 years) to adolescents (aged 12-16 years). Besides specific age groups, NSCs targeted people who were physically inactive or people in a low socioeconomic position. NSCs focused on hard-to-reach groups, such as adolescents (especially female adolescents), children who were physically inactive, people with a low socioeconomic position or multiple problems or constraints, people with a language barrier, young adults with depression, older people, and young adult refugees.

Level of Experience With Gamification

Quotes relating to the questions posed to NSCs are provided in Textbox 1. Overall, 20 (80%) of the 25 NSCs had some experience with gamification in general, and gamification was integrated into their program more naturally (quote 1, Textbox 1). In general, NSCs wanted to learn more about the possibility of applying gamified apps and were positive about committing themselves to adopting gamification but were still looking to see how they could apply it in practice (quote 2, Textbox 1). Examples of current applications of gamification were (1) translating web-based games (eg, Fortnite [Epic Games, Inc]) to real-life activities; (2) adding points systems, competition, and prize-winning to their current activities (eg, photo challenges and social media leaderboards); (3) implementing smart devices, such as light poles (eg, Interactive Play System cones changing colors) or smart walls; (4) reinventing a common sport (eg, James Bond game); and (5) gamified bicycle routes. Many NSCs reported a lack of experience with gamified apps. Those who had some experience implemented gamified apps sporadically. Examples of gamified apps were (1) popular social and dance-related media apps (eg, TikTok [ByteDance] and Just Dance [Ubisoft Inc]), (2) apps particularly designed to increase PA (eg, Missie Master [8D Games BV], Fitcoins [It's My Life–Corporate & Individual well-being BV], Strava [Strava Inc], City Legends [CityLegends BV], Jachtseizoen [StukTV], and VR game), or (3) apps designed by the employer to link a reward system to their current PA offer.

Textbox 1. Numbered quotes, listed per theme level of experience with gamification, defining gamification, skills, and knowledge.

Level of experience with gamification

- Quote 1: "I think [gamification] comes back, in a light form in a lot of activities in our work as [NSCs], making an activity playful." [Executive neighborhood sport coach; NSC]
- Quote 2: "I would like to broaden my er, my world. Ehm, with regard to app use.... I think there is much more to be achieved than we as an organization are currently doing." [Executive NSC]

Defining gamification

- Quote 3: "You have certain game elements...that you have in games, such as competition, leaderboards...and translate that into our own sports-promotion activities. That can be done in many ways...by means of apps, but that can also be done by being critical: well, you have sports equipment...a traditional football and a volleyball, but now there are also a lot of exercise products that are completely separate from a certain sport with the main aim of being fun.... For me, it is actually a very broad term, but to summarize it is about translating game elements elsewhere to that traditional sports world." [Executive NSC]

Skills

- Quote 4: "I'm not constantly thinking about [designing new content for the app]. So that's quite a shame, eh, that we don't all have that [creative skill] from ourselves, but at the same time I don't think you can eh, force something like that. You have to have a little, er, [technical] feeling and I just have that a little less than my colleagues." [Executive NSC]
- Quote 5: "One says, you have to start small.... One of our [executive NSCs] used to promise a lot and was very enthusiastic and creative, but, in the end, they do not manage in 'how are we going to apply that in a good way?' And, in the end, they get frustrated because it doesn't work, so that's from a practice point-of-view." [Coordinating NSC]
- Quote 6: "This is [an effective] tool, at least if promotion eh, support from the municipalities and other parties, when this is assured, then this could be the tool." [Executive NSC]
- Quote 7: "It should actually be ensured that it will just become something normal. And it shouldn't be that they do it because it's new and then they um, again um, ignore it because um, the novelty wears off. So, it has to – they have to be stimulated every time, uh, to use the app, I think." [Executive NSC]

Knowledge

- Quote 8: "In our work it is difficult to determine first, what exactly do we want, where, in which direction do we want to go, do we have enough evidence for this, do we have to find out whether this is already happening elsewhere, in other municipalities or cities, what are their experiences with this and then we already notice that we have lost quite a bit of time just figuring that out before anything really gets off the ground." [Coordinating NSC]

Defining Gamification

The definition of gamification varied among NSCs, and, at the onset of the interview, not all NSCs (8/25, 32%) were acquainted with the term. Many NSCs stated that they found it difficult to define gamification. They defined gamification mostly in terms of applying game elements, either on the web or offline, with the overall aim of promoting behavioral change. Others defined it in terms of the direct translation of web-based games to offline activities (eg, playing Super Mario [Nintendo] in real life), the application of different game elements (eg, competition or leaderboards) to offline traditional sport activities, or playful learning (quote 3, Textbox 1). Some NSCs defined gamification as the trend of increasingly making use of digital games or being increasingly more on the web and stated that they were especially confused by multiple terms, such as gamification, gaming, and esports used interchangeably.

Barriers to, and Facilitators of, Implementing Gamification

Overview

NSCs made a distinction between implementing gamification during their program (eg, integrating gamification on the site) or offering it as an extension to their program (eg, offering a gamified app during holidays, when NSCs are not physically present). In addition, 7 topics relating to barriers to, and facilitators of, gamification implementation were identified, namely, skills, knowledge, expected effects, responsibility, social support, financial costs, and time. Barriers and facilitators were discussed equally often, except for expected effects and responsibility, which were raised more often.

Skills

NSCs with gamification experiences felt very capable of applying this to their program compared with NSCs with no former experience. They felt more capable of applying gamification tools, which they often already applied unconsciously and did not require technical skills. Creative skills also appeared necessary. Some gamified apps offered the possibility to ideate and create new content, for example, challenges. Although this feature supported NSCs to use apps, it sometimes also impeded structural implementation. NSCs noticed that they continuously needed to create new content to keep the app up-to-date. Thinking continuously about new content was considered tiresome and could, together with a lack of creativity to ideate new content, hinder the implementation of a gamified app (quote 4, Textbox 1).

The development of their creative skills was influenced by starting with small steps and their former education (quote 5, Textbox 1). Several requirements need to be met to use the potential of gamification fully, such as a successful promotion of gamified apps (quote 6, Textbox 1). NSCs pointed out that they lacked skills in promoting gamification tools among the target group. In some cases, their employer took over the promotion (eg, public relations department), yet, neither succeeded in attracting (app) users (long term), which eventually resulted in the decision to stop offering a gamified app. Moreover, NSCs confirmed that it was a challenge to keep the target group engaged, especially when the novelty effect wore off (quote 7, Textbox 1).

Knowledge

NSCs indicated that their knowledge of gamification was limited, as keeping track of all trends demanded a lot of time. An overload of apps in different app stores hampered the search for suitable gamified apps. A clear overview of gamification tools (eg, examples from other municipalities), in addition to workshops, would help NSCs acquire new knowledge. Proven effects and shared experiences contributed to the decision to implement gamification (quote 8, Textbox 1).

Expected Effects

NSCs generally believed in the positive effects of gamification. Contributory factors included their own experiences, scientific evidence on the effectiveness of gamification, and the target group experiencing it as fun. However, not having an affinity for gamification, irrespective of experience, hampered implementation (quote 9, Textbox 2). NSCs stated that gamification could contribute to lowering the threshold to engage in their program, to reaching a broad target group that is often perceived as difficult to reach (eg, people who were inactive), and to reaching people from a distance (eg, during holidays). Further, gamification was considered easy to organize, and gamified apps were appreciated in terms of having one place where all information could be bundled, and valuable insights could be found based on user data. However, NSCs also noticed risks with regard to gamified apps. They feared that the target group's (especially children's) total screen time would increase and that the target group would be distracted by other apps or notifications on their phone while using the intended gamified app, and therefore NSCs feared that they would contribute to the digital divide (eg, by excluding people who have no phone or speak another language).

Textbox 2. Numbered quotes, listed per theme expected effects and responsibility.

Expected effects

- Quote 9: "I don't have anything with that at all, not myself, not personally. So um, I'm not into eh, iPads or computers. I don't have anything with that at all. So – I don't like it anyway." [Coordinating neighborhood sport coach; NSC]

Responsibility

- Quote 10: "I also think that as part of the role as NSC we should simply keep up with the times and this is no longer just the standard games as before. But we, uh, have to go along with it." [Executive NSC]
- Quote 11: "I like to move with the times...then I'd rather be too early with something than...too late." [Executive NSC]
- Quote 12: "Um, the question is, whose task is it? Maybe of the municipality? or education? Ehm, and I think that er, that issue has never actually been mentioned and as long as, as long as no one actually raises it, it will actually not be taken up, eh, I think." [Coordinating NSC]
- Quote 13: "To share the knowledge, that would be my task.... So, I should actually acquire the knowledge first and then share it among our [executive NSCs]. So, it should be the responsibility of the [coordinating NSCs] to train." [Coordinating NSC]
- Quote 14: "The [executive NSCs] we employ are responsible for one sport. And they don't yet have enough knowledge to continue with the bigger piece. And they are used to just providing fun sports lessons and being enthusiastic about their sport. But [gamification] requires something completely different – that has a completely different goal than if you try to get the kids excited to start playing [one particular] sports and let them discover what they like .... So, that's quite a big shift for them. So, it requires a different way of looking at how you organize your lessons and a different way of looking at the children you have in your group and that takes quite a lot." [Coordinating NSC]
- Quote 15: "Sometimes you just need to be handed the [gamification] solution to eventually do it." [Executive NSC]
- Quote 16: "Eh, if this is an assignment from the municipality, eh, then I feel that we should just, eh, take it up together." [Executive NSC]
- Quote 17: "Who takes care of it and is also going to implement it and, er, everything that comes with it. So, the implementation of the lessons, the implementation of new elements eh, having knowledge about it, but also the communication of, okay, how are we going to promote it?" [Coordinating NSC]
- Quote 18: "It is good that a number of colleagues are in the lead and are really going to pick that up and roll it out and then maybe give me a concrete assignment of, you now have to come up with a mission and then I will think about it. But I don't quickly start from myself." [Executive NSC]

Responsibility

NSCs viewed the adoption of gamification in their professional responsibilities as a means of keeping up with the latest developments and trends (quote 10 and Q11, Textbox 2). At the same time, NSCs questioned whose responsibility it was to adopt gamification eventually (quote 12, Textbox 2). One coordinating NSC considered knowledge transfer as part of their responsibility (quote 13, Textbox 2). Another coordinating NSC indicated that imposing the responsibility on executive NSCs could be challenging (quote 14, Textbox 2). Appointing a responsible NSC in the team and receiving a direct assignment by the supervisor or policy makers were deemed to promote implementation (quotes 15 and 16, Textbox 2). Yet, many NSCs indicated that it was difficult to find suitable, but indispensable, persons to enthusiastically promote gamification in the field (quote 17, Textbox 2). Reinforcement by colleagues or supervisors was considered essential to keep reminding them to ideate and create new content or updates for a gamified app. A clear assignment by supervisors can support NSCs. However, once they noticed that the gamified app was not or barely used, they felt demotivated to create new content or to promote the gamified app. NSCs clearly designated reinforcement as a responsibility of coordinating NSCs (quote 18, Textbox 2).

Social Support

NSCs received both direct support from their employer and support from external parties, such as schools, municipalities, or commercial sports clubs.

Support by Employer

Overall, NSCs emphasized that they experienced a lot of freedom in performing their job. Freedom was allowed, as long as activities aligned with national or local sports agreements that often reflected the needs of the neighborhood for which they worked (quote 19, Textbox 3). NSCs felt supported by their employer to apply gamification (quote 20, Textbox 3). However, several NSCs asserted that they did not receive active support to apply gamification. They often used social media to get inspiration on how to apply gamification. Sharing this content with their direct colleagues contributed to the implementation of gamification tools.

Textbox 3. Numbered quotes, listed per theme social support, external support, financial costs, and time.

Social support

- Quote 19: “I do have a lot of freedom and that stems, I think, from the vision of, er, our employer, that, er, every neighborhood actually needs customization. So, what works in my neighborhood may not work in another neighborhood for example. So, it is also necessary to have some freedom, to be able to test some things and then also build on that.” [Executive neighborhood sport coach; NSC]
- Quote 20: “I just notice, we are with quite a large team of [executive NSCs] and everyone has their own expertise and their own eh, eh, eh, thing they get energy from. And I do notice that, as far as possible, efforts are made to give people tasks that suit them best.” [Executive NSC]

External support

- Quote 21: “Financial support from the municipality is necessary...what you often see in municipal processes is that they are quite slow and start slowly.” [Executive NSC]
- Quote 22: “If the municipality would focus on that and if the municipality had the vision to do more with it, um, financial support would be desirable.” [Executive NSC]
- Quote 23: “Certain choices that are made higher up and which you as an [NSC] cannot influence.” [Executive NSC]
- Quote 24: “The municipality actually thought the results were too, too small. Eh, while the investment, uh, was quite high. So eh, quite a lot of time and energy eh, went into that, but actually too little [impact], in a structural way.” [Coordinating NSC]
- Quote 25: “I am getting more and more budget....I looked for more eh, partners who eh, who have similar initiatives in the city. So uh, I looked at what we, what we can uh, do together. Eh, little by little, the more the municipality and other parties experience it, the more enthusiastic they become, the more eh, the more budget is available and the more they are convinced that it can really be an added value eh, for the city.” [Coordinating NSC]

Financial costs

- Quote 26: “Money is always an uh, an obstacle, let me put it this way. So, you do indeed have to have good considerations and good arguments that it has an eh, that it has added value and there is always – you always have to argue that very well and eh, eh, have that information before the choice would indeed be taken.” [Coordinating NSC]

Time

- Quote 27: “To shape it into an uh, a concept idea that is realistic, feasible, and that really, uh, can take place, also needs time.” [Coordinating NSC]
- Quote 28: “That will take a lot of time. Ehm, so if that threshold is lowered, it will become easier to apply it in practice.” [Executive NSC]
- Quote 29: “Of course, you have to make time to find out how it works. How are you going to apply it? But on the other hand, it also eases your work sometimes, as the app takes over a lot.” [Executive NSC]
- Quote 30: “The goal was to, uh, actually get people moving. Eh, without having to be physically present and that was eh, ideally eh, a very nice goal for us. Only in practice it turned out differently. Eh, mainly because it just takes a lot of time to prepare. Ehm, but once it’s in practice, it’s done.” [Executive NSC]
- Quote 31: “I think it’s not so much a question of do you have time, but more of, do you make time?” [Executive NSC]

External Support

Support from outside the organization was rarely mentioned, except for NSCs who indicated that support from external parties (eg, schools and commercial sports clubs) contributed to a more sustained implementation of gamification. In general, a strong collaboration and exchange between various stakeholders was considered important. NSCs perceived pressure to adopt and implement gamified apps when they noticed that colleagues outside their organization kept up with gamified app trends. NSCs lacked highly needed support and vision from policy makers (quotes 21 and 22, Textbox 3). Furthermore, NSCs mentioned policy makers’ power, which they could not influence (quotes 23 and 24, Textbox 3). One NSC mentioned the importance of starting small to slowly convince the municipality and other organizations and to build a sustainable gamification network (quote 25, Textbox 3). NSCs stated that it was part of their role to create sustained networks in the neighborhood. However, making external organizations enthusiastic about gamification, or providing more information about the gamification concept or the added value of gamified apps, were perceived as barriers.

Financial Costs

Challenges with regard to costs included (1) high product costs (eg, expensive physical gamification tools or subscriptions to gamified apps), (2) difficulties finding suitable subsidies to afford gamification tools or gamified apps, and (3) substantiating the budget plan to policy makers with persuasive arguments. Regarding high product costs, it was mentioned that it was financially challenging for smaller municipalities to subscribe to a gamified app compared to larger municipalities, as often the same price was applied and was not linked to the number of inhabitants and therefore (possible) users. In addition to subscription costs, expensive on-site products (eg, smart playgrounds) that required subsidies from municipalities were mentioned as a barrier. Furthermore, some NSCs experienced difficulty finding suitable subsidies or finding different municipal subsidies to combine, whereas others seemed to know all the ins and outs of finding the right subsidies. Justification or argumentation was important to receive the subsidy eventually. An adequate level of knowledge about gamification tools and gamified apps (eg, including scientific effects) and expected outcomes was required to justify their subsidy plans (quote 26, Textbox 3).

Time

For small gamification adaptations, time was not identified as an impeding factor, as this felt more intuitive for NSCs to align with their current way of working and their perceived freedom to plan their activities. However, especially preparatory work, such as justifying costs, finding scientific evidence or suitable applications, and good practices was identified as challenging (quotes 27 and 28, Textbox 3). NSCs indicated that the time investment could be worth it (quotes 29 and 30, Textbox 3). NSCs framed it as the willingness to prioritize time, which was seen as being crucial to the sustainable provision of an up-to-date app (quote 31, Textbox 3).

Discussion

Principal Findings

This study aimed to better understand the perceived barriers to, and facilitators of, NSCs' use of gamification. The results reveal that NSCs have limited experience with gamification; this is in line with earlier research showing that only 4% of lifestyle professionals in the Netherlands use gamified tools [37]. In comparison with their use of gamified apps, NSCs apply gamification (without technology) more naturally in their daily work. Perceived barriers and facilitators related to skills, knowledge, expected effects, responsibility, social support, financial costs, and time. No other research has been done on NSCs' implementation of gamification, but we can compare our results with a study focusing on the implementation of digital health tools by lifestyle professionals in the Netherlands [37]. That study found that lifestyle professionals were motivated to use digital coaching tools but required more content-specific exchanges with colleagues and a complete overview of available tools. They lacked training during their education and experienced a high financial burden when implementing digital coaching tools. All these factors align with the results of this study in terms of expected effects, knowledge, social support, skills, and financial costs [37]. Regarding responsibility and time, our findings in this study are different. Lifestyle professionals perceived the successful implementation of digital coaching as time-intensive, and hours spent could not be claimed from health insurance. In comparison, the NSCs in this study did not consider time to be a barrier. Rather, their perceived freedom in their work contributed to implementing gamification. However, both executive and coordinating NSCs felt uncertain about which of the 2 should take responsibility for implementing gamification, whereas this did not appear as a barrier for lifestyle professionals [37].

Former research among intermediaries, such as physiotherapists, physicians, and nurse practitioners, investigated the implementation of health interventions in primary care. Structurally implementing existing health guidelines (ie, PA guidelines), exercise referral schemes, or interventions (ie, mobile health, eHealth, and combined lifestyle interventions) in organizational structures and regulations were identified as a common barrier to successful implementation [30,37-44]. Besides NSCs, school teachers are important intermediaries and implementers of gamification to promote PA. They already have experience with implementing gamification with the aim of promoting PA in schools [45,46]. Schools are often considered as a place where a diverse population, including students that are often considered hard to reach, can be addressed in a structural manner (eg, integration in the curriculum). This is the first study to focus on the implementation of gamification by NSCs as intermediaries. Offering interventions via intermediaries may contribute to the successful implementation of interventions. Intermediaries can reach populations that may benefit the most from the interventions and are often considered hard to reach. Our research reveals that NSCs perceive advantages in implementing gamification (ie, expected effects) for hard-to-reach populations that are often known to engage in lower levels of PA, to reach people from a distance, and to lower the threshold to engage in their program. Expected effects emerged as one of the most frequently mentioned themes in our study. Furthermore, NSCs perceive that they have the freedom to choose suitable activities themselves and are in charge of allocating their time to a range of diverse activities. This suggests that NSCs form a specific group of intermediaries that hold promise to integrate gamification in their current work.

Coordinating and executive NSCs' roles and responsibilities regarding the adoption and implementation of gamification appear to be unclear; this emerged as a frequently mentioned theme. This is in line with earlier research indicating that a blueprint for NSCs' function is not in place [47] and at the same time not desired, as the freedom to implement PA activities and allocate their time independently is part of the function description [48]. In general, both coordinating and executive NSCs see gamification implementation as part of their function but experience difficulties in successfully establishing collaborations with other parties to structurally implement gamification. Moreover, a clear vision on the part of municipal policy makers could facilitate the structural implementation of gamification. As a result, strategic implementation at a systemic level is often lacking [24]. A responsible person who is enthusiastically involved and reinforces colleagues often seems to be lacking, although such a person is considered crucial for the strategic implementation of gamification in the long term to prevent NSCs from implementing gamification only sporadically. Clear assignments by the manager or municipal policy makers may support successful implementation in the future [43,44,49].

Research has shown that scaling up digital health innovations is often hindered by barriers, such as a lack of evidence or long-term financial funding, and therefore often depends on the acceptance of different individual stakeholders working in different domains or different levels of systems. Research suggests that a higher level of coordination and knowledge sharing across digital health projects is needed [50]. A promising pathway to facilitate scaling up is to incorporate systems thinking in the implementation process. Systems thinking helps to elucidate how situations and experiences are connected and influence implementations. Viewing gamification through the conceptual lens of systems thinking is deemed to have the potential to create harmonized solutions that are relevant to individuals and take the various mutually influencing levels of the system into account [51]. Systems thinking is in line with our study, as different levels in the system, such as research, policy, and practice, do not seem to align well during the implementation phase. For example, policy needs to be informed by researchers to support the scientific effects of gamification (eg, on health outcomes). In contrast, practice (eg, NSCs) lacks subsidization and policy makers' vision. A better alignment among the 3 different levels of the system together with end users is crucial [52] to ensure adoption, implementation, and sustainability and therefore effects on health outcomes (ie, increased PA). Implementation science can facilitate this need to translate research into practice and contribute to system change. Including different stakeholders from different system levels through the development of the gamification tool is crucial. Integrating a horizontal systems approach (ie, sports clubs, schools and PA organizations) with a vertical systems approach (ie, local-, regional-, national-level governments) may strengthen synergetic effects among a varied group of stakeholders and further strengthen sustainable implementation and even scale up of gamification and gamified apps [53,54].

Strengths and Limitations

Several limitations of this research should be considered. First, no generalizations can be made beyond the study sample. NSCs seemed to focus on children and adolescents during the interviews, although this age group was not the sole focus of this study. Possibly, NSCs relate the concept of gamification and gaming to a younger age population. As we recruited via a contact person in each organization, it might also be possible that the contact person made a preselection beforehand. According to the national NSC monitor, many NSCs do focus on children or adolescents, therefore our sample seems to be in line with the general NSC profile [55]. In addition, as the NSCs' job description varies between municipalities, it is difficult to determine whether our sample reflects the diversity of NSC profiles currently present across municipalities. In the Netherlands, municipalities can employ executive or coordinating NSCs, or NSCs that fulfill both functions. However, some municipalities employ only coordinating NSCs or only executive NSCs, who may either lack vision, usually developed by coordinating NSCs, or lack executive activities performed by executive NSCs [48]. In our study, the interviewed NSCs in the 5 municipalities are all employed as either coordinating or executive NSCs.

Several strengths of this study can be identified too. We conducted a substantial number of qualitative interviews that led to data saturation. In addition, in terms of method, we managed to inform our analysis based on well-established theoretical models, the COM-B and TDF, that cover the wide spectrum of behavioral determinants. Coding the interviews according to the COM-B model and TDF shows that both are relevant in implementation science and can identify factors facilitating or hindering the implementation of innovation [30,38-41,56]. Moreover, the analysis was performed by 2 coders, thereby further strengthening the credibility of the study. In terms of gamification experience, we reached a diverse sample including nonexperienced, inexperienced, and experienced gamification NSCs. As this was the first study to focus on intermediaries promoting PA in the neighborhood via gamification in their daily work, we managed to contribute to a novel and relevant scientific and societal topic.

Implications

For Practice

By linking the identified facilitators and barriers to the behavior change wheel [29], we can identify several relevant intervention functions, such as education (eg, providing information), training (eg, practicing technical and creative skills in workshops), modeling (eg, providing best practices and clear implementation guidelines), and environmental restructuring (eg, support a restructuring of the organization where NSCs are employed). From the results, we formulated 5 recommendations for policy makers, industry, intermediaries, and professionals (Textbox 4).

First, NSCs indicated that they lacked not only sufficient skills training to implement gamification but also education about the scientific effects and an overview of the different tools. Hence, it is recommended to provide a clear overview of tools and best practices, for example, via education and workshops. Second, NSCs felt supported by their employer who granted them a lot of freedom to design activities in line with local needs and wishes. However, NSCs indicated a lack of exchange with colleagues and external parties. A network within but also outside the organization or municipality appears to be important in terms of sharing content, best practices, and keeping up with the latest trends and developments. This relates to intersectoral collaborations [37,43,44,47,57], which might be needed among NSCs in the Netherlands to learn how to better collaborate with other parties. Here, NSCs' professional organizations could play an important role in facilitating a network [37]. Third, coordinating and executive NSCs were uncertain about their responsibility to adopt gamification, a frequently mentioned theme. Clarifying NSCs' responsibility, as indicated by NSCs during the interviews, for example, by appointing a dedicated gamification NSC to provide a clear assignment to executive NSCs or to allocate hours to NSCs, may help the sustainable implementation of gamification. Fourth, NSCs perceive large barriers with regard to financial costs, as product costs are high and suitable subsidies are lacking. A clear overview of subsidy options may help to better connect and scale up initiatives and integrate gamification and gamified apps sustainably. Fifth, NSCs indicated that they lacked sufficient promotion skills that they considered necessary for the successful implementation of gamification and gamified apps. Supporting NSCs to successfully embed the gamification tool in a larger promotion campaign might impact the implementation of an intervention.

Textbox 4. Actions that should be taken to enable all relevant stakeholders, policy makers, industry, intermediaries, and professionals to exploit the potential of gamification.

Recommendations

- Establish a sustainable *network* of organizations to strengthen the offer within one municipality and to exchange ideas and best practices beyond municipalities
- Clarify the *responsibility* of neighborhood sport coaches (NSCs), for example, appoint a dedicated NSC to provide a clear assignment or to allocate hours
- Provide a clear *subsidy* overview that helps NSCs to connect initiatives and integrate gamification and gamified apps sustainably
- Offer guidance on how to *promote* gamification and gamified apps among the target group to secure book long-lasting engagement

For Research

One of the barriers identified by intermediaries was the lack of a clear overview of gamification that has proven effective. Research is often struggling with conclusive results on the effects of gamification and often lacks rigorous study designs [13,22,58]. A white paper that translates research results in a comprehensive manner could support intermediaries in the future to understand and refer to the proven effects, for example, to justify financial subsidies. Furthermore, more quantitative research is necessary to identify the determinants that significantly explain NSCs' implementation of gamification across the Netherlands and how these determinants influence different stages of the implementation phase (ie, adoption, implementation, and sustainability) [59]. As differences between NSC profiles depend on the municipality, it is difficult to assess which resources contribute to the implementation of gamification, for example, small versus large municipalities' offering. Moreover, to understand the implementation of gamification at the systems level, it is important to better align research with practice and policy, as all 3 subsystems depend on one another. Future studies may want to consider integrating the focus on different levels of the system and how they can be better aligned to implement long-lasting gamification interventions with effects on health outcomes.

Conclusions

This study aimed to assess the barriers and facilitators that NSCs perceive toward using gamification in their daily work. NSCs highly valued the application of gamification to stimulate PA in the neighborhood. Different barriers and facilitators relating to 7 themes emerged, namely, skills, knowledge, expected effects, responsibility, social support, financial costs, and time. As this is one of the first studies to focus on NSCs that implement gamification, different practice-based and research-based implications can be considered. Providing a clear overview of tools and best practices, a clear overview of subsidies available to help NSCs connect initiatives and integrate gamification sustainably, and guidance on how to promote gamification among the target group are important actions that can be undertaken by means of written documentation. Certain restructuring policies can assist the establishment of a sustainable network of organizations to strengthen the offer within and beyond the municipality and to clarify NSCs' responsibilities. Further research is needed to measure the effects of gamification and needs to be approached by the triangle of research, practice, and police to implement gamification in a systems approach.

Acknowledgments

This work was supported by the mVital@2040 project, which is a part of the Vitality Academy and connected to the EWUU (Eindhoven University of Technology, Wageningen University & Research, Utrecht University, and University Medical Centre Utrecht) Alliance. The project and AS were funded by Wageningen University & Research. MS initiated and acquired the funding for the mVital@2040 project. The authors would like to thank the company that was responsible for writing out the transcript.

Authors' Contributions

AS was responsible for leading all stages of this study. AS and MS developed the study design. AS conducted the data collection and executed the coding. KV served as the second coder. AS analyzed the data and drafted the manuscript, which was written together with KV, MS, and EdV. The manuscript was eventually reviewed and adapted by KV, MS, and EdV. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Since the early 2000s, there has been a growing interest in using exercise video games (exergames) and virtual reality (VR)–based interventions as innovative methods to enhance physical rehabilitation for individuals with multiple disabilities. Over the past decade, researchers and exercise professionals have focused on developing specialized immersive exercise video games for various populations, including those who have experienced a stroke, revealing tangible benefits for upper limb rehabilitation. However, it is necessary to develop highly engaging, personalized games that can facilitate the creation of experiences aligned with the preferences, motivations, and challenges communicated by people who have had an episode of stroke.

Objective: This study seeks to explore the customization potential of an exergame for individuals who have undergone a stroke, concurrently evaluating its usability as a technological tool in the realm of physical therapy and rehabilitation.

Methods: We introduce a playtest methodology to enhance the design of a VR exergame developed using a user-centered approach for upper limb rehabilitation in stroke survivors. Over 4 playtesting sessions, stroke survivors interacted with initial game versions using VR headsets, providing essential feedback for refining game content and mechanics. Additionally, a pilot study involving 10 stroke survivors collected data through VR-related questionnaires to assess game design aspects such as mechanics, assistance, experience, motion sickness, and immersion.

Results: The playtest methodology was beneficial for improving the exergame to align with user needs, consistently incorporating their perspectives and achieving noteworthy results. The pilot study revealed that users had a positive response. In the first scenario, a carpenter presents a game based on the flexion-extension movement of the elbow; the second scenario includes a *tejo* game (a traditional Colombian throwing game) designed around game mechanics related to the flexion-extension movement of the shoulder; and in the third scenario, a farmer challenges the player to perform a movement combining elbow flexion and extension with internal and external rotation of the shoulder. These findings suggest the potential of the studied exergame as a tool for the upper limb rehabilitation of individuals who have experienced a stroke.

Conclusions: The inclusion of exergames in rehabilitation for stroke-induced hemiparesis has significantly benefited the recovery process by focusing on essential shoulder and elbow movements. These interactive games play a crucial role in helping users regain mobility and restore practical use of affected limbs. They also serve as valuable data sources for researchers, improving the system's responsiveness. This iterative approach enhances game design and markedly boosts user satisfaction, suggesting exergames have promising potential as adjunctive elements in traditional therapeutic approaches.

Introduction

Background

In recent years, technological advances have influenced motor rehabilitation interventions for survivors of stroke, with the introduction of exergames, known as "serious games for health," which help motivate individuals in their rehabilitation [1-4]. However, the development of such exergames needs to consider users' needs and rehabilitation goals [5].

Virtual reality (VR) immersive [6] systems have become increasingly popular in rehabilitation, as they offer immersive and engaging activities, improving motivation and skill acquisition [7]. Nevertheless, systematic reviews have noted that most VR apps primarily focus on balance and gait, with limited attention to upper extremity rehabilitation [8,9].

Efforts have been made to design exergames tailored for survivors of stroke, but challenges remain, including limited user involvement and lack of immersive VR integration [10,11].

This study aims to address these challenges by designing a VR-based upper limb rehabilitation exergame using a user-centered approach, involving survivors of stroke in the design process and conducting playtests with an immersive VR setup [12]. The methodology aims to improve interdisciplinary collaboration and facilitate the involvement of clinicians in the design process [13,14]. The primary objectives are to provide personalized upper arm physiotherapy for survivors of stroke through an improved VR exergame and to assess its usability through user feedback [15]. This work encourages collaboration among clinicians, researchers, and designers to create an engaging rehabilitation exercise that complements the recovery process for survivors of stroke, ultimately enhancing their quality of life.

Related Work

VR-Based Physical Rehabilitation for Stroke

Experts in rehabilitation, kinesiology, and neuroscience are integrating VR systems with exergames to enhance the appeal and effectiveness of rehabilitation processes [16]. Early studies, such as those by Henrique et al [17] and Burke et al [18], demonstrated the positive impact of exergames on balance, gait, and upper limb motor function in patients with stroke, highlighting improved therapy adherence [14,16-20]. However, systematic reviews have indicated that most VR apps for after-stroke therapy primarily focus on balance and gait, with limited attention to upper extremity rehabilitation [3,21,22]. To address this gap, we aim to evaluate the potential of an exergame for upper limb rehabilitation using immersive VR systems [22].

In addition, prior research has shown that complementing or replacing standard rehabilitation with VR-based rehabilitation can result in significant improvements in gait speed, balance, and mobility in patients with stroke [3,17,21-23]. Our work aims to contribute to the development of guidelines for using VR-based rehabilitation in conjunction with conventional therapy, with a focus on upper limb rehabilitation.

Although some researchers, such as Reis et al [10], Leung et al [11], and Horsham et al [24], have proposed methodologies for developing specific exergames for stroke rehabilitation, there is still limited knowledge regarding immersive VR-based designs targeting upper limb rehabilitation [10,11,24]. Therefore, we intend to involve survivors of stroke in an iterative playtesting process to develop an upper limb VR-based rehabilitation system and bridge this gap.

Playtesting as an Iterative Design for Stroke

This section covers research related to the use of playtesting as an iterative user-centered design (UCD) methodology. UCD has played a significant role in the development of games for rehabilitation and overall health [25,26], as it is a methodology that allows active participation of the target population in the system's prototyping process. UCD, applied in game design, often advocates for an interactive and participative methodology that includes multiple playtests with end players. Playtesting is an activity carried out with potential users or players who interact with game prototypes developed in the early stages, making it easier to gather individual opinions and ideas that contribute to improving the gameplay aspects of exergames during their development [27,28]. Playtesting is a key and standardized methodology used in game studios to iterate and systematically improve games before they are released to the public [29].

A relevant example is the work of Duval et al [30], who conducted a collaborative study with 14 clinicians, focusing on therapeutically validating the game based on their opinions rather than those of users. Duval et al [30] obtained significant findings by addressing the adoption of therapy and personalizing it according to the characteristics valued by medical professionals. In contrast, other UCD works, such as the study by Aguilar et al [31], have not used playtesting but have used usability tests involving scales and flow state questionnaires. Findings from 3 years of experience with exergames developed for older adults using UCD methods concluded that devoting the key to engaging with end users and considering feedback and opinions can be considered the best practice guide for the development of therapeutic games [32]. We believe that playtesting can be beneficial for the design process of games for health, as it is strongly recommended to involve the target audience during the game design and development processes. By doing so, developers increase the likelihood of creating games that consider the specific preferences, motives, and characteristics of survivors of stroke in need of physical therapy [21]. By including survivors of stroke in interactive playtesting and, consequently, in enhancing a VR exergame, we begin to understand how this design methodology affects the subsequent use of the exergame as a therapeutic tool.

Methods

In this section, we introduce the interdisciplinary team that worked on the improvement of the VR exergame we used in the playtesting session and the pilot study, as well as the description of the VR exergame. Furthermore, we present the playtesting methodology and the pilot study methodology.

Interdisciplinary Team

The structured design team was composed of an expert clinical physiatrist who advised the movements that users with stroke are likely to perform from a clinical viewpoint; a physiotherapist who provided permanent follow-up in all sessions with the users; a designer of exergames who helped implement the UCD methodology to have clear game mechanics; an expert in biomechanics who analyzed ranges of movement, postures, and gestures; a user experience researcher who organized all sessions with the users; 2 professional game programmers who created the game prototypes; and 2 users who experienced stroke episodes and interacted with the system and based on the answers they gave us an improved exergame. For 2 months, this group convened weekly to discuss the exergames' requirements, technologies, and overall scope of the project. The discussions were centered on defining the activities in the internet-based environment and strategies for the recruitment of potential users. At the end of the design process, the group of game developers with programming experience used the Unity game engine (Unity Technologies) to materialize the ideas.

The main topics addressed by the interdisciplinary team were (1) the definition of the main objectives and roles of the project; for example, project management was assumed by the exergames designer, and the user experience researcher assumed the role of project manager and conducted most of the fieldwork; (2) socialization of playtesting activities, including user recruitment and experimental protocol; and (3) reconsideration and further adjustment of game design elements, such as game mechanics and their mapping with therapeutic objectives.

Design of the VR Exergame

Prior Design of the VR Exergame

We performed a rapid contextual design based on a previous study, where user profiles were defined using user personas [33]. In this study, we characterized 4 persona roles that distinguish them as gamers: apathetic, empathetic, beginner, and experienced. Specifically, we used the results of the user modeling process to define certain game elements. For example, we found that users showed interest in sports games. Hence, body interaction familiar with certain sports games was an important requirement to be integrated into the exergames. In addition, users were comfortable with game content related to their daily lives. Therefore, incorporating cultural activities into the exergames could be a promising approach. In addition, in this prior study, we considered the following clinical requirements when developing the VR exergame [34,35].

Population specificity: according to previous studies [36], most users who have experienced a stroke are older than 40 years, and few are younger than 30. These studies also showed that the older population has little experience with VR. In contrast, therapist experience suggested that ranges of motion vary across users who have experienced a stroke. Therefore, designers should be careful when adapting internet-based therapy to a wide range of capabilities [37].

Motor learning: different principles of motor recovery should be considered in the creation of the activities to be performed within the exergames, such as a meaningful task, intensive and repetitive practice, movements close to the normal range, muscle activation that drives the practice of movement, and variability and progression of training [10,38,39].

Rehabilitation movements: the movements suggested by clinicians to perform upper limb physical therapy in paretic users are listed in Table 1. These are shoulder flexion and extension, elbow flexion and extension, and Kabat diagonals. Kabat diagonals are internal and external rotation movements of the shoulder. According to Della Tommasina et al [40], a repetitive process of these movements is necessary to perform physiotherapy, from which a more effective range of motion recovery will be obtained [41]. The elbow and shoulder are the upper limbs' main joints, articulating the arm's largest segments. These joints require a greater range of motion in flexion and extension and often affect and limit arm motion when a stroke episode occurs. Hence, we decided that users in a seated position should perform different arm movements while playing the VR-based rehabilitation exergame, targeting multiple possible physical rehabilitation needs in the upper limbs of people with stroke.

Table 1. Rehabilitation movements proposed for the exergame.

	Movement	Application	Action in the exergame
Elbow	Flexion and extension	Improvement in the width of movement in daily life activities	Destroying blocks with a hammer
Shoulder	Flexion and extension	Improvement in the width of movement in daily life activities	Throwing *tejos*
Elbow	Interior and exterior extension	Improved range of motion in the daily life activities	Cutting grass with a machete

Complementary therapy: we propose a therapy that uses the VR-based rehabilitation exergame to complement the rehabilitation process instead of replacing the traditional one, such as the one proposed by Goncalves et al [42]. We are confident that users who have experienced a stroke will play an exergame with engaging activities because they are developed based on their needs and motivations. Therefore, the exergames will allow a disruptive experience different from conventional therapies, generating interest, excitement, and willingness to carry out their rehabilitation process without neglecting the conventional therapy recommended by clinical specialists [38]. Considering the rapid contextual design and the clinical requirements named in this study, in a prior study, we developed a VR exergame following the well-known game design methodologies by Schell [29], as we contextualize in the following subsection.

Motion Health VR: VR Exergame for Stroke Rehabilitation

In a prior study, we established a game design concept and game mechanics using the methodology proposed by Schell [29] and a complete contextual design conducted with users with stroke. This study covers a more systematic and complete description of the playtesting sessions conducted with players with stroke to iterate and improve the game based on the initial concept. Knowing the preferences, ages, and profiles of potential users, we decided to explore a design concept for the cultural regions of Colombia (the Caribbean, Pacific, Andean, Orinoco, and Amazon). We discovered that older adults are inclined to engage in activities in the countryside and typical and authentic Colombian games. We discussed this exergame concept with the clinicians of our design team, gathering feedback regarding the potential movements to be performed, particularly in the context of mapping them for stroke rehabilitation therapies. Considering the scope of the project and previous research conducted with local users, development capabilities, and timelines, we decided to start by developing a game design concept related to the activities of the Colombian Andean region. The Andean region is the central region of Colombia and has crosscutting activities that are representative of the entire country and run throughout the central Andes. The population of this region practices sports, such as *sapo* and *tejo* (throwing games), rowing, and other more well-known sports, such as basketball and boxing. They also engage in other daily activities, such as fruit picking, horseback riding, and bush cutting [43]. Aligned with these cultural activities, we designed game scenarios that focused on a local setting using Colombian games. The design team analyzed existing VR games to establish game mechanics that could involve desired rehabilitation movements, always considering the player's motivators and needs. This analysis facilitated communication between the team of clinicians and specialists and the design and development team while also helping to specify the activities that would be familiar and engaging to the users. Therefore, we called the VR exergame "Motion Health VR." The exergame comprises 3 main scenes in which players must develop 3 different activities: hammering, throwing a metal disk (a traditional Colombian game called *tejo*), and cutting bushes while riding a horse.

The exergame presents 3 meticulously crafted scenarios, each aligned with its unique reference to Figure 1. In the "carpenter" scenario (Figure 1A), players engage in a dynamic elbow flexion and extension challenge, wielding a hammer to systematically crush boxes that vary in color and size, demanding specific ranges of motion. Players must skillfully adjust their proximity to the boxes to adapt to this diverse challenge, seamlessly weaving in back-and-forth and crossbody-reaching motions. Between the box-smashing activity, a captivating puzzle gradually unveils itself, featuring distinct Andean wildlife. Upon completing the activity, players earn the gratifying experience of visualizing the completed animal puzzle. As players enhance their hammering skills, the game dynamically escalates in difficulty either by increasing hammering frequency or by reducing box sizes. In the second scenario, inspired by Colombia's traditional *tejo* game (Figure 1B), players embark on a shoulder-focused flexion and extension adventure, mirroring the popular sport played nationwide. Throwing a metal disk toward an explosive target known as a *mecha* on a clay court, players must adjust their shoulder movements according to the target's distance, finetuning their range of motion for precise throws and aiming to maximize target hits with minimal repetitions. In the third scenario, the "farmer" (Figure 1C), players are challenged with a multifaceted movement that combines elbow flexion, extension, and internal and external rotation of the shoulder, akin to Kabat diagonals. In this rural setting, players ride an internet-based horse while wielding a machete, a staple tool in the Colombian countryside, tasked with clearing the obstructive bushes that appear on both sides of the road. With one arm gripping the machete and the other resting on the horse's rein, players face escalating challenges as the game progresses.

Figure 1. The presented scenarios of the Motion Health VR exergame with (A) a carpenter, (B) a throwing activity, and (C) a farmer, based on the movement of the Kabat diagonals.

Playtesting Sessions

Iterative game design involves playtesting sessions with end users, who will shape the game features before its final deployment. The main objective of playtesting sessions is to iterate different playable prototypes to improve the overall playability of the game, thus increasing the likelihood of adoption. In addition, playtesting allows the researcher to assess the ability of potential players to perform the proposed activities and understand game feedback. We developed playtesting sessions using the VR exergame designed in a prior work.

The playtest sessions were guided by a researcher accompanied by a clinical specialist who helped contact different users who had experienced a stroke. Owing to the COVID-19 pandemic, visits to each user were scheduled in such a way that biosafety protocols were maintained (eg, distancing, constant use of masks, and hand and footwear disinfection). Upon arrival at the agreed location, stakeholders performed the recommended distancing protocols. Then, the researcher prepared the experimental protocol, which consisted of setting up a table, a chair without a hand rest, and verifying the internet connection. Prototypes of the exergames were developed before the playtesting sessions and ported to the VR headsets (Oculus Rift in the first 4 iterations and Oculus Quest in the final version). Disposable headset protectors and cleaners were used to maintain biosafety measures. Table 2 presents the structure of the playtest sessions.

Table 2. Protocol for conducting playtests.

Actions	Considerations	Time (min)
Brief introduction of the dynamics of the session and interaction between the researcher and the user with stroke to obtain informed consent	—[a]	10
A quick explanation of how the VR[b] system works and what to expect from the activity	Preparation and arrangement	5
System implementation (HMD[c], headphones, and controls)	—	—
Free play or natural interaction with the system	Manifestation of difficulties, in real time if necessary	5
Receive feedback or explore ideas while users play	Formulate the questions established for the session	10
Conclude the session with questions about the experience	Questions	10

[a]Not available.

[b]VR: virtual reality.

[c]HMD: head-mounted display.

A total of 4 playtesting sessions involving 9 end users who had experienced a stroke were conducted. Each session was performed with a minimum of 2 users chosen considering their availability (Multimedia Appendix 1 lists the users who participated in each session and their demographic information). After playtesting, we recorded a video summarizing the session and documented a brief analysis that was subsequently discussed with the research and design teams. After each playtest, the team held a general meeting where all the discussions were presented. The subsequent playtest was scheduled after the implementation of the suggested game changes.

Pilot Study: Evaluation of the Game Experience and Usability of the Exergames

After conducting game playtests and completing a playable prototype of the VR exergame (4 iterations), we decided to carry out a pilot study to evaluate the usability of the game with a group of users who had experienced a stroke, in which 2 users who participated in one of the 4 iterations were part of the pilot study group.

We conducted a 20-minute session that was part of the rehabilitation therapy in which users who had experienced a stroke played the iterated version of the Motion Health VR exergame. We ported the final version of the game to the standalone VR headset, Oculus Quest 2, as it has several advantages, such as being wireless, comfortable, and having a high image resolution.

Users

This usability study was developed with 10 users who had experienced a stroke contacted through the clinician and therapist of the design team. We chose this sample size conveniently, considering the availability of users, which was very limited. In contrast, the small sample size allowed us to follow the biosafety protocols required for the COVID-19 pandemic, which was still ongoing in Colombia at the time of the study. The inclusion criteria for the study were being aged >50 years, having experienced a stroke and having hemiparesis or monoparesis, being able to read and write, not having serious vision problems (eg, strabismus), and not having diagnosed cognitive disabilities (eg, dementia).

Ethical Considerations

The bioethics committee of the local university approved this study, which was also approved by the bioethics committee of a local rehabilitation center (52–050623). Users volunteered for this study and agreed to participate by signing an informed consent form.

Usability Study

Two questionnaires (instruments) were used to assess the game user experience immediately after interacting with the immersive game.

Virtual Reality Neuroscience Questionnaire

The Virtual Reality Neuroscientific Questionnaire (VRNQ) measures the quality of user experience, game mechanics, and in-game assistance. It comprises 20 questions, each scored on a Likert-type scale ranging from 0 to 5 [44]. The advantage of using this questionnaire is that it provides the limits to assess the suitability of the software in VR [44]. VRNQ produces a total score that reflects the overall quality of the VR software and 4 categories as follows: (1) game experience, where the level of immersion and pleasure of the experience are evaluated; (2) game mechanics, where user interaction in the internet-based environment is evaluated; (3) game assistance, where the exergame instructions, indications, arrows, and labels are evaluated; and (4) motion sickness, which evaluates whether you experience nausea, disorientation, fatigue, and instability.

Immersive Tendencies Questionnaire

The Immersive Tendencies Questionnaire (ITQ) determines the differences in an individual's tendencies to experience immersion and presence after interacting with a VR scenario. ITQ comprises 18 questions rated on a Likert scale from 1 to 7, resulting in a possible score ranging from 18 to 126. In the original study, the mean score of the samples was 76.66 [45]. This questionnaire is considered a standard in VR research and has been widely used in different applications [22]. A user with a positive immersive tendency based on the ITQ score is likely to experience higher levels of VR presence, which has been associated with better task performance [22,41,46]. This questionnaire is useful because it allows the evaluation of immersion in a way that does not depend on the specific internet-based environment, making it possible to determine independently if an internet-based environment performs poorly or if the statistical sample has low immersion trends. Some ITQ questions are as follows:

- Does it often happen that while daydreaming, you forget what is happening around you?
- Does it happen to you that you are so engrossed in a movie that you forget what is happening around you?
- Do you identify with television characters?
- When you use an exergame, does it occur to you that you feel like you are inside the game instead of sitting down using the controller?
- Do you stay scared for a while after watching a scary movie?

Experimental Setup

The researcher and the physical therapist held the interaction session at each participant's home, where they chose a comfortable space to set up the VR system. The setup consisted of a chair in which the user with stroke was seated with the Oculus Quest 2 wearable headset and its respective wireless controllers. The researchers were able to see what the players were doing via the official Meta Quest app using an electronic tablet in real time.

Protocol

The users began the pilot study session seated, using the headset and holding the controllers. We conducted the session in the following order. The user who had experienced a stroke performed an upper body warm up for 5 minutes, guided by the physical therapist. The researcher and physical therapist prepared the user for the game by helping them put on the VR system. The researcher started the exergame, which was presented throughout the session, accompanied by a physiotherapist. After the interaction, the user who had experienced a stroke completed the 2 proposed questionnaires. Given the biosafety regulations established by the Colombian government because of the COVID-19 pandemic, all those involved in the sessions always wore masks. In addition, the researcher cleaned all VR and mounting elements each time they were used.

Data Analysis

The questionnaires were scored following the instructions of previous works. Descriptive statistics, such as mean and SD, were calculated and reported [47,48].

Results

Overview

The results are presented in 2 subsections. The first subsection details the transformation process of the game after conducting 3 playtesting sessions and iterations involving the end users and the interdisciplinary design team. The second subsection presents the preliminary results of a pilot study evaluating the user experience of the final game with a group of 10 players with stroke.

Playtesting

The following subsections detail the results of the iterative design process of the Motion Health VR exergame, reporting the details of the playtesting sessions and the modifications made to each iteration. The overall objectives of the playtest were to validate the acceptance and playability of users with stroke and to explore whether they were able to perform the activities proposed in the VR scenarios and game mechanics. In addition, analysis of errors and optimization of game mechanics were crucial to improve playability. A total of 9 users with stroke were involved throughout the 4 playtesting sessions conducted (Multimedia Appendix 2), focusing on certain game elements (eg, mechanics and esthetics) via playable prototypes and reporting back to the design team.

Analysis of Playtest 1

This version of the exergame was created to test the first 2 scenarios. Players 1 and 2 (U1 and U2) participated in this session following the protocol in Table 2. We used a VR-ready laptop and an Oculus Rift headset with controllers. The playtesting goals were to evaluate the appropriateness of the proposed range of movement for hammering and throwing the disk and to explore button combinations for performing the activity using the controllers. We found that (1) the game should consider different scales of spasticity to provide a more adaptive experience [49]; (2) the buttons should be suspended from their functions to avoid triggering involuntary functions; and (3) a rest period should be granted to the user because, as recommended by the physiotherapist, long periods of exercise generate symptoms of fatigue.

Analysis of Playtest 2

The objective of these playtests was to test the modifications introduced in the first 2 scenarios based on the considerations in the Analysis of Playtest 1 subsection. Players U3, U4, and U5 participated in this playtest following the protocol in Table 2. A VR-ready laptop and an Oculus Rift headset with controllers were used. Figure 2 shows the evolution of the 2 scenarios after the first playtest, showing the improvement in content according to the real scenarios where these activities were performed.

Figure 2. The final version of each scenario of the Motion Health VR exergame: (A), the carpenter scenario, (B) the tejo scenario, and (C) the farmer scenario.

Users with stroke reported an improvement in the simplicity of the interaction, as they found it much easier to perform the movement owing to an initial calibration of the position added to the 2 scenarios, which adjusts the player's position concerning the internet-based surroundings, ensuring objects are at a reachable distance. In addition, we found that (1) the objects in each scenario should be in a static position; thus, people can avoid unnecessary displacements within the internet-based space that can generate dizziness; (2) we need to improve the auditory feedback of scenarios to create an immersive experience; and (3) we need to improve the calibration scene to allow players with low mobility to perform the tasks.

Analysis of Playtest 3

The third scenario was prototyped, and the game mechanics were ready for playtesting. The objective of this playtest was to test whether players could easily understand and interact in the farmer scenario by performing the proposed movements, that is, riding the horse while holding the rein with the unaffected arm and cutting bunches with the machete using the affected arm. Players U6 and U7 (Multimedia Appendix 3) participated in this test following the protocol in Table 2. We used a VR-ready laptop and an Oculus Rift headset with controllers. We found that (1) it would be useful to place the avatar on the horse from the beginning and (2) the game should allow cutting bushes to be performed using both arms and provide adequate time to switch the game controller between hands because the players become tired after certain repetitions.

Analysis of Playtest 4

After iterating each scenario and exploring potential pitfalls and interaction errors, a final playtesting session was scheduled to test the overall functioning of the integrated system. This prototype of the exergame presented an embellishment of the contents (Figure 2), which was an improvement in the overall esthetics of the game. In addition, a structured exercise session was recommended by the clinical rehabilitation experts, following a 15-minute session (similar to other studies of the same nature [50]). Therefore, the 3 scenarios were presented in sequence and switched after 5 minutes (approximately). Players U3, U4, and U5 participated in this test following the protocol in Table 2. We used a VR-ready laptop and an Oculus Rift headset with controllers.

We found that (1) scene transitions should be smoothed and (2) the game should implement rest periods between each scenario, as users still manifested mild fatigue from performing so many repetitions while preparing for the next mechanic.

Finally, we integrated the above recommendations into the scenarios and developed the final prototype of the Motion Health VR exergame.

Evaluation of Game User Experience

This section presents the results of evaluating the game user experience of the co-designed Motion Health VR exergame involving 10 users with stroke (Multimedia Appendix 4). For this part, the game was modified to a more portable, standalone, and easy-to-use headset, the Oculus Quest 2. Only the final deployment platform was changed (from wired to wireless VR), and no other changes were made. The questionnaires were administered at the end of the session, asking users to rate their experience in a wide range of aspects following the ITQ and VRNQ.

Virtual Reality Neuroscientific Questionnaire

The results of administering VRNQ are reported as average values with SD (Table 3). Each category had a maximum of 35 points. Gaming experience was rated at a mean of 24.8 (SD 4.5), game mechanics mean 23.8 (SD 5.5), game assistance mean 23.9 (SD 5.5), and motion sickness (inversely proportional), mean 31.1 (SD 5.6). Consequently, the maximum possible general score for this test was 140, in which the exergame Motion Health VR obtained a mean of 103.6 (SD 19.4). This level of quality is considered more than adequate as it exceeded 100 points. From this, it can be concluded that the users experienced a high level of immersion during their video game experience, and the quality of the Motion Health VR exergame obtained a general average of mean 103.6 (SD 19.4), which is considered an adequate quality because it exceeded 100 points [47]. On the basis of this result, we observed that users had a high immersion index; the experience with the exergames was very pleasant; and the quality of the graphics, sound, and technology, in general, was perceived as very positive. Finally, the system showed the best results in the motion sickness index, which shows that exergames did not cause major side effects associated with cybersickness or nausea [47,51].

Table 3. Virtual Reality Neuroscientific Questionnaire (VRNQ) categories.

VRNQ categories	Score, mean (SD)
Game experience	24.8 (4.5)
Game mechanics	23.8 (5.5)
Game attendance	23.9 (5.5)
Motion sickness	31.1 (5.6)

Immersive Tendencies Questionnaire

ITQ was used to evaluate users' immersion experience and presence following their engagement with the exercise. The overall ITQ score averaged 60.8 (SD 11.6), signifying that participants with a history of stroke perceived relatively low to moderate levels of immersion and enjoyment (Table 4). In terms of concentration (mean 22.3, SD 2.9, with a maximum score of 35), users consistently achieved high scores, indicating that the game effectively captured their attention.

Regarding immersion (mean 17.9, SD 4.7, with a maximum score of 35), users reported a sense of engagement with the game. In terms of emotions (mean 14.6, SD 5.1, with a maximum score of 28), the findings suggest that users developed a strong emotional connection with the game [33,51,52].

Table 4. Immersive Tendencies Questionnaire (ITQ) categories.

ITQ categories	Score, mean (SD)
Concentration	22.3 (2.9)
Immersion	17.9 (4.7)
Emotion	14.6 (5.1)
Enjoyment	6.1 (2.2)

Discussion

Principal Findings

This study summarizes our efforts to report methodological approaches extensively used in game design that have a significant value when used to design VR exergames for stroke. We also showed the results of a preliminary usability test conducted involving 10 users with stroke who played the Motion Health VR exergame after completing 4 iterations using playtesting sessions. Overall, the VR exergame exhibited medium-to-high levels of game user experience and low levels of perceived symptoms associated with VR, such as nausea and dizziness. Moreover, regarding enjoyment, users expressed a high willingness to participate in therapies and continue with the sessions. The user experience questionnaires showed that users experienced increased immersion, emotional connection, and enjoyment with the VR exergame, although the concentration remained consistent. These results are consistent with previous research using immersive VR in older adults [53] and people with stroke [54,55]. Furthermore, we have carefully reported the methodological aspects related to playtesting sessions with users with stroke and specific procedures to conduct such sessions. From the playtesting sessions, we can extract the value of evaluating prototypes in the early stages of the game design process because this prevents researchers from struggling with complex interactivity and usability issues later during the trials. As reported in the study by Toro et al [56], early involvement of end users in VR systems for exercise promotion is a desired practice, and it is not commonly used among those creating custom-made exergames for older adults [57-59].

Playtesting as a Tool for Iterative Design

Playtesting is a part of the iterative design methodology used in different UCD approaches [51,60]. In our case, we performed playtest with several users who had experienced a stroke, which allowed us to improve the content, playability index, and game mechanics from an ergonomic approach to provide greater user comfort. Although prior designs of physical rehabilitation games for stroke have involved UCD [61], involving users with stroke in playtesting and follow-up sessions is not common [50]. We suggest that designers consider including playtesting with users with stroke because, in terms of rehabilitation therapy performance, playtesting revealed important details, such as the importance of performing a calibration stage or removing the buttons and other interactions with the VR equipment. We found that this stage provides exergames with the characteristics to adapt to the physical needs of each user, such as the range of motion and spasticity scale of each user [62]. In the context of serious games, the importance of adaptive games has increased, as every user has different requirements [62].

Furthermore, the playtesting methodology allowed us to strengthen relationships with all stakeholders, from developers to clinicians. This aligns with the findings of previous studies that have emphasized how involving multiple stakeholders in the design process leads to a more suitable and user-centered prototype [63]. The importance of maintaining close relationships with stakeholders has also been underscored, and this study reaffirms the relevance of this challenge in the successful implementation of playtesting. Effective collaboration between developers and clinicians, driven by the willingness and availability of both parties, has been a recurring theme in the literature [62]. Previous studies have pointed out the pivotal role of this relationship in the success of VR rehabilitation programs following stroke.

In particular, we noticed that playtesting allowed a stronger relationship with patients with stroke, increasing their willingness to participate in future studies. Although other researchers have reported difficulty finding specific populations to be involved in studies [64,65], considering our final results, we highly recommend that research teams plan to conduct multiple playtests before conducting studies.

Finally, we consider that after performing 4 playtests, based on the observations of the users who had experienced a stroke and the recommendations of the clinicians, an optimal version of the exergame was obtained, which could also be used by designers to facilitate piloting and prevent errors during data collection. As mentioned in this study, the inclusion of playtests and the collaboration of specialized professionals in programming and design align with the best practices recommended by previous research [66].

Usability of UCD VR Games in Patients With Stroke

We observed that ITQ and VRNQ scores were below the expected mean, as reported in the Results section. Similar results have been reported previously because there were some concerns about the usability of VR in older adults, including those who have had strokes. A systematic review of clinical and research applications of VR in older people identified usability issues, such as discomfort, cybersickness, and difficulty with the equipment [67]. Therefore, based on the current results, the design team must improve the gameplay mechanics and usability of the VR exergame to achieve better results in gameplay experience metrics before the subsequent trial. Nevertheless, the system scored high in usability, as its overall score was higher than expected (100 points). Furthermore, as our results showed that the VRNQ category with the highest score was motion sickness, meaning that users who experienced a stroke felt little nausea, our work aligns with studies using similar VR apps [8,20,47]. These usability results can guide other exergame designers to adjust their apps to suit older adults.

Use of Interactive Technology for Telehealth Care

The use of portable and autonomous technologies, such as the Oculus Quest 2 headset, during the pandemic has been an innovative response supported by this research [68]. This reinforces the notion that virtualization of health care, driven by technology, is becoming increasingly important. A recent review describing the promising landscape of telerehabilitation tools aided by serious games for upper limb stroke rehabilitation highlights the evidence of efficacy, the need for further research in this area, and the promise of digitally connected games to complement conventional rehabilitation [69]. Nevertheless, although VR has never been more accessible before, the reality is that the cost-effectiveness of its use in telehealth programs in both rural and urban areas in Latin America is still very limited [70]. In summary, our study contributes to emerging efforts in which interdisciplinary collaboration and the use of innovative technology during times of crisis, such as the pandemic, continue to draw a research pathway in this continually evolving field [63,71,72].

Limitations

We developed this study between August 2020 and June 2021, when most rehabilitation centers were closed owing to COVID-19 pandemic restrictions. Therefore, accessing users with stroke was a difficult task that we overcame with the help of the therapists. They provided us with the contact list of their former users, and we contacted them personally. Notably, although we took all safety precautions, people with stroke feared contagion and only a couple of them participated in the playtesting sessions. We acknowledge the lack of homogeneity in the sample of users who participated in the playtesting because stroke is a condition caused by several factors and affects both sexes, and users who have experienced a stroke tend to have a wide range of ages and ethnicities. The small sample size may limit the generalizability of our findings. Moreover, this limitation was difficult to address because of the COVID-19 pandemic restrictions that were under regulation when we developed this study. That is why, for the pilot study, we limited the users' age to >50 years. VR is a technology that is constantly changing and improving, in the sense that we started playtesting with the Oculus Rift headset and then moved on to using the Oculus Quest 2 for the pilot study because of its portability advantages. We overcame these technological changes because of the cross-platform features offered by the game engine used (Unity).

However, VR content development is a challenge when designing deployable solutions. Nonetheless, despite the pandemic situations in which this study was developed, the iterative design and preliminary study were carried out owing to the implementation of portable and autonomous tools, such as the Oculus Quest 2 VR headset, which are becoming increasingly important in the virtualization of health care delivery.

The duration of the usability study was very short, and users only interacted with the final game in a single session lasting approximately 15 minutes. A short-term study may not adequately capture the long-term benefits or challenges of using VR exergames for stroke rehabilitation. We plan to extend this initial pilot study and conduct a single-arm longitudinal study involving a similar group of users for 12 sessions for 3 months. Furthermore, this study did not include a control group for comparison. Without a control group undergoing traditional rehabilitation methods, it is challenging to conclusively attribute improvements to the VR exergame alone. Finally, although the study emphasizes the iterative design process and user feedback, it is difficult to know how these design changes directly affect the rehabilitation outcomes. Future studies with this game should include rehabilitation outcomes such as upper limb range of motion and spasticity levels.

Conclusions

Our research has conclusively demonstrated that creating VR exergames for stroke rehabilitation by involving end users early in the design stages brings advantages such as reducing interaction errors and unnecessary game design elements that do not contribute to the therapy. UCD is highly recommended as a design methodology for creating games specifically tailored to the rehabilitation of users who have experienced strokes. The results of this study support the effectiveness of multiple playtesting in producing therapeutic games that align with the needs and abilities of users with stroke, such as creating familiar internet-based environments and activities and removing unnecessary motion that could lead to motion sickness. This conclusion underscores the importance of adopting a patient-centered approach in the development of medical apps and technologies for rehabilitation. Our findings have yielded promising results regarding the use of immersive VR in the context of upper limb stroke rehabilitation. Users who immersed themselves in internet-based environments using custom-built exergames showed good levels of immersion and enjoyment and reduced levels of perceived nausea or dizziness. These results suggest that VR technology holds potential as a therapeutic tool for the treatment of users with stroke-related impairments, especially for at-home therapies. However, further research and long-term follow-up are required to fully understand the scope and limitations of this technology in the rehabilitation of this user group. The use of playtesting as an iterative tool for enhancing video game design enables comprehensive interaction with the user. This interaction allows for genuine customization of the therapy, leading to the development of a video game tailored specifically for users who have experienced stroke.

Acknowledgments

The authors would like to thank Felipe Gomez for his contribution as a physical therapist to the design team. The authors also thank game programmer Ricardo Arango, who contributed to the construction of the exergames. Finally, the authors would like to thank the Comfamiliar Hospital and all the users who helped with testing the exergames.

Abstract

Background: A frequent rehabilitation goal for children with gait disorders is to practice daily-life walking activities. Unfortunately, these are often difficult to practice in a conventional therapeutic setting. Virtual reality (VR) with head-mounted displays (HMDs) could be a promising approach in neurorehabilitation to train such activities in a safe environment. First, however, we must know whether obstacles in VR are indeed mastered as obstacles.

Objective: This study aimed to provide information on whether VR is feasible and motivating to induce and practice movements needed to master real obstacles in children and adolescents with gait disorders. Furthermore, this project aims to evaluate which kinds of everyday walking activities are appropriate to be practiced in VR.

Methods: In this cross-sectional study, participants stepped over a bar, crossed a gap, balanced over a beam, and circumvented stationary obstructions arranged in a course under real physical and virtual conditions wearing a VR HMD. We recorded the respective primary outcomes (step height, step length, step width, and minimal shoulder-obstacle distance) with motion capture. We then calculated the mean differences and 95% CI of the spatiotemporal parameters between the VR and physical setup and later compared them using noninferiority analysis with margins defined a priori by a clinical expert panel. Additionally, the participants responded to a standardized questionnaire while the therapists observed and evaluated their movement performance.

Results: We recruited 20 participants (mean age 12.0, range 6.6-17.8 years) with various diagnoses affecting their walking ability. At 3.77 (95% CI 1.28 to 6.26) cm, the mean difference in step height of the leading foot in the overstepping task did not exceed the predefined margin of –2 cm, thus signifying noninferiority of the VR condition compared to mastering the physical obstacles. The same was true for step length (–1.75, 95% CI –4.91 to 1.41 cm; margin –10 cm), step width (1.05, 95% CI 0.20 to –1.90 cm; margin 3 cm), and the minimal shoulder-obstacle distance (0.25, 95% CI –0.85 to 0.35 cm; margin –2 cm) in the other tasks. Only the trailing foot in the overstepping task yielded inconclusive results.

Conclusions: Children with gait disorders perform everyday walking tasks like overstepping, crossing, balancing, or circumventing similarly in physical and VR environments, suggesting that VR could be a feasible therapeutic tool to practice everyday walking tasks.

Introduction

In pediatric neurorehabilitation, children and adolescents with congenital or acquired lesions of the sensorimotor system often experience impairments in gait [1,2]. Consequently, recovery of walking ability is a frequent rehabilitation goal in pediatric neurorehabilitation [3]. Thereby, the focus is on promoting everyday life activities and ensuring meaningful participation for the child and their family [4]. Therapies targeting gait encompass a wide variety of therapeutic approaches. In our clinic, Swiss Children's Rehab, these therapies include, for example, conventional physical therapy, including task- and everyday life–oriented training, rehabilitation robots, and sports therapy. Normally, these therapies occur in a conventional therapeutic setting. However, within this setting, many everyday walking tasks, such as, for example, crossing a wide gap to board public transportation or avoiding contact with people or obstacles while navigating through crowded places, cannot be reasonably practiced.

In recent years, immersive virtual reality (VR) has become increasingly popular. Since companies have made the technology more accessible to the community through more affordable and easy-to-use devices, the use of VR has increased, as have the areas of its use [5]. Accordingly, this upswing in VR could be promising for its implementation in neurorehabilitation. Immersive VR puts users directly into virtual scenarios and gives the illusion of a full physical presence, providing rich sensory fidelity (high degree of reliability) [6,7]. To experience immersive VR, head-mounted displays (HMDs) are most suitable and can convey many of the abovementioned impressions [8]. A potential goal of using VR in pediatric neurorehabilitation could be to enhance children's abilities in their daily lives by practicing task-specific activities relevant to their everyday lives while still being in a safe therapeutic environment. Furthermore, its game-like attributes and animations can increase children's motivation and enhance their active participation by minimizing their focus on task repetitions [9,10]. Additionally, as VR is an accessible and affordable technology, it could enable home training. Moreover, a significant advantage of using VR in children aged between 6 and 18 years could be that they experience higher levels of presence and "realness" within a virtual environment compared to adults [11].

Recent studies have already investigated the effectiveness of acquiring different cognitive and motor tasks with VR. In the pediatric field, VR has been mainly used for pain management [6] or educational purposes [12,13], as well as to create relaxing and learning opportunities for children diagnosed with autism spectrum disorder [14,15] or attention deficit hyperactivity disorder [16]. However, the long-term effects of VR on developing children are unknown, and cybersickness or fatigue of the eyes and brain are potential disadvantages [6,17,18]. According to the authors' best knowledge, no evidence exists of using immersive VR as a gait therapy intervention in children with gait disorders. When including results from augmented reality studies, a systematic review showed moderate evidence for improved gait-related outcomes when gait training was enhanced with commercially available videogame systems, such as the Nintendo Wii or Microsoft Xbox Kinect, in children with cerebral palsy (CP) [19]. Furthermore, a systematic review and meta-analysis from Chen et al [20] showed a large effect size of d=0.861 for improved motor function in children with CP when comparing commercially available game systems with conventional therapy or controls (eg, no intervention). However, such systems lack essential aspects of VR since they are usually presented on a 2D screen or as floor projections [8] and, therefore, do not transmit the entire concept of VR, including full physical presence and immersion.

Immersive VR offers many advantages regarding task-specific training, motivation, "realness," and costs [5-7]. Still, it remains uncertain whether the use of VR in children with gait disorders is a feasible approach to inducing and practicing the movements required to perform everyday gait activities. Reasons to assume that VR in children with gait disorders might not be feasible are the lack of visual information of the lower extremities and the difference in the perception of virtual obstacles by the children [6,11,21]. Therefore, a prerequisite for the meaningful use of VR in training everyday gait activities would be that the children master obstacles presented in VR like they master physical obstacles. Thus, this project aims to provide information on whether a VR setup is feasible and motivating to induce and practice movements that are needed to master real obstacles in children and adolescents with gait disorders. Furthermore, this project aims to evaluate which kinds of everyday walking activities are appropriate to be practiced in such a VR setup. To evaluate this, we compare the spatiotemporal parameters of performing certain everyday walking tasks in a virtual and a physical environment using a noninferiority analysis. The noninferiority analysis should indicate that the virtual setup is not unacceptably worse than the physical setup.

Methods

Ethical Considerations

This cross-sectional study took place at the gait laboratory of Swiss Children's Rehab, University Children's Hospital Zurich, during a single 60-minute session. The ethics committee of the Canton of Zurich confirmed through a clarification of responsibility that no approval was needed for this study (Req-2021-00364).

Participants

We included children and adolescents aged between 6 and 18 years with gait disorders undergoing inpatient or outpatient rehabilitation at Swiss Children's Rehab. In line with recommendations for comparative studies, which propose 8 to 25 participants [22], we aimed to include 20 participants. All children who were receiving physiotherapy at the time of recruitment were screened according to the inclusion and exclusion criteria and recruited consecutively within 3 months. To be eligible to participate, they had to be able to walk short indoor distances without assistive devices or with crutches. Additionally, they had to be able to follow simple verbal instructions. Exclusion criteria were a history of seizures, epilepsy, blindness, or inability to use the HMD (eg, cybersickness, open wounds on the head).

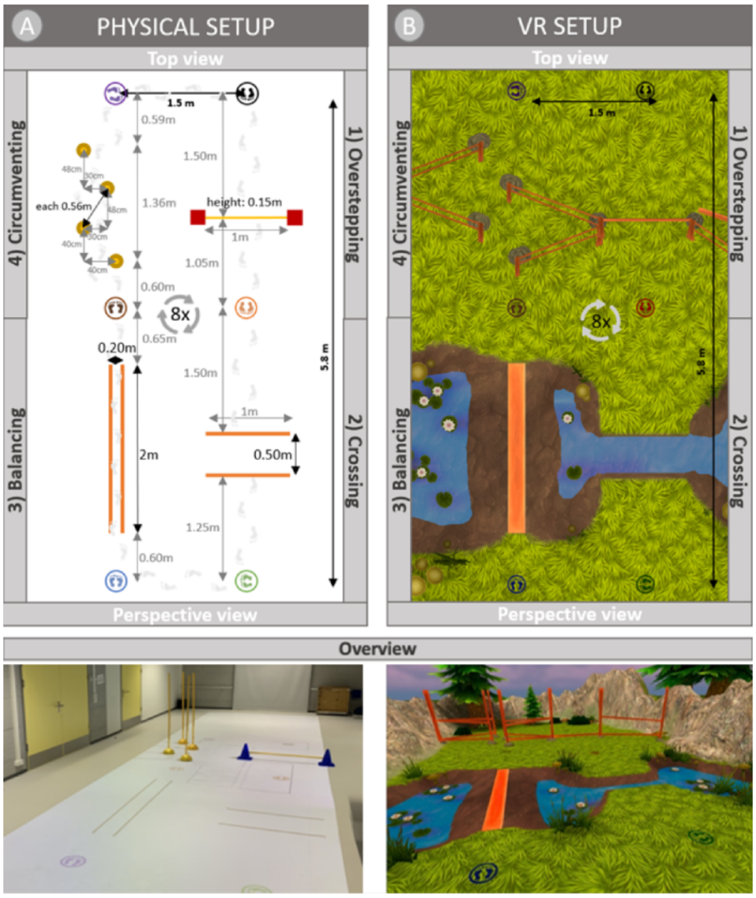
Participants’ characteristics were collected from the patient records. The physiotherapist rated the functional mobility level using 2 performance measures: the Functional Mobility Scale (FMS) and the Gillette Functional Assessment Questionnaire (FAQ) walking scale [23]. The FMS describes the participant’s level of functional mobility by assessing the assistive device used in everyday life over 5 m, 50 m, and 500 m on a scale from 1 (uses a wheelchair) to 6 (independent on any terrain). The FAQ assesses functional walking abilities on a scale from 1 (can not make any steps at all) to 10 (walks, runs, and climbs on even and uneven terrain). Finally, the lower extremity proprioceptive impairments of the participants were rated with the percentage score of the proprioception subsection of the Fugl-Meyer (FM) assessment for the lower extremities [24]. We assessed proprioception at the hip, knee, ankle, and toe joints while the participant was supine and barefoot.

According to good clinical practice standards, we obtained written informed consent from the participants and their legal representatives before participation.

Experimental Setup

The participants had to perform everyday walking tasks in 2 different conditions: physical setup and VR setup. In the physical setup, the participants had to master real (physical) obstacles (Figure 1A). The 4 obstacles, including overstepping, crossing, balancing, and circumventing, were arranged in a course. In the VR setup, the participants had to master the same 4 obstacles virtually. The obstacles were incorporated into an everyday environment (Figure 1B). The VR setup matched the locations and dimensions, but not the appearance of the physical obstacles. This discrepancy was chosen intentionally since we wanted to incorporate the obstacles into an everyday environment as they would appear in future applications. During the development process, it was ensured that the environment was designed as stimulatingly as possible, since interaction and sensorimotor contingencies are crucial contributors to a full VR experience [8]. Nevertheless, to compare the 2 conditions, we also had to keep the VR environment simple to avoid the participants being distracted from their tasks.

Figure 1. (A) Scheme of physical setup, and (B) the appearance of the VR setup when wearing the HMD.



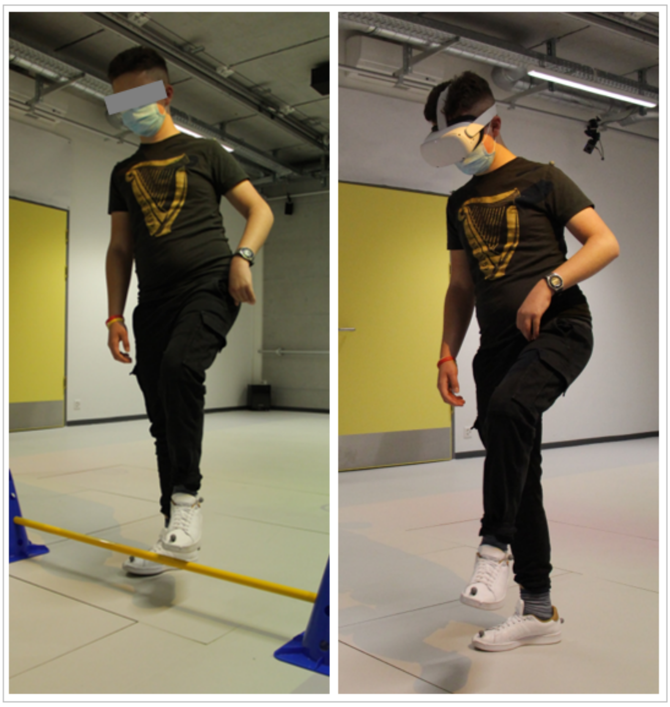
For this setup, the commercially available VR HMD Meta Quest 2 (Meta Platforms) was used. We aligned the coordinate systems of the physical and the virtual world, using the hand-tracking function of the Meta Quest, and scaled and rotated the virtual world based on 2 points. To test the alignment between the 2 conditions, we checked that the scaling coefficient was near 1.0.

To minimize the influence of fatigue, we randomized the sequence of the conditions and the starting position within the obstacle course. We used a minimization method (randomization factor 1), including the factors of gender, age, and functional walking ability defined by the FAQ. During the session, the physiotherapist accompanied the participants to ensure their safety and provide assistance if necessary.

Task Description

For the overstepping task, the participants had to step over a 15-cm-high obstacle, which consisted of a plastic bar mounted on 2 cones (physical setup) or the lower part of a fence (VR setup; Figure 2). In the physical setup, participants had to cross two 3-cm-wide lines projected on the ground with a beamer, whereas they had to cross a small stream in the VR setup. In both setups, the gap was 50 cm, thus exceeding the average step length of children with CP aged between 7 and 14 years (Gross Motor Function Classification System [GMFCS] levels I and II) or traumatic brain injury (TBI) [25-27]. For the balancing task, we instructed the participants to walk between two 2-cm-wide lines projected 20 cm apart on the floor in the physical setup and a 20-cm-wide wooden panel over a pond in the VR setup. Circumventing was performed by walking around 4 plastic poles (physical setup) or fence posts (VR setup). The distance of the poles was 56 cm, corresponding to approximately 1.7 times the average shoulder width of children aged between 6 and 18 years [28,29]. With an estimated protective zone of 30 cm around the obstacle [30], even smaller participants would sidestep, while taller participants could still pass through the obstacles, even when relying on crutches. In addition to the 4 tasks, the participants walked 6.5 m in a straight line without any obstacles, both with the HMD (walking on green grass) and without the HMD.

Figure 2. Execution of the overstepping tasks in the physical and virtual reality setups.



Measurement Procedure

Task execution was recorded with a total of 12 Vicon Vero 2.2 high-speed cameras (Vicon Motion Systems). We placed 9 infrared reflective markers of 16 mm diameter on specific anatomical landmarks at both feet (3 markers each) and shoulders (3 markers). The markers were attached to the shoes as the participants performed the tasks with shoes and orthotics (if needed) as in everyday life.

After measuring the participants' height and shoulder width and attaching the 9 reflective markers to the defined positions, the measurements started with either the physical or the VR condition. The participants first walked 4 times along the 6.5-meter walkway at self-selected walking speeds. Afterward, they performed 2 accommodation rounds of the obstacle course to familiarize themselves with the condition and the tasks. The physiotherapist could provide physical support if the participants had difficulties with any obstacle. Finally, we instructed the participants to always step over the obstacle and cross the gap with the leg they had spontaneously used in the first round.

According to Redekop et al [31], reliability with an interclass correlation coefficient of 0.90 is given for an average of 6 strides when examining discrete gait parameters in children with CP. Therefore, 8 trials per condition were recorded to have 2 spare measurements if any unexpected errors arose while reviewing the recordings. Once the 8 valid attempts per task were recorded, the participants had a short break, during which they answered the first part of the questionnaire. Subsequently, the same procedure was repeated with the second condition, followed by the second part of the participants' questionnaire and the proprioception subsection of the FM assessment performed by the investigator. Meanwhile, the physiotherapist completed the therapist's questionnaire and rated the participant's FMS and FAQ.

Data Processing

Vicon data were processed using Nexus Motion Capture Software (version 7.2; Vicon Inc). Processing of the raw data included visual determination and defining gait events like foot strike, foot off, etc. We analyzed the data from the first 6 valid trials for each condition and task. Then, the data were exported to MATLAB R2021a (version 9.10; MathWorks) to calculate the spatiotemporal parameters. For the spatiotemporal parameters, we calculated the mean of the 6 valid trials per task for each participant and condition individually. A negative mean difference between the VR and physical setup indicated a smaller value in the VR setup.

Outcome Measures

For the 4 tasks, we selected spatiotemporal parameters (Figure 3) in line with the literature [27,32-35]. We calculated the walking speed, step length and width, and double-stance phase during normal walking with and without the VR HMD. Additionally, we recorded the time to master each task and the number of failures, indicating unsuccessful obstacle negotiations.

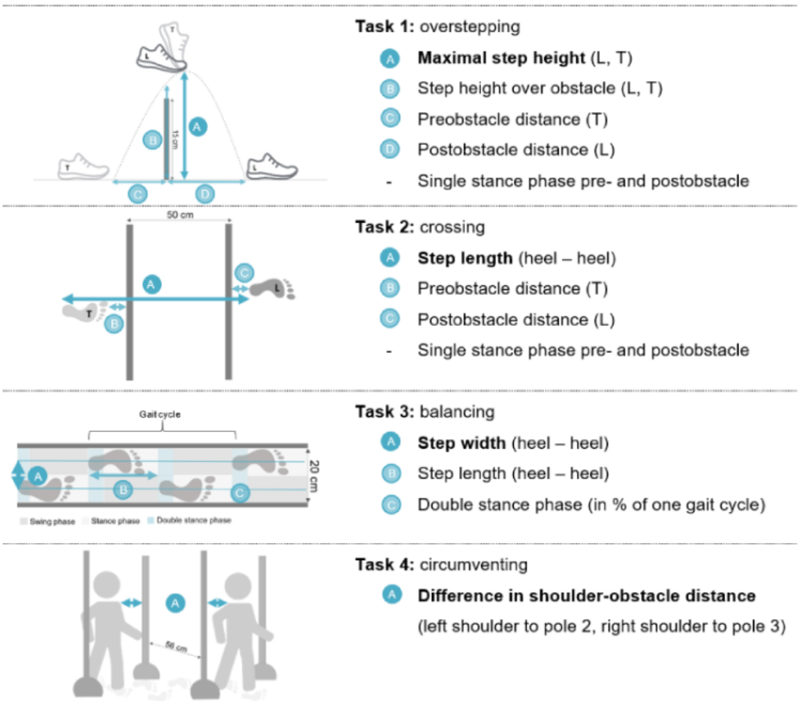


Figure 3. Investigated spatiotemporal parameters for each task. (A) represents the respective primary outcomes. L: leading foot; T: trailing foot.

The participants answered standardized questions covering their movement ability, spatial presence, and enjoyment during task execution on a visual analog scale (VAS). In addition, the physiotherapists rated the participants' movement execution, level of engagement, and meaningful use on a 5-point Likert scale.

Statistical Analysis

Participants' clinical and functional characteristics are presented using descriptive statistics. A normal distribution could be assumed for the differences between the primary outcomes (Shapiro-Wilk test; P>.05). Therefore, the mean differences and their SDs were subsequently calculated. Additionally, the primary spatiotemporal parameters were analyzed using noninferiority testing with 95% CIs and a priori defined margins of noninferiority [36]. The noninferiority margins, which served as boundaries for the 95% CI of the mean differences, were defined for each task by a panel of 15 expert physiotherapists (n=14 women; n=1 men). These margins represent the maximum difference between the VR and the physical setup defined as acceptable while still considering the conditions to be equal [37]. To determine the maximum tolerated deviation, the physiotherapists compared the tasks with everyday life tasks and considered what deviation they would accept in conventional therapy for the respective task. A normal distribution could not be assumed with 15 responses; therefore, we described the margins using nonparametric parameters such as the median and IQR. Descriptive statistics are used to present the participants' and therapists' questionnaire responses. Additionally, to analyze the difference in fun between the 2 conditions, we used the Wilcoxon signed rank test with continuity correction.

Results

Participants

All patients that were examined for eligibility within the recruitment agreed to participate. In total, 7 girls and 13 boys with different gait disorders participated in this study. Their mean age was 12.0 (SD 3.5) years, and their mean height was 1.46 (SD 0.21) meters. All participants were able to follow the instructions and remained compliant during the measurements. None of the participants reported cybersickness. The spectrum of functional mobility was broad, including FMS levels 3-6 for 5 m and 50 m and 1-6 for 500 m, as well as levels 6-10 of the FAQ. However, most participants could walk independently on all surfaces without any walking device, for at least short to medium distances (FMS 5 m and FMS 50 m ≥5 each). Participants' lower extremity proprioception (FM score) ranged from normal to mildly impaired. A total of 9 of the 20 participants had already used a VR HMD at least once before this study. Participants' clinical and functional characteristics are presented in Table 1.

Table 1. Clinical and functional characteristics of the participants.

ID	Sex	Age (years)	Height (cm)	Diagnosis[a]	FMS[b]	FAQ[c]	FM[d]	Mobility aid[e]
1	Male	13.4	155	Unilateral spastic cerebral palsy (I)	6/5/5	9	93%[f]	None

[a]In children and adolescents diagnosed with cerebral palsy, the Gross Motor Function Classification System Level is given in parentheses.

[b]FMS: Functional Mobility Scale 5/50/500 m.

[c]FAQ: Gillette Functional Assessment Questionnaire-walking scale.

[d]FM: Fugel-Meyer assessment.

[e]Mobility aid used in both conditions.

[f]Due to restricted movements in certain joints or due to pain, not all movements of the FM could be performed by these participants. Therefore, for these participants, the relative value is not calculated from the maximum score (16 points), but from the individual maximum score (8-14 points).

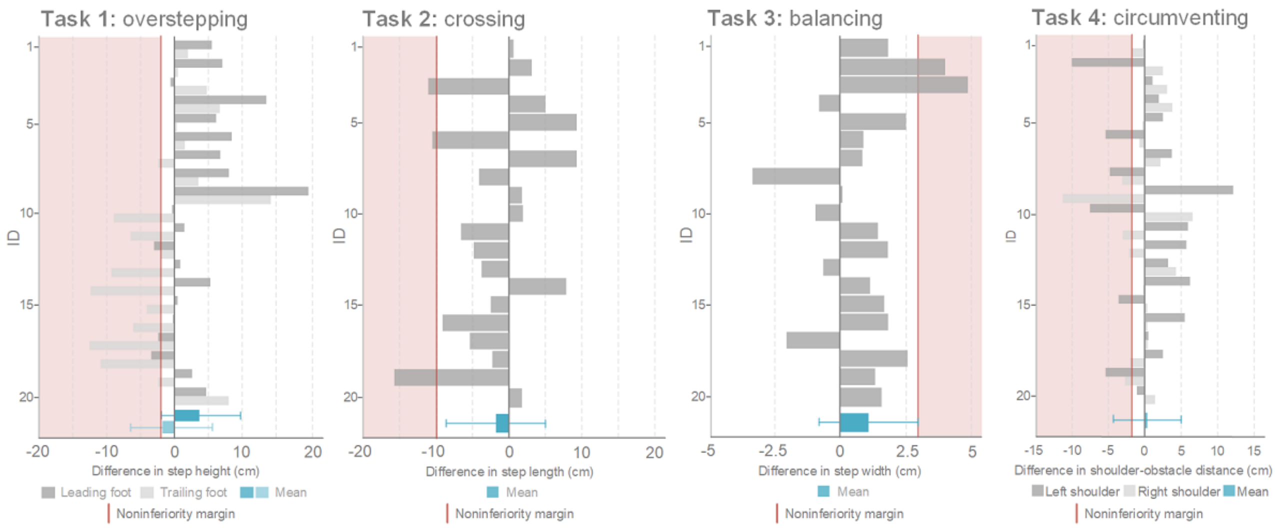
[g]Did not need a mobility aid, but needed close supervision of their physiotherapist.

The participants had to walk the obstacle course from 8 to 16 times to obtain 6 valid trials per task. This resulted in 25-39 recordings per participant for the entire measurement. The most frequent reason why a trial was considered invalid was crossing the obstacle with the wrong leading foot. Furthermore, some attempts were declared invalid when the instructions were not followed or the recording of the markers failed. There were no missing data, except for participant 9 (only 5 valid crossing task trials in the physical setup) and participant 10 (only 5 valid overstepping task trials in the physical setup).

Spatiotemporal Parameters

The differences between the VR and the physical condition varied widely between the participants and tasks (Figure 4).

Figure 4. Differences per participant and task for the primary outcomes. The blue bars represent the mean differences and SD over all participants.



During normal walking, step length and gait speed decreased, and step width slightly increased in the VR condition compared to the physical setup (Table 2). In task 1, participants lifted the leading foot 3.77 cm higher and the trailing foot 1.75 cm lower in the VR setup when overstepping the obstacle. In task 2, they decreased the step length by 1.75 cm in the VR setup. As in normal walking, step width and the double stance phase increased, while step length decreased in the VR setup of the balancing task. For task 4, the distance from the shoulder to the obstacle did not differ between the 2 conditions.

Table 2. Spatiotemporal parameters for the conditions and tasks.

Task and parameter	Physical setup	Virtual reality setup	Difference[a]
Task 0: normal walking, mean (SD)			
Step length (cm)	60.44 (10.22)	54.91 (7.11)	–5.53 (7.14)
Step width (cm)	9.29 (3.92)	9.48 (3.07)	0.19 (2.07)
Gait speed (m/second)	1.10 (0.23)	0.95 (0.20)	–0.15 (0.24)
Double stance phase (%)	24.75 (4.41)	27.48 (3.82)	2.72 (4.21)
Task 1: overstepping			
Max step height (L[b]; cm)[c], mean (SD)	27.53 (4.74)	31.31 (7.21)	3.77 (5.69)
Max step height (T[d]; cm)[c], mean (SD)	28.30 (6.27)	26.55 (8.47)	–1.75 (7.07)
Step height over obstacle (L; cm), mean (SD)	24.77 (5.18)	25.30 (8.29)	0.53 (5.64)
Step height over obstacle (T; cm), mean (SD)	25.32 (5.61)	18.80 (9.06)	–6.52 (8.28)
Preobstacle distance (T; cm), mean (SD)	16.45 (7.66)	10.17 (9.01)	–6.28 (5.60)
Postobstacle distance (L; cm), mean (SD)	19.60 (5.67)	24.45 (6.97)	4.85 (5.58)
Single stance preobstacle (T; seconds), mean (SD)	0.70 (0.17)	0.75 (0.16)	0.05 (0.10)
Single stance postobstacle (L; seconds), mean (SD)	0.62 (0.14)	0.60 (0.10)	–0.01 (0.12)
Total time (seconds), mean (SD)	3.64 (1.49)	4.03 (1.16)	0.39 (0.84)
Total failures max step height <16 cm (L), n (number of children)	1 (1)[e]	4 (2)[e]	3 (1)[e]
Total failures max step height <16 cm (T), n (number of children)	1 (1)[e]	15 (3)[e]	14 (2)[e]
Task 2: crossing			
Step length (cm)[c], mean (SD)	83.81 (7.11)	82.06 (9.32)	–1.75 (7.22)
Preobstacle distance (T; cm), mean (SD)	6.36 (4.55)	–5.91 (8.27)	–12.27 (8.87)
Postobstacle distance (L; cm), mean (SD)	3.29 (5.99)	13.82 (7.50)	10.53 (6.96)
Single stance preobstacle (T; seconds), mean (SD)	0.61 (0.14)	0.69 (0.17)	0.08 (0.15)
Single stance postobstacle (L; seconds), mean (SD)	0.54 (0.08)	0.54 (0.09)	0.00 (0.07)
Total time (seconds), mean (SD)	4.05 (1.26)	4.69 (1.11)	0.64 (0.79)
Total failures step length <51 cm, n (number of children)	14 (7)[e]	31 (10)[e]	17 (3)[e]
Task 3: balancing			
Step width (cm)[c], mean (SD)	5.36 (2.92)	6.41 (2.69)	1.05 (1.93)
Step length (cm), mean (SD)	52.73 (8.51)	47.31 (11.56)	–5.41 (8.45)
Double stance phase (%), mean (SD)	28.58 (5.35)	32.55 (6.05)	3.97 (6.39)
Total time (seconds), mean (SD)	4.44 (1.43)	5.31 (1.72)	0.87 (1.88)
Total failures step width >19 cm, n (number of children)	6 (3)[e]	5 (3)[e]	–1 (0)[e]
Task 4: circumventing			
Minimal shoulder-obstacle distance (cm)[c], mean (SD)	10.66 (3.36)	10.41 (3.77)	0.25 (4.44)
Total time (seconds), mean (SD)	5.25 (2.48)	5.76 (1.98)	0.50 (1.51)
Total failures minimal distance <2 cm, n (number of children)	3 (3)[e]	13 (7)[e]	10 (4)[e]

[a]The differences were calculated by subtracting the value of the physical setup from the value of the virtual reality setup. Consequently, negative differences indicate a lower value for the virtual reality setup.

[b]L: leading foot.

[c]Primary outcomes (also used to define the number of fails).

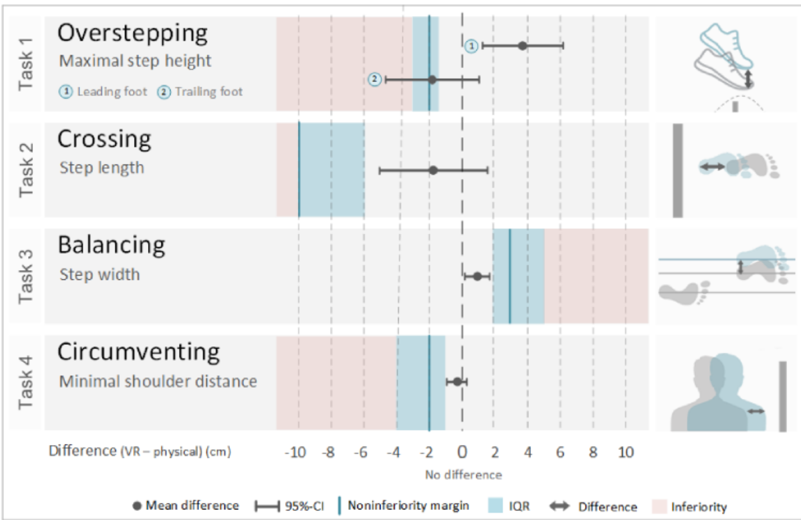
[d]T: trailing foot.

[e]The number of children that made these fails.

Noninferiority Analysis

We applied noninferiority analyses [37] to compare the differences in the primary outcomes between the VR and physical setups for each task according to the a priori defined noninferiority margins. As depicted in Figure 5, the noninferiority analysis revealed noninferiority for the leading foot and was inconclusive for the trailing foot when overstepping the obstacle. For crossing, balancing, and circumventing, the results of the statistical analysis showed noninferiority in all cases.

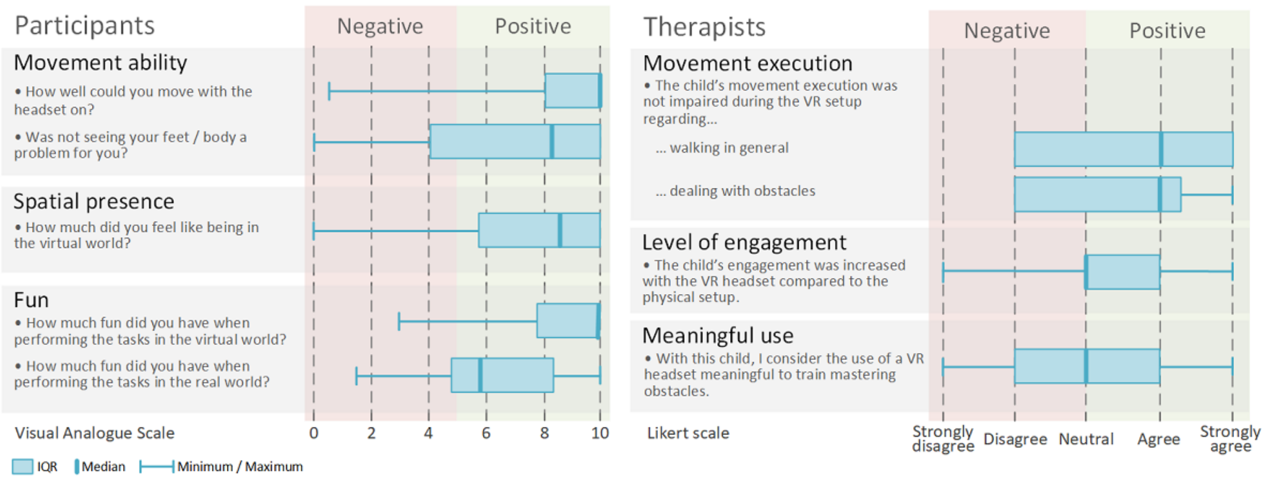
Figure 5. Noninferiority analysis for the primary outcomes. A negative mean difference indicates a smaller value in the virtual reality (VR) setup than in the physical setup. The noninferiority margins in blue represent the maximum difference between the two conditions while still considering the conditions to be equal. As long as the 95% CI of the mean difference does not exceed this margin, the VR setup is noninferior to the physical setup. Inferiority of the VR setup is assumed when the 95% CI touches the red inferiority area and, at the same time, does not cross the line of no difference between the two conditions.



Questionnaires

When asked how well the participants could move around using the HMD, 75% (15/20) of the participants scored ≥8 and did not feel restricted in their ability to move around. Not being able to see their body or feet was no problem (score ≥7) for most (14/20, 70%; Figure 6) participants. Most participants (14/20, 70%) felt physically present in the virtual scenario (score ≥7), even if the environment and the objects did not seem entirely realistic to them. The participants had fun in both conditions; however, the VR setup was rated significantly better (P<.001).

Figure 6. The participants' and therapists' views on the use of the virtual reality (VR) head mounted display (HMD) in physiotherapy.



According to the therapists, movement execution during the VR setup was not impaired in 65% (13/20) of the participants when walking normally or dealing with obstacles. The most common reason why therapists considered mild impairment in movement execution while wearing the HMD was a more cautious and slower gait pattern. The therapists perceived the level of engagement in the VR setup to be lower in 4 participants, similar in 7 participants, and higher in 9 participants. Therapists had ambivalent views regarding the meaningfulness of using VR to train for mastering obstacles. Reasons for considering the application meaningful included increased enthusiasm for movement, the challenge of altered visual control, and, therefore, the increased awareness of the children's bodies. Reduced speed, reduced focus on the given instructions, lack of feeling the edges of the obstacles, and consequences, such as stumbling when not lifting the foot high enough, were reasons against VR being a meaningful application for some participants. The balancing task was the task most often considered meaningful by the therapists.

Discussion

Principal Findings

This study aimed to provide information on whether a VR setup is feasible and motivating to induce and practice movements that are needed to master real obstacles in children and adolescents with gait disorders. Furthermore, this study aimed to evaluate which kinds of everyday walking activities are appropriate to be practiced in such a VR setup. To achieve these goals, a virtual and a physical condition, the latter resembling therapeutic setup, were compared with each other. We chose a noninferiority analysis to quantify the differences between spatiotemporal parameters defined a priori. This noninferiority analysis revealed that for 3 of the 4 walking tasks encountered in everyday life, mastering the virtual obstacles provided by an HMD was noninferior to mastering the physical obstacles. Thus, the results suggest that children and adolescents with gait disorders can practice crossing a wide gap, balancing on a narrow area, and circumventing stationary obstacles appropriately in a virtual setup. Furthermore, overstepping a virtual obstacle with the leading foot was also noninferior; only the results for the trailing foot were inconclusive.

Comparison to Previous Work

Normal Walking

The participants walked slower in the VR compared to the physical setup, which corresponds to the findings of Almajid et al [38] and Horsak et al [39]. Almajid et al [38] found that younger and older adults needed significantly more time to perform the timed up-and-go test when wearing an HMD, even without the projection of a virtual scene. In the study of Horsak et al [39], healthy individuals also demonstrated a slower walking pattern when walking in an overground VR environment compared to a real environment. This effect should be considered when wearing an HMD in rehabilitation. Still, the mean gait speed during normal walking in the VR setup was within the range of self-selected walking speed in children aged between 7 and 14 years with CP (GMFCS levels I and II) and TBI [25-27]. Although the participants' FMS and FAQ values were in the upper range of the scales, their gait speed in the physical setup was still below the average of typically developing youths [40]. The reduced gait speed in the VR setup was accompanied by a decreased step length and a slightly prolonged double stance phase.

The mean step length in both conditions was above the average step length of 50 cm reported for children aged between 7 and 14 years with CP (GMFCS stages I and II) and TBI, but below the average step length of 68 cm reported for typically developing children of the same age [25-27]. The double-stance phase of our participants during normal walking was in both conditions remarkably longer than in typically developing youths aged between 5 and 21 years [40]. Several therapists observed that the movements of their patients were constrained at the beginning of wearing the HMD, especially during normal walking. This could be because more than half of the participants had never worn a VR HMD before participating in this study. However, the difference in double stance time between the VR and physical setup was considerably smaller compared to the difference in double stance time between typically developing individuals and individuals with blindness [41].

Overstepping

First, the noninferiority analysis demonstrated that the maximal step height of the leading foot when stepping over the virtual obstacle was noninferior compared to the physical obstacle. This indicated that participants raised their leading foot to the same height when overstepping the virtual obstacle. However, they lifted their trailing foot considerably less high in the VR condition. This finding is supported by a study by Hagio and Kouzaki [42], in which healthy adults overstepped a virtual and physical obstacle. While the vertical height of the leading foot correlated highly (r=0.77) between the VR and physical condition, the correlation was lower for the trailing foot (r=0.47). As Kim et al [43] describe, an explanation for the difference between the leading and trailing foot in the VR setup could be the missing visual information regarding the height of the foot and, therefore, not being able to correct its height. Further results from Hagio and Kouzaki [42] suggest that visuomotor transformation in the leading leg contributes to a motor plan for trailing limb toe trajectories while stepping over an obstacle.

Crossing

Second, although the primary outcome parameters were mostly comparable between the virtual and physical setups, the movement was slightly displaced when overstepping or crossing the obstacles in the VR setup. Participants stepped too close to the obstacle or even over the edge of the obstacle. In general, however, the steps were almost the same length and height in the VR and physical setups, just at different locations. As the HMD blocks out the physical world, a lack of spatial information about the environment and the body's state relative to the environment could be a reason for the slightly displaced movement execution in the VR condition. However, most participants indicated on the VAS that not seeing their feet or body was not a problem for them. Furthermore, almost half of the participants scored 100% on the FM assessment, which tests the proprioception of the lower extremities. Nevertheless, using a fully immersive VR, Kim et al [43] investigated how visual information about the lower extremities is integrated with information about the environment to facilitate successful obstacle avoidance in healthy young adults. Their study revealed that visual information about the lower extremities promoted more consistent behavior while stepping over an obstacle.

Balancing

Third, in both conditions of the balancing task, the step length was slightly decreased, and the double stance phase increased compared to the corresponding normal walking condition. As reduced step length and prolonged double stance phase are considered indicators of reduced balance [41], we can assume that the participants made a real effort to balance over the physical and virtual obstacles. Although the participants rated this task as rather difficult, they produced only a small number of failures. The step width, which we considered crucial for successfully completing the balance task, was, on average, 1 cm larger in the VR than in the physical setup. However, the noninferiority analysis illustrated that the step width in the VR setup was noninferior to that of the physical condition. Therefore, we assume that the participants successfully balanced over the obstacle in VR and in reality.

Circumventing

Fourth, when moving in public areas, it becomes essential to circumvent stable objects or moving people, have a stable base of support, and balance in a narrow space. Several studies have investigated the critical point (the ratio between aperture width and shoulder width at which a shoulder rotation occurs at the time of crossing) and safety margin (the space that is maintained between the shoulders and the obstacles at the time of crossing) for aperture crossing [30,44]. Whenever the participants had to rotate their shoulders, they maintained a larger safety margin when crossing [44]. For example, the critical point for circumventing poles, calculated from the mean shoulder width of the participants and the distance between the poles, was a ratio of 1.3 [44]. The present study's ratio between the aperture width and the mean shoulder width equaled 1.6. Assuming that participants did not rotate their shoulders at such a ratio, the safety margin was slightly less than the 30 cm observed in the study of Hackney et al [30]. However, the safety margins of 10 cm of the VR and physical setup equal those of young, healthy adults who had to avoid poles with an aperture/shoulder width ratio of 1.3 [44]. The results of the noninferiority analysis suggest that participants successfully circumvented the obstacles in the VR setup. In addition, Hackney et al [45] recently showed that individuals who had to avoid obstacles in a virtual scenario wearing an HMD behave similarly with virtual poles and avatars, indicating generalization to a wide range of applications in VR.

Questionnaires

In summary, the participants were very positive toward training walking tasks in a VR setting. Due to its game-like features, the participants experienced significantly more fun in the VR than in the physical setup. How VR-assisted physical therapy might affect a participant's enjoyment and motivation over time needs to be investigated in the future. The physiotherapists did not observe a difference in the participants' engagement level between the VR and physical setup, indicating that the participants made similar efforts in both conditions. Thus, a comparison between the 2 conditions was feasible.

Limitations

This study has several limitations. First, the group size of 20 participants was rather small. However, it is in line with recommendations [22], as the purpose of this study was to provide information on whether a VR setup is feasible and motivating to induce movements that are needed to master real obstacles and which kinds of everyday walking activities are appropriate to be practiced in such a VR setup. To examine the appropriateness and effectiveness of VR training, more participants would have to be included in the next study. Despite the considerable heterogeneity of this study, noninferiority could still be shown in 3 tasks.

Second, even though the dimensions and locations of the obstacles did match in both conditions, the different visualizations of the physical setup and the VR setup could have impacted the participants' gait. However, this limitation was chosen intentionally, as we wanted the obstacles to look like they would appear in future applications.

Third, a panel of experts decided on specific margins to define noninferiority, as no reliable reference values for the noninferiority analyses existed in the literature. In order to minimize this limitation for a further project, additional external experts could be asked and added to the panel.

Fourth, the gait laboratory is frequently used for clinical gait analysis. Therefore, the Vicon cameras pointed to the middle of the room. Since the recording area for this study was slightly broader, some markers disappeared at times from the measurement volume, which is one reason why some participants had to complete more than 8 rounds to record sufficient valid trials. Consequently, the high number of repetitions might have bored and fatigued some participants, which might have decreased their concentration toward the end. With verbal input for the participants and breaks between the trials if needed, we tried to keep the number of trials and the fatigue of the participants as low as possible.

Fifth, a slight misalignment between the real and virtual setups might have introduced an unknown error in calculating the parameters. We calibrated the alignment immediately before putting the HMD on the participant's head to minimize this error.

Sixth, the feet were not visible to the participants in the VR condition. We assume that a lack of spatial information rather than impairments in proprioception might have caused failures such as stepping over the edge, as the FM assessment did not indicate major lower limb proprioception impairments in the participants. A further study investigating the influence of foot projection in VR could provide further information regarding the influence of the visability of the feet.

Conclusions

This is the first study showing that children and adolescents with gait disorders master various obstacle tasks, such as overstepping a bar, crossing a wide gap, balancing on a narrow area, and circumventing stationary obstacles, similarly in VR and physical conditions. Only the results for the trailing foot in the overstepping task were inconclusive. Therefore, we conclude that using a VR setup to practice mastering obstacles with children and adolescents with gait disorders is feasible and motivates them to practice everyday walking tasks. In the long run, the feasibility of using HMDs in a clinical therapy setting, patient motivation over a longer period of time, the appropriateness and effectiveness of such VR interventions, and identifying potential responders to such interventions require further investigations.

Acknowledgments

The authors would like to thank the participants and their physiotherapists for the time and effort they have dedicated to this project. The project was financially supported by the J&K Wonderland Foundation (Steinhausen, Switzerland) and the Promedica Foundation (Chur, Switzerland).

Data Availability

The data sets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

All authors contributed to the conceptualization and methodology of the study. CA-R obtained ethical approval. SR performed participant recruitment. SR, AK, and CA-R assisted with the measurements. SR and AK were involved in the data analysis. SR provided the figures. SR and CA-R were responsible for writing the first draft. All authors critically reviewed the manuscript.

Abstract

Background: Digital health technologies have the potential to improve health outcomes for older adults, especially for those recovering from stroke. However, there are challenges to developing these technologies, such as *data absenteeism* (where older adults' views are often underrepresented in research and development) and *technology chauvinism* (the belief that sophisticated technology alone is the panacea to addressing health problems), which hinder their effectiveness.

Objective: In this study, we aimed to address these challenges by developing a wearable glove integrated with culturally relevant exergames to motivate older adults to exercise and, for those recovering from stroke, to adhere to rehabilitation.

Methods: We conducted a moderated usability study with 19 older adults, of which 11 (58%) had a history of stroke. Our participants engaged in a 30-minute gameplay session with the wearable glove integrated with exergames, followed by a quantitative survey and an in-depth interview. We used descriptive analysis to compare responses to the System Usability Scale between those who had a history of stroke and those who did not. In addition, we analyzed the qualitative interviews using a bottom-up thematic analysis to identify key themes related to the motivations and barriers regarding the use of wearable gloves for rehabilitation and exercise.

Results: Our study generated several key insights. First, making the exergames exciting and challenging could improve exercise and rehabilitation motivation, but it could also have a boomerang effect, where participants may become demotivated if the games were very challenging. Second, the comfort and ease of use of the wearable gloves were important for older adults, regardless of their stroke history. Third, for older adults with a history of stroke, the functionality and purpose of the wearable glove were important in helping them with specific exercise movements.

Conclusions: Our findings highlight the importance of providing contextual support for the effective use of digital technologies, particularly for older adults recovering from stroke. In addition to technology and usability factors, other contextual factors such as gamification and social support (from occupational therapists or caregivers) should be considered to provide a comprehensive approach to addressing health problems. To overcome data absenteeism and technology chauvinism, it is important to develop digital health technologies that are tailored to the needs of underserved communities. Our study provides valuable insights for the development of digital health technologies that can motivate older adults recovering from stroke to exercise and adhere to rehabilitation.

Introduction

Background

There has been an increasing trend in the development and implementation of digital health technologies for older adults, known as *gerontechnologies*. However, there are challenges to developing these technologies, such as *data absenteeism* (where older adults' views are often underrepresented in research and development) and *technology chauvinism* (the belief that sophisticated technology alone is the panacea to addressing health problems) [1]. Gerontechnologies aim to assist older adults in healthy aging through the promotion of physical exercise and empowering them to maintain a certain level of functional independence throughout their later years and delay the onset of frailty [2,3]. For instance, examples of such technologies are the use of *exergames* to motivate physical activity or virtual reality technology for the purposes of pain management and therapy [4,5]. Other types of health technologies, such as wearables, are also becoming common among older adults. Existing commercial products such as FitBit (Google, Inc) and Apple Watch make it easy for older adults to track and monitor their health [6]. To date, such digital health technologies targeted at older adults have received substantial attention and investments, ranging from US $1.1 billion to US $3.1 billion between 2019 and 2020, and it is expected to grow in the next few years [7,8].

While there are several studies documenting the positive impact of digital health technologies on older adults' physical and mental health, there are 2 key gaps in existing public health literature [9,10]. First, very few studies have explicitly addressed the problems of *data absenteeism* and *technology chauvinism*. Second, as many of the existing health technologies are developed in a clinical setting for data collection, few researchers have examined how to develop technology that is fun, relatable, and equitable for the older adults [11]. The overall objective of the study was to address the problem of data absenteeism and technology chauvinism in the development of digital health technologies—a stretchable wearable glove integrated with exergames—by examining the motivations and barriers of older adults without a history of stroke and those recovering from stroke in the use of such technologies through the lens of equity.

Theoretical Framework: Data Absenteeism and Technology Chauvinism

While the momentum to build and develop different digital health technologies by academia or industry is noteworthy, it is important to adopt the lens of equity in building such technologies for older adults. Older adults are often disadvantaged as compared to the general and younger population in terms of their access, use, attention, and processing of health information from digital health technologies [12]. Not giving attention to the context in which such digital health technologies are developed and introduced may result in the unintentional consequence of exacerbating the health disparities between those who are well resourced and those with less resources [13]. In advocating for technology and big data use through an equitable lens, Lee and Viswanath [1] argued for the need for health communication and informatics scholars and technology developers to pay attention to the 2 perennial problems: data absenteeism and technology chauvinism.

Data absenteeism refers to a situation where data from underserved populations are not represented. For example, recent studies of large-scale national programs that use wearables to boost physical activity, such as Singapore's National Steps Challenge, which offers free wearables and gamified mobile apps to encourage participants to walk 10,000 steps, show that older adults are often underrepresented in the data. This gap aligns with previous findings indicating that users of such technology tend to be younger and more educated and possess a higher degree of eHealth literacy [14,15].

In contrast, *technology chauvinism*, refers to the blind faith in big data systems or technology platforms in addressing health disparities. One of the most infamous cases was the use of Google Flu Trends to predict the outbreak of influenza, where search trends overestimated the prevalence of influenza as compared to official sources [16,17]. To address the problems of data absenteeism and technology chauvinism in the use of digital health technologies to improve physical activity among healthy older adults and those recovering from stroke, it is vital to involve them from the start of the research process and engage them to codevelop wearable gloves and exergames. This is consistent with studies of the principles of user-centered design, where it is crucial to be intentionally inclusive in the process by incorporating the target group as full partners in the decision and design groups as part of the research process. This ensures that their participation and input are not merely symbolic or exploitative, but rather meaningful and beneficial for them as a whole [18].

Context of the Study: Motivating Rehabilitation and Exercise Using Wearable Gloves and Exergames

In recent years, there has been a surge in the exploration and creation of wearable glove technologies aimed at enhancing exercise motivation and aiding stroke recovery. The smart glove industry is projected to reach a value of US $3.9 billion by 2028, with an annual growth rate of 10% [19]. These innovative gloves are developed in 2 main styles: rigid hand exoskeletons and soft assistive gloves. The latest soft rehabilitation gloves are being designed to support bending, straightening, and spreading or closing of each finger to address the difficulties some patients face in performing hand grabbing motion [20].

There are several existing studies that have documented the efficacy of the use of wearable gloves for patients with stroke in improving upper limb movement across several metrics. For instance, Yurkewich et al [21] tested the Hand Extension Robot

Orthosis (HERO) Grip Glove among 11 participants with difficulty in finger extension in their poststroke journey and found that the glove significantly improved their water bottle grasp and index finger movement and extension and enabled individuals who are lacking grip strength to handle blocks, use a fork, and write with a pen. Wang et al [22] conducted a study where 69 patients with severe upper limb impairment following a stroke were divided into three treatment groups: (1) repetitive transcranial magnetic stimulation, (2) soft robotic glove use, and (3) standard treatment, and the results showed that the group assigned to use the robotic gloves achieved better upper extremity scores compared to those in the standard treatment group.

Given that the use of wearable gloves is comparable to neurostimulation or neuromodulation techniques in improving movements for patients with stroke, other research teams have incorporated the use of other forms of stimulation (ie, tactile sensations) in wearable gloves to improve its efficacy. Seim et al [23] conducted a pilot study involving 16 patients with chronic stroke, where participants were randomly placed into 2 groups for an 8-week period: one group received a vibrotactile stimulation glove, and the other group received a similar glove without vibration (acting as the control condition). The outcomes demonstrated that those using the vibrotactile stimulation glove experienced notable enhancements in finger mobility and improvements in the range of motion of their elbows and shoulders compared to the control group.

While these studies have found improvements in upper limb movements through the use of wearable gloves in their respective sample, it was unclear why or how they were effective. In a systematic review of wearable technology for improving activity in adult patients with stroke, Parker et al [24] found that, overall, very few studies have found evidence for the use of wearable gloves to improve rehabilitation. Thus, a significant oversight in many recent advancements in these state-of-the-art wearable gloves is the lack of consideration for how their target user group might engage with these technologies and the probability of their adoption as consumer products. Examples of these gaps in knowledge would be ideas about what could motivate a potential consumer to purchase the wearable glove product and incorporate it into their daily rehabilitation routine, and ultimately, what could be the barriers that prevent them from making the gloves a staple part of their rehabilitation journey. Examining how specific design features affect the perceived usefulness and perceived ease of use of the product could also affect their decision to adopt these fancy wearable gloves into their routines [25].

Addressing the Gaps in Wearable Gloves Research: Integrating Wearable Gloves With Exergames

One of the ways to improve rehabilitation through wearable gloves among older adults is through the gamification of the rehabilitation process. This is done through the use of specialized video games that simulate exercise, known colloquially as *exergames*. It is an area of health technology that has gained interest in recent years, especially among older adults. According to Harrington et al [26], the use of exergames may address barriers to older adults being physically active and exercising. These video games demand that the player physically moves their body to advance within the game or program [27]. Therefore, the implications surrounding the movement-centric nature of the gaming technology means that it has the potential to be used in rehabilitative health care practices also.

Existing systems such as the Nintendo Wii Fit, a low-cost commercial gaming system, have been found to be effective in improving clinical measures of balance in older adult patients [28,29]. Thus, exergames are able to transform exercise, through the process of gamification, by introducing alternative motivators such as entertainment and encouragement into activities that would otherwise be considered as physically strenuous [30]. A study by Yu et al [31] found that exergames as an intervention using the Xbox Kinect significantly improved the physical activity level, leg strength, and cardiopulmonary endurance of healthy older adults. Although exergames make physical exercise and rehabilitation more accessible, there are still obstacles to the uptake of these innovations in health technology among older adults.

One key aspect in which exergames have been shown to aid the rehabilitation process is adherence to exercise. Research by Oesch et al [32] on the difference between conventional self-regulated exercise and exergames revealed that exergames showed heightened levels of adherence to rehabilitation exercise routines within the first 2 weeks of introduction. However, the same study also showed that the motivation levels reversed after the first 2 weeks.

Understanding the Motivations and Barriers

One of the main goals of using a gamified wearable glove is to further motivate patients and older adults who are undergoing hand rehabilitation by increasing the movement of their hands through gameplay using wearable gloves and, subsequently, reduce the barriers to use of technology through seamless incorporation of the gaming medium. In addition, the hand movement data that the gloves are capable of collecting can further assist health care professionals in providing focused rehabilitation activities to their individual patients.

As such products are aimed to be used by patients and older adults, one must also consider motivations and barriers to adoption. This is because new technologies (ie, the wearable gloves) may present potential problems from the perspective of the consumers (older adults and health care professionals), such as being incompatible with existing products or technologies and individuals' needs [33]. In this regard, health care technology has never really seen the introduction of gloves with the technological capability of collecting vast amounts of data from each exergaming session. Traditionally known as "haptic gloves," these wearable devices offer force feedback and originated in the virtual reality gaming industry. They have the potential for gathering data for video game technology developers, although their application in rehabilitation and health care is quite rare [34]. Thus, to understand older adults' needs, it is paramount to investigate their motivations and barriers regarding the use of wearable gloves and exergames and whether their past experiences with rehabilitation have any effect on their perception of these products.

Study Objectives

This study aims to answer the following research questions (RQs) regarding the general usability of these wearable gloves in the context of the rehabilitation process:

- RQ1: What are the motivations and barriers toward the use of an integrated wearable glove system with exergames?
- RQ2: What are the differences between older adults without a history of stroke and older adults with a history of stroke regarding their perceptions about an integrated wearable glove system with exergames?

Methods

Wearable Glove and Exergame Development

Before the study, the research team worked with a start-up company that specializes in the development of rehabilitation gloves to develop a wearable data glove that could be integrated with exergames. Figure 1 shows the glove prototype that was developed for both survivors of stroke and older adults, specifically to capture hand motion for gesture recognition and for data visualization with the help of the multiple sensors integrated within the gloves. The bendable and flexible sensors embedded in the glove cover the joints on each individual finger and capture bending data signals from finger movement. This technology supports the training of specific wrist, hand, or finger movement and finger joints mobilization activities that is commonly found in the rehabilitation process, as seen in Figure 2.

The gloves were designed to be integrated with existing in-house exergames developed by the research team at the university. The exergame system consists of exercises and games that could be personalized for each individual user to suit different durations and number of repetitions for a particular exercise [35,36]. These exergames were specifically created to suit older adults to promote successful aging by motivating exercise, where they aim to improve physical and cognitive functional capacity through easy-to-follow actions and interface and culturally relevant game themes [37].

While there were a series of 9 exergames developed to date, the research team integrated the wearable glove with 1 exergame called “Chinatown Race” (Figure 3), where players are required to dodge barriers while aiming to collect coins to score points while running down a road in an online Chinatown setting. The avatar is controlled through rotation of hand and finger movements that would be detected by the wearable glove. As shown in Figure 2, participants had to perform movement 5 and movement 8 to slide the avatar toward left and right, respectively. To catch the lantern power-ups in the game, participants had to flex their pointer finger, as seen in movement 2.

Figure 1. Prototype of the wearable glove.

Figure 2. Specific hand motions for rehabilitation: (A) idle, (B) finger trigger, (C) up, (D) down, (E) right side, (F) right, (G) left, and (H) left side.

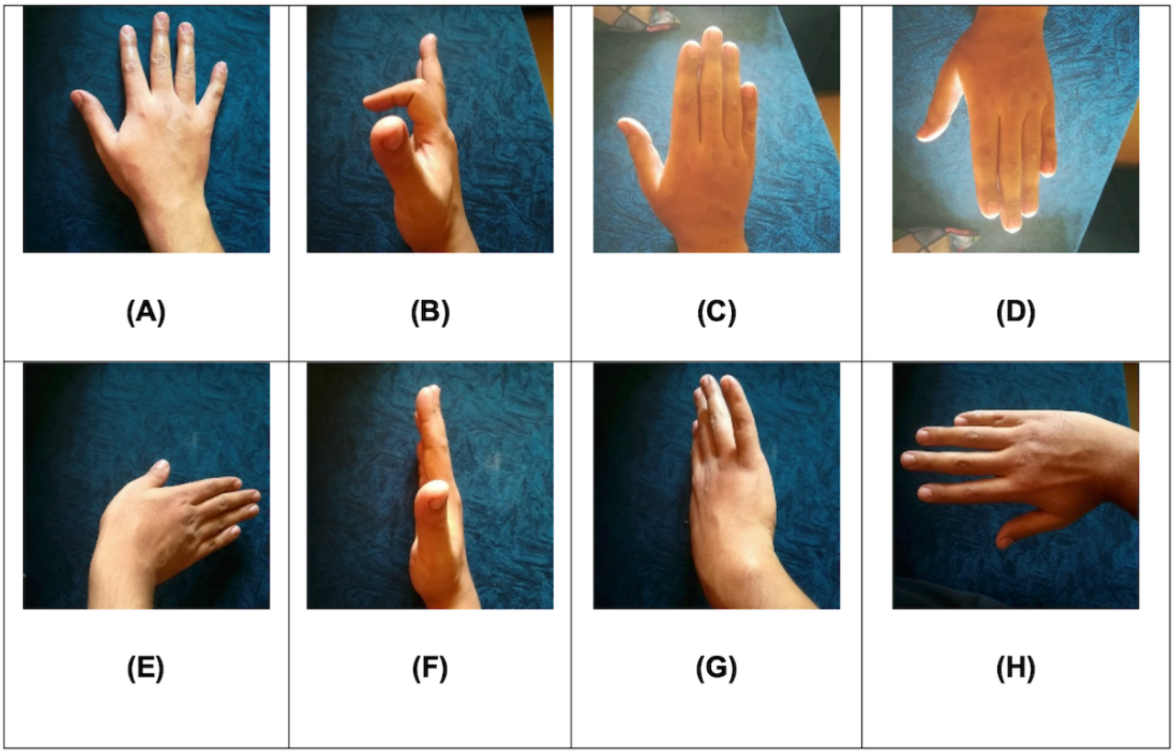

Figure 3. Screenshot of the Chinatown Race gameplay.

Participants and Recruitment

After the development of the wearable glove and integration with the exergame, we conducted a moderated usability study with 19 participants aged ≥50 years, recruited from an older adult activity center with a convenient sample of individuals with and without a history of stroke (n=11, 58% had a history of stroke and n=8, 42% did not). The average age of the participants was 66.8 (SD 4.5) years, and 53% (10/19) were women and 47% (9/19) were men. Of the 19 participants, 13 (68%) belonged to the Chinese ethnic group, while 4 (21%) belonged to the Malay ethnic group. There was also 5% (1/19) Burmese and 5% (1/19) Singh individuals who participated in the study. Overall, 74% (14/19) of the participants were considered to have lower levels of education below an “A-Level” certification. The inclusion criteria for the study were that participants had to be (1) aged at least 50 years and (2) willing and able to use the wearable glove to play the designated exergames and participate in a qualitative interview and survey. The moderated usability sessions were conducted in either English or Chinese depending on the language preference of the participants.

Ethical Considerations

Before the study, we obtained approval from the institutional review board of from the institutional review board of Nanyang Technological University, Singapore (IRB-2022-405). Written informed consent was also obtained from the participants. They were briefed about the procedures involved in the use of the wearable glove and exergames; they were also informed that the risks were minimal in the gameplay and that they could exit the study without any penalty. Upon successful completion of all the tasks in the moderated usability study, the participants were given a voucher worth SGD 50 (US $37) as incentive. To safeguard participants' privacy, the data were de-identified before analysis.

Study Design and Procedure

The moderated usability study session was designed to be a 1-hour long session, which consisted of a series of tasks involving participants' use of the wearable glove and exergame, led by 1 moderator and 1 technical specialist. The moderator guided the participants through the required activities and conducted the interview and survey upon the completion of the tasks. The technical specialist ensured that the devices were working as intended and handled all the technical difficulties that arose during the session.

In the session, participants were required to complete the following tasks:

1. Navigation of wearable glove and exergames: Participants were taught the basics about how to use the wearable gloves and control functions on the exergame dashboard.
2. Chinatown Race gameplay: Participants had to use the wearable glove to engage in Chinatown Race gameplay, where they had to move their avatars to avoid barriers and collect lanterns to score points by using hand and finger rotation.
3. Qualitative interview: This is a qualitative interview through which the moderator obtained feedback about participants' attitude and perceptions regarding the wearable glove and exergame.
4. System Usability Scale (SUS) survey: The moderator administered a short SUS scale, which is a 10-item measure of the usability of systems.

Measures of SUS

The SUS scale (Cronbach α=.95) was adapted from Chu et al [37], and participants provided their responses to the following items measured using a 5-point scale (1=strongly disagree and 5=strongly agree): (1) I think that I would like to use the glove frequently, (2) I found the glove unnecessarily complex, (3) I thought the glove was easy to use, (4) I think that I would need the support of a technical person to be able to use the glove, (5) I found the various functions of the glove to be well integrated with the game, (6) I thought there was too much inconsistency with the glove, (7) I would imagine that most people would learn to use the glove very quickly, (8) I found the glove very cumbersome to use, (9) I felt very confident using the glove, and (10) I needed to learn a lot of things before I could get going with the glove.

The qualitative interviews were analyzed using a bottom-up thematic analysis to identify key themes regarding the motivations and barriers toward the use of wearable gloves for rehabilitation and exercise among older adults who had a history of stroke and those who did not. The thematic analysis was performed in accordance with the steps described by Proulx et al [38] regarding usability testing of wearable gloves: (1) the recordings were transcribed, (2) the transcript was first read by a member of the research team to develop the coding frame, and (3) the coding frame was refined to identify different types of motivators and barriers regarding the use of wearable gloves and exergames. Next, descriptive analysis was conducted to compare the differences in responses to SUS items between older adults who had a history of stroke and those who did not. This is consistent with the studies by Tong et al [39] and Casterlé et al [40].

Results

Competition as a Motivation

RQ1 involves the motivations and barriers toward the use of a wearable glove integrated with exergames. Multimedia Appendix 1 shows the summary of the mean scores of participants' responses to SUS items. From the qualitative interview, one of the key motivations identified was that a certain *degree of competition* was required to ensure that the older adults are engaged and motivated. For instance, the inclusion of features such as collectible coins, lanterns, and a scoring system presented a form of incentive for the participants to continue persevering to complete the game. These features made the game fun, as there was a tangible goal associated with each movement that they made within the game. Some even noted that it spurred them to strive to get better at the game, as a participant mentioned the following:

> *To score the highest score, that is very exciting.* [Participant 10; with a history of stroke]

As such, the competitive element of the gameplay objectives plays a key role in motivating older adults to continue playing and, in essence, adhere better to their rehabilitation practices. However, they need to be familiar enough with the game systems and movements for them to attribute poor performance with their own lack of skill rather than an external device, which would otherwise deter them from continuing to play the game.

Helplessness as a Barrier

Regarding RQ1, we found that a significant barrier to using the integrated wearable glove is the feeling of helplessness, particularly if it is in the context of technical difficulties. While the participants mostly agreed that the exergame navigation was easy to understand because of the simple nature of the menu layout and user-friendly, large, and visible buttons, the older adults were not familiar with the movement system of the wearable gloves. Therefore, while they had very clear intentions regarding navigating the menu, the disconnect between intention and execution made the process a lot more difficult than intended for the participants. This became even more apparent when participants were asked to describe if anything was confusing about the gameplay movements of Chinatown Race, to which many expressed the following general sentiment:

> *Not confusing, only unfamiliar with the controls [in reference to glove].* [Participant 2; without a history of stroke]

Therefore, it was evident to a certain degree that the overall experience of playing the game was hindered because the gameplay affordances provided by the glove apparatus were not intuitive to the participants. This, in turn, had a demotivating effect on the participants as their ultimately poor gameplay would then be attributed to an external factor such as the glove and the game system, making them feel somewhat helpless as they struggled to competently dodge all the obstacles and collect the harder-to-collect lantern items that required them to hyperextend their thumb. This is exemplified when looking at "necessity of support" (ie, question 4 of the SUS scale), where the participants were asked to rate how much technical support they would require to use the gloves. The patients with a history of stroke were more likely to want to get more help (mean 2.45, SD 1.51) as compared to those who had no history of stroke (mean 3.45, SD 1.37). This could be attributed to how older adults with a history of stroke may have experienced feelings of helplessness using novel rehabilitation technologies in the past and therefore might show an aversion to new technologies.

RQ2 deals with the differences between older adults without a history of stroke and those with a history of stroke regarding their perceptions about the glove integrated with exergame. Our findings indicated that the rehabilitation history influenced the level of critique from user groups when engaging with the integrated glove. The comfort level of the glove was a major theme; in the SUS questions, participants who did not have a history of stroke indicated that comfort level was very important (mean 3.78, SD 0.97) as compared to those with a history of stroke (mean 4.18, SD 0.60).

When asked about what could be improved to make the overall experience of playing Chinatown Race using the wearable gloves better, there was a noticeable difference regarding the category of improvement suggested by both groups. The comments by participants with a history of stroke tended to pertain toward making the controls more intuitive:

> *Improve the controls, like grabbing action for the lantern instead of thumb extension.* [Participant 4; with a history of stroke]

In contrast, comments by participants who did not have a history of stroke were more likely related to areas such as game design and esthetics (collectible items or general color contrast):

> *Barrier needs to be bigger in size and have more contrasting colours so that it can be seen from the distance.* [Participant 19; without a history of stroke]

This difference could suggest that older adults with a history of stroke were more focused on the movements associated with the gloves and what their actual bodies were doing in relation to the game than whether the game was appealing enough to be played effectively. A possible attribution for this difference could be how the older adults with stroke have an acute awareness that the exergame is a tool to be used in a long and tedious process that they have experienced previously, and therefore, they have deeper awareness of what is essentially important in the actual process of rehabilitation. In contrast, the older adults without a history of stroke could be looking at the exergame and the wearable gloves as just another gaming device, and therefore, their criticism would be directed toward the exergames as a game than as a rehabilitation tool.

Finally, for RQ2, our results showed that the valence of anticipation regarding using a new device varies based on their history with stroke. This is seen when looking at "intention to frequently use," which refers to question 1 of the SUS scale used in the survey. It must be noted that the group without a history of stroke indicated more eagerness to use the glove with exergame (mean 4.38, SD 0.71) as compared to those with a history of stroke (mean 3.18, SD 1.47). It could be because participants who have had stroke before maintained a level of cynicism toward such novel methods for stroke rehabilitation as they have been through the rehabilitation process previously. Furthermore, it might be due to barriers related to perceptions of the ease of use. Participants without a history of stroke indicated that the glove was easy to use (mean 4, SD 1.50), and the score was slightly higher than those with a history of stroke (mean 3.64, SD 1.50). It might also be due to the visual esthetics, as there is a "box" attached to the glove that contains the wiring. A participant noted the following:

> *The box is big and is not needed...The extra electronic devices seem delicate and can break.* [Participant 9; with a history of stroke]

While the box itself is safely secured and presents no actual hindrance to the gameplay experience, the apparently excessive amount of gadgetry can scare older adults who are not familiar with the durability that most present-day technology have and, at worst, can incite a certain fear response within them to abstain from handling something they think can break any minute.

Discussion

Principal Findings

Several key findings were generated from this study. First, this study addresses the problem of data absenteeism and technology chauvinism by engaging older adults— those with and those without a history of stroke—to provide insights into the potential motivations and barriers regarding the use of integrated wearable glove with exergame solution for rehabilitation and exercise at the early stages of the development process. Most notably, while technologies such as wearable gloves and exergames play a pivotal role in the rehabilitation process, it is reductionistic to assume that the technology itself would be the panacea to addressing health issues. For instance, although older adults with and those without a history of stroke indicated that the glove and exergames were well integrated, we found that individuals who have a history of stroke were more likely to indicate that they would still require help in operating the wearable glove compared to those who have not experienced stroke, which was perceived to be complicated. This finding is supported by the "blind faith" aspect of technology chauvinism research: if technology is offered as a solution in isolation without paying attention to the larger social context of the participants, it would not be effective [13]. This is supported by our findings where older adults with a history of stroke indicated that they would need the support of a technical person to be able to use it effectively and that it could be unnecessarily complex. Thus, solutions that embrace the development and implementation of wearable gloves with exergames need to consider designing the technology such that it can be used in a community setting by tapping into the social and support networks of older adults as co-users to improve adherence and uptake. This is consistent with the study by Proulx et al [38], where they examined occupational therapists' perceived usability and utility of a similar wearable glove for rehabilitation. In their study, while the researchers found that the occupational therapists rated the usability of such gloves ranging from "moderate to good" on the SUS, they shared that the gloves would be challenging for patients if they did not have the assistance of a therapist, owing to the physical and cognitive deficits of patients with stroke. The therapists also suggested that the development of wearable gloves would need to account for different contexts, such as using the gloves with therapists or with the assistance of a caregiver.

Second, it was noted that although older adults indicated that the gloves were relatively easy to use and that they intend to use them frequently, the comfort level while using the glove is an important factor for older adults with a history of stroke. This is corroborated by existing studies of technology acceptance and usability, which suggests that the practicality of use is a fundamental cornerstone in the acceptance and integration of technology into a daily routine. Our finding is consistent with that of the study conducted by Yurkewich et al [21], where they designed the HERO Grip Glove to help patients with stroke to perform activities of daily living and finger movement. While participants reported that they were relatively satisfied with the glove in terms of safety, security, and general ease of use, they had the lowest satisfaction regarding the ease of wearing the glove.

Third, we found that it is crucial to consider how gameplay could motivate or demotivate older adults from using wearable gloves. Existing studies of commercial device-based hand rehabilitation for patients with stroke have shown that game-based training using wearable gloves was generally positive in improving hand function and that they would be received favorably as they would be perceived as entertaining [41]. However, our study showed that the design of gameplay would need to aim for a fine balance in managing the difficulty level for a diverse group of patients and players, such that players would find the game challenging enough to sustain their interest, but it would not be very complex to demotivate them. This is important because our results showed that some older adults could be easily demotivated by some of the gameplay scenarios, especially when they feel that they cannot achieve the objectives (ie, collecting lanterns and points and avoiding barriers) or when their perceived expectations of their personal performance do not match with their scores. This results in some of them being demotivated, not enjoying the gameplay, and feeling helpless as they felt that there was nothing they could do to improve their scores.

Finally, it could be observed that individuals with a history of stroke show a stronger aversion to using rehabilitative technology and would thus require more assistance and technical support. This is an interesting as it suggests that those with previous experience with such novel rehabilitative technology may have a predisposed resignation that they would not be able to fully use these new technological methods in their recovery and would thus rather heavily rely on some form of instruction or expertise in conducting the rehabilitation exercises. Patients with a history of stroke have experienced rehabilitation in the past and thus could experience resistance to new rehabilitation technology due to a bias or preference to use what they are already familiar with [42].

In the case of patients with a history of stroke, they might prefer to use something that worked for them in the past because there is precedence of that working. Thus, getting used to a completely new device in stroke rehabilitation presents a level of psychological uncertainty or risk perception associated with the new method and would thus cause them to feel like they may not be able to adapt or manage it efficiently without proper assistance [43].

Implications

The theoretical implication of the findings from this study has shown that the motivation levels toward new technology among a homogenous group of people can differ depending on their personal experiences related to the purpose of the proposed technology. For instance, in this study, it was demonstrated that even among older adult patients, the mere experience of a stroke altered their perception toward the wearable gloves by a significant degree compared to those who did not have a history of stroke. Therefore, it is crucial that future studies consider medical conditions or individuals' experiences when designing health technologies.

The practical implication of the findings of this study illustrates how future exergames can be properly and suitably designed for an aging audience, for example, ensuring that visual elements can be differentiated from one another in a very clear manner and that the video game's difficulty level is attuned not to be extremely difficult but moderately challenging to both prevent the demotivation of the players and encourage continued gameplay, which basically means that the patients continue the rehabilitation process through the exergame medium. In addition, digital health technologies must be designed to have clear affordances without visibly looking like it would be very difficult or complicated to use, as this has an effect on the users' perception about the apparatus, which would inadvertently affect their motivation to buy and use the product.

Limitations

Similar to all studies, there are several limitations in our research. The first limitation of this study would be the lack of a substantial sample size. The sample size of 19 is very small to draw concrete quantitative conclusions and comparison between the focus groups, and therefore, any findings and results that were gleaned from the study are educated guesses and conjecture. However, it should be noted that the opinions shared by the older adults during the study are ideas that people in the target group actually have, but they need to be carefully examined in future studies. Second, our participants only used the wearable gloves and games in 1 session with 2 games. We are cognizant that our participants who willingly participated in our research may be qualitatively different from those who did not join. Third, we are mindful that older adults who did not have a history of stroke might have other health conditions that the research team is not aware of that might influence their perceptions about the wearable glove and gameplay.

Conclusions

In summary, there is tremendous potential in the use of digital health technologies such as wearable gloves and exergames to motivate older adults to exercise and, for patients recovering from stroke, to adhere to rehabilitation exercises. While we recognize the benefits of such digital health technologies, without representation from older adults in such studies, any technology development and implementation may face the problem of data absenteeism and technology chauvinism. Thus, to achieve a more equitable and inclusive use of digital health technologies, researchers need to consider both the individuals and the contexts in which the technologies are used.

Acknowledgments

This study was supported by the Singapore Health Technologies Consortium (HealthTEC) under the National Research Foundation (021293-00001), Ministry of Education AcRF Tier 1 grant (RG38/22), and Social Science and Humanities Research Fellowship (SSRC2022-SSHR-006). The authors would like to acknowledge StretchSkin Technologies Pte Ltd, particularly Mr Mayank Rajput and the engineers, for their contributions in the wearable glove product development. The authors would also like to acknowledge the work of Mr Ming Kiang Chua, Mr Nigel Tan, and Mr Xue Wei Tan, who were student interns at NTU for contributing to the development of Virtual Exercise Therapy exergames and the implementation of the usability study. Finally, the authors are grateful to Ms Polly Lim from the Home Nursing Foundation for helping them recruit older adults for the study.

Abstract

Background: Finding enjoyable and effective long-term approaches to rehabilitation for improving the upper limb (UL) function of people with multiple sclerosis (MS) is challenging. Using virtual reality (VR) could be a solution to this challenge; however, there is a lack of reporting on the views of people with MS and clinicians on VR-based approaches and recommendations for games for rehabilitation.

Objective: This study aims to identify common UL problems and their related current therapeutic approaches for people with MS, and to explore the opinions of people with MS and specialist clinicians on VR and obtain suggestions for the development and design of VR games.

Methods: Separate focus groups were conducted with people with MS, recruited through the MS Society UK's research network, and clinicians, recruited through the MS Trust Therapists in MS network. A total of 10 people with MS (2 focus groups) and 8 clinicians (5 physiotherapists, 2 occupational therapists, and 1 MS nurse in 2 focus groups) were involved. The focus groups were recorded and transcriptions were analyzed using theme-based content analysis.

Results: People with MS commonly reported that their UL problems interfered with activities of daily living and resulted in the loss of meaningful hobbies such as writing. Many people with MS neglected UL exercise and found strategies for adapting to the UL impairments. Similarly, clinicians stated UL rehabilitation was neglected within their service and that it was challenging to find interesting treatment strategies. VR was suggested by both participant groups as a solution, as it was convenient for people with MS to access and it could provide a more engaging and disguised approach to exercise. There were shared concerns with cybersickness and disengagement with using VR approaches. Both groups agreed games should be meaningful and adaptable for users but suggested different VR activities, with clinicians suggesting games directly reflecting activities of daily living and people with MS suggesting more abstract activities.

Conclusions: VR was well received by both people with MS and clinicians for UL rehabilitation. Recommendations were made for the development of VR rehabilitation games which are personalized and customizable for the varying abilities of people with MS.

Introduction

Background

Multiple sclerosis (MS) is an inflammatory demyelination disorder of the central nervous system that is estimated to affect 2.8 million people worldwide [1]. Over a third of the people with MS have upper limb (UL) dysfunction, including weakness, tremors, and spasms in one or both ULs [2]. This can result in difficulties with activities of daily living (ADL), negatively impacting quality of life and the likelihood of remaining in employment [3,4]. Problems specifically with dexterity are related to higher health care costs [5] and a higher association with depression-like psychological measures compared to problems with lower limb function [6]. Rehabilitation and physical exercise improve motor function for people with MS [7,8]. The evidence regarding UL rehabilitation is lacking in comparison with the lower limb, despite the high frequency of UL impairments and their impact on ADL [9]. In addition, there are particular challenges in finding effective yet motivating rehabilitation strategies in MS due to the long-term, progressive nature of the disease and diversity of symptoms [10].

Virtual reality (VR) is increasing in popularity in rehabilitation research and is proposed as a possible approach to encourage long-term rehabilitation [11]. VR includes digital environments that often simulate real-world experiences with reported benefits of high motivation and engagement, with real-time feedback [12]. VR has shown promising results within MS populations, but this evidence is limited in comparison with stroke, especially regarding UL function [13]. Our systematic review, investigating the effect of VR in improving UL function in MS, found early, but limited, evidence suggesting VR has the potential to improve function in people with MS [14]. There was also a low number of dropouts in most studies within the review, supporting that VR could improve adherence compared with conventional rehabilitation; therefore, VR could be useful in conditions such as MS, where prolonged rehabilitation is required.

VR is often investigated alongside video games played within a VR setting, which can be commercially available or specifically tailored games designed with a target population in mind. Commercially available exercise games, targeted at a healthy population, can be unsuitable for disabled individuals and lead to discouragement and anxiety [15]. It is beneficial to involve a sample of target users in the creation and development of effective VR-based gamified approaches [16]. This process is known as coproduction [17]. To date, no study has systematically coproduced VR games specifically for UL rehabilitation in people with MS.

Objectives

The aims of this study were to determine the views of people with MS and specialist clinicians on UL dysfunction or function in MS, challenges faced by clinicians when delivering UL therapy, barriers and motivators for exercise in MS, opinions on VR, and suggestions for development and design of VR games. These findings will guide the future development of VR applications and interventions for UL rehabilitation for people with MS.

Methods

Ethical Considerations

Ethics approval for this study was provided by the School of Health and Life Sciences Ethics Committee at Glasgow Caledonian University (HLS/PSWAHS/20/002). Informed consent was obtained from the participants and clinicians.

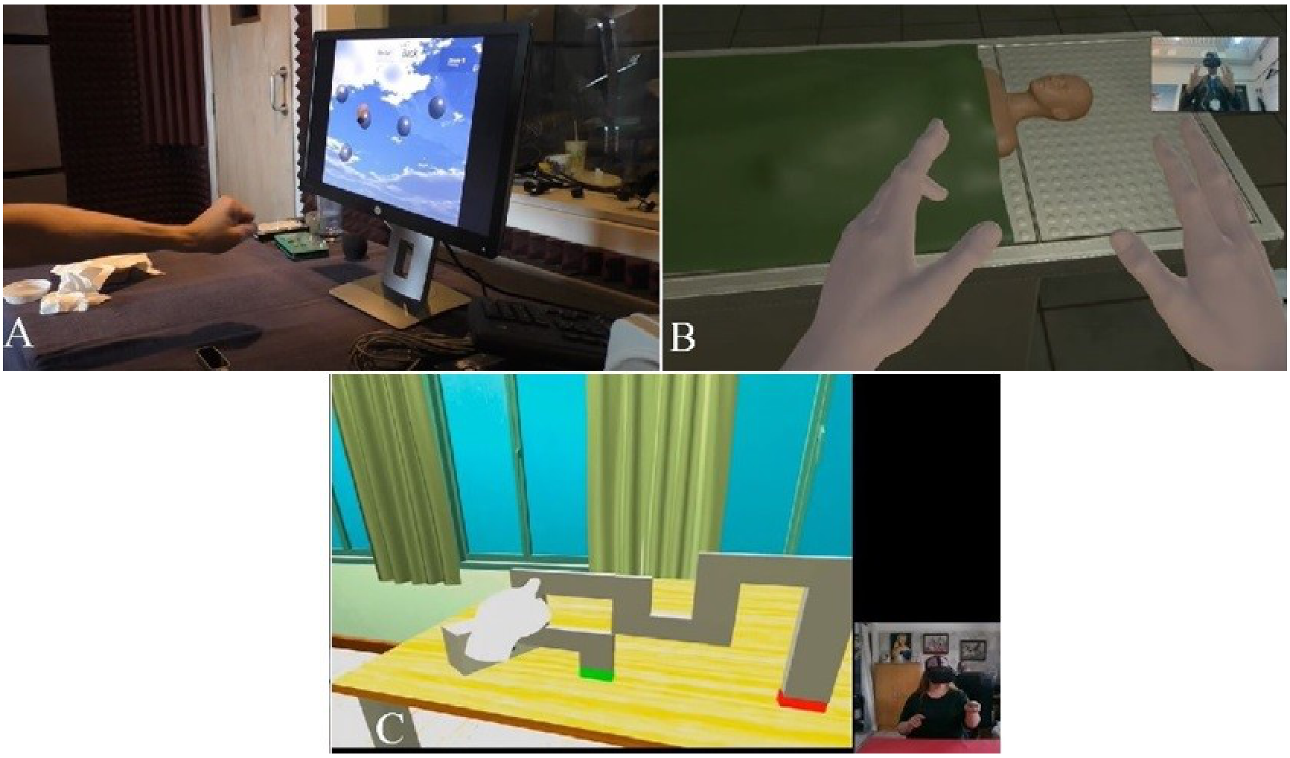
Recruitment

The study aimed to recruit up to 12 people with MS and 12 specialist MS clinicians to take part in online focus groups. The sample size was determined in line with the design of other similar studies and general recommendations for qualitative analysis [18,19]. To be included in the study, people with MS were required to be aged ≥18 years and have a diagnosis of MS (self-reported) with self-reported UL impairment. Clinicians were required to have experience (any duration) in delivering MS rehabilitation within the National Health Service (NHS) or the third sector. In addition, all participants were required to have access to and the ability to operate videoconference software. There were no specified exclusion criteria. Participants with MS were identified through the MS Society UK's research network, which advertised the study to its members. Those who were interested in participating contacted the research team directly and were emailed a participant information sheet. In terms of recruitment of clinicians, the MS Trust Therapists in MS network advertised the study to its members. Interested clinicians contacted the research team and were emailed a participant information sheet.

Coproduction Focus Groups

The focus groups for people with MS and clinicians were conducted separately with a maximum of 5 people per focus group. To comply with COVID-19 pandemic regulations at the time, focus groups were held online using Zoom (Zoom Video Communications) or Teams (Microsoft Corp) videoconference software; this also provided an opportunity for recruitment of participants from across the United Kingdom and Ireland. The focus groups were conducted in a semistructured style using a focus group schedule split broadly into three sections important for the development of VR interventions for UL problems in people with MS: (1) UL dysfunction and exercise or therapy; (2) opinions on VR; and (3) suggestions for development and design of any developed VR games (Multimedia Appendix 1). In addition, clinicians were asked what information and feedback they would want from a patient's VR therapy session. The questions included prompts that allowed more targeted responses from participants regarding their experiences and views [20]. Within the focus groups, participants were shown three videos demonstrating different commercially available head-mounted devices (HMDs) and hand-tracking devices: (1) a nonimmersive VR set up using a Leap Motion controller and computer monitor, which is a hand motion capture device that allows users to visualize their hand movements and interact with virtual environments; (2) immersive VR using the Oculus Rift HMD with a mounted Leap Motion device for hand tracking; and (3) immersive VR using the Oculus Quest, with in-built hand tracking (Figure 1 [21,22]; Multimedia Appendix 2). Videos were shown as participants were unable to try these devices since the focus groups were online due to the COVID-19 pandemic. These videos attempted to contextualize and demonstrate the different VR and motion capture devices in terms of users interacting with environments, possible hand movements, and previous games developed from prior research. After watching the videos, participants were encouraged to share their initial thoughts on each of the technologies. The focus groups involving people with MS and clinicians lasted approximately 90 minutes and 60 minutes, respectively. The focus groups were facilitated by a female researcher (AW) who had been involved in the recruitment of participants and an additional senior, female researcher (LP) attended.

Figure 1. Stills from videos shared with participants during focus groups, demonstrating different virtual reality technology. (A) Video 1 shows Leap Motion only; (B) video 2 shows Leap Motion and Oculus Rift; and (C) video 3 shows Oculus Quest.



Data Analysis

All focus groups were audio recorded and transcribed verbatim. Qualitative analysis of the data was performed based on theme-based content analysis (TBCA) as described in the study by Neale and Nichols [23]. This qualitative method groups responses into content-related themes to enable researchers to view the user preferences more easily and has been used to influence the development or evaluation of a VR environment [23-25]. TBCA is a flexible qualitative data analysis method that involves five key steps: (1) data collection, (2) data collation, (3) raw theme definition and classification, (4) higher order theme selection, and (5) presentation of classification matrix [23]. Owing to the large number of higher order themes, we added an additional step by grouping the higher order themes into main themes. The raw themes were assigned independently by 2 researchers in the transcripts of people with MS (AW and LF) and clinicians (AW and LP). After agreement on the raw themes, the responses were then independently grouped by 2 researchers (AW and LP) into higher order themes. Any discrepancies in assigning the themes were resolved through consultation with a third reviewer, if necessary. Once the higher order themes were determined, the main themes were determined by 2 researchers (AW and LP). The main themes with their associated raw and higher order themes are presented in tables. The raw and higher order themes were quantified manually within the matrix based on the number of responses necessary to display popularity or consensus [23], and example quotes for each higher order theme were included. Focus groups of people with MS and clinicians were analyzed separately to allow comparison of the findings between the 2 groups.

Results

Participant Demographics

A total of 10 people with MS were recruited to the study and took part in 1 of 2 focus groups, each of which had 5 participants. Most participants with MS were female (7/10, 70%), with a mean age of 56.4 (SD 16.5) years and a mean time since diagnosis of 14.4 (SD 12.3) years. Participants had varying MS types (Table 1).

A total of 8 clinicians were recruited (5 physiotherapists, 2 occupational therapists, and 1 MS specialist nurse). Among them, 6 participants worked in the NHS and 2 worked in other settings. There were 2 focus groups for clinicians with 4 participants in each group. All clinicians were female, with a mean age of 46.2 (SD 9.6) years, and the mean length of experience was 17.9 (SD 10. 2) years.

Table 1. Demographic details of people with multiple sclerosis.

Participant ID	Age (years; mean 56.4, SD 16.5)	Sex	Multiple sclerosis type	Time since diagnosis (years; mean 14.4, SD 12.3)
P1	60	Female	SPMS[a]	30

[b]RRMS: relapsing-remitting multiple sclerosis.

[c]PPMS: primary progressive multiple sclerosis.

People With MS: TBCA

Overview

Following TBCA of the focus groups of people with MS, 20 higher order themes were determined based on the grouping of the assigned raw themes. These 20 higher order themes were grouped into four main themes: (1) Impact of MS on the UL; (2) Exercising with MS; (3) Views of people with MS on VR; and (4) Recommendations for development and user requirements (Table 2). A full version of this table, including more example quotes from participants, is available in Multimedia Appendix 3.

Table 2. Main, higher order, and raw themes from theme-based content analysis of people with multiple sclerosis focus groups.

Main theme and higher order themes (number of responses)	Raw themes (number of responses)
Impact of MS[a] on the UL[b]	
Interference with functional activities (35)	Dressing (8); eating (6); dropping items (5); writing (5); grooming (3); dependence on others for activities of daily living (3); carrying items (3); and traveling (2)
Symptoms and signs that impact activities (25)	Fatigue (10); numbness (6); sensory overload (4); weakness (3); tremors (2); proprioception (2); and coordination (1)
Strategies people with MS adopt to assist with ADL[c] (24)	Strategies for functional activities (8); adapting (7); making a difference (5); technology assistance (2); and mobility-assistance equipment (2)
Struggle with loss of meaningful activities and skills (14)	Loss of skills (6); impact of losing ability to write (4); and keeping meaningful activities (4)
UL actions people with MS find difficult (13)	Dexterity (6); range of motion (4); and grip (3)
Sharing and sympathy (13)	Sharing strategies (4); sharing advice on exercise (4); taking advice (3); and sympathizing (2)
Difficulty with progression and unpredictable nature of MS (10)	Variation in MS (6); unpredictable (2); and progression (2)
Exercising with MS	
Views and attitudes on exercise (49)	Maintenance (10); negative perceptions of exercise (8); keeping muscle strength (8); determined to exercise (7); benefits of exercise (6); multitask approach (4); legs focus (3); and in control (3)
Previous experience of UL rehabilitation or exercise (40)	Outcomes from UL exercise or rehabilitation (12); neglecting UL exercise or rehabilitation (10); UL equipment (6); UL physiotherapy (4); driven for UL exercise (3); UL exercise resources (3); and adherence (2)
Barriers to exercise (28)	Personal barriers (8); environmental barriers (8); COVID-19 barriers (7); and verbal disengagement (5)
Facilitators to exercise (28)	Verbal encouragement (10); health care professionals (8); MS center (4); gym facilitators (3); and pushing self for results (3)
Adverse effects of exercise (11)	Induce symptoms (4); tiring (3); recovery time after exercise (2); affecting socializing (1); and overdoing exercise (1)
Approaches to exercise used by people with MS (26)	Routine (7); exercise bikes (6); exercise aims (5); low impact or stretching exercise (4); and physiotherapy approaches (4)
Views on group vs individual exercise (26)	Competition in exercise (10); motivation of group exercise (5); downsides of group exercise (5); importance of socializing in exercise (2); camaraderie (2); enjoyment (1); and interest in group exercise (1)
Views of people with MS on VR[d]	
Positive views on VR (55)	Home use (9); outcome benefits (6); personal opinions on VR (5); fun (5); adaptable (5); positives of technology (5); wireless convenience (5); accessibility convenience (4); incentives (3); meaningful (3); online socializing (2); and immersion (1)
Negative views on VR (40)	Cybersickness (17); HMD[e] discomfort (6); technology discomfort (5); HMD dislike (3); disengagement (3); accessibility concerns (3); and unsuitability (3)
Views on trying or participating in VR rehabilitation (25)	Openness to VR (12); challenging (4); safety considerations (3); need results (2); technology considerations (2); and unsuitable for them (2)
Recommendations of people with MS for development and user requirements	
Considerations for development of VR games (84)	Mindful of target audience (9); tracking progress (8); discouragement of feedback (8); knowing UL outcomes (7); end result (6); score targets (6); challenging self (6); competition in games (5); education (5); time feedback (4); supervision (4); community involvement (3); multipurpose (3); continuous development (3); be fun (3); hardware (2); and learning patterns concern (2)
Suggestions for VR activities (36)	Suggested UL actions (9); game ideas (7); real-life vs abstract tasks (4); haptic activities (4); strength in games (4); writing and drawing (3); demonstrated games (3); additional objectives (2); and atmosphere (1)
Importance of choice (23)	Offer different movements (8); having a variety of games (6); personal preferences (6); and variety of different levels (3)

[a]MS: multiple sclerosis.

[b]UL: upper limb.

[c]ADL: activities of daily living.

[d]VR: virtual reality.

[e]HMD: head-mounted device.

Impact of MS on the UL

The most common higher order theme was "Interference with functional activities" with 35 responses (Table 2). Participants reported a wide range of activities they found difficult to perform due to their MS, the most frequent being ADL, including personal care, eating, and carrying heavy items. "Symptoms and signs that impact activities" had the second highest number of responses (n=25), where participants particularly noted the impact of fatigue on activity (n=10); however, sensory problems such as numbness and pins and needles were also highlighted. Other MS symptoms impacting UL function were, for example, weakness, tremors, and coordination problems. In "Strategies people with MS adopt to assist with ADL" (n=24), because of losing function, participants discussed the use of assistive equipment, for example, button fasteners, specialized cups, and voice control. Other strategies included using their less affected hand or pacing to manage fatigue. The remaining 4 higher order themes had fewer responses. In brief, dexterity, range of joint movement, and grip were the main "UL actions people with MS find difficult" (n=13). These were often compounded by the unpredictability and progressive nature of MS ("Difficulty with progression and unpredictable nature of MS," n=10). Participants reported the emotional impact of losing the ability to carry out personal and meaningful activities specifically because of loss of UL function ("Struggle with loss of meaningful activities and skills," n=14), with one participant stating the following:

> *I used to be a writer and it was very, very hard because I couldn't write anymore...I was really motivated [to relearn writing], felt really cut off from the world.* [P8; age 70 years; male participant with primary progressive multiple sclerosis]

The final higher order theme was "Sharing and sympathy" (n=13 responses), where participants empathized and shared experiences and suggestions of assistive equipment.

Exercising With MS

Most responses under this main theme related to "Views and attitudes on exercise" (n=49; Table 2). Participants were motivated to exercise with a "*use it or lose it*" attitude and a desire to, if not improve then at least maintain, their function and prevent further deterioration. Participants also described negative perceptions of exercise, such as finding it "*very boring*" and guilt from not participating in exercise. In "Previous experience with UL rehabilitation or exercise" (n=40), many participants (5/10, 50%) discussed not undertaking any UL exercise or rehabilitation, currently or previously. Many UL programs previously undertaken by some participants aimed to build strength, reduce pain, and improve hand function with varying outcomes. There were similar numbers of responses in terms of "Barriers to exercise" (n=28) and "Facilitators to exercise" (n=28). Personal barriers to exercise included comorbidities, MS symptoms (fatigue, pain, and bladder and bowel dysfunction), difficulty using exercise equipment, and expense. The COVID-19 pandemic had negatively impacted the participants' exercise due to services closing down. Environmental barriers to exercise included lack of local facilities and not having space to exercise at home. Verbal encouragement was described as both a barrier (could be off putting) and a facilitator (motivating) to exercise. Other facilitators were seeing improvements, feeling motivated, and the attitudes of health care professionals, personal trainers, and carers. Conversely, health care professionals with a lack of experience in MS overwork people with MS, leading to exhaustion ("Adverse effects of exercise," n=11). Participants undertook many different forms of exercise ("Approaches to exercise used by people with MS," n=26), including exercise bikes, Pilates and yoga, dog walking, and gym exercises. There were varying "Views on group versus individual exercise" (n=26). Some found competition within a group to be motivating while others did not, with one participant suggesting social support and camaraderie was more important than competition:

> *I'm not too fussed about being in competition with others, but if it was a more social thing that would maybe encourage me to perhaps join in a group that's doing something together.* [P4; age 58 years; female participant with secondary progressive multiple sclerosis (SPMS)]

Negative aspects of group exercise included the fear of letting others down.

Views on VR

The initial reaction to VR was positive ("Positive views on VR," n=55; Table 2). Participants stated it looked fun or enjoyable with the potential to improve or maintain muscle strength, dexterity, and spatial awareness, especially with repeating the actions and concurrently perhaps learning a new skill (for example, playing the piano):

> *I think [VR's] still very good because... it's...maintaining those motor skills that is so easily slip away when you're not using them.* [P9; age 60 years; male participant with SPMS]

There were positive comments in relation to the convenience and accessibility of VR facilitating exercise at home at a suitable time and eliminating travel to physiotherapy services and gyms. Participants highlighted that the wireless HMD was more convenient as it was portable and did not need a computer. The advantage of linking up with others online was raised. However, "Negative views on VR" (n=40) were related to concerns regarding cybersickness, linked to dizziness and balance problems:

> *With MS a lot of people suffer from nausea or motion sickness. That can be a concern for the headsets.* [P6; age 28 years; female participant with relapse and remitting multiple sclerosis]

Other negative responses related to the HMD discomfort regarded weight, usability concerns, wearing it with glasses, and being disconnected from the real world. Two participants indicated that interest in VR may reduce over time. Participants were also concerned about fatigue and the usefulness of VR for UL sensory dysfunction. Most participants (6/10, 60%) expressed they were open to trying VR ("Views on trying or participating in VR rehabilitation," n=25), but would like to understand the benefits, long-term outcomes, and any safety issues.

Recommendations for Development and User Requirements

With regard to "Considerations for development of VR games" (n=84), a variety of UL movements was desirable with clarity in terms of the aim and outcome in relation to the UL being important (Table 2). Competition within the VR games, interacting with others or challenging themselves, were frequently discussed as being motivating. Tracking improvements during VR gameplay was vital to some participants, including monitoring improvements in score, exercise time (rather than countdown which could be stressful), and progressive challenges. The games should offer the ability to challenge users, with one participant saying the following:

> *That challenge to try and be better the next time, whereas if you've got no idea...you've got nothing to fight against or to work against.* [P10; age 84 years; female participant with SPMS]

Conversely, other participants emphasized the potential demotivating effect of feedback given the progressive nature of MS, by warning that score feedback should not be "*disheartening*," and should therefore be made optional to the user. There was a strong feeling that the VR games should be "*fun*" with abstract gameplay potentially being more fun. Participants felt that demonstrations and supervision to assess progress were important. They also stated that the VR games had to account for the differences in the ability of people with MS and that older people may need more basic VR games. The idea of the VR games having an educational outcome or in learning a new skill was suggested to help with engagement. Participants suggested that reaching, punching, and other aerobic activities could be incorporated ("Suggestions for VR activities," n=36). Having haptic approaches was frequently proposed with gripping, squishing games, such as kneading bread. Participants proposed activities with a cognitive element, such as a puzzle or maze, and whole limb movements, such as Whack-a-Mole (Mattel), writing or drawing. Participants liked the VR piano which had been demonstrated. There was a variety of opinions in terms of abstract or real-life activity with most preferring abstract games but some ADL-type activity was also suggested. "Importance of choice" (n=23) related to having variety in games, UL movements, and levels of difficulty with abstract games or real-life gamified tasks, with 1 participant declaring the following:

> *I'd like to make sure I'm not doing a whole lot of exercises that are all doing the same things...Got to be mixing them up: one for coordination, one for dexterity.* [P1; age 60 years; female participant with SPMS]

Clinicians: TBCA

Overview

From the clinician focus groups, there were 15 higher order themes grouped into four main themes: (1) Current methods and challenges for delivering UL rehabilitation; (2) Clinicians' views on VR; (3) Recommendations for development and user requirements; and (4) Implementation of VR into practice (Table 3). A full version of this table, including more example quotes from participants, is available in Multimedia Appendix 4.

Table 3. Main, higher order, and raw themes from theme-based content analysis of clinician focus groups.

Main themes and higher order themes (number of responses)	Raw themes (number of responses)
Current methods and challenges for delivering UL[a] rehabilitation	
Challenges clinicians face when delivering exercise for people with MS[b] (52)	MS-specific challenges (13); patient adherence (11); service challenges (9); UL-related challenges (7); patient differences (6); challenges with current methods of delivery (4); COVID-19 impacts (2)
Recommended UL exercises for people with MS (29)	Actions (10); systematic approach (7); functional tasks (6); strength and range of movement (5); relapse care (1)
Experience with long-term, progressive condition (24)	Deterioration (11); acceptance in patients (8); difficulty with patient improvements (5)
Factors clinicians consider when prescribing exercise for the UL (22)	Meaningful and patient-focused (9); patient assessments (6); symptoms (4); repetition (3)
Current methods of UL exercise delivery for people with MS (15)	Technological approaches (4); programs (4); accessible equipment (3); clinician routines (2); patient lead (2)
Socializing in exercise (14)	social motivation (6); support (5); recommending social exercise (3)
Clinicians' views on VR[c]	
Positive views on VR (50)	Solutions to current challenges (10); personal opinions on VR (7); facilitating movements or tasks (6); VR-specific qualities (6); meaningful (5); engagement (5); visualization (4); novel (3); cognitive appeal (2); adaptability (2)
Negative views on VR (38)	Disengagement (10); cybersickness and safety (8); HMD[d] discomfort (7); accessibility concerns (5); feedback concerns (5); validity concerns (3)
Questioning benefits and the unknowns of VR (14)	Questioning purpose of VR (4); questioning benefits of VR (4); neural mechanisms (3); research (2); different VR systems (1)
Clinicians' recommendations for development and user requirements	
Considerations for developing VR games for people with MS (41)	Communication between clinician and patient (12); purposeful (7); social components (7); selecting tasks (4); slower tasks (3); competition (3); feedback for clinician (3); positive feedback (2); end point (2)
Suggestions for VR activities (18)	Activities of daily living (6); hobbies (6); objectives (6)
Importance of choice (15)	Preferences (6); having variety (5); setup (4)
Implementation of VR into practice	
Suggestions for incorporation of VR into practice (18)	Home use (7); VR in clinics (7); long-term treatment (4);
Challenges with implementation of VR into practice (24)	Funding (7); demanding on services (6); availability of equipment (5); risk (3); adjustment (2); uncertainty of practice (2)
Finding the target audience for VR (8)	Who would use VR (3); niche group (3); age (2)

[a]UL: upper limb.
[b]MS: multiple sclerosis.
[c]VR: virtual reality.
[d]HMD: head-mounted device.

Current Methods and Challenges for Delivering UL Rehabilitation

"Recommended UL exercises for people with MS" (n=29) included strength training and active movements related to functional activity, such as hand-to-mouth movements (Table 3). Treatment for the UL often involved equipment such as Therabands and Theraputty but also technology such as the Gloreha robotic system and functional electrical stimulators with different models of care for UL exercises described as part of community-based classes, within third sector organizations and online programs ("Current methods of UL exercise delivery for people with MS," n=15). Within "Factors clinicians consider when prescribing exercise for the UL" (n=22), most responses were regarding meaningful and goal-focused exercises. Clinicians also considered the patient's symptoms, for example, spasticity, pain, and the ability of patients. The importance of repetition of movement was reinforced. Most responses (n=52) were in relation to "Challenges clinicians face when delivering exercise for people with MS." Clinicians expressed that UL-focused exercise was neglected compared to the lower limb and the challenge of making UL exercise interesting:

> *A bit more difficult for upper limb things...it's much easier to maybe...go for a walk with somebody or you know, or cycle or whatever. Upper limb is maybe a wee bit more difficult.* [C6; physiotherapist]

Clinicians also mentioned the use of Theraputty described as "*juvenile*" and lists of exercises "*boring*."

Service-related challenges included limited time and capacity to see patients and large geographic areas to cover. Other challenges were keeping patients engaged with exercise in the long term, especially at home, and finding an activity that would be attractive to patients. Under "Experience with long-term, progressive condition" (n=24), clinicians raised being realistic about improvements with a progressive condition while also keeping patients motivated, minimizing deterioration or maintenance, rather than improving:

> *Trying to motivate people with progressive MS, you're trying to get them to continue to maintain where they are rather than improve.* [C5; occupational therapist]

Clinicians expressed the positive benefits of "Socializing in exercise" (n=14) for support and motivation.

Clinicians' Opinions on VR

Clinicians were very positive about VR (n=50), describing it as being interactive, fun, meaningful, and a novel potential approach to rehabilitation, which could help engagement (Table 3). They were positive about the escapism aspect and the potential to improve mental health:

> *What appeals about VR stuff is that it is focused and takes you into a different place...You're doing tai chi on a beautiful, Japanese garden rather than actually in your grumpy living room...I think even that in terms of the escapism aspect, maybe from a mental wellbeing.* [C1; physiotherapist]

Clinicians liked the visual feedback to help with, for example, coordination, but which could also reinforce movements and introduce a cognitive component. Clinicians commented that VR provided the opportunity to undertake activities not possible within the clinic and to exercise without the activity seeming like an exercise. Most of the "Negative views of VR" (n=38) were regarding patient safety using VR headsets, especially cybersickness, including dizziness and disorientation, specifically in patients with vestibular issues. Other general concerns with HMDs were usability with glasses, the weight of the HMD, and feeling claustrophobic. Clinicians suggested that VR activities should not be too simplistic to avoid patronizing patients and at an appropriate skill level. The longevity of engagement of patients after the initial novelty was questioned. Clinicians also questioned the use of VR for activities that can be done in the real world and similarly how VR activities might translate to real function. The importance of feedback on the quality of movement as well as the quantity was highlighted. Finally, accessibility and digital poverty were also raised. The final higher order theme was "Questioning benefits and the unknowns of VR" (n=14), where some clinicians felt there was insufficient evidence on the purpose and benefits of VR and its effect on neural mechanisms:

> *I think it's important to think about how is [VR] different to just doing [activities] in real life as well...What can you augment in your rehab through this virtual reality that you can't just do in real life anyway?* [C7; physiotherapist]

Recommendations for Development and User Requirements

Under "Considerations for developing VR games for people with MS" (n=41), clinicians discussed the importance of the VR games having purposeful activity, translation of tasks into real life, and having an end point (Table 3). The games should consider movements of individual joints of the UL with extension movements at the wrist and fingers being important as where people with MS lose the most function. Games should incorporate strength, coordination, proprioception, and range of motion exercise as well as exercises for the core. Feedback was important, with clinicians able to monitor the program. Clinicians were not interested in scores for the games but wished feedback on the quality of the movements and patient engagement. Clinicians stated that undertaking VR activities with others or in group settings with elements of competition was desirable. Clinicians provided "Suggestions for VR activities" (n=18), including ADL such as putting on makeup; writing or chopping vegetables; and hobbies including pottery, sewing, or piano playing. Clinicians raised the "Importance of choice" (n=15) in the VR setup, choice of games, and choice within games, for example, levels of difficulty, to appeal to as many people as possible:

> *I think, it is about having a variety of things that push as many buttons with patients that you can manage and cover as many options as you can.* [C2; physiotherapist]

Implementation of VR Into Practice

Under "Suggestions for incorporation of VR into practice" (n=18), clinicians felt long-term, regular use of VR was needed for positive outcomes (Table 3). Home use was felt to encourage frequent use, with clinicians monitoring progress remotely, thus saving in person contact time. There were a number of "Challenges with implementation of VR into practice" (n=24) with cost and funding (service and individual) being the most commonly reported, which included potential increased demand on services:

> *I know if I brought it to my bosses they would want a breakdown of cost of monthly rate, how are we going to utilise it, how often are we going to utilise it. What figures could we get from this particular item and what outcomes could we achieve.* [C4; MS specialist nurse]

Equipment-related challenges were ownership, availability, supply of equipment, and infection control. A full risk assessment would be required before implementation and guidance would be needed on intervention duration and frequency. Clinicians discussed for whom VR would be appropriate, in terms of age or other factors, and identified this as an area for future research ("Finding the target audience for VR," n=8).

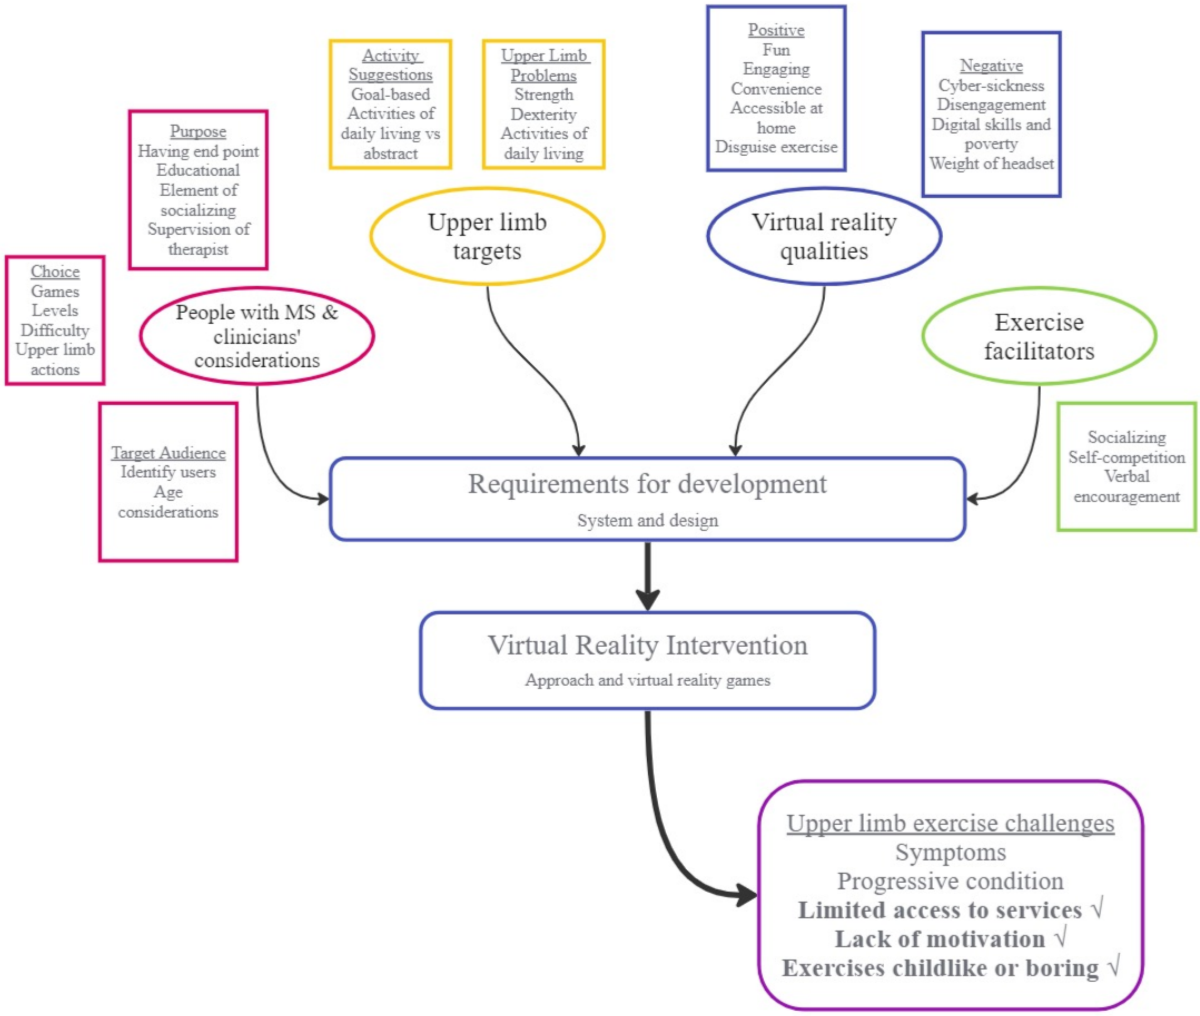
Discussion

Principal Findings

This study aimed to explore the views of people with MS and clinicians on UL impairment associated with MS and the potential role of VR as a rehabilitation approach to address this impairment. The discussion focuses on the combined findings from the 2 groups of participants: people with MS and clinicians (Figure 2). Figure 2 is a visual representation of the principal findings based on the higher number of responses assigned, which should inform the development of VR applications and interventions aiming to improve the UL function for people with MS and how VR could tackle challenges of existing UL exercise raised by clinicians and people with MS in this study.

The findings agree with those of previous studies that people with MS commonly have UL impairments that impact function, including problems with dexterity and ADL, which leads to loss of meaningful activities [26-28]. Despite UL difficulties, UL exercise was neglected due to MS symptoms, such as fatigue, lack of motivation, and dislike of exercise, as well as the challenges clinicians faced regarding time constraints and finding appropriate therapies that were not childlike or boring. Lack of focus on UL rehabilitation has been reported previously in MS [9] and in other long-term neurological conditions such as stroke [29]. The progressive and unpredictable nature of MS was raised by both groups, and consequently, clinicians raised the importance of setting realistic expectations with therapy, sometimes focusing on maintenance of function rather than improvement.

Figure 2. Flow diagram of the results from theme-based content analysis of people with multiple sclerosis (MS) and clinicians' coproduction focus groups and how this will guide the requirements for developing virtual reality–based games or interventions, which will aim to tackle certain achievable upper limb exercise challenges within MS.



Both groups (people with MS and clinicians) were optimistic about the use of VR and believed VR could be a solution to their exercise challenges. Positive comments, including avoiding traveling, being accessible, and being engaging or fun addressed the identified barriers for UL rehabilitation. This concurs with previous VR studies [30,31] and specifically in UL rehabilitation in MS, with a recent home-based, feasibility study using the Oculus Quest 2 VR headset in which participants described VR as fun, interesting, and innovative [32]. Participants in the study by Kamm et al [32] suggested adding difficulty levels and scoring to their exercises, competitive elements previously described to be motivating by people with MS using nonimmersive exercise games delivered through the Nintendo Wii [33]. In this study, both groups were especially positive regarding the immersive approach of the Oculus Quest. Participants thought the escapism properties and visualization of movements could potentially "disguise exercise," which may occur with the "fun" element of VR reducing the perception of exertion during exercise [34], therefore encouraging more UL therapy.

Negative views about VR were also expressed, mainly the potential for cybersickness. Cybersickness is thought to be caused by conflict of stimuli, leading to nausea, disorientation, and pain in the eyes and head [35]. Women are more susceptible to cybersickness [36], which is relevant in MS, with a higher number of women affected. Although cybersickness with VR has been reported previously in people with MS [37], there are development strategies for reducing cybersickness, such as designing VR activity with less overall movement within the virtual environment. Cybersickness is, however, thought to reduce over time with exposure to VR [38]. There were unnecessary concerns raised for those wearing glasses as the HMD can accommodate glasses, but there were valid concerns about the weight of the HMD for some users. Disengagement was another concern both groups expressed, with limited data on long-term adherence to VR in MS rehabilitation. Exercise is a behavioral intervention, and long-term adherence to exercise can be supported by evidence-based behavior change techniques [39]. These behavior change techniques, such as goal setting, rewards, and feedback, can be incorporated into VR games or activity to support long-term engagement in UL exercise. While VR can be more engaging than other methods of exercise [40], frequent performance, feedback on progress, and adjusting levels of difficulty can maximize VR engagement for those with long-term neurological conditions [41]. Finally, clinicians had specific concerns regarding digital poverty, the technical ability of people with MS, and insufficient technical services to support VR.

Considerations for VR game development align with user-centered design principles for VR in motor rehabilitation in survivors of stroke, such as being fun, tracking progress, having an element of competition, challenging oneself, and providing feedback [42], and are not specific to any clinical population. Participants raised that VR development should be mindful of the different end users (people with MS) who may differ in ability and preferences. Clinicians suggested VR would appeal to younger individuals with MS, whereas people with MS felt older people with MS might need more basic gameplay. While there is some, albeit limited, evidence for lower usability scores for older VR users compared with younger users, there can be higher user enjoyment [43], and there is moderate evidence for good usability of VR in older populations [44]; therefore, this concern may be overly cautious.

Consideration of the end user links to the importance of choice when designing VR interventions, with a variety of games to appeal to as many as possible. Participants felt the games should include different movements, levels of immersion, level of difficulty, or feedback on performance. Accommodating individual preferences is a key element for the design of VR games for rehabilitation, as it increases user engagement [45]. However, our previous systematic review found that a choice of games was rarely included in VR interventions in MS [14].

There were differing views in terms of the type of feedback people wished from VR. Some people with MS wanted to track scores and visualize results, which is supported by reward theories for users during both entertainment and serious games [46]. Conversely, concerns were raised about feedback potentially being discouraging or demotivating, especially given the variable nature of MS. As an example, countdown timers provide slight pressure to motivate players to increase engagement [47]; however, in this study, people with MS felt they could be stressful. Feedback on the duration of exercise completed was appealing to people with MS, as reported previously [19]. As well as the quantity of VR exercise, clinicians also wished feedback on the quality of movement when performing the games. Rehabilitation often involves highly repetitive movements to stimulate neuroplasticity; however, stroke specialist therapists have also previously reported concerns that quality of movement in VR rehabilitation for UL maybe sacrificed for a good gaming outcome [18], although this has not been explored in people with MS. Both groups were interested in the reported outcomes of using VR approaches which, if positive, would increase engagement.

Clinicians and people with MS felt VR activity had to be related to the patient's personalized and meaningful goals, which is known to increase motivation in physiotherapy settings [48]; however, this is often neglected in VR regimes [14]. Goals need to be adjusted over time in a progressive condition, such as MS, and to avoid disengagement as raised earlier. Participants with MS frequently stated that their goals were related to not only improvement but also the maintenance of ability and the prevention of further deterioration. In terms of suggestions for VR activities, the groups differed with clinicians suggesting ADL or hobby simulations and people with MS being more ambivalent, stressing activity to be fun with a variety of real-life and abstract VR games. Previous studies of VR have often involved ADL activities such as cooking or other kitchen activity [49,50]. Although VR can provide a safe environment to practice ADL for people with mobility issues [51] people with MS in this study were less interested in ADL, especially kitchen simulations. Both groups suggested an "end result," such as creating a drawing, or learning a new skill would be positive and facilitate a feeling of accomplishment. There were also suggestions from people with MS to incorporate haptic activities, such as grabbing and gripping. However, the user is not able to receive tactile feedback when interacting with a virtual environment, and handheld controllers may need to be considered for some VR activities [52]. Another solution could be to incorporate pseudo haptics, the use of different stimuli such as visual or auditory stimuli, to mimic a variety of haptic properties in a virtual environment [53]. This is an emerging field that could be explored in VR for people with MS. Similarly, as many of the participants suggested finger-related exercises, it is important that VR systems use good hand-tracking motion capture devices to allow visualization of the movement of fingers and wrists within a VR setting.

Many people with MS were supportive of VR for home use, as being more convenient and accessible. However, there was recognition that users needed demonstration of the technology and a level of clinician supervision. Assessing quality of movements and monitoring of patient progress are reported challenges for VR home use [54]. A recent study with a small number of participants found VR to be feasible for home-based UL rehabilitation in people with MS, after 3 supervised sessions [32], but larger studies of home-based VR for UL rehabilitation are required. There was agreement in both groups that an element of social interaction could be considered in the development of VR games. Generally, there is a lack of evidence on the effect of socialization within UL therapy, but it may improve adherence and motivation [55] and provide better outcomes [56]. Specifically in relation to VR, there is some evidence that social aspects increase motivation through competition [57], but participants in our study were more interested in self-competition rather than competing against others. This is similar to a study of a walking app for MS where users were less interested in sharing their goals or achievements with others [58].

Strengths and Limitations

Recruiting participants through online sources may result in a biased sample, as those comfortable with technology and access to online services are more likely to take part. Being online allowed the involvement of people with MS with varying abilities and clinicians who worked in the NHS and the third sector across the United Kingdom. However, the online nature meant it was not possible for participants to physically test the VR equipment and explore their reactions. While it can also be challenging to engage all participants in online focus groups, this was resolved by asking questions using participants' names or by getting participants to use the raise hand function within the videoconference software and encourage discussion between participants.

The TBCA methodology groups responses into themes to quantify them but does not allow consideration of the interaction between participants. Participants had a number of specific questions, such as the long-term outcomes of using immersive VR, the optimal target users for VR (level of disability), and the extent of translation of VR activity into "real-life" function. However, there is currently a lack of literature to provide responses to these questions, which highlights areas for future research.

Conclusions

This is the first study exploring the views of people with MS and clinicians in terms of VR for UL rehabilitation for people with MS and has highlighted the current challenges in UL rehabilitation even though UL impairment is common and impacts meaningful activity. Overall, people with MS often found dexterity-related activities difficult, which impacted multiple ADL and challenges faced in therapy related to motivation, lack of resources, and difficulty finding interesting UL exercises. There was positive support for VR for UL exercise. Overall, to improve engagement and satisfaction for the user, this study suggests any VR games developed for people with MS should (1) be fun and engaging; (2) have clear aims related to the individual user's goals; (3) offer personalization, such as a variety of games (abstract and ADL based), different movements, levels of difficulty, and methods of feedback; (4) monitor quality as well as quantity of movement during gameplay; (5) incorporate design features to reduce the potential for cybersickness; (6) consider if the games can incorporate education or skill development; (7) incorporate aspects of social interaction; and (8) consider including haptic properties. The findings support the need for the creation of bespoke serious games rather than using commercially available exercise games, which can discourage users with motor dysfunction [15,59]. Overall, future development of VR games for UL rehabilitation should focus on a personalized and customizable approach to encourage long-term engagement to improve meaningful outcomes for people with MS.

Acknowledgments

The authors would like to thank all the participants who took part in this study, as well as the MS Society, UK, for funding this study (grant number 115).

Authors' Contributions

AW, MP, EC, and LP designed and conceptualized this study. AW, LF, and LP performed the analysis. AW and LP wrote and prepared the manuscript, with support from MP, EC, and LF.

Abstract

Background: Restoring hand and finger function after a traumatic hand injury necessitates a regimen of consistent and conscientious exercise. However, motivation frequently wanes due to unchallenging repetitive tasks or discomfort, causing exercises to be performed carelessly or avoided completely. Introducing gamification to these repetitive tasks can make them more appealing to patients, ultimately increasing their motivation to exercise consistently.

Objective: This study aims to iteratively develop a serious virtual reality game for hand and finger rehabilitation within an appealing and engaging digital environment, encouraging patient motivation for at least 2 weeks of continuous therapy.

Methods: The development process comprised 3 distinct stages, each of which was subject to evaluation. Initially, a prototype was created to encompass the game's core functionalities, which was assessed by 18 healthy participants and 7 patients with impaired hand function. Subsequently, version 1 of the game was developed and evaluated with 20 patients who were divided into an investigation group and a control group. On the basis of these findings, version 2 was developed and evaluated with 20 patients who were divided into an investigation group and a control group. Motivation was assessed using the Intrinsic Motivation Inventory (IMI), while the application's quality was rated using the Mobile Application Rating Scale and the System Usability Scale. User feedback was gathered using semistructured interviews.

Results: The prototype evaluation confirmed the acceptance and feasibility of the game design. Version 1 significantly increased motivation in 2 IMI subscales, *effort* ($P<.001$) and *usefulness* ($P=.02$). In version 2, a significant increase in daily performed exercises was achieved ($P=.008$) compared to version 1, with significantly higher motivation in the IMI subscale *effort* ($P=.02$). High Mobile Application Rating Scale scores were obtained for both versions 1 and 2, with version 2 scoring 86.9 on the System Usability Scale, indicating excellent acceptability. User feedback provided by the semistructured interviews was instrumental in the iterative development regarding improvements and the expansion of the playable content.

Conclusions: This study presented a virtual reality serious game designed for hand and finger rehabilitation. The game was well received and provided an environment that effectively motivated the users. The iterative development process incorporated user feedback, confirming the game's ease of use and feasibility even for patients with severely limited hand function.

Introduction

Background

Our hands are essential tools for managing daily life and are thus at high risk of injury. Therefore, comprehensive and successful rehabilitation to quickly restore hand function is essential for patients' quality of life and ability to work. A key factor in successful rehabilitation is to maintain patients' motivation to conscientiously participate in the process [1]. However, this is complicated by the fact that as part of their therapy, patients may experience pain reactions during or after exercise and must endure them. In addition, long-term repetitive activities are often monotonous and tend to be performed more and more carelessly without the supervision of an occupational therapist or physiotherapist [2]. However, to achieve the best possible outcome of the therapeutic process, it is necessary for patients to perform their exercises regularly, usually even daily [3,4].

In the last decade, serious games for health have become more popular and have shown a positive effect on the rehabilitation process [5,6]. The application of serious games for health covers a wide range of domains, such as training for behavioral change [7], cognitive exercises [8], the treatment of perceptual disorders [9], or physiotherapeutic exercising (eg, for pain [10] or multiple sclerosis [11,12]). The concept of gamification is an attempt to enrich a context, for example therapeutic exercising, with elements and principles used in game design [5,13]. The main target here is to positively influence the player's attitude, enjoyment, and perceived usefulness toward the game [14]. Gamification can also contribute to improving personal health behavior [15].

The use of video games allows for the creation of exciting adventures for patients who are experiencing certain limitations due to age, illness, or disabilities and can significantly improve their mood [16]. The highly immersive experience that can be generated by the application of virtual reality (VR) technology promises to increase the positive effects on the rehabilitation process even further. The term *virtual reality* in the context of rehabilitation is often used to describe any type of computer-based system, regardless of the level of immersion. Strictly speaking, however, VR refers to a system in which the viewer is surrounded by a computer-generated 3D environment and can move around in this artificial world in real time, view it from different angles, and interact with it [17]. The cost of such immersive systems dropped dramatically after 2013, for example, a 90° field-of-view head-mounted display (HMD) was US $35,000 in 2013 and US $600 in 2016, thus enabling affordable VR hand therapy [18].

Serious Games for Health Regarding Hand Rehabilitation

Input systems for the real-time capture of the patient's hand and finger movements presented in the literature range from haptic devices, such as joysticks [19], robots that allow the fingers to be moved in a targeted manner [20], and data gloves [21,22], to wearable inertial tracking devices [23] and optical tracking systems with either externally placed cameras, such as the Nintendo Wii [24], or low-cost, camera-based tracking systems (eg, the Leap Motion controller that can be used stationary in front of a screen [25,26] or mounted onto a VR HMD). An alternative built-in-one setup is provided by the Meta (formerly Oculus) Quest 2 HMD [12,27]. Such markerless optical tracking generally enables a very simple setup and is also especially beneficial for patients with severely injured skin, burns, or allodynia [18,28].

Many VR and non-VR applications designed for arm and hand rehabilitation can be found in the literature, for example, for the purpose of grasping exercises after-stroke rehabilitation [21] or dexterity training for multiple sclerosis [12]. For practicing the hand and fingers in particular, several examples are given for rehabilitative tasks and activities to be performed in VR, such as playing a virtual piano, catching butterflies, picking flower petals, or solving puzzles [29,30]. Furthermore, assessment-like tasks can be found in VR, such as stacking cylinders into a pegboard or stacking cubes [31,32]. Most of these examples lack a concept that motivates the patient to stick with the game for a longer period but rather rely on the effects of technological novelty and already existing intrinsic motivation. Some tasks provide concepts, such as point systems, eventually combined with playtime and connected to a leaderboard. These rather competitive game elements influence mainly extrinsic motivation and have little effect on intrinsic motivation [33].

Creating Motivational Serious Games for Health

Various types of players exist, and they differ in the degree to which they can be motivated by intrinsic or extrinsic motivation [34]. Although both are vital for engagement, games often focus on extrinsic motivators, such as rewards, achievements, or points, which can be harmful to intrinsic motivation [35]. Intrinsic motivation, by contrast, can be supported by self-initiation and choice [36]. Concepts from self-determination theory, such as competence, relatedness, and autonomy, can help create designs that provide sustaining engagement [37]. Game-based approaches related to self-determination theory can also be drawn from behavior change technology [38,39]. Other key factors in intrinsic motivation are informational feedback and clear game goals, which serve as proof of effectiveness for the patient and can also contribute to extending health beneficial behavior beyond the context of the game [40,41]. Work on gamification discusses the roles of intrinsic and extrinsic motivation, as both are important and not sufficiently studied empirically [33,42].

Objectives

The primary objective of this study was to iteratively design and evaluate a serious game for the rehabilitation of hand and finger function in a patient-centered approach. In contrast to hand rehabilitation games presented in the literature, StableHandVR (BG Klinik Tübingen) had a stronger focus on different motivational factors to promote sustained user engagement for a variety of player types. Similarly, the game was designed to be feasible even for patients with severely limited hand function. The secondary objective was to compare the motivational effects of the rehabilitation game across the design iterations and a control group.

Methods

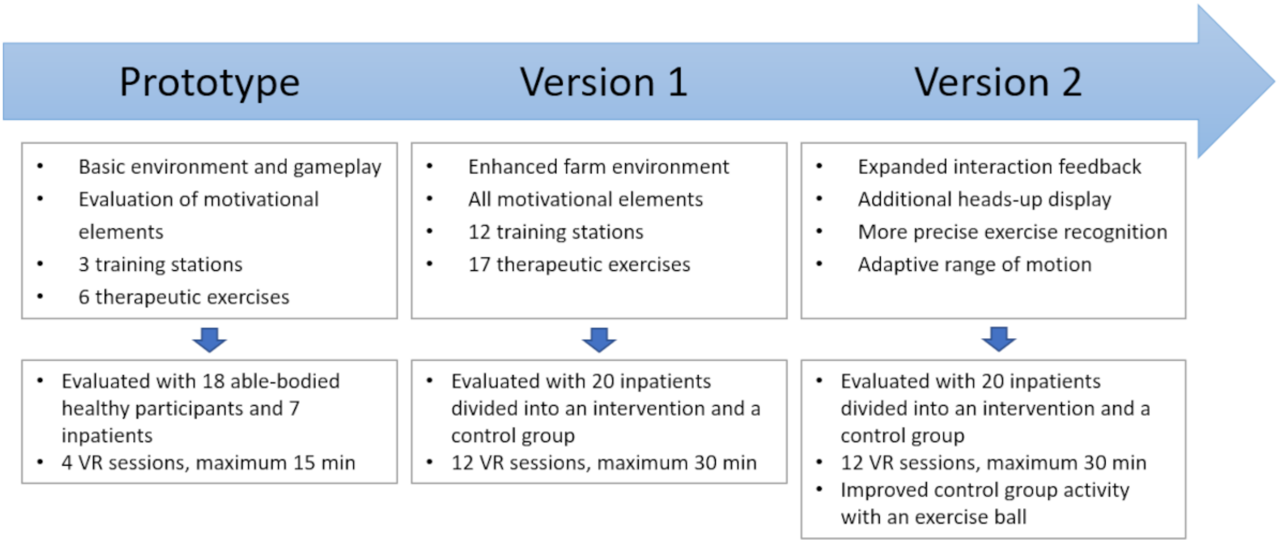
Ethical Considerations

Participant recruitment for the study was conducted in compliance with the Declaration of Helsinki and followed the ethical guidelines by the University of Tübingen, Germany. This study was also approved by the ethics committee of the University Clinic of Tübingen (470/2019B02). Before the initiation of the study, informed consent was obtained from all participants. All data used for this study was anonymized. No compensation was provided to the participants.

Study Design

This study presents the iterative design and development process of the serious game StableHandVR in 3 steps. First, a prototype was created, which provided the core game mechanics and was tested for usability and feasibility. In total, 4 game elements to maintain motivation were designed and evaluated; additional user feedback was collected. On the basis of this preliminary investigation, version 1 of the game was developed expanding the playable content to 3 weeks of training. An intervention group played the game, while a control group watched 360° videos in VR for 12 days during inpatient rehabilitation to evaluate motivational effects. Subsequently, based on the repeatedly gathered feedback and user observation, version 2 was developed and evaluated with the control group's activity being expanded to the use of a training ball to exercise the injured hand while watching the VR videos. Figure 1 presents an overview of the 3 development stages and their evaluation.

Figure 1. StableHandVR underwent 3 successive iterations of development and evaluation. VR: virtual reality.



Apparatus and Setup

All versions of the game were developed in Unity (version 2021, Unity Technologies) for the Meta Quest 2 HMD, running as stand-alone application. The game relied primarily on the use of the inbuilt optical finger and hand tracking feature of the Meta Quest 2; no controllers were required. A physiotherapist could optionally supervise by streaming the visual contents of the HMD onto an Android tablet. The study was conducted in treatment rooms at the hospital with an exercise area of approximately 2×3 meters.

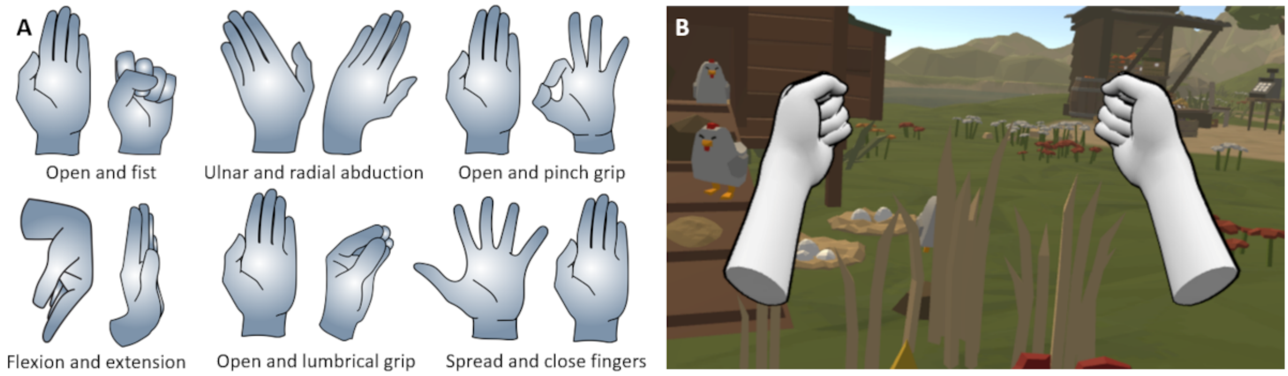
Basic Game Design

StableHandVR aimed to transfer traditional physiotherapy hand and finger exercises into an immersive and motivating virtual world. The inspiration for placing StableHandVR in a natural environment was derived from a study conducted in the 1980s on patients undergoing postoperative recovery [43]. An early feasibility study coined the setting of the game to be a farm environment that provided several training stations to perform exercises [27]. Each station of StableHandVR included a specific task (eg, feeding and milking the cows, preparing a meal, or repairing a tractor), and its completion was divided into 6 exercises, each to be repeated 10 times. Therefore, 60 exercise repetitions had to be performed at each station, and the station's environment would adapt with each repetition, according to the task at hand.

Therapeutic Exercises

The exercises integrated into the serious game were selected by a peer group of physiotherapists and are based on conventional hand mobility therapy [4]. They involved hand and finger movements, wrist movements, and forearm rotations. The prototype included a set of 6 basic exercises, such as closing the hand into a fist or gripping for holding a book (Figure 2).

Figure 2. (A) Overview of the 6 exercises that were used in the prototype. (B) Preview hands as seen in version 2 demonstrated each exercise to the user.



In version 1, the number of exercises was expanded to a total of 17 different movements (a complete list is presented in Multimedia Appendix 1). Throughout the game, the difficulty of the exercises progressively increased. This was achieved by incorporating compound movements, such as simultaneously closing the hand into a fist while pronating the wrist. Moreover, each movement provided the option to be performed with both hands moving in synchrony or in opposite directions, thus adding a further level of complexity and skill requirement to the gameplay.

Performing the exercises neither involved direct interaction with the environment, such as plucking flower petals with the fingertips [44], nor a direct transfer of the patient's hand movements to control the environment [45]. Instead, the environment would adapt automatically at each successful repetition of the exercise, according to the respective task of the station. This design decision was made to ensure good optical tracking of the hands by always being positioned to be clearly visible to the cameras. Furthermore, the original exercise should not be falsified or complicated by being combined with a virtual interaction. Moreover, this design allowed a dynamic composition of exercises for each station on each training day, adjustable for every patient.

In the prototype, preview hands were introduced that would appear in front of the player to demonstrate and clarify the requested hand movements at the beginning of each exercise. The preview hands disappeared after 2 complete repetitions. In version 2, the 3D hand model was expanded by a forearm to provide a more comprehensive visualization of the exercises containing a rotation of the wrist. In addition, instead of dark gray hands, the color was changed to a lighter gray, and the outlines of the hands were highlighted to enhance visibility (Figure 2).

Exercise Tracking and Dynamic Range Adjustment

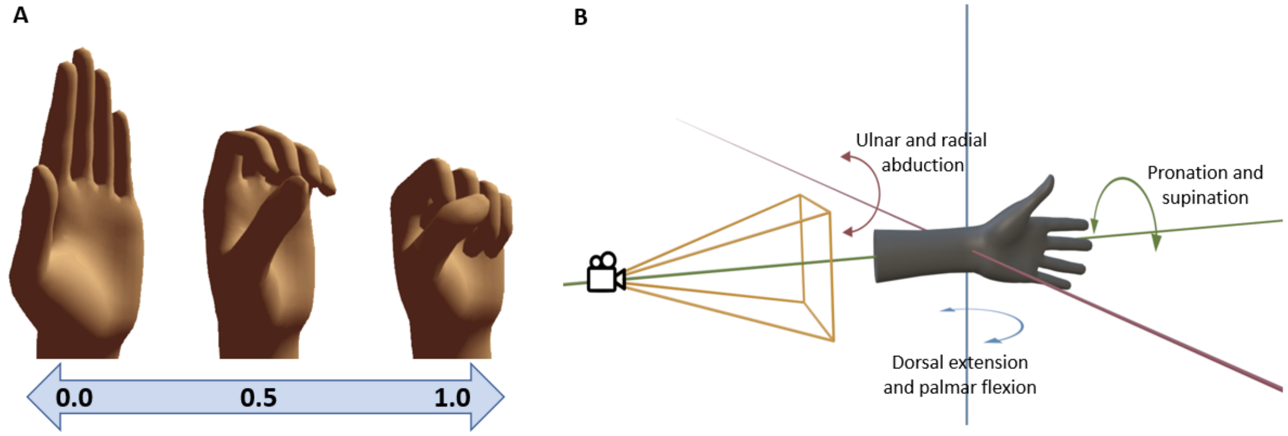
For the prototype, a dedicated component was developed to define and track exercise movements. This component used the hand position model supplied by the Meta Quest software development toolkit. In detail, it made use of the flexion angles of the finger joints within the provided hierarchical bone model to store and reproduce hand positions. By using the HMD, it was then possible to record various hand positions, such as an open hand or a closed fist, and subsequently use these stored positions to define exercise movements by specifying a respective start and end position as well as optional middle positions.

Due to the absence of a forearm in the tracking model of the Quest software development toolkit, the direct extraction of wrist rotation angles was not available. To compensate for this limitation, a reference coordinate system was used in replacement of a forearm bone to determine the rotation of the wrist. This coordinate system had its origin at the player's wrist and was spanned by the vertical axis of the VR environment and a forward axis based on the player's view direction and the forward direction of the hands, leveled within the VR environment by setting its vertical component to 0 (Figure 3). To accurately measure wrist rotation, it was necessary for the player to keep their arms bent forward during the exercise.

In addition to the interface for defining hand and finger exercises, the component was also able to track their execution. Therefore, the players' hand positions were compared to the specified exercise and expressed as a floating-point number within the interval (ie, 0,1). In this representation, 0 denoted the start position, and 1 indicated the end position. If the hand position deviated from the movement, the position was represented as –1.

For each exercise that was newly introduced, the game initially measured the range of motion (ROM) achieved by the player as represented within (0-1). This range was subsequently used to set a minimum target for the player to be exceeded when exercising. In version 2, an adaptive approach was implemented, where the target ROM was recalculated daily, based on the average ROM achieved in the preceding days. The tracking accuracy was also enhanced in version 2 by adding an additional middle position (Figure 3) to all exercise definitions, thus providing a more precise mapping of the player's ROM and adjustment to their skill.

Figure 3. (A) For each exercise movement, a start and end position were defined to determine the position of the hands within the interval (0,1) during exercising. In the second version, additionally a middle position was defined for more accurate measurement. (B) As Meta Quest 2 does not provide wrist tracking, its rotation had to be determined using a reference coordinate system. This coordinate system had its origin at the player's wrist and was spanned by the vertical axis (blue) and the leveled view direction (green). The third axis (red) was defined as perpendicular to the plane spanned by the first 2. This required the forearms to be held approximately along the view direction while exercising.



Interaction Design

Outside of the exercises, the player also used their hands to interact with the game (Figure 4). In the prototype, a teleportation system was created that enabled the player to switch between stations through predefined teleport points by pointing at them. In version 1, a waypoint network was established to allow the player to explore the farm environment also beyond the stations. Starting from version 1, the player was accompanied by a dog character that would provide guidance when touched. The dog's advice was displayed as text within a speech bubble. Nonplayable characters (NPCs) would respond to the player in a similar manner. In version 2, several improvements were implemented regarding the interaction. The teleport system was enhanced by introducing a navigation arrow with the purpose of guiding the player toward the next task. The touch interactions with the dog as well as with NPCs were improved by providing audiovisual feedback. All stations were fully supplemented with audio feedback during exercising; furthermore, an exercise counter was added that would display the number of remaining repetitions during an exercise.

Figure 4. Examples of in-game interaction: (A) petting the dog, (B) teleporting, (C) interaction with a nonplayable character, and (D) performing exercises at the Fireplace station.

Motivational Game Elements

Overview

In total, 4 game elements were developed to sustain patient motivation over the course of a 3-week treatment. These different elements were designed to cater to both intrinsic and extrinsic motivation, ensuring a wide range of motivational factors. The design prioritized preventing patient frustration resulting from limited hand movement and potential therapy-related discomfort, such as pain. At the same time, the game aimed to provide a challenge to less restricted or more competitive players, ensuring they remain engaged without getting bored. Furthermore, there should be no incentive to perform the exercises sloppily, for example, a time challenge. These motivational elements underwent first evaluation in the prototype and were further refined in versions 1 and 2.

Storytelling

The farm was populated with NPCs, which would provide the player with daily tasks, for example, to gather carrots from the vegetable field (Figure 5). In the prototype, initially only 1 NPC was implemented. However, starting from version 1, the farm was populated with 7 NPCs who assigned the player 2 daily tasks, each involving exercises at specific stations. Once the player completed these daily tasks, they gained access to exercise at all the other unlocked stations.

Figure 5. (A) A nonplayable character providing a daily task for the player. (B) The assessment station as seen in version 2 gave an overview of the player's progress. (C) Traffic Light Hands indicate that the movements were performed well. Yellow or green color indicated that the player had reached or exceeded their personal limit. As in version 2, this limit was adjusted daily according to their previous performance. (D) From version 1, the farm contained 12 stations that were unlocked over the course of the game.

Unlocking Rewards

Over the course of the game, the player was rewarded with additional exercise stations. In the prototype, the player unlocked a third station over the first 3 days to become playable on the fourth day. Starting from version 1, the player was rewarded with stations on each day after fulfilling their daily tasks, thus subsequently revealing all 12 stations over the course of the game (Figure 5).

Traffic Light Hands

Different hand colors were used to provide immediate feedback on the execution of movements. This was intended to guide the player toward performing terminal and correct movements while encouraging them to push their personal limit. A red hand color indicated that the patient reached their initially measured ROM, and the game recognized this as a successful repetition. As the patient continued to exceed this ROM, the hand color transitioned from red to orange and finally to green. In version 2, this system was adjusted daily based on the patient's ROM (Figure 5).

Scoring

In the prototype, the player received score points while exercising, based on the aforementioned achieved ROM. A highscore board placed in the middle of the farm presented the scores for each exercise. In version 1, the scoring system was omitted, and in version 2, an assessment station was introduced. This station provided players with visual feedback on their ROM progress throughout the training period for each exercise (Figure 5).

Evaluation

Overview

For all evaluations of StableHandVR, in-house patients from the hospital were recruited. These patients were undergoing inpatient rehabilitation because of limited hand function to such an extent that it restricted their professional and everyday activities. An overview of the type of injuries is given in Table 1. The patients took part in the VR sessions as part of their daily therapy schedule. Prerequisites for participation were basic mobility of the hand (no paralysis or total stiffness); limited hand function; no severe pain at rest (≥9 on a scale of 0-10); and the hand had to be free of stabilizing structures, such as splints, casts, or Kirschner wires. Inclusion criterion for all participants was a minimum age of 18 years.

Table 1. An overview of the injuries of the inpatients that were recruited for the evaluation of the prototype (n=7), version 1 (n=20), and version 2 (n=20).

Type of injury	Prototype, n (%)	Version 1, n (%)	Version 2, n (%)
Fractures in the wrist and hand area	3 (43)	11 (55)	6 (30)
Crush injuries or soft tissue injuries in the hand area	1 (14)	2 (10)	3 (15)
Tendon injuries in the area of the hand	0 (0)	2 (10)	1 (5)
Dislocations or ligament injuries in the area of the hand	1 (14)	1 (5)	1 (5)
Combination of the above points	2 (28)	4 (20)	9 (45)

Evaluation of the Prototype

The evaluation of the prototype involved 1 group of 25 participants consisting of 18 (72%) able-bodied individuals and 7 (28%) inpatients from the hospital (women: n=14, 56%; men: n=11, 25%. The age of the participants ranged from 18 to 56 years, with a mean age of 30.68 (SD 13.3) years. Among the 25 participants, 9 (36%) had prior experience with VR.

Each participant underwent 4 VR sessions conducted over 4 consecutive weekdays, with each session limited to 15 minutes. During each session, participants completed 1 exercise station and had the option to voluntarily complete a second one. In addition, only 1 of the 4 possible motivational game elements (Storytelling, Unlocking Rewards, Traffic Light Hands, and Scoring) was active during each of the sessions. In total, 3 motivational elements were evaluated in a randomized order over the first 3 sessions. In the fourth session, the player was consistently rewarded with access to a third exercise station, thus representing the fourth element, Unlocking Rewards.

After each session, participants rated their experience using 3 scales from the Intrinsic Motivation Inventory (IMI) questionnaire [46], specifically *interest and enjoyment*,*effort* and *pressure* on a 7-point Likert scale. In addition, participants were interviewed to gather their feedback on the game, suggestions for improvements, and ideas for additional content. The open-ended answers were evaluated based on the grounded theory [47] and thematic analysis [48].

Evaluation of Version 1

In total, 20 inpatients (women: n=6, 30%; men: n=14, 70%) from the hospital were equally assigned to either intervention or control group. The age ranged from 24 to 70 years, with a mean age of 48.8 (SD 12.3) years. Of the 20 inpatients, 8 (40%) had prior experience with VR.

During their 3-week inpatient rehabilitation program, both groups completed 12 VR sessions on consecutive weekdays in addition to their regular rehabilitation therapy. Each VR session was limited to 30 minutes and was supervised by a physiotherapist. In the intervention group, patients played the VR game and completed 2 mandatory tasks in each session. Additional training stations that were already unlocked could be voluntarily explored. New exercises were introduced every fourth day. In the control group, patients used the VR headset to watch a 360° video during each session, with durations ranging from 10 to 15 minutes. Following the final session, both groups were surveyed using the *interest and enjoyment*, *effort*, *usefulness*, and *pressure* subscales of the IMI questionnaire. The intervention group also evaluated the VR game using the Mobile Application Rating Scale (MARS) questionnaire [49], with the scales *engagement*, *functionality*, *aesthetics* and *impact on knowledge and attitudes* rated on a 5-point Likert scale, and was interviewed to gather feedback on the game. For further analysis of the user behavior, the game automatically recorded all user interactions in a time log.

Evaluation of Version 2

In total, 20 inpatients from the hospital were equally assigned to either the intervention or control group. One patient dropped out after the second session in the intervention group and another after the third session in the control group. The intervention group dropout was due to a dislike for the game, while the control group dropout was due to a transfer to another hospital. Both dropouts were replaced by 2 additional patients. All following analyses refer to the 18 remaining original patients and the 2 replacements.

The age of the final 20 patients (women: n=10, 50%; men: n=10, 50%) ranged from 22 to 61 years, with a mean age of 38.1 (SD 12.9) years; Of the 20 inpatients, 5 (25%) had prior experience with VR. The evaluation of version 2 followed a similar approach as version 1, with 2 modifications to the test protocol. First, the activity of the control group was extended by incorporating a crumple ball exercise for patients to engage their injured hand while watching the VR content. This addition aimed to provide an unspecific exercise for the injured hand. Second, patients in the intervention group had to rate the game using the System Usability Scale (SUS) [50] on a 5-point Likert scale after the last session. This measure was introduced to gather validated feedback on the usability of the game.

Data Analysis

All statistical analyses were performed with MATLAB for Windows (version R2021a; MathWorks) with a significance level of α=.05. To assess demographic effects, patients from the evaluations of versions 1 and 2 were consolidated and categorized into 5 age groups (<30, 30-39, 40-49, 50-59, and >60 years), into a group of women or men, and a VR-experienced versus no VR-experience group. All data gathered from the automatic tracking were tested for normal distribution using the Kolmogorov-Smirnov test. Due to the small sample sizes, nonparametric tests were used for all analyses. For multiple pair-wise comparisons, the Kruskal-Wallis test was used with the *P* level adjusted by Bonferroni correction. For single pair-wise comparisons, the Wilcoxon rank sum test was used. Demographic data, temporal data, and variables gathered from questionnaires were represented as mean (SD); the number of stations per day and the duration of exercise repetitions, gathered from the automatically tracked in-game data were represented as mean (SE).

Results

Prototype Results

All 25 participants completed the 4 VR sessions, and none of them reported vertigo or discomfort at any point. Over the course of the 4 sessions, all participants learned to operate the game without assistance. The mean VR playtime for each session decreased from 14.5 (SD 0.65) minutes for the first session to 10.6 (SD 0.82) minutes for the last session. All participants were able to perform the 6 exercises in a way that the game could recognize them. The mean duration needed to perform 1 repetition of an exercise decreased from the first to the fourth session from 7.1 (SD 0.35) to 6 (SD 0.38) seconds for the patients and from 5.6 (SD 0.26) to 4.7 (SD 0.24) seconds for the able-bodied participants.

The evaluation of the game elements with the IMI questionnaire resulted in high scores for all 4 elements on the 2 subscales *interest and enjoyment* and *effort* and low scores on the *pressure* subscale (Multimedia Appendix 2). There were neither substantial differences between the elements nor over the course of the 4 days. When asked about their most favored motivational element in the interviews, the Traffic Light Hands and Unlocking Rewards both were mentioned most frequently (8 mentions), followed by Storytelling (6 mentions) and Scoring (3 mentions), which lacked significance for many participants, as they always achieved the full ROM and therefore the maximum number of points.

The overall feedback gathered from the interviews was highly positive; the farm setting displayed in the game was widely regarded as pleasant and appealing (10 mentions). The direct feedback of the Traffic Light Hands (6 mentions), the interactive aspects of the station environments that would adapt during the execution of the exercises (5 mentions), the animals on the farm including the dog companion (4 mentions), and the general idea of gamifying a rather boring rehabilitation activity (4 mentions) were also positively mentioned. The least favored experiences were the recognition of the exercises (4 mentions), and the low number of exercise stations (4 mentions). The most mentioned suggestions for improvements were more variety in general (6 mentions), more exercise stations (4 mentions), enhanced storytelling (2 mentions), more variety in exercise movements (2 mentions), and a larger farm area to explore (2 mentions). When asked about suggestions for additional content, many suggestions were made for additional training stations related to farm work, mostly regarding animals (7 mentions) but also regarding the farm infrastructure (4 mentions), such as the farmhouse or the tractor, and activities regarding the lake (3 mentions).

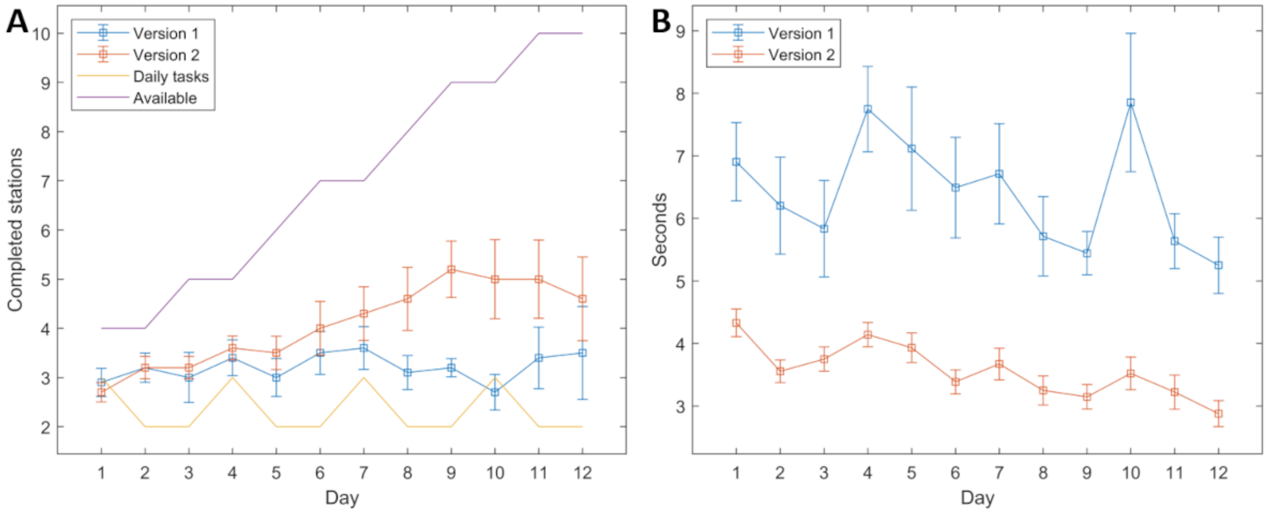
Version 1 Results

All 20 patients in both groups completed the 12 VR sessions; no patient reported any experience of discomfort or motion sickness. The mean VR playtime of the intervention group was 25.3 (SD 5.9) minutes on the first day and 26.4 (SD 10.6) minutes on the last day, with a mean playtime of 22.8 (SD 7.1) minutes over all days. The mean number of stations played per day was higher than the mandatory amount specified by the daily tasks on all days except for the 1st and the 10th day (Figure 6). Due to their limited hand function, some patients had problems performing the exercises such that they were recognized by the game, especially on the 10th day when the last set of exercises was introduced. The mean duration of the execution of 1 exercise repetition increased strongly on the days when new exercises were introduced (Figure 6) but decreased over the course of the 12 days from 6.9 (SE 0.62) seconds to 5.3 (SE 0.45) seconds.

The MARS rating resulted in high scores for all subscales: *engagement* (mean 4.18, SD 0.42), *functionality* (mean 4.17, SD 0.47), *aesthetics* (mean 4.2, SD 0.48), and *impact on knowledge and attitudes* (mean 4.7, SD 0.35; Multimedia Appendix 3). All IMI subscale scores were slightly higher in the intervention group than in the control group (Multimedia Appendix 4); significant differences were found for the subscales *effort* (*P*<.001) and *usefulness* (*P*=.02).

The user observation indicated that most patients could navigate the game independently without assistance after the initial 2 days, except when new exercises were introduced. The visual and textual instructions provided by the preview hands and the dog companion were occasionally unclear, requiring clarification from the assisting physical therapist. Some patients had difficulties with orienting themselves on the farm, especially on the first days. At the training stations, it was not always clear for some patients where the action was taking place to signify task completion. Patients mentioned difficulties regarding exercise counting, and they expressed the need for a visible counter and more auditory feedback at the stations to signal when a repetition was completed.

Figure 6. (A) The mean number and SE of completed stations in version 1 and version 2 as well as the minimum amount demanded by the daily tasks and the maximum possible number of stations for each day. (B) The mean duration and SE that were required to execute 1 repetition of 1 exercise in version 1 and version 2. New exercises were introduced on days 1, 4, 7, and 10.



Both groups reported perceiving the VR sessions as a vacation from their inpatient stay. They were able to momentarily forget about their injuries, felt being transported to another place, and experienced a sense of tranquility. The feedback from the intervention group regarding their game experience again was highly positive. The Traffic Light Hands were frequently mentioned for motivating patients to extend their limits toward terminal movements (6 mentions) and providing feedback on correct exercises (4 mentions); the immersive scenario, which made patients lose track of time during practice (6 mentions), and the virtual representation of their hand, which made them forget their injury (4 mentions), were also mentioned frequently. Some participants expressed their wish for an option to observe their progress, for example, as a score system that was not present in version 1.

Version 2 Results

A total of 20 patients completed the 12 VR sessions, of whom 19 (95%) did not report any discomfort or motion sickness and 1 (5%) answered with "don't know." The mean VR playtime of the intervention group was 20.3 (SD 5.9) minutes on the first day and 16.7 (SD 8.5) minutes on the last day, with an overall mean of 20.9 (SD 8.9) minutes on all days. The mean number of stations played was higher than in version 1 after the second day (Figure 6), and the overall mean of stations played was significantly higher (P=.008). All patients were able to perform the exercises in a way that was recognized by the game. The mean duration for performing 1 exercise repetition decreased from 4.6 (SE 0.24) seconds on the first day to 2.6 (SE 0.23) seconds on the last day. On the days with new movements being introduced, the increases were not as pronounced as in version 1 (Figure 6). The overall mean duration for performing 1 exercise repetition was significantly lower than that in version 1 (P<.001).

Compared to version 1, the MARS rating resulted in slightly higher scores for the subscales *engagement* (mean 4.24, SD 0.71) and *functionality* (mean 4.28, SD 0.42) and in slightly lower scores for the subscales *aesthetics* (mean 4.0, SD 0.63) and *impact on knowledge and attitudes* (mean 4.14, SD 0.73; Multimedia Appendix 3). The SUS rating resulted in a mean score of 86.9 (SD 3.3), which ranges in the fourth quartile and represents excellent acceptability. The scores of the IMI subscales were higher for the intervention group (Multimedia Appendix 4) than for the control group, with significant differences for the subscale *effort* (P=.02).

Similar to version 1, the user observation indicated that patients were able to operate the game without assistance after the first 2 days but required some assistance in learning new exercise movements. Orientation on the farm and at the stations was comprehensible for all patients, and performing the exercises caused the patients less difficulty than in version 1. Both groups reported the relaxing effect of the VR experience, and the most mentioned categories regarding the overall feedback from the interviews were similar to version 1: the Traffic Light Hands (5 mentions), the immersive game experience (5 mentions), and the virtual representation of the hands (3 mentions). Furthermore, the execution of the exercises was mostly described as working well (5 mentions). The newly designed Scoring element, providing a progress overview of the ROM at the assessment station, experienced the same issues as in the prototype, namely, always showing the possible maximum of points for the most exercises. Therefore, it was described as not very meaningful and was predominantly not used. Suggestions were made to provide other scenarios, such as a dungeon- or sci-fi–themed environment. Patients also raised the wish for a more personalized experience, and suggestions were made, for example, custom paint for the farmhouse or customizable virtual hands. Finally, recommendations for activities regarding the lake were mentioned again, such as fishing or riding a boat.

Demographic Effects

Regarding age, the 40- to 49-year age group showed the lowest number of completed stations among all age groups as well as the lowest IMI scores for *interest and enjoyment*, *effort*, and *usefulness*, while high scores for *pressure* were reported. The 30- to 39-year age group completed the most stations, and the <30-year age group reported the highest IMI scores for *interest and enjoyment*, *effort*, and *usefulness* and the lowest *pressure* score. Men played more stations than women patients and accordingly had higher IMI scores for *interest and enjoyment*, *effort*, and *usefulness*, with a lower *pressure* score. Patients with no prior VR experience completed more stations per day than patients with prior VR experience. However, the latter rated higher IMI scores for *interest*, *effort*, and *usefulness* but also a higher score for the *pressure* scale. The complete list of values is presented in Table 2.

Table 2. Number of stations completed per day and Intrinsic Motivation Inventory scores (1-7 scale)[a].

Demographic group	Stations per day, mean (SE)	Interest and Enjoyment, mean (SD)	Effort, mean (SD)	Pressure, mean (SD)	Usefulness, mean (SD)
Gender					
Men (n=11)	3.89 (0.6)	6.4 (0.6)	6.1 (1.0)	2.0 (0.6)	6.5 (0.6)
Women (n=9)	3.34 (0.5)	6.3 (1.1)	6.0 (1.0)	1.9 (0.7)	6.3 (1.2)
VR[b] Experience					
Prior VR experience (n=4)	3.04 (0.5)	6.4 (0.9)	6.1 (0.6)	2.2 (0.7)	6.5 (0.5)
No prior VR experience (n=16)	3.79 (0.6)	6.3 (0.8)	6.0 (1.0)	1.9 (0.7)	6.4 (0.9)
Age group (y)					
<30 (n=2)	3.58 (0.3)	6.6 (0.6)	7.0 (0)	1.5 (0.7)	6.9 (0.2)
30-39 (n=4)	4.98 (1.5)	6.0 (0.6)	5.8 (0.7)	1.7 (0.4)	6.3 (0.6)
40-49 (n=3)	2.97 (0.9)	5.9 (2.0)	5.7 (1.5)	2.1 (0.7)	5.5 (2.1)
50-59 (n=8)	3.08 (0.3)	6.6 (0.5)	6.0 (1.0)	2.1 (0.8)	6.8 (0.2)
>60 (n=3)	4.05 (1.1)	6.3 (0.3)	6.3 (0.7)	2.0 (0.3)	6.1 (0.4)

[a]The data were consolidated from version 1 (n=10) and version 2 (n=10) and categorized by demographic groups.

[b]VR: virtual reality.

Discussion

Principal Findings

In this study, we iteratively developed a serious health game for hand and finger rehabilitation with the deliberate goal of contributing to the long-term engagement of patients. The game was developed for the Meta Quest 2 because this HMD with built-in finger tracking allowed for a very simple and fast setup. A second reason for this decision was the finger tracking of the device, which produced better results than the Leap Motion or UltraLeap controllers when performing certain finger positions that were considered important, for example, the thumb touching ≥1 long fingers.

The iterative development and evaluation steps ensured a patient-centered design process by user observation and feedback through semistructured interviews. In general, participants reported a high level of immersion that allowed them to temporarily escape from their inpatient setting into another world. This was reported by both the intervention group and control groups and impressively confirms the potential of VR as described in the literature [18,51]. The setting of the farm environment and the display of nature were overall received very positively, a design decision that was also inspired by literature [43]. However, in the original intervention group of version 2, one patient quit after the second session because they did not like the game in general. In terms of engagement, we observed the entire spectrum from patients who tended to be underchallenged to patients well within their physical and cognitive limitations. We attribute these differences not only to varying levels of hand function but also to contrasting user preferences (eg, purpose vs mastery) [34], possibly coined by the practice of playing video games.

We expected a decrease in motivation related to the higher age of the participants and thus less familiarity with video games [52]. The familiarity was reflected by the IMI subscale *pressure*, which was clearly lowered for the <30- and 30- to 39-year age groups. However, while the 40- to 49-year and 50- to 59-year age groups completed the fewest stations per day, the >60-year age group reached the second highest value, only surpassed by the 30- to 39-year age group and before the <30-year age group. Differences in the number of stations completed between genders are smaller than between VR and no VR experience. The other IMI scales *interest*, *effort*, and *usability* show only minor deviations for all demographic groups. From these findings, it could be concluded that while age, gender, or the effect of technological novelty due to using VR for the first time might affect the overall motivation, these demographic effects did not harm the intrinsic motivation of the patients.

Compared to their control groups, higher IMI scores were measured for both intervention groups, and significant differences were found for the subscales *effort* in version 1 and version 2 and *usefulness* in version 1. It should be mentioned that, surprisingly the control groups were also very motivated to watch the videos, which again demonstrates the potential of using VR in the context of rehabilitation. However, we assume that in an unsupervised setting, the motivation in the control groups would have decreased more compared to the intervention groups [2] because the game, as used in our study, still represented a form of supervision. The assurance of performing the therapeutic exercises correctly may have been a key factor for the significantly higher IMI subscale *usefulness* of the intervention group, as scored in version 1 [41]. According to the MARS questionnaire, awareness for conscious health behavior could be raised for the intervention groups, which is linked to perceived attitude, enjoyment, and especially usefulness [14,15].

To engage a wide range of player types, 4 motivational game elements offering different motivational factors were developed. The element Storytelling should provide tasks and a context, Unlocking Rewards should offer new incentives for discovery, the Traffic Light Hands would provide direct feedback, and the Score would provide long-term feedback [34]. Among these 4, the first 3 elements can be considered rather successful, as they scored high on the IMI questionnaire and the subscales *effort* and partially also *usability* were significantly higher than in the control groups. In particular, the Traffic Light Hands received positive feedback in the interviews. This direct biofeedback, which is a critical factor for intrinsic motivation [41,53], not only encouraged patients to perform terminal movements but also gave them confidence to exercise correctly.

In contrast, the Scoring element already proved to be unsuccessful in the prototype stage because it lacked meaningfulness in terms of showing the patient's ROM improvement. This was mainly caused by the fact that many players were able to perform most exercises with full range from the beginning. Due to the ambiguity, the element was discontinued in version 1 to avoid negative feedback and discouragement. Due to the frequent demand to visually represent the progression of ROM, the element was reintroduced in version 2 with a different design, which did not work properly for the same reasons. Therefore, the resulting lack of competitive motivational elements might be the main reason why the game was not challenging enough for some patients [34]. Furthermore, the lack of visualization of the therapy progress deprived patients of evidence of efficacy, which is also a key motivating factor for health games [41].

The comparison of versions 1 and version 2 shows a significantly higher number of stations played per day, from which it can be concluded that the overall motivation in version 2 was higher. Besides the improved interaction feedback, also reflected by a high SUS score, the most obvious improvement was the tracking accuracy of the therapeutic exercises, which can clearly be seen by the mean time that was required for a single exercise repetition being reduced by almost half. This circumstance may be mainly responsible for the fact that more stations were played. However, this interpretation must also consider that the mean age of the patients in version 2 was 10 years lower than in version 1. In both versions, a similar amount of time was spent in the game, on average approximately 22 minutes. As there were no significant differences in the IMI scores between version 1 and version 2, we conclude that the improvements did not affect the intrinsic motivation, which was already high in version 1.

Limitations

Patients attended the VR sessions after their daily rehabilitation routine and may have been exhausted, which could potentially affect their motivation negatively. By contrast, we can assume that by being part of their daily routine, the supervised participation in VR sessions, although voluntary, was accompanied by stronger motivation than if it had been unsupervised [2]. The large variation in the degree of injury and impairment between individual patients may have influenced the outcome of measured and observed motivation. A larger sample size would better compensate for this effect.

Due to the short evaluation time of only 12 days, it was only partially possible to measure the long-term course of motivation.

Outlook and Future Challenges

While we acknowledge the challenges in making the game equally appealing and challenging for all patients, our approach of incorporating a mix of extrinsic and intrinsic motivational elements was generally successful. By individually adjusting the composition of the movements, the challenge level of the game could be easily increased for underachieving players. It has also become apparent that there is a great need for a working score system or at least a therapy progress indicator. To build up compliance and adherence among patients, this proof of effectiveness is a key factor and needs to be improved. Due to the missing forearm tracking and inaccuracies in detecting individual phalanges [54], especially within an unusual finger or hand position, the correct execution of the patient's movements and the assessment of their ROM was limited. We expect this feature to improve over the next few years, enabling us to overcome these limitations. In the meantime, a point system could be implemented that is simply based on the number of exercises already completed.

In the context of the general shortage of therapists, it would be beneficial to use StableHandVR in an unsupervised setting, for example, at home for several weeks, following the inpatient stay. The evaluation of StableHandVR in an unsupervised setting for an extended period would also be an exciting next step from the perspective of this study. In such a setting, we see the biggest challenge for our game, both in terms of user engagement and in substituting the physical therapist, whose assistance is currently still required for correctly learning new exercises.

Finally, StableHandVR could easily be transferred into other domains where hand and finger exercises are required, such as in stroke rehabilitation [21] or multiple sclerosis [12]. As StableHandVR allows for the simple creation of additional therapeutic exercise movements, it could be extended within a short time for other motor exercises. Furthermore, we think that the promising use of different motivational elements as in StableHandVR would also be beneficial for a variety of other applications that use gamification in a therapeutic context to achieve user engagement.

Conclusions

This study showcased a VR game designed for hand and finger rehabilitation exercises. The iterative development process allowed user feedback to be incorporated into further development. The game was well received, offering an engaging environment and various elements that effectively motivated the users. Despite impaired hand function, the tracking of therapeutic movements proved to be reliable in operating the game. The high SUS score confirms the ease of use of the game, even for patients with physical limitations. With ongoing technical advancements in optical finger tracking, we anticipate even greater accuracy in the future, paving the way for automated medical assessments and telerehabilitation scenarios. This creates the potential for StableHandVR to become an unsupervised yet engaging VR health game for postrehabilitation home use.

Acknowledgments

Funding for this project was provided by the German Social Accident Insurance (Deutsche Gesetzliche Unfallversicherung [DGUV]; FR237). The authors thank student Dominik Lammer for his valuable assistance in designing and implementing the prototype and version 1.

Authors' Contributions

MB contributed to the game design, implemented all versions, contributed to the evaluation, analyzed the data, and wrote the manuscript. JM contributed to the game design, contributed to the evaluation, and revised the manuscript. TG contributed to the game design, performed the experiments, collected the data, and revised the manuscript. FK contributed to the game design, contributed to the interpretation of the results, and revised the manuscript. AD and JK contributed to the critical revision of the intellectual content and approved the final version. CP contributed to the methodology and the game design, revised the manuscript, and oversaw overall direction and planning. All authors provided critical feedback and helped shape the research, analysis, and manuscript. All authors contributed to the article and approved the submitted version.

Abstract

Background: Few gamified cognitive tasks are subjected to rigorous examination of psychometric properties, despite their use in experimental and clinical settings. Even small manipulations to cognitive tasks require extensive research to understand their effects.

Objective: This study aims to investigate how game elements can affect the reliability of scores on a Stroop task. We specifically investigated performance consistency within and across sessions.

Methods: We created 2 versions of the Stroop task, with and without game elements, and then tested each task with participants at 2 time points. The gamified task used points and feedback as game elements. In this paper, we report on the reliability of the gamified Stroop task in terms of internal consistency and test-retest reliability, compared with the control task. We used a permutation approach to evaluate internal consistency. For test-retest reliability, we calculated the Pearson correlation and intraclass correlation coefficients between each time point. We also descriptively compared the reliability of scores on a trial-by-trial basis, considering the different trial types.

Results: At the first time point, the Stroop effect was reduced in the game condition, indicating an increase in performance. Participants in the game condition had faster reaction times (P=.005) and lower error rates (P=.04) than those in the basic task condition. Furthermore, the game condition led to higher measures of internal consistency at both time points for reaction times and error rates, which indicates a more consistent response pattern. For reaction time in the basic task condition, at time 1, $r_{\text{Spearman-Brown}}$=0.78, 95% CI 0.64-0.89. At time 2, $r_{\text{Spearman-Brown}}$=0.64, 95% CI 0.40-0.81. For reaction time, in the game condition, at time 1, $r_{\text{Spearman-Brown}}$=0.83, 95% CI 0.71-0.91. At time 2, $r_{\text{Spearman-Brown}}$=0.76, 95% CI 0.60-0.88. Similarly, for error rates in the basic task condition, at time 1, $r_{\text{Spearman-Brown}}$=0.76, 95% CI 0.62-0.87. At time 2, $r_{\text{Spearman-Brown}}$=0.74, 95% CI 0.58-0.86. For error rates in the game condition, at time 1, $r_{\text{Spearman-Brown}}$=0.76, 95% CI 0.62-0.87. At time 2, $r_{\text{Spearman-Brown}}$=0.74, 95% CI 0.58-0.86. Test-retest reliability analysis revealed a distinctive performance pattern depending on the trial type, which may be reflective of motivational differences between task versions. In short, especially in the incongruent trials where cognitive conflict occurs, performance in the game condition reaches peak consistency after 100 trials, whereas performance consistency drops after 50 trials for the basic version and only catches up to the game after 250 trials.

Conclusions: Even subtle gamification can impact task performance albeit not only in terms of a direct difference in performance between conditions. People playing the game reach peak performance sooner, and their performance is more consistent within and across sessions. We advocate for a closer examination of the impact of game elements on performance.

Introduction

Background

In 1886, James Cattell observed that it takes people longer to name the colors and pictures of objects than it does for them to read the corresponding word [1]. This experiment, along with others, paved the way for the development of what Cattell would call *mental tests* and what we now call *cognitive tasks*. On the basis of these and other results, JR Stroop developed a test of cognitive ability in which study participants read the color but not the meaning of a color word aloud [2]. The results revealed an interference effect if the word color and word meaning did not match. Typical cognitive tasks require people to respond to such visual or auditory cues, and data about their responses, often reaction time and accuracy, are collected. These data can then be used to study human cognition, create population norms, and inform medical decisions, such as dementia diagnoses [3].

Cognitive tasks are most useful when collecting high-quality, high-quantity data. However, this is a challenging process. Traditionally, capturing large data sets has been time consuming and expensive, requiring highly trained professionals to administer and score tasks with individual participants. With technological advancements, tasks can now be administered via computers, deployed remotely, and automatically scored [4,5]. This automation makes it easier to collect large quantities of data but raises new concerns about data quality. Many factors influence cognitive test performance beyond cognitive capacity, such as motivation, stereotype threat, and fatigue [6,7]. Cognitive tasks are often repetitive and boring, leading to high attrition rates [8] and suboptimal effort from participants [9,10].

In attempts to improve the quality of data collected by such tasks, researchers have increasingly turned to gamification, with the hope that tasks can be made more engaging through the addition of game elements, such as points and graphics.

Cognitive Task Gamification

Overview

Deterding et al [11] defined gamification as “the use of game design elements in nongame contexts.” In the context of cognitive tasks, this process typically involves layering game elements over an already existing task. For example, the Go No-Go task has commonly been gamified by adding points [12], narrative elements [13], and fun graphics [14] to the basic task.

Enjoyment and Motivation

Typically, tasks are gamified with the intent of increasing participant enjoyment and motivation. Nicholson [15] noted that gamification can target both extrinsic and intrinsic motivations depending on the game elements used. Reward-based elements, such as points, achievements, and badges, target extrinsic motivation, whereas elements such as play, exposition, and choice target intrinsic motivation. By targeting motivation, researchers aim to combat attrition and encourage repeated, prolonged play [16-18].

However, there is little examination of whether participants experience increased enjoyment when tasks are gamified. In a systematic review of gamified attention tasks, only 25 of the 74 studies reported results from an evaluation of gameplay [16]. When enjoyment is measured, the research shows mixed results. Some studies have found that gamification increases motivation; for example, participants in a stop signal task study experienced higher enjoyment and more flow-like experiences in the gamified condition (as opposed to the basic task) [19].

Other studies have found that certain game elements, especially thematic or narrative elements, can have a negative effect on self-reported enjoyment of cognitive tasks [8,20,21], possibly due to the “chocolate-covered broccoli” effect [22]. Tasks can only be gamified and retain the important elements of a task. When participants expect a fun game and must still complete a repetitive cognitive task, they may experience even lower enjoyment than if they expected a boring task [20]. Game elements can also be used to introduce other emotions. For example, Levy et al [23] found that some older Jewish participants were uncomfortable with their cooking-themed game as they required making recipes containing pork products.

Do these mixed findings imply that researchers should move away from gamifying tasks? Not necessarily, participants might not *enjoy* assessment games more than a control task, but the data they produced may still be of higher quality.

Performance

Groening and Binnewies [24] note that enjoyment is only one way to operationalize motivation, one closely linked to intrinsic motivation. They found that adding achievement-based game elements to a series of simple tasks did not improve self-reported motivation but did improve persistence—when participants could earn achievements, they engaged with a Stroop task for longer before voluntarily switching tasks, compared with when no achievements were available. Similarly, Mekler et al [25] found that when they gamified an image annotation task, participants generated significantly more annotations, despite no reported differences in intrinsic motivation or competence need satisfaction when compared with the basic task.

Adding game elements to a task may improve performance (without affecting enjoyment) in various ways. For example, Jung et al [26] compared the performance of participants who were given a numeric goal (ie, generating 22 ideas) with those who were asked to “do their best.” Participants who were given a specific goal generated higher quantity and higher quality responses. When completing cognitive tasks, participants are often instructed to respond “as quickly and accurately as possible.” This nebulous goal can be clarified and reinforced through game elements that provide immediate feedback such as scoring points for fast reactions or losing points for incorrect responses.

When designing gamified tasks for research and assessment purposes, it may be beneficial to focus on influencing performance rather than on enjoyment. Levy et al [23] noted that changes in emotions can influence cognitive abilities, which may interfere with the collection of valid and reliable data when using games as scientific tools. When Vanden Abeele et al [27] compared 2 games designed to measure psychoacoustic thresholds in preschoolers, they found that the more fully developed and motivating game was able to detect lower thresholds. As another example, Delisle and Braun [28] found that changing a task to resemble a fast-paced videogame normalized the performance of participants with attention-deficit/hyperactivity disorder (ADHD), meaning that participants with and without ADHD performed similarly on a gamified task (but differently on a standard task). In some cases, such an effect may be desired, but it depends on why the task is used and gamified.

Psychometric Properties of Gamified Tasks

Tasks may also be gamified with the goal of improving the psychometric properties of a task, such as validity (how well a task measures what it claims to measure) and reliability (how consistent the measurement obtained by the task is) [29]. There are also different types of evidence for reliability that must be considered when gamifying cognitive tasks. Internal consistency refers to the stability of the task data within an assessment; for example, the similarity of a participant's reaction time at the beginning of a task to their reaction time at the end of the task. Test-retest reliability refers to the stability of the task data over time; for example, how similar a participant's score on a task is at one time point compared with their score on the task a month later.

Typical cognitive tasks are boring, repetitive, and long partly because of the issue of reliability. From one trial to the next, people will perform quite differently, so multiple trials are needed to decrease measurement noise [30]. Adding game elements to a task may change the reliability of its measurement. Participants may be sufficiently engaged that their performance is more stable over time; for example, perhaps only 20 trials are needed for a reliable measure, instead of 200. Friehs et al [19] found that response variability in a gamified stop signal task was lower than that in the nongame version. Shorter tasks would require fewer resources to administer and would reduce the burden on participants, which would be particularly beneficial for clinical and pediatric populations.

Game elements also offer the ability to guide participants' performance. Most cognitive tasks use measures of reaction time and accuracy, which leads to classic speed-accuracy trade-offs—the faster a participant responds, the less accurate they will be, and vice versa. Individual participants also favor speed or accuracy differently than one another [30]. These behaviors can be manipulated through instructions (eg, asking participants to respond as quickly as possible). Game elements can also indirectly encourage participants to emphasize speed or accuracy, for example, by awarding points or feedback for faster or more accurate responses, generating more consistency across participants [30,31].

This Study

Overview

Few gamified cognitive tasks are subjected to rigorous examination of psychometric properties [16], despite their use in experimental and clinical settings. Parsons et al [32] noted that psychology lacks a standard practice of reporting the reliability of cognitive task measurements. This problem is exacerbated when tasks are adapted, such as gamification. Even small manipulations of cognitive tasks require extensive research to understand their effects [33].

In this study, we sought to research how game elements can affect the reliability of scores on a cognitive task, specifically the Stroop task. As a typical cognitive task that demonstrates robust experimental effects in the general population [34], the Stroop task is well suited for this research.

The Stroop Task

Building on the 1886 work by Cattell [1] with cognitive tasks, in 1935, Stroop [2] conducted an experiment in which he asked participants to either name the colors of colored rectangles or name the colors of mismatched words (eg, the word "blue" printed in red ink). Participants responded much more slowly when naming incongruent colored words, a paradigm we now call the Stroop effect [2].

Since Stroop's first experiment and subsequent development of the experimental protocol [35-37], the Stroop task has become one of the most widely used tasks in both cognitive and clinical psychology [34,38]. Recently, the Stroop task has been gamified for experimental and clinical applications. For example, Groening and Binnewies [39] used the Stroop task to investigate the effects of game elements on participants' motivation and performance. They found that when points and story elements were added to the task, participants were more persistent (they engaged with the task for longer before switching to a new task) and reported higher motivation. Gomez-Tello et al [40] used gamified tasks as part of a battery of tests for neuropsychological screening of children and found evidence of the Stroop effect in a gamified version of the task. However, previous studies have not considered the reliability of the Stroop effect in a gamified task, either in terms of internal consistency or test-retest reliability. Thus, we have little guidance when gamified tasks can or should not be used in assessments.

We created 2 versions of the Stroop task, with and without game elements, and tested each task with participants at 2 time points. In this paper, we report on the reliability of the gamified Stroop task in terms of internal consistency and test-retest reliability, compared with the control task. We also compared the reliability of these scores on a trial-by-trial basis. Our objective was to demonstrate how game elements can affect the reliability of scores on a Stroop task.

Methods

Ethical Considerations

This research project was approved on ethical grounds by the University of Saskatchewan Research Ethics Board (BEH 17-418). The participants were given GBP £6 (USD $8.3 at time of study) compensation at each time point.

Tasks

The control task was designed using the basic computerized Stroop task described by Macleod [34] and Hedge et al [41] as models. Participants were shown words in the middle of their screen in various colors (red, blue, green, or yellow). The word could be the same as the font color (congruent condition), a noncolor word (lot, ship, cross, or advice; neutral condition), or a nonmatching color word (eg, the word "blue" shown in green; incongruent condition). After each word, participants were asked to press a key corresponding to the font color (z-key for red, x-key for blue, n-key for green, and m-key for yellow). The participants first completed a training exercise to learn each keymap. The task consisted of 240 trials in each condition (congruent, neutral, and incongruent) for a total of 720 trials.

The gamified version was designed to increase reliability by manipulating the speed-accuracy trade-off [30] and improving engagement through game elements. On the basis of prior research, which demonstrated increased enjoyment from points and decreased enjoyment from themes added to a gamified task [20], we focused on adding points-based game elements to the Stroop task. Points-based elements also target extrinsic motivation (rather than intrinsic motivation), which may be more effective in influencing participant performance [24]. We followed the feedback category of the Gameful Design Heuristics from Tondello et al [42], which states that the system should offer users clear and immediate feedback, actionable feedback, and graspable progress.

Using feedback also allowed us to manipulate the speed-accuracy trade-off by preferentially awarding points for faster (but still correct) answers. In the game version of our task, participants saw their response time for each trial and whether they answered correctly. A record of the fastest response time was also displayed at the corner of the screen. They lost 5 points for any incorrect answer, gained 5 points for any correct answer, and were rewarded with a bonus of 25 points for responses that broke their previous "fastest time" record. A progress bar at the bottom of the screen tracked the points (Figure 1).

Figure 1. Game version of the task after a correct response was entered.

Participants

Participants were recruited through Prolific, a web-based platform for recruiting research participants. Web-based platforms are commonly used in human-computer interaction research to conduct studies [43] and have been shown to yield reliable data when precautionary methods for data gathering and analysis are used [44,45]. Each participant completed either the control task or the gamified task at 2 time points, 3 weeks apart (time 1 and time 2). The participants signed a consent form, were given instructions and training for the task, and then completed the task. After completion, they answered questionnaires collecting demographic information, including information about their experience with the task (Intrinsic Motivation Inventory [46]), their general gaming behavior, and self-reported attentional control (Attentional Control Scale [47]).

The study design was between-subjects, with half the participants completing the control version of the task and the other half completing the points version. The participants were randomly assigned to a condition. The study took approximately 40 minutes to complete.

Our analyses were based on the methods of Parsons et al [32] and Hedge et al [41]. Both studies used the same data sets, which had data from 47 (study 1) and 56 (study 2) participants for the Stroop task. In these studies, this sample size was sufficient to observe effects with medium effect sizes. Thus, based on these prior studies, we aimed to obtain approximately 50 participants for each condition [48].

We only analyzed data from participants who had completed both sessions. We also set quality thresholds and removed participants who did not meet them at either time point. Finally, we also removed outlying data points, such as individual trials that were much slower than the average for each participant, to reduce noise in the data, as the study was web-based, and we could not otherwise account for participant distraction from the tasks.

Statistical Analysis

Reaction Time and Error Rate Data

We conducted 2-way ANOVAs with task type (basic or game) and trial condition (congruent, neutral, or incongruent) for reaction time and error rate data. We used 1-way ANOVAs to compare the effect of task type on the skewness and kurtosis of the distribution of reaction time data for each participant. In addition, we conducted 3-way repeated measures ANOVAs (task type × trial type × time) for reaction time cost and error rate cost data. We also created groups representing low and high attentional control based on the median of 51.0 of our participants and then conducted 3-way repeated measures ANOVAs (task type × attention × time) for reaction time cost and error rate cost data.

Internal Consistency and Test-Retest Reliability

For measuring and reporting reliability, our analysis followed the recommendations from Parsons et al [32]. To evaluate internal consistency, we used a permutation approach, which involves repeatedly randomly splitting the data, calculating the reliability estimate, and then averaging all estimates. This approach provides a more stable estimate, independent of how trial stimuli and conditions are presented [32]. To evaluate test-retest reliability, we calculated the Pearson correlation between each time point. We also used intraclass correlation coefficients (ICCs) to indicate the degree of consistency and agreement between each time point. On the basis of Parson recommendations, we used ICCs labelled ICC(3,1) and ICC(2,1), as described by Shrout and Fleiss [49]. Finally, we plotted the test-retest reliability as the number of trials increased. To achieve this, we followed the method used by Hedge et al [41].

Results

Participants

For the first round of data collection (time 1), we received 135 responses, followed by 78 responses for time 2.

All participants met the criteria for questionnaire speed of completion (participants needed to spend an average of 1.5 seconds per item) and variance (participants needed to show some variance across items). In total, 13 participants were excluded because they too frequently provided an incorrect response on the Stroop task (total incorrect responses>1 SD above the mean number of incorrect responses) and because they responded to trials too slowly (mean reaction time>3 SD above the group mean reaction time). Before calculating the group mean reaction time, we also removed any individual trials that were slower than the average for each participant (reaction time>3 SD above the individual mean reaction time), as well as any remaining outlier trials that were slower than 2000 milliseconds. At time 1, we removed 1667 trials (out of 50,400). At time 2, we removed 1976 trials (out of 49,680). Notably, both at time 1 and time 2, significantly fewer trials needed to be removed from the game condition compared with the basic version; 38.6% of the removed trials were in the game condition at time 1, and 32.9% were in the game condition at time 2.

After exclusions, 65 participants remained (50 female, 13 male, 1 nonbinary, and 1 prefer not to disclose; mean age 23.91, SD 4.64 years), with 31 participants in the basic task condition and 34 participants in the game condition. Our sample had a high proportion of women because of the web-based platform we used [50]. The participants had a mean score of 51.8 (SD 7.54) on the Attentional Control Scale.

Intrinsic Motivation Inventory

At both time points, the basic task and game conditions showed no significant differences for any of the Intrinsic Motivation Inventory subscales (interest, competence, effort, and pressure).

Reaction Time and Error Rate Data

We averaged the reaction times and error rates across participants and then analyzed each measure by task type and trial condition at each time point. We also calculated reaction time and error rate costs (mean incongruent trials and mean congruent trials). Table 1 presents the descriptive statistics for each measure.

Histograms of reaction time for all participants are presented in Figure 2 by task type and time point. One-way ANOVAs revealed no significant effects of task type on the skewness and kurtosis of the distribution of reaction time data for each participant (Table 2).

The 2-way ANOVAs for reaction time and error rate demonstrated evidence of the Stroop effect at both time points (significant differences between incongruent trials and both congruent and neutral trials). Furthermore, congruence sequence effect analysis revealed the expected adaptive control effect but no effect of task condition, time, or an interaction between the 2 emerged. There were also significant differences between task conditions at time 1: participants in the game condition had faster reaction times and lower error rates than those in the basic task condition. There were no significant differences at time 2 (Tables 3 and 4).

Two-way repeated measures ANOVAs (task type × time) for reaction time cost and error rate cost data showed no significant interaction effects (Table 5). The 3-way repeated measures ANOVAs (task type × trial condition × time) for reaction time and error rate data showed no significant interaction effects (Table 5). On the basis of grouping our participants into low and high attentional control categories, we found a significant 3-way interaction between time, task type, and attention category for the error rate (Table 5). Participants who scored low in attentional control and were in the basic task condition had a lower error rate cost at time 1 than at time 2. In the game condition, participants who scored low on attentional control had a higher error rate cost at time 1 than at time 2. The error rate cost for participants who scored high on attentional control showed an opposite pattern. There were no significant simple 2-way interactions between task type and attention category at either time point.

Table 1. Descriptive statistics for reaction time and error rates, at times 1 and 2 for each task type.

	Time 1, mean (SD)	Time 2, mean (SD)
Basic task		
Congruent reaction time (milliseconds)	678 (103)	659 (104)
Neutral reaction time (milliseconds)	671 (94.0)	656 (94.7)
Incongruent reaction time (milliseconds)	796 (124)	758 (118)
Reaction time cost (milliseconds)	118 (50.9)	98.8 (39.8)

[a]Owing to the interaction violates the assumption of sphericity (*P*<.001), *P* values are derived using the Greenhouse-Geisser statistic.

Internal Consistency

Overview

We estimated the internal consistency of the basic task by using a permutation-based split-half approach [32] with 5000 random splits. Internal consistency ranged between 0 and 1, with higher numbers representing more consistency across an individual's complete set of trials.

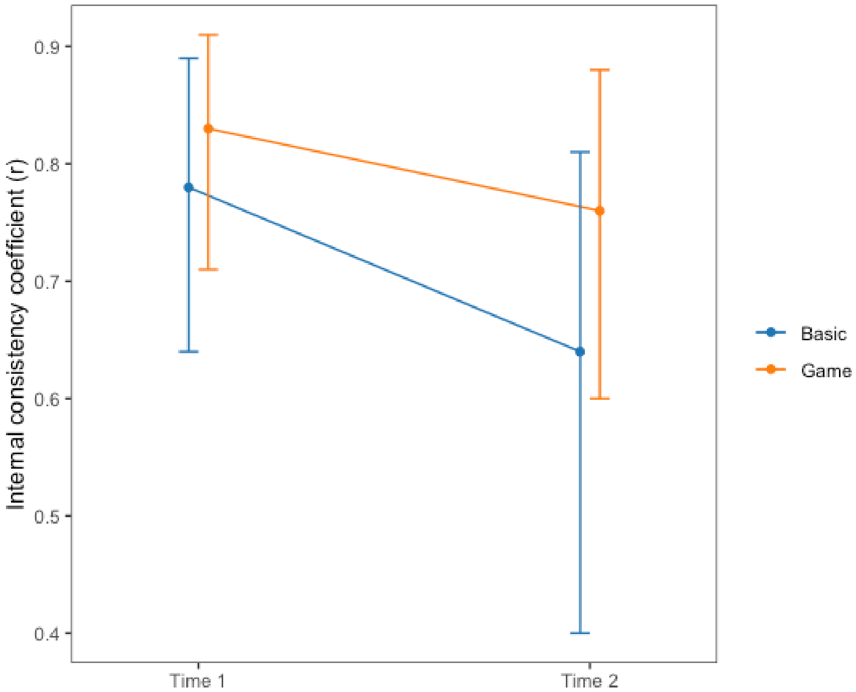
Reaction Time

When using the reaction time cost, the (Spearman-Brown corrected) split-half internal consistency for the basic task at time 1 was $r_{\text{Spearman-Brown}}$=0.78, 95% CI 0.64-0.89. At time 2, $r_{\text{Spearman-Brown}}$=0.64, 95% CI 0.40-0.81.

For the game condition at time 1, the split-half internal consistency was $r_{\text{Spearman-Brown}}$=0.83, 95% CI 0.71-0.91. At time 2, $r_{\text{Spearman-Brown}}$=0.76, 95% CI 0.60-0.88.

The internal consistency values were higher at both time 1 and time 2 for the game condition (Figure 3); however, converting the correlations to Fisher *z* scores indicated no significant differences between groups at each time point.

Figure 3. Internal consistency of reaction time cost for each time point and task type.



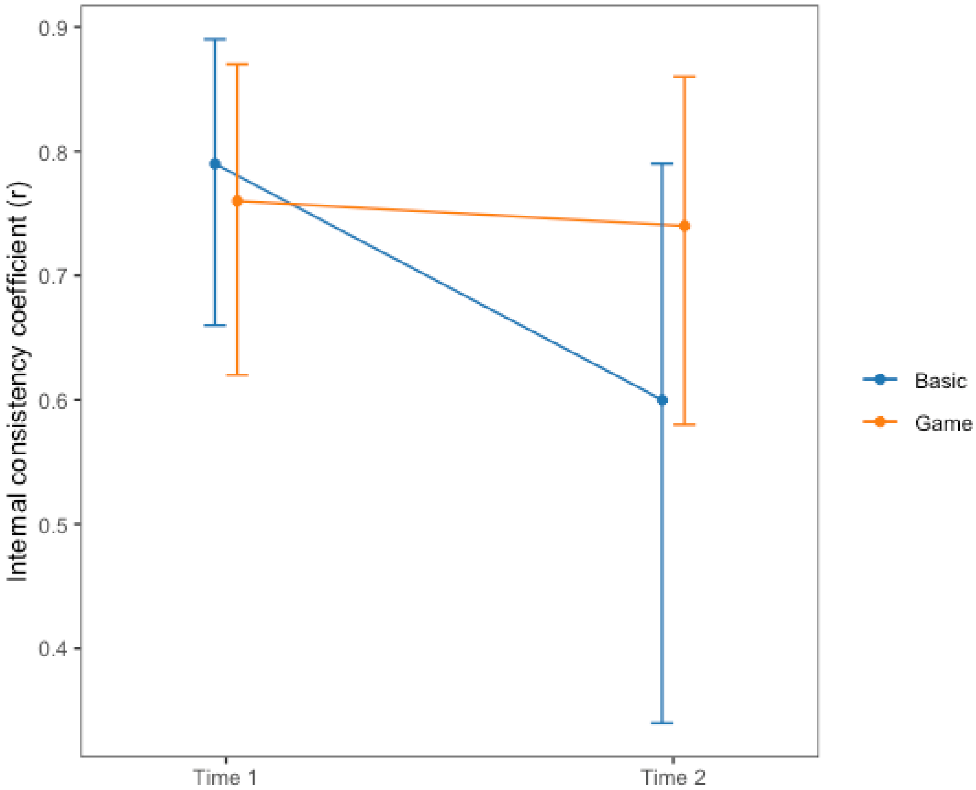
Error Rate

When using error rate cost, the (Spearman-Brown corrected) split-half internal consistency for the basic task at time 1 was $r_{\text{Spearman-Brown}}$=0.79, 95% CI 0.66-0.89. At time 2, $r_{\text{Spearman-Brown}}$=0.6, 95% CI 0.34-0.79.

For the game condition at time 1, the split-half internal consistency was $r_{\text{Spearman-Brown}}$=0.76, 95% CI 0.62-0.87. At time 2, $r_{\text{Spearman-Brown}}$=0.74, 95% CI 0.58,0.86.

The internal consistency values were higher at time 2 for the game condition at time 2 (Figure 4); however, similar to the reaction time data, converting the correlations to Fisher *z* scores indicated no significant differences between groups at each time point.

Figure 4. Internal consistency of error rate cost for each time point and task type.



Test-Retest Reliability

Reaction Time

Using reaction time cost data, for the basic task, the Pearson correlation between each time point indicated a test-retest reliability of 0.68, 95% CI 0.43-0.84. This correlation was significant (t_{29}=5.04; P<.001). For the game condition, we found a test-retest reliability of 0.58, 95% CI 0.31-0.77. This correlation was also significant (t_{32}=4.07; P<.001).

We also estimated the test-retest reliability between time 1 and time 2 with ICCs using the *psych* package in R (R Foundation for Statistical Computing) [51]. ICCs were used to measure the reliability of a measure between 2 time points. The ICC value can range from 0 to 1, with higher values indicating higher reliability. We report the results of 2-way mixed-effects models for absolute agreement, ICC(2,1), and consistency, ICC(3,1).

Using reaction time cost data, for the basic task, the estimated agreement was 0.61, 95% CI 0.36-0.78, and the estimated consistency was 0.66, 95% CI 0.46-0.80. For the game condition, the estimated agreement was 0.48, 95% CI 0.16-0.69, and the estimated consistency was 0.58, 95% CI 0.35-0.74.

Typically, cognitive tasks require many trials to reduce measurement noise. We plotted how ICC(3,1) changes as the number of trials increases, to see if a more stable estimate could be determined with fewer trials when using game elements. Figure 5 shows how the reliability of the Stroop effect (reaction time cost) changes with an increasing number of trials.

To investigate why the game condition shows lower test-retest reliability, we also plotted how the reliability of reaction time changes over time for each trial type (neutral, congruent, and incongruent trials; Figure 6). Comparing the plots suggests that the game condition reaches a higher level of consistency sooner for incongruent trials, compared with both neutral and congruent conditions. The basic task showed similar patterns of consistency across all trial types.

Figure 5. Test-retest reliability of reaction time cost as the number of trials increases for each task type.

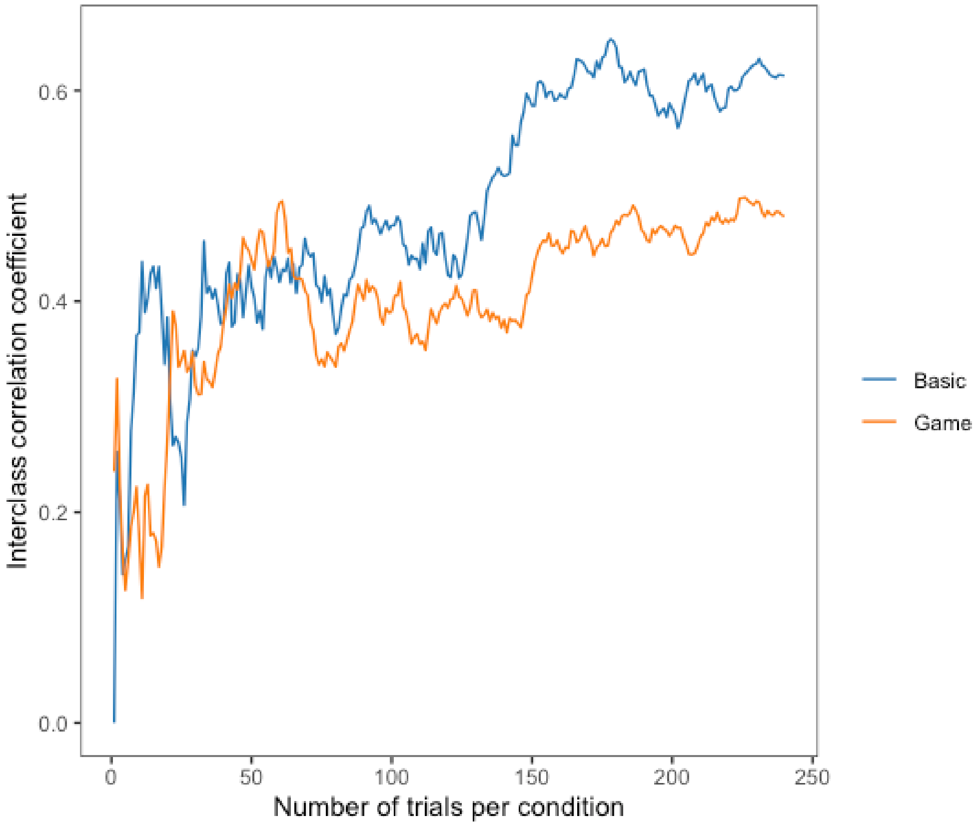


Figure 6. Test-retest reliability of reaction time as the number of trials increases for each trial type and task type.

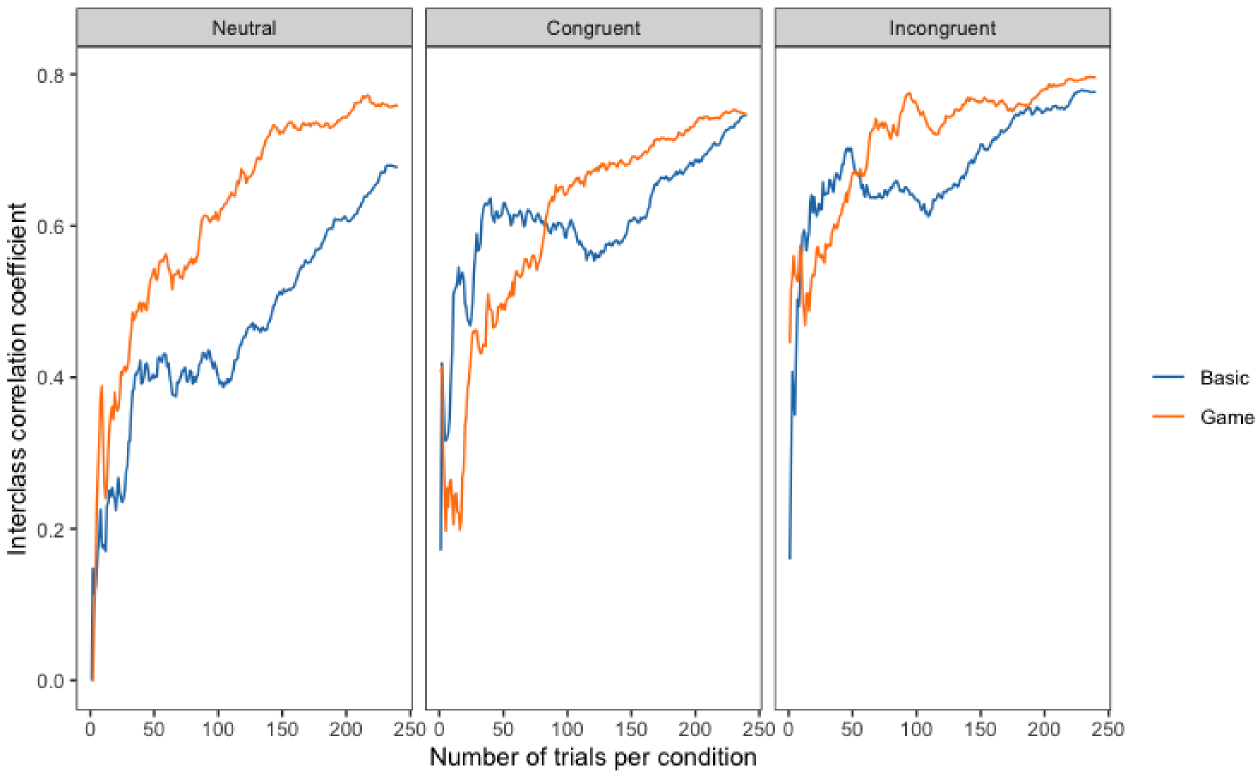

Error Rate

Using error rate cost data, for the basic task, the Pearson correlation between each time point indicated a test-retest reliability of 0.55, 95% CI 0.24-0.76. This correlation was significant (t_{29}=3.56; *P*=.001). For the game condition, we found a test-retest reliability of 0.62, 95% CI 0.35-0.79. This correlation was also significant (t_{32}=4.45; *P*<.001).

Using error rate cost data, for the basic task, ICC(2,1) (estimated agreement) was 0.53, 95% CI 0.28-0.71, and ICC(3,1) (estimated consistency) was 0.53, 95% CI 0.28-0.71. For the game condition, ICC(2,1) was 0.62, 95% CI 0.42-0.77, and ICC(3,1) was 0.62, 95% CI 0.41-0.77.

We plotted how ICC(3,1) changes as the number of trials increases, to determine whether a more stable estimate could be determined with fewer trials when using game elements. Figure 7 shows how the reliability of the Stroop effect using the error rate cost changes with an increasing number of trials.

Similar to the reaction time, we plotted how the reliability of the number of errors changes over time for each trial type (neutral, congruent, and incongruent trials; Figure 8). The basic task showed similar patterns of consistency across all the trial types, whereas in the game condition, only the neutral and congruent conditions were similar—the reliability of the incongruent trials continued to increase over time.

Figure 7. Test-retest reliability of error rate cost as the number of trials increases, for each task type.

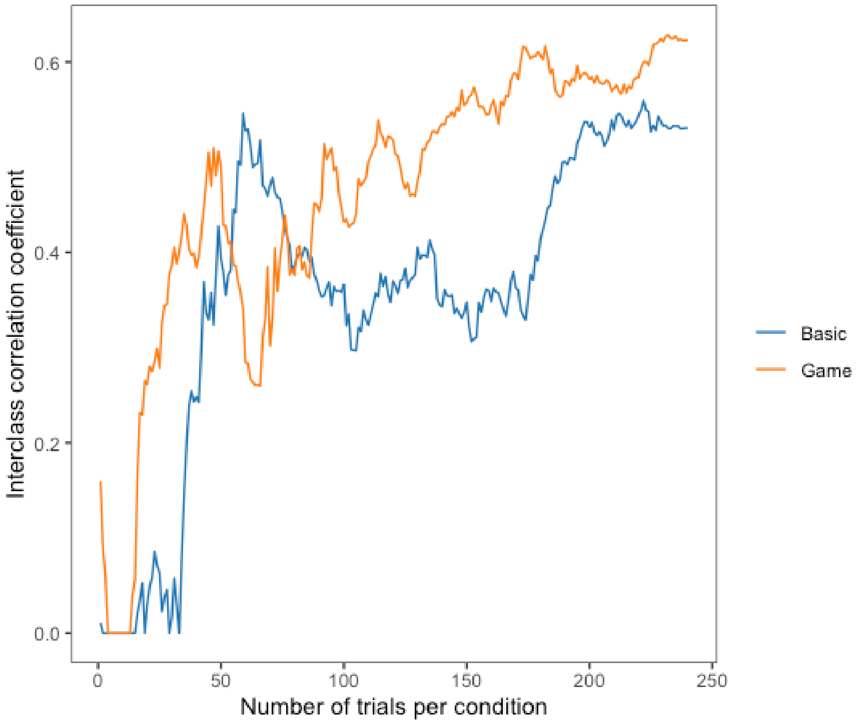

Figure 8. Test-retest reliability of error rate as the number of trials increases for each trial type and task type.

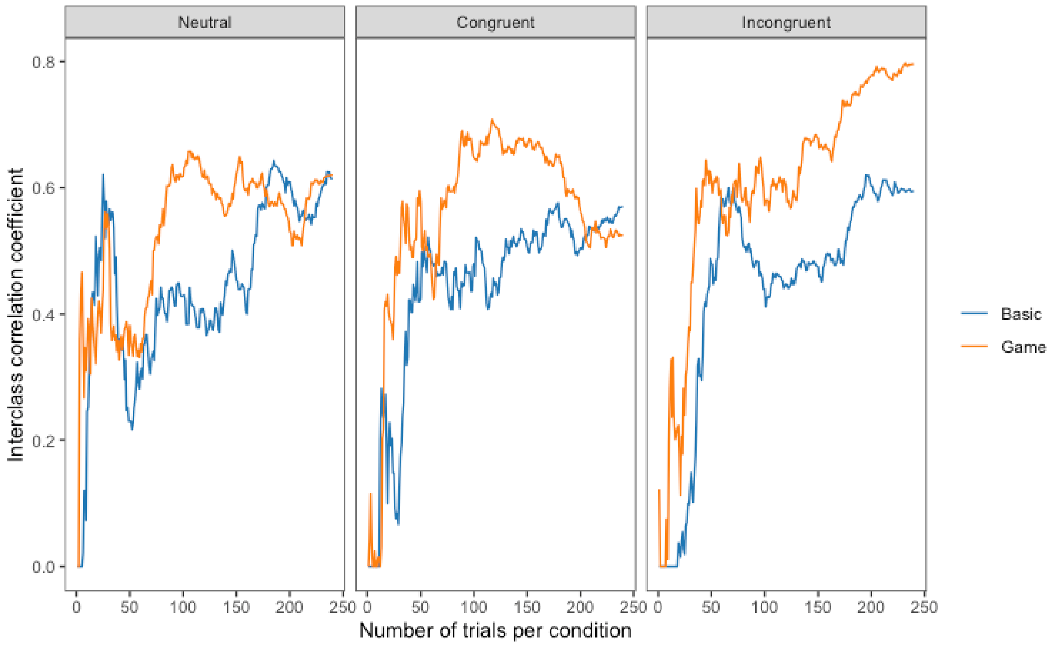

Discussion

Summary and Explanation of Findings

Performance

Both versions of the task demonstrated the Stroop effect, meaning that the effect is robust to the addition of certain game elements. Gamification can affect the validity of cognitive tasks; for example, adding graphics (especially those that change the stimuli participants respond to) can worsen performance compared with a control task [8,12,21]. In this study, in the game condition, reaction times and a progress bar were perpetually displayed on the screen. Graphics indicating gained or lost points also appeared between stimuli. These elements did not interfere with the validity of the Stroop task.

There were no significant differences in performance-based measures between the basic task and game conditions, with one exception: Participants in the game condition had significantly faster reaction times and lower error rates than those in the basic task condition but only at time 1. There may be several reasons for these results.

Points that function as extrinsic motivators have been shown to improve performance in cognitive tasks [25]; however, this effect may be short lived. Nicholson [15] noted that reward-based game elements can drive immediate spikes in engagement but only as long as continuous rewards are provided. In our game condition, participants were continually awarded points for accurate responses; however, for reaction time, they were only awarded bonus points for responses that broke their previous "fastest time" record. There is a physical limitation on how quickly participants can react to stimuli—once that threshold is met, it will be near impossible to improve further, and the motivating influence of the bonus points may be diminished.

In the game condition, participants may also learn faster and reach their "peak performance" sooner. Participants were quickly incentivized to put forth their best effort. This effect may be particularly pronounced when the cognitive demands of the task are higher. When we plotted the reliability of reaction time and error rate as the number of trials increased, the incongruent trials showed an improved pattern of consistency only in the game condition. Specifically, after approximately 50 to 100 trials, the reaction time remained consistent in the game, whereas there was a significant variation in the basic version, with a noticeable drop after 50 trials. A similar pattern was observed for the error rates. For the basic task, the plots of all 3 trial types showed similar patterns across both performance measures. This is especially noteworthy because incongruent trials are arguably the most important trials in the Stroop task, as they are the trials wherein cognitive conflict needs to be resolved. Improved performance in the incongruent trials also explains why the reliability of the Stroop effect (reaction time cost) appeared lower in the game condition—participants in that condition performed better and more consistently in the incongruent trials.

The differences between the basic task and game conditions may be emphasized by incongruent trials because they are more cognitively demanding than the congruent and neutral trials. Evidence suggests that game elements can differentially affect cognition depending on how participants experience the demands of the task. For example, gamification can normalize the performance of participants with ADHD [28].

Another indication of improved performance consistency comes in the form of a significantly smaller number of outlier trials that need to be removed from the game condition compared to the basic version. Approximately twice the number of far-out outlier trials were removed from the basic task. These trials were not considered valuable data and were essentially lost time for both the researcher and the participant. By reducing the number of trials that needed to be removed from performance, the time investment for participants was reduced. Furthermore, this means that the previous results are a conservative estimate of the game's reliability advantage because the most egregious outliers were already removed from the analysis.

Enjoyment

There were also no differences in the self-reported measures of motivation between the basic task and game conditions. These results align with those of other studies, which found that achievement-based game elements are only effective in promoting performance and not motivation [24,25].

Levy et al [23] note how carefully games must be designed to appropriately function as scientific tools and highlight the importance of using the research and data collection goals to inform the choice of game design. For this study, we specifically chose game elements that we thought would influence performance rather than enjoyment. Gamified tasks may be more successful if the game elements are just "good enough" to achieve the goals of the study without interfering with the validity of the task [23]. Because we wanted to improve participant performance irrespective of enjoyment, we did not add extraneous game elements, even if those elements would have made the game more fun.

Limitations and Future Work

One limitation of our study is the small sample size. The 2 task conditions were designed with subtle differences in the form of points and feedback. While this design was intentional, we also had a relatively small sample size, which may not have been powerful enough to reveal the small effects of our slight manipulation. We recruited 135 participants for time 1 with the intent of having at least 50 participants per condition. However, only 78 participants returned at time 2. It was difficult to incentivize participants to return to a web-based study. Future studies may find significant effects with a larger sample size.

Another limitation is that our sample was heavily skewed toward young adult female participants. We recruited participants through a web-based platform called Prolific. At the time of our study, a young woman made a video describing her hustle as a participant on the platform. Her video went viral on TikTok, resulting in an influx of new signups to Prolific, most of whom were, similar to the creator, female adults in their 20s [50]. However, given the fundamental nature of this research, this sampling bias is unlikely to have influenced the results.

The addition of points and feedback is one simple approach to gamification. Other game elements may produce different results. As discussed, we had theoretical and practical reasons for using points, but even within the category of points and achievement-based game elements, we could have made different design and mechanical choices. For example, adding a leaderboard system may have influenced participant behavior because of increased competition. Mekler et al [25] found that for an image annotation task, participants in the point condition significantly outperformed those in a control condition, where no game elements were used. However, participants in the points condition were, in turn, significantly outperformed by those in conditions where leaderboards and levels were used.

Future studies should investigate other game elements. Other cognitive tasks could also be investigated to determine how game elements affect reliability across task types that target different cognitive domains. Our same methods for investigating reliability could be applied to any gamified task.

Implications

In this study, we show that the Stroop effect is robust to the addition of simple points-based game elements. Adding points to a Stroop task does initially increase participant reaction time, but this gamification may be most effective in the short term. Our results also suggest that game elements may differently influence *parts* of a cognitive task, such as the more cognitively demanding incongruent trials.

We also provide an example of reporting psychometric data for a gamified task. Despite a long history of cognitive task gamification, the field lacks standard practices regarding how these tasks are made and measured [16]. Any advancement in how these tasks are designed and used requires a stronger base of knowledge on how individual game elements affect cognitive behavioral measures [25,32]. One of the most cited reasons for gamifying tasks is to address the limitations of standard neuropsychological testing [16]; however, these games will never be acceptable replacements for traditional tests if they are not subjected to the same rigorous standards of reliability and validity.

The results of this study suggest a potential advantage of using game-like tasks to assess cognitive functioning, especially for difficult-to-reach populations or individuals who cannot be subjected to prolonged testing. For example, gamified tasks have been shown to provide a more engaging environment that creates a more captivating setting that may aid in collecting data from populations with a lower attention span, such as children or groups of patients with concentration or attention deficits [52].

Our results suggest that the game condition may provide faster onboarding to true performance and improved consistency, as demonstrated descriptively through the lower proportion of outlier trials removed, the reaction time distributions, the split-half internal consistency values for reaction time and error rate, and reaction time cost by trial number charts. This faster onboarding is also supported by the significantly faster reaction times and lower error rates in the game condition at time 1. However, these trends do not result in significant performance differences between the basic task and game conditions in analyses of reaction time cost and also do not influence test-retest reliabilities, suggesting that the game elements we included neither significantly improved nor compromised performance in a gamified Stroop task.

Abstract

Background: Implicit bias is as prevalent among health care professionals as among the wider population and is significantly associated with lower health care quality.

Objective: The study goal was to develop and evaluate the preliminary efficacy of an innovative mobile app, VARIAT (Virtual and Augmented Reality Implicit Association Training), to reduce implicit biases among Medicaid providers.

Methods: An interdisciplinary team developed 2 interactive case-based training modules for Medicaid providers focused on implicit bias related to race and socioeconomic status (SES) and sexual orientation and gender identity (SOGI), respectively. The simulations combine experiential learning, facilitated debriefing, and game-based educational strategies. Medicaid providers (n=18) participated in this pilot study. Outcomes were measured on 3 domains: training reactions, affective knowledge, and skill-based knowledge related to implicit biases in race/SES or SOGI.

Results: Participants reported high relevance of training to their job for both the race/SES module (mean score 4.75, SD 0.45) and SOGI module (mean score 4.67, SD 0.50). Significant improvement in skill-based knowledge for minimizing health disparities for lesbian, gay, bisexual, transgender, and queer patients was found after training (Cohen *d*=0.72; 95% CI −1.38 to −0.04).

Conclusions: This study developed an innovative smartphone-based implicit bias training program for Medicaid providers and conducted a pilot evaluation on the user experience and preliminary efficacy. Preliminary evidence showed positive satisfaction and preliminary efficacy of the intervention.

Introduction

Implicit Bias in Health Care Settings

Defined as unconscious associations or negative evaluations of a person or group of people on the basis of nonrelevant characteristics [1], implicit biases have been found to be prevalent among the general population against "marginalized" groups such as those from minority racial, ethnic, or socioeconomic backgrounds [2]. Implicit biases, which present in health care settings as irrational and unconscious perceptions, stereotypes, or prejudices among health care providers when interacting with patients, are especially concerning [3]. Past research has found that implicit bias in health care settings is associated with a decrease in overall quality of care, with impacts including increased risk of misdiagnosis [4-7], inaccurate patient pain perception [8,9], differential treatment recommendations for patients who belong to sexual orientation or gender identity minority groups [10-12], and negative perceptions of patients from racial minority backgrounds [13-17]. Implicit biases may also exist during interactions between health care professionals, such as selection bias when choosing candidates for future health care practitioner residency [18], which may have wider implications for the quality and safety of patient care. Furthermore, such implicit biases have been found within adult and pediatric health care settings [19] across medical conditions including ADHD, asthma, cardiology, and child abuse, which could affect quality of care for these vulnerable populations [20-22].

Existing Efforts to Reduce Implicit Bias in Health Care Settings

In response, increasing efforts have been devoted to addressing the significant threat posed by implicit bias toward health care services and patient outcomes. The first type of interventional efforts focus on "environmental engineering," with the goal to minimize mechanisms in health care settings that may give rise to biased interactions between health care professionals and patients. One example of this type of intervention is the development and implementation of automatic patient care prompts through electronic portals, where computer algorithms are standardized for all patients regardless of sociodemographic backgrounds, attempting to reduce opportunities for human interference (beyond the algorithm development phase) [23]. A second type of intervention uses cognitive rehearsal to walk practitioners through potentially harmful scenarios to practice their ideal response; this has shown promise at changing health care practitioner behavior to reduce bullying and workplace turnover [24,25]. While not widely used in combatting health care bias explicitly, the methodology shows a clear avenue for its application to bias training.

A third type of intervention, which will also be the focus of this study, attempts to develop educational programs with the goal of improving knowledge and awareness of implicit bias among medical students or health care professionals, which can range from traditional educational seminars to experience-oriented storytelling, to highlight the importance of patient perspectives in daily practice [26-28]. Such efforts have so far yielded positive results where health care professionals were found to become more aware of their own biases and have resulted in improved communication between health care professionals and marginalized patient groups [29,30].

Application of Augmented Reality–Based Medical Training

Despite the promising results from educational programs in the existing literature, one limitation in existing approaches for implicit bias training is the lack of immersive learning experiences that may provide optimal learning outcomes and behavior changes. As a cutting-edge technology that prioritizes experiential learning, virtual reality (VR) and augmented reality (AR) could provide an ideal solution with immersive learning experiences for implicit bias training. For example, one recent study examined biases during interactions between virtual health care providers and virtual patients for medical triage training. Regardless of the skin tone of the avatar (ie, the health care provider), it took participants more time to initiate assistance and they were more likely to make errors when triaging dark-skinned virtual patients compared to light-skinned virtual patients [31].

AR, as a more recent member of the x-reality technologies, is posed to offer an even better learning experience that combines the immersion provided by VR and tailored customization that adapts to users' dynamic environments. Adoption of AR in medical education has been found in a wide range of medical branches from surgery (eg, laparoscopic procedure training) to anatomy [32]. Furthermore, because AR-based training is readily available on consumer-grade mobile devices such as smartphones and tablets, its mobility provides medical professionals with remote accessibility to training content regardless of their physical location (this advantage has been further acknowledged during the COVID-19 pandemic) [33]. However, despite the increasing adoption of AR in medical training, a recent systematic review has found little evidence on the availability of AR-based implicit bias training among health care professionals in the literature [33].

This Study

To address this important gap, this study aimed to develop a mobile training program, VARIAT (Virtual and Augmented Reality Implicit Association Training), specifically for improving the awareness of implicit biases among health care providers when interacting with patients in daily practice. The design considerations for developing this novel AR-based implicit bias training program are described, followed by a preliminary examination of initial user feasibility and learning outcomes, including user reactions; relevance to practice; and changes in knowledge, attitudes, and behavioral skills related to implicit bias before and after receiving the training program.

Methods

Designing the VARIAT Program

Overview of Technical Design Considerations

The VARIAT program focused on delivering an immersive, interactive learning experience to the broadest possible audience in self-contained segments, allowing users to complete the training over time and a variety of sessions while retaining their progress across sessions. When building the 3D worlds for delivery on the broadest number and sizes of mobile devices, simplified, realistic, and familiar spaces were built, including offices, lobbies, and examination rooms where the learner could experience the simulations. Characters in the world were designed with exaggerated cartoon features to provide visual distinction with skin tone, hair, size, outfits, and accessories, while minimizing unnecessary details and maximizing ease of recognition for interaction on mobile-sized screens. The approach to world design addressed design and performance considerations, allowing production of additional characters and scenarios without significant technical overhead in either the creation process or the learner's experience on their device. The dialogue and training content was presented via text.

Hardware Requirements and Considerations

One key goal of the VARIAT program was the need to maximize audience reach and minimize specialty equipment for learners to access the content. At the time of its development, most iPhones and Android devices had the cameras, accelerometers, and gyroscopes needed to provide users the ability to see into and navigate virtual worlds by simply holding up and moving their devices. When the VARIAT program was introduced, learners needed at least an iPhone 8 with iOS 13 or an Android device running Android 9 or higher.

Software Requirements and Considerations

The maturity of the mobile app environment offers many development tools and approaches for developing mobile apps. For the VARIAT program, the developers used the Unity game engine (Unity Technologies) for game content with ARKit (Apple Inc) and ARCore (Google LLC) for the augmented reality component and deployed both iOS and Android apps that were readily available in their respective app stores. Blender (Blender Foundation) was used for 3D modeling and animation, and Photoshop (Adobe) was used to create 2D assets.

The learner downloads the app from the Apple App Store or Google Play on their device, and their progress is maintained on the device with evaluation, progress, and study data synchronized as the learner completes various modules. When synchronized, the data are stored and managed using Google Big Query Workspace, which produces data feeds for training evaluators and researchers.

Overview of Content Design Considerations

Training Framework of the VARIAT App

The VARIAT game was designed based on the integration of evidence-based cognitive psychology with the latest simulation technologies, including VR (eg, a simulated experience of interacting with a virtual clinician-patient scenario that is vulnerable to implicit biases in a virtual environment using 6-degrees-of-freedom motion- and gesture-based interactions) and AR (eg, converting a user's physical environment into a clinic's waiting room for interactive experiences). The goal of the app is to improve awareness of implicit biases among Medicaid providers, to educate them on how these biases can lead to inequitable care, and to offer strategies and resources that may minimize health disparities. This mobile app can be installed on any Apple iOS and Android device and is designed to be completed in one sitting or in short segments.

The game consists of 2 distinct but interconnected modules, targeting implicit biases within medical settings toward patients from minority racial backgrounds, with low socioeconomic status (SES), or from a minority sexual orientation or gender identity (SOGI) group. Learners enter an AR-based interactive role-playing game, in which they encounter a series of 6 scenarios. Each scenario takes approximately 5 minutes to complete and is related to the specific implicit bias being addressed in that particular module (Race/SES or SOGI). Each scenario within the module is designed to address specific issues related to disparities in medical settings that relate to the overall theme of the module. The primary outcome measure of this training program is to evaluate providers' attitudes and beliefs on key concepts related to implicit biases and health disparities in a medical setting before and immediately following the training.

Race/SES Module

The first module within the VARIAT mobile game is the race/SES module, which consists of 3 scenarios dealing with issues of racial bias, transportation and food instability, and implicit bias. The first scenario in this module addresses issues of racial bias within a health care setting and prompts the user to consider how issues of racial and ethnic identity could impact treatment recommendations and the resulting care for patients of minority groups. The next scenario is designed to promote self-reflection on how socioeconomic factors like unreliable transportation or housing could affect a patient's ability to show up for health care visits or comply with care recommendations by medical providers. The last scenario is designed to help users understand how implicit bias from medical providers could impact patient perception and negatively impact patient care.

Each scenario contains prompts where the user is asked to make a choice about the "case" presented within the VARIAT AR game. The user is then given information about the scenario and resources for how to better understand the specific issues for each scenario with the goal to educate them on how to improve practitioner behavior as it relates to the theme of the module. A summary of the scenarios and objectives for this module can be found in Multimedia Appendix 1.

SOGI Module

The second module in the VARIAT mobile game is the SOGI module, which consists of 3 scenarios dealing with issues of SOGI implicit bias, inclusivity for patient care settings, and lesbian, gay, bisexual, transgender, queer (LGBTQ+) patient considerations. The first scenario helps portray the way that microaggressions and implicit biases in patient-provider communication can promote negative disparities in treatment for SOGI minority patients. The second scenario asks users to design their own patient waiting room and helps educate and guide users on what considerations should be made to ensure a medical setting is a safe and welcoming environment for SOGI minority patients. The last scenario in the module helps users recognize the harmful effects of biased behavior toward LGBTQ+ patients and offers space for self-reflection on how to reduce enacted bias for this patient group.

The scenarios in this module also contain prompts for users to answer to better assess their understanding of key concepts or takeaways from each scenario. The SOGI module places an increased emphasis on self-reflection as the scenarios are designed to help users draw parallels to their own experiences in medical practice through reflective exercises following the conclusion of each scenario within the module. A summary of the scenarios and objectives for this module can be seen in Multimedia Appendix 2.

User Workflow

On start-up, users are given some brief instructions on how to prepare themselves for immersion in the VARIAT AR game.

Users are then instructed to select any available module to start engaging with the content within. Once a module is selected, participants are placed in a virtual hospital setting and can check on the various patients within. When selected in the AR game, these patients display information on their illnesses and present the user with additional narratives about the patients from the "staff" in the AR game. Users are then given different decision options on what to do for each patient's individual case. After helping these patients, the user is provided with information and resources that relate to the content of the module. Unbiased choices "score" higher than choices that are considered to have been influenced by implicit biases toward marginalized patients. After completing the tasks in their module, the users are given a summary of their scores for that module with feedback on how to improve, and additional information to support that improvement relative to the context of their scenario. After completing a module, users are sent back to the home screen, where they can replay the same module or select a new module to explore. A depiction of the app layout, user experience, and scenario prompts is presented in Multimedia Appendix 3.

User Experience and Preliminary Efficacy of the VARIAT Program

Participants and Procedure

Eighteen clinicians (n=12 female) who were predominantly White (non-Hispanic) participated in the VARIAT training. Physicians comprised 8 of the 18 (44%) participants, and 12 of the 18 participants had more than 5 years' experience in health care. The most common workplace setting was hospitals, with private practices, health care system–affiliated clinics, and other workplace settings reported as well. Most participants estimated that Medicaid patients comprised more than 30% of their total caseload, with reported ages of patients seen varying between children, adults, and older adults. Demographic information is reported in Table 1 for the total number of participants (N=18), participants who participated only in the race/SES module (n=7), participants who participated in only the SOGI module (n=5), and participants who completed both the race/SES and SOGI modules (n=6). Participants were recruited through professional networks and were eligible for the study if they were Medicaid providers.

Table . Demographic information for the participants.

Variables		Overall (n=18), n (%)	Race/SES[a] only (n=7), n (%)	SOGI[b] only (n=5), n (%)	Race/SES and SOGI (n=6), n (%)

[a]SES: socioeconomic status.

[b]SOGI: sexual orientation and gender identity.

[c]Combined category.

[d]Multiple answers selected.

Questionnaires were administered to participants remotely through the VARIAT app, and data collection took place from March to June 2020.

Measures

User Experience Measures

Users' reactions to both the race/SES and SOGI modules of the VARIAT program were assessed by asking participants about their perception of the modules after the test. After experiencing the AR simulation, users were asked questions designed to test their engagement with the AR experience, such as if they felt a sense of "being there" in the AR experience or how real they found the AR experience to be. These answers were scored on a scale of 1 to 5, with higher scores indicating stronger agreement. Participants were also asked questions about how they might apply the AR experience to their job with questions such as "How do you think this training will help you on the job (Mark all that apply)?" with different response items to assess perceived benefits from the training. These items were scored using dichotomous coding for each option (0 for not applicable and 1 for applicable).

Preliminary Efficacy Measures

Training outcomes were reported through changes in affective knowledge and changes in skill-based knowledge measured by comparing pre-post test responses. Affective knowledge (items assessing how participants expect their perceptions to impact their patients) was measured by agreement with items that were adapted from the California Brief Multicultural Competence Scale [31]. Example items include the following: "I am aware of how my own values might affect my patients" or "I am aware of institutional barriers that affect patients." Skill-based knowledge was assessed differently for the race/SES and SOGI modules, with questions referring to each respective population focused on in the module. Race/SES skill-based knowledge was measured by rating participant agreement with the following internally developed statements: "I am confident that I can recognize the role that implicit bias plays in leading to inequitable care for patients of low socioeconomic status," and "I am confident that I can apply strategies and use resources to minimize health care disparities for patients with low socioeconomic status." SOGI skill-based knowledge was measured similarly, with "race/SES population" being replaced with "LGBTQ+ population" in the skills-based questions. Training outcomes were reported for each module separately, with the race/SES module (n=13) and SOGI module (n=11) consisting of all participants that completed each module. All measures were scored on a scale of 1 to 5, with higher scores representing stronger agreement.

Data Analysis Plan

All analyses were conducted using SPSS Statistics (version 27.0; IBM Corp). Demographic characteristics were described using frequencies and percentages for the categorical variables. Demographic characteristics were reported across 4 participant groupings: participants who took only the Race/SES module, participants who took only the SOGI module, participants who took both the Race/SES and SOGI modules, and an overall group of all unique participants.

After testing for normality using the Shapiro-Wilk test, the training reactions and pre-post skills and attitude outcome data were found to not be normally distributed ($P<.001$). As a result, we used nonparametric tests for analyzing these 2 outcome domains. For the usability data, we used the Wilcoxon signed-rank test to measure the continuous reaction items and report the mean and SD for participants who used both the race/SES module and the SOGI module. The categorical training reaction items were reported using frequencies and percentages. For analyzing the skills and attitudes outcome data, the Wilcoxon matched-pairs signed-rank test was used to report the mean, SD, effect size (Cohen *d*), and 95% CI for pre-post changes in scores. The scores for each module were analyzed separately for all participants who took each respective module. Given that some participants completed both modules (n=6), there is a small amount of overlap in participant representation across all reported outcome data. All data and study materials will be made available on request.

Ethical Considerations

The Ohio State University (OSU) Institutional Review Board has determined this study was exempt from review according to the Policy on Human Subjects Research of the OSU Human Research Protection Program.

Results

User Experience (Training Reactions)

For perception of the AR experience, participants who received training in the race/SES and SOGI modules reported similar ratings for the overall AR experience. Participants reported positive feelings of "being there" (race/SES module: mean score 4.62, SD 1.56; SOGI module: mean score 3.91, SD 1.97) and high relevance of the AR training to their respective jobs (race/SES module: mean score 4.75, SD 0.45; SOGI module: mean score 4.67, SD 0.50) across both modules. Participants across both modules perceived the AR experience as being "a little" realistic, with the SOGI participants reporting less realism on average (mean score 2.91, SD 1.64) compared to the race/SES participants (mean score 3.77, SD 1.83). For the reported intention to apply the AR experience to their jobs, only the participants who received training in the race/SES module responded to this item. On average, these participants reported that they were less likely to apply the AR experience to their jobs (mean score 2.31, SD 1.11).

Assessing the perceived benefits of the AR experience to the participants' jobs revealed that the race/SES and SOGI modules had some key differences in support across beliefs. Participants from both the race/SES and SOGI modules reported varying levels of positive agreement that the experience could improve their relationships with their patients (8/11, 73% SOGI participants; 8/13, 62% race/SES participants) and avoid undesirable events in patient care (8/11, 73% SOGI participants; 8/13, 62% SES participants). Conversely, 9 of 11 SOGI participants (82%) showed adequate agreement with the belief that the training would help improve tailored care and 7 of 11 participants (64%) believed that the training would improve patient satisfaction. For the race/SES participants, 7 of 13 (54%) showed moderate agreement with beliefs about improving tailored care, while 6 of 13 (46%) agreed that the training could improve patient satisfaction. The race/SES participants showed higher agreement with the belief that the module would improve their community resources (9/13, 69%) compared to the SOGI module participants (5/11, 45%). A detailed summary of user experience findings is reported in Table 2.

Table . User experience (training reaction) outcomes.

Variables		Race/SES[a] (n=13)	SOGI[b] (n=11)	Effect size (Cohen *d*)
Augmented reality experience scores, mean (SD)				
	Feeling of "being there"[c]	4.6 (1.6)	3.9 (2.0)	0.40
	Realism of augmented reality[c]	3.7 (1.8)	2.9 (1.6)	0.49
	Relevance to job[d]	4.8 (0.5)	4.7 (0.5)	0.17
	Intention to apply augmented reality experience[d]	2.3 (1.1)	N/A[e]	N/A
Participants reporting applicability to job, n (%) [f]				
	Improve relationship with patients	8 (62)	8 (73)	N/A
	Improve patient satisfaction	6 (46)	7 (64)	N/A
	Improve tailored care	7 (54)	9 (82)	N/A
	Avoid undesirable events	8 (62)	8 (73)	N/A
	Improve community resources	9 (69)	5 (45)	N/A
	Other benefit	0 (0)	1 (9)	N/A

[a]SES: socioeconomic status.

[e]N/A: not applicable.

[f]Multiple answers selected.

Preliminary Efficacy

For the skills questions, there was no significant difference in pre-post scores assessing the changes in awareness of implicit bias for patients of varying race/SES groups (pre: mean 4.31, SD 0.48; post: mean 4.46, SD 0.52; *d*=0.22; 95% CI −0.77 to 0.33) or the ability to manage health disparities caused by race/SES group (pre: mean 3.85, SD 0.56; post: mean 4.31, SD 0.48; *d*=0.52; 95% CI −1.10 to 0.07) . This pattern was true for measuring awareness of implicit bias for LGBTQ+ patients (pre: mean 4.36, SD 0.51; post: mean 4.73, SD 0.47; *d*=0.54; 95% CI −1.16 to 0.11). For minimizing health disparities realted to LGBTQ+ status, there was a significant difference between pre- and posttest scores (pre: mean 3.91, SD 0.94; post: mean 4.64, SD 0.51; *d*=0.72; 95% CI −1.38 to −0.04) with participants scoring closer to "strongly agree" after experiencing the AR experience.

For the attitudinal questions, there were nonsignificant improvements in the race/SES module in assessing how personal values affected patients (pre: mean 3.92, SD 0.95; post: mean 4.31, SD 0.84; *d*=0.44; 95% CI −1.01 to 0.14), how institutional barriers affect patients (pre: mean 4.23, SD 0.60; post: mean 4.31, SD 0.48; *d*=0.12; 95% CI −0.66 to 0.43), and participants' ability to identify reactions based on stereotypes (pre: mean 4.15, SD 0.56; post: mean 4.38, SD 0.51; *d*=0.53; 95% CI −1.10 to 0.07). For the SOGI module, changes from pre to posttraining were also nonsignificant for all attitudinal items (pre: mean 4.18, SD 0.87; post: mean 4.45, SD 0.52; *d*=0.30; 95% CI −0.90

to 0.31), institutional barrier items (pre: mean 4.36, SD 0.67; post: mean 4.36, SD 0.67; *d*=0.00; 95% CI −0.59 to 0.59), and items related to identifying stereotypical reactions (pre: mean 4.36, SD 0.51; post: mean 4.36, SD 0.92; *d*=0.00; 95% CI −0.59 to 0.59). A summary of preliminary efficacy findings for each module can be found in Table 3.

Table . Race/socioeconomic status (SES) pre- and posttest skills and attitude outcomes (n=13).

Variables		Pretest score, mean (SD)	Posttest score, mean (SD)	Cohen *d* (95% CI)
Skills questions				
	Implicit bias (race/SES)	4.3 (0.5)	4.5 (0.5)	0.22 (–0.77 to 0.33)
	Minimize health disparities (race/SES)	3.9 (0.6)	4.3 (0.5)	0.52 (–1.10 to 0.07)
Attitudinal questions				
	How my values affect patients	3.9 (1.0)	4.3 (0.5)	0.44 (–1.01 to 0.14)
	How institutional barriers affect patients	4.2 (0.6)	4.3 (0.5)	0.12 (–0.66 to 0.43)
	Identify reactions based on stereotypes	4.2 (0.6)	4.4 (0.5)	0.53 (–1.10 to 0.07)

Discussion

This study developed a VR and AR implicit association training program for Medicaid providers based on cognitive psychology and the latest mobile simulation technologies. Designed to improve awareness of implicit biases related to patients' SES and sexual orientation/gender identity, learners are able to complete six 5-minute interactive role-playing scenarios on their smartphones. Results of pilot user experience research among 18 participants found adequate acceptability and preliminary efficacy (ie, a nonsignificant increase in most outcomes) of the VARIAT program. These findings are consistent with recent literature in cognitive psychology about the possible benefits of AR interventions for health care providers [34-37].

While researchers have spent the last 20 years attempting to reduce implicit bias [38-41], few attempts have been made to integrate the latest immersive technologies, such as AR and VR, with provider-level implicit bias training. For example, a recent meta-analysis of 492 interventions on implicit biases found only a handful of studies attempting to change implicit bias used any kind of VR or AR [42]. Narrowing down to implicit bias training in the health care setting, another recent literature review found few studies that focused on addressing bias at the provider level [43-46]. Therefore, while implicit bias in health care more broadly has been long recognized as a prominent issue [3], there is an important gap in research that develops technology-assisted training programs so that such programs can be more readily available for health care providers and so that implicit bias training can be received at a time and location that works best for them rather than having to attend in-person training sessions. The VARIAT program reported in this study addresses this critical literature gap by offering a convenient and publicly available program that can be integrated into medical training for health care professionals interacting with Medicaid patients, whose training may have important beneficial impacts on patients from disadvantaged backgrounds and those who experience reduced access to high quality of care due to multiple individual and societal barriers [47]. For example, the VARIAT program is brief and can be completed on a mobile device during "fragmented" time windows that fit within the often-chaotic work schedule of medical professionals. Therefore, medical institutions may consider integrating the VARIAT training as a regular refresh of lengthier and more comprehensive in-person or on-site bias-reduction training for their health care professional teams.

Furthermore, among the studies that focused on mitigating health care provider biases, few documented detailed feasibility and efficacy data [48-51]. This study is among the first in the literature to measure both positive provider reactions and efficacy outcomes at multiple levels, including user experience with AR, perceived utility in users' professional work, and perceived attitudes toward patients and skills in mitigating implicit biases at work. It was interesting to find that although the study participants perceived relatively high levels of immersion ("being there"), AR realism, and job relevance from the VARIAT training, they expressed low levels of intention to apply this experience to their daily work. One possible explanation for this discrepancy might be the challenges of translating learned knowledge to behavioral changes, as commonly seen in educational interventions, potentially due to the limited scenarios provided by the training compared to the broad variations in participants' own daily work experiences. The collection of both pre- and postintervention efficacy outcomes further allowed us to measure the potential interventional effects of each of the VARIAT training modules (race/SES and SOGI). However, it should be noted that this paper focused primarily on sharing with the scientific community the development processes and design considerations of a novel implicit bias training program for Medicaid providers. Therefore, caution should be applied when interpreting the preliminary results of this pilot user experience study.

Study Limitations

There are several important limitations to this study. First, the current iteration of the VARIAT program is being delivered on mobile devices. This training program might elicit different user experiences and efficacy outcomes should it be delivered on other platforms such as through an immersive VR headset. Second, the study sample for this user experience testing study was small and potentially unbalanced. Larger sample sizes and a more rigorous study design (eg, a randomized controlled trial) should be used in future research to formally evaluate the efficacy of the VARIAT program with sufficient statistical power and without inflating the type II error rate [52,53]. Third, the present version of the VARIAT program only consisted of 2 modular domains for implicit bias training, race/SES and SOGI, with only 3 training scenarios for each module due to limitations on study resources and team expertise. Further, although these modules were developed by an interdisciplinary team of clinicians and researchers, patient communities were not involved in the design process. Future research will invite patient advisory groups into the development and refinement process of additional modules and scenarios for VARIAT to provide training in more comprehensive implicit bias domains during clinician-patient interactions. Fourth, this study used only self-reported measures developed by the study team to assess the efficacy outcomes, which may not be able to accurately measure biases that are inherently "implicit." Future efficacy trials of the VARIAT program (and interventions alike) should incorporate validated implicit bias assessment tools such as the Implicit Association Test (IAT), which has been increasingly used by health care professionals in the existing literature [54]. Finally, several limitations of the study design should be noted. For example, this study did not restrict or record the number of times participants were allowed to undergo the training, which may have impacted usability and efficacy outcomes. Additionally, this study used an immediate pre-post training design. A more distant posttraining evaluation should be conducted to allow for examination of the impact of the modules on biases over time.

Conclusions

This study presents a novel intervention (VARIAT) that uses immersive mobile technology to improve awareness of implicit bias related to race/SES and SOGI among Medicaid providers. This publicly available training program has found a promising avenue for future research and practice in reducing implicit bias in health care workplaces. Future research should be conducted to formally evaluate the VARIAT program with large samples and implicit bias testing measures, as well as incorporate additional training domains to provide impactful benefits to both health care professionals and their patients.

Acknowledgments

This Medicaid Equity Simulation Project is funded by the Ohio Department of Medicaid and administered by the Ohio Colleges of Medicine Government Resource Center. Abstract

Background: Removable partial denture (RPD) design is crucial to long-term success in dental treatment, but shortcomings in RPD design training and competency acquisition among dental students have persisted for decades. Digital production is increasing in prevalence in stomatology, and a digital RPD (D-RPD) module, under the framework of the certified Objective Manipulative Skill Examination of Dental Technicians (OMEDT) system reported in our previous work, may improve on existing RPD training models for students.

Objective: We aimed to determine the efficacy of a virtual 3D simulation–based progressive digital training module for RPD design compared to traditional training.

Methods: We developed a prospective cohort study including dental technology students at the Stomatology College of Chongqing Medical University. Cohort 1 received traditional RPD design training (7 wk). Cohort 2 received D-RPD module training based on text and 2D sketches (7 wk). Cohort 3 received D-RPD module pilot training based on text and 2D sketches (4 wk) and continued to receive training based on 3D virtual casts of real patients (3 wk). RPD design tests based on virtual casts were conducted at 1 month and 1 year after training. We collected RPD design scores and the time spent to perform each assessment.

Results: We collected the RPD design scores and the time spent to perform each assessment at 1 month and 1 year after training. The study recruited 109 students, including 58 (53.2%) female and 51 male (56.8%) students. Cohort 1 scored the lowest and cohort 3 scored the highest in both tests (cohorts 1-3 at 1 mo: mean score 65.8, SD 21.5; mean score 81.9, SD 6.88; and mean score 85.3, SD 8.55, respectively; *P*<.001; cohorts 1-3 at 1 y: mean score 60.3, SD 16.7; mean score 75.5, SD 3.90; and mean score 90.9, SD 4.3, respectively; *P*<.001). The difference between cohorts in the time spent was not statistically significant at 1 month (cohorts 1-3: mean 2407.8, SD 1370.3 s; mean 1835.0, SD 1329.2 s; and mean 1790.3, SD 1195.5 s, respectively; *P*=.06) but was statistically significant at 1 year (cohorts 1-3: mean 2049.16, SD 1099.0 s; mean 1857.33, SD 587.39 s; and mean 2524.3, SD 566.37 s, respectively; *P*<.001). Intracohort comparisons indicated that the differences in scores at 1 month and 1 year were not statistically significant for cohort 1 (95% CI –2.1 to 13.0; *P*=.16), while cohort 3 obtained significantly higher scores 1 year later (95% CI 2.5-8.7; *P*=.001), and cohort 2 obtained significantly lower scores 1 year later (95% CI –8.8 to –3.9; *P*<.001).

Conclusions: Cohort 3 obtained the highest score at both time points with retention of competency at 1 year, indicating that progressive D-RPD training including virtual 3D simulation facilitated improved competency in RPD design. The adoption of D-RPD training may benefit learning outcomes.

Introduction

The partially edentulous population is increasing because of increased life expectancy and an aging population [1]. Removable partial dentures (RPDs) possess the advantages of cost-effectiveness and needing a less invasive procedure compared to fixed and implant-retained restorations; thus, RPDs remain an attractive treatment option for partially edentulous patients [2].

The design of RPDs is a crucial technical step that greatly impacts the long-term success of dental treatment and warrants high standards due to the complex structure and variation in the oral morphology of individual patients [3,4]. Poor RPD design can exacerbate plaque retention, leading to gingivitis, periodontitis, and other oral diseases [5]. RPD design has traditionally been a complex subject to teach and learn [6]. Unfortunately, shortcomings in RPD design training and competency acquisition among dental students have persisted for decades [7]. The lack of student supervision by qualified instructors and progressive training patterns, as well as the absence of practice on real patients, have been found to be the main factors limiting successful training in RPD design [8,9]. The lack of competency in RPD design can hamper clinical practice among dentists, often leading to the assignment of the task to dental technicians. Dental technicians, however, lack direct observation of the oral soft and hard tissues of the patients. This factor can limit the quality of prosthesis design and can cause patient discomfort, resulting in additional repairs and medical disputes [10].

Using a pencil-drawn design of the RPD framework on a physical cast or a paper prescription has always been the classic approach for teaching RPD design in most dental schools [11]. However, this classic approach is marked by several constraints. The cumbersome processes used where teachers collect, rate, and hand out paper prescriptions can result in communication gaps and potential wastage of time [11]. The COVID-19 pandemic has further limited the availability of real, patient-based physical casts, thus eroding practice time for RPD design on patient models [12]. Although advances in the dental laboratory digital workflow facilitate the use of computer-aided design (CAD) and computer-aided manufacturing (CAM) in the fabrication of RPDs and communication between dentists and dental technicians [13], multiple surveys confirm that CAD/CAM RPD design courses continue to present significant barriers to widespread adoption in dental education settings due to the cost, lack of faculty, and lack of time available within the curriculum. Moreover, the education editions of commercial CAD software programs for dental laboratories remain expensive and require instructors proficient in CAD/CAM technology to facilitate teaching. Furthermore, the learning curve to master the skills of using commercial CAD software is steep and requires a long time commitment, which presents a problem in undergraduate dental education settings.

In our previous work, we reported a digital RPD (D-RPD) module under the framework of the certified Objective Manipulative Skill Examination of Dental Technicians (OMEDT) system, which is a free web-based application for computer-aided drawing and 2D sketch–based RPD design training for dental and dental technology students [14]. This prospective cohort study aimed to report a significant update to the D-RPD module and to further explore the optimal design of the D-RPD module for teaching. We specifically asked the following questions: (1) How can a progressive approach using case-based virtual 3D simulation be incorporated in a D-RPD design training module to better prepare students for the needs of practice? (2) What is the efficacy of digital training approaches in RPD design compared to traditional training? (3) Does a virtual 3D simulation–based progressive digital training module benefit long-term RPD design competency acquisition and retention?

Methods

Development of a Progressive D-RPD Module Incorporating Case-Based Virtual 3D Simulation

The virtual 3D simulation was based on casts from actual patients. In order to construct patient-based virtual casts, a desktop portable application, showModels, has been developed with the Unity engine and C++ version 11 and C# version 4.0. All clinical cases used in the RPD design training were collected from the Dental Technology Laboratory of the Stomatology Hospital of Chongqing Medical University. Virtual casts were constructed from physical plaster casts of clinical patients using LabScanner (E4; 3shape) and saved in the stereolithography file format using Format Converter (Autodesk; Delcam Exchange) to remove possible surface texture indicators. Since any prepared rest seats on a patient's physical casts may provide hints for RPD design, such rest seats on the virtual cast were filled using 3D reverse software (Geomagic Wrap; 3D System). The resultant virtual casts of real patients may be rotated or zoomed in and out to view the cast details, and the user may specify whether to display the maxillary or the mandibular cast (Multimedia Appendix 1).

Participants and Recruitment

Eligible participants (junior students majoring in dental technology) were recruited at the Stomatology College of Chongqing Medical University. The RPD design theory curriculum in dental technology was organized by the Stomatology Hospital of Chongqing Medical University. All participants provided signed informed consent. The prospective cohort study began in September 2020 and ended in September 2022.

Ethical Considerations

The Research Ethics Committee of the Affiliated Hospital of Stomatology, Chongqing Medical University, approved this study protocol (COHS-REC-2022; LSNo. 096). Data reporting followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines for cohort studies.

Intervention Design

The study protocol and the participant flow diagram are depicted in Figure 1. A description of the training methods implemented is presented in Multimedia Appendix 2. In brief, after following the same RPD design theory curriculum, all participants were divided into 3 cohorts. Cohort 1 included 43 participants who received traditional RPD design training for 7 weeks. They received an RPD design task from the principal investigator each Monday, completed the RPD design using a paper prescription and red and blue pencil, and submitted it by Sunday. Cohort 2 included 36 participants who received D-RPD module training based on literal descriptions and 2D sketches for 7 weeks. They received literal case descriptions and 2D sketches for uniformly depicting missing teeth issued by the principal investigator in the D-RPD module every Monday, drew RPD designs using the D-RPD module, and submitted designs by Sunday. Cohort 3 included 30 participants who received D-RPD module training based on a literal description and 2D sketches for 4 weeks and continued to receive progressive instruction with the updated D-RPD module training based on the virtual casts of real patients for 3 weeks. The 7 RPD design tasks received by the 3 cohorts were all the same, and the types of dentition defects covered Kennedy classes I, II, III, and IV, with only some differences in presentation form. We set 1 month as the retention interval to avoid temporary effects from practice [15]. At 1 month and at 1 year after the training, RPD design tests using 3D virtual casts were administered using the updated D-RPD module and carried out for all of the cohorts. During the retention interval, participants' D-RPD module accounts were blocked to prevent participants from using the module for additional training. Within 1 year of completing their training, participants start a uniform dental laboratory internship, and the internship outline has uniform requirements for the design of RPDs with the same workload. For cohorts 1 and 2, a separate D-RPD module introductory session was held prior to the testing to ensure that the cohort could successfully complete the RPD design task using the updated D-RPD module.

Recruitment of the Expert Panel and Development of the Scoring Rubrics

The principal investigator recruited an expert panel to develop the scoring rubrics [16] (Table 1), and the exercises of all 3 cohorts were rated accordingly. The expert panel consisted of a dental technician experienced in the field of RPD manufacturing and a clinical prosthodontist recruited from the Stomatology Hospital of Chongqing Medical University. The expert panel was blinded to the cohort assignments, had not participated in the teaching of the participants, and did not know about the participants' major or nature of the intervention.

Table . The scoring rubric used to assess the removable partial denture design test task.

Scoring component	Met clinically acceptable criteria	Needs improvement	Clinically unacceptable
Case observation (20 points)	The missing tooth position was identified accurately and marked correctly on the drawing (20 points).	N/A[a]	The missing tooth position was identified inaccurately, marked incorrectly on the drawing, or both (0 points).
Design choices (40 points)	Design choices are ideal for the case (28-40 points).	Design choices have some flaws but are adequate (15-27 points). Examples include the following: no missing component; indirect retainer present but not in the optimal position; design choices do not violate biological principles; clasp choice adequate but not optimal for the case; inappropriate choice or extension of major connector; justified use of clasps/rests but excessive framework components.	Any missing component or inappropriate design for the case (0-14 points). Examples include the following: missing indirect retainer in a case requiring one; missing reciprocation; clasp choice inappropriate for situation; design choices violate biological principles; excessive and unjustified use of clasps/rests.
Drawing (20 points)	Drawing is ideal. Metal components are painted in blue and resin bases are in red (14-20 points).	Drawing has some flaws but is adequate (7-13 points). Examples include the following: components are represented by corresponding colors; minor inadequacy or inconsistency of spacing between components; components are occasionally not connected; the finish line is not drawn.	Drawing has major flaws (0-6 points). Examples include the following: components are not represented by corresponding colors; major inadequacy or inconsistency of spacing between components; component positioning significantly off optimal position; any component position that violates biomechanical design principles; components are frequently not connected; the finish line is not drawn.
Consistency with task description (10 points)	Exactly as described in the task description (8-10 points). Criteria include the following: clearly presents the requirements implied in the description, and the design is well aligned with the corresponding description; gives consideration to both aesthetics and function.	Some deviation from the task description, but it is acceptable (5-7 points). Examples include the following: conventional design carried out without addressing case-specific modifying factors or requirements listed in the task description; only function considered, consideration for aesthetics lacking.	Serious violation or deviation from the task description (0-4 points). Examples include the following: the design does not match the task description; lack of aesthetic and functional considerations.
Neatness and accuracy in presentation (10 points)	Neat and accurate, no inconsistencies between the table and drawing (8-10 points).	Some inaccuracy and neatness flaws, but it is adequate (5-7 points). Examples include the following: minor erasures; minor neatness issues but still legible.	Major inaccuracy and neatness flaws (0-4 points). Examples include the following: missing information; major neatness issues; writing not legible; any inconsistencies between the table and drawing.

[a]N/A: not applicable.

Data Collection

The main metrics collected were the time(s) to complete the RPD design exercise and the RPD design score (100 points) based on the scoring rubrics by the expert panel.

Statistical Analysis

Scores (ie, total points for each assessment) and time (ie, seconds needed to perform each assessment) were summarized descriptively as means and SDs, coefficients of variation (defined as the ratio of the SD to the mean), and IQRs [17]. Due to the small sample size, normality was tested using the Shapiro-Wilk test, and the homogeneity of variance was tested using the *F* test [18]. The results showed that the time and score data had a skewed distribution and heterogeneity of variance. Therefore, the nonparametric method was used to compare the data sets in this study. Since the Kruskal-Wallis test is widely used to determine whether 3 or more independent data sets are different on some variable of interest [19], it was used to compare the cohorts at the same time point (1 mo or 1 y later), using the 3 data sets in each analysis process. When the value of the Kruskal-Wallis statistic is calculated as statistically significant, it indicates that at least 1 of the compared groups is different from the others. Therefore, we chose the Bonferroni method for further analysis with pairwise multiple comparisons to locate the source of significance. As for in-cohort comparisons at different time points, the Wilcoxon matched-pairs test is a frequently used nonparametric test for paired data, especially for nonnormal data and categorical data, such as was present in this cohort study. Hypothesis tests were 2 sided with a significance threshold of P=.05. At the same time, when multiple sets of data are being processed and compared simultaneously, there is increased risk of a type I error, so to identify significant correlations, threshold levels of significance for correlation coefficients were adjusted for multiple comparisons; we used a set of κ correlation coefficients with Bonferroni correction to strictly control the occurrence of false positives (after Bonferroni correction, we used a significance threshold of *P*=.016) [20]. Statistical analysis was performed using SPSS (version 26.0; IBM Corp).

Results

This cohort study included 109 participants: 58 (53.2%) women and 51 (56.8%) men, with a mean age at the beginning the study in September 2020 of 22.5 (SD 0.7) years (Table 2). All 3 cohorts completed the experiment.

Table . Baseline characteristics of the participants in this cohort study. *P* values were estimated using the Kruskal-Wallis test.

Characteristics		Participants overall (n=109)	Cohort 1 (n=43)	Cohort 2 (n=36)	Cohort 3 (n=30)	*P* value
Gender, n (%)						.57
	Female	58 (53.2)	26 (60.5)	18 (50)	14 (46.7)	
	Male	51 (46.8)	17 (39.5)	18 (50)	16 (53.3)	
	Other	0 (0)	0 (0)	0 (0)	0 (0)	
Age (years), mean (SD)		22.5 (0.7)	22.3 (0.7)	22.6 (0.7)	22.5 (0.7)	.40

Intercohort Comparison of Performance

Scores

The scores of cohorts 1, 2, and 3 after 1 month showed a statistically significant difference (mean 65.8, SD 21.5; mean 81.9, SD 6.9; and mean 85.3, SD 8.6, respectively; *P*<.001). Pairwise comparisons showed that the mean score of cohort 1 was 16.1 points less than the mean score of cohort 2 (95% CI –23.0 to –9.0; *P*=.03) and 19.5 points less than that of cohort 3 (95% CI –26.7 to –12.2; *P*<.001), whereas the difference in scores between cohorts 2 and 3 was not statistically significant (95% CI –7.3 to 0.48; *P*=.29). At testing after 1 year, the scores of cohorts 1, 2, and 3 showed a statistically significant difference (mean 60.3, SD 16.7; mean 75.5, SD 3.9; and mean 90.9, SD 4.3, respectively; *P*<.001). Pairwise comparisons showed that the mean score of cohort 1 was 15.2 points less than that of cohort 2, but this was not significantly different (95% CI –20.5 to –9.9; *P*=.06). Meanwhile, the mean score for cohort 3 was 30.6 points higher than that of cohort 1 (95% CI –36.0 to –25.2; *P*<.001), and the mean score of cohort 3 was 15.4 points higher than that of cohort 2 (95% CI –17.4 to –17.3; *P*<.001); both represented a highly significant difference (Table 3 and Figure 2).

Table . Intercohort comparison of the score and time spent on removal partial denture (RPD) design tests conducted after 1 month and after 1 year; intracohort comparisons of the score and time spent between the 1 month and 1 year time points.

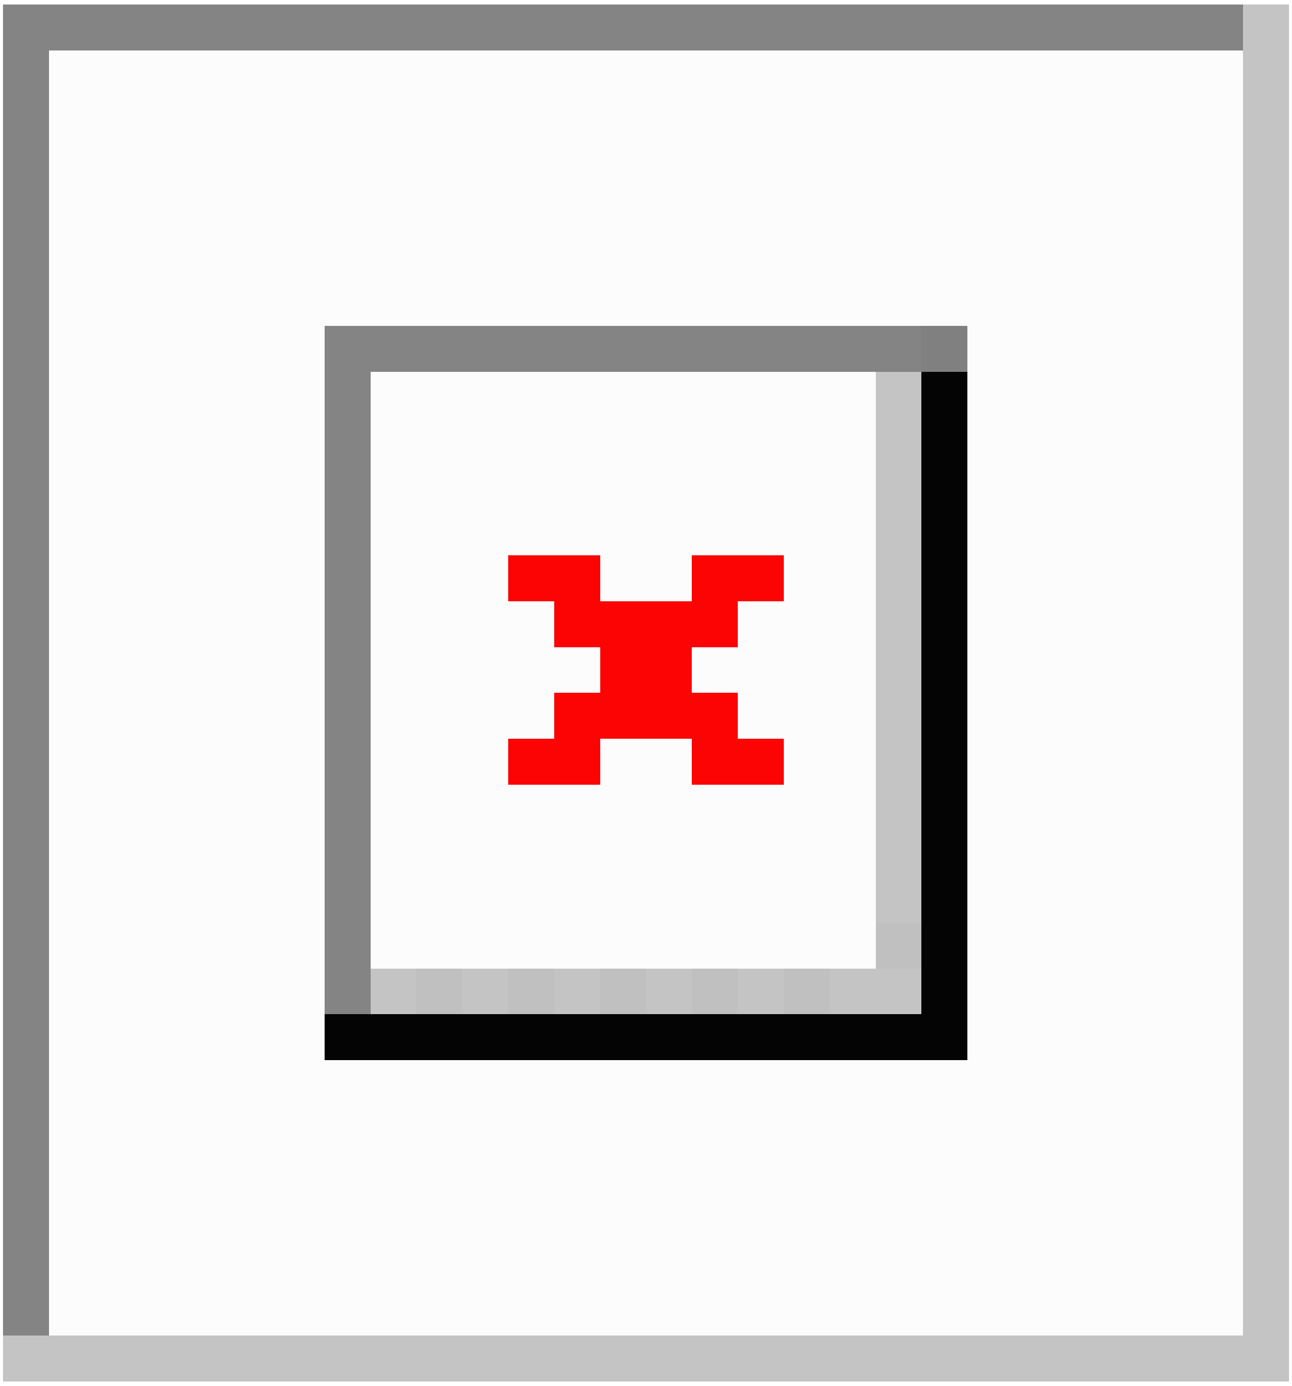
Time Spent

No significant difference was noted in the time spent by the 3 cohorts on the test after 1 month (cohorts 1-3: mean 2407.8, SD 1370.3 s; mean 1835.0, SD 1329.2 s; and mean 1790.3, SD 1195.5 s, respectively; *P*=.06). Pairwise comparisons also did not show any significant differences (cohorts 1-3: 95% CI –33.8 to 1179.5; *P*>.99; 95% CI 14.4-1120.6; *P*>.99; 95% CI –576.7 to 666.0; *P*>.99, respectively). However, the mean time spent on the test after 1 year did show a statistically significant difference between the cohorts (cohorts 1-3: mean 2049.2, SD 1099.0; mean 1857.3, SD 587.4; and mean 2524.3, SD 566.4, respectively; *P*<.001). Pairwise comparisons showed that the mean time spent by cohort 1 was 745.1 seconds shorter than that by cohort 3 (95% CI –868.3 to –82.0; *P*<.001), and the mean time spent by cohort 2 was 667.0 seconds shorter than that by cohort 3 (95% CI –951.6 to –382.4; *P*=.004); both represent a statistically significant difference, while the difference between cohorts 1 and 2 was not statistically significant (95% CI –195.7 to 579.3; *P*>.99) (Table 3 and Figure 3).

Figure 3. Intercohort comparison and intracohort comparison of the time spent on the removal partial denture (RPD) design test. ns: not significant. **P≤.01, ***P≤.001.



Intracohort Comparison of Performance at Different Time Points

Scores

The difference in scores between the tests conducted 1 month and 1 year later for cohort 1 was not statistically significant (95% CI –2.1 to 13.0; *P*=.16). For cohort 2, the mean score obtained on the test conducted 1 month later was 6.4 points higher than that obtained 1 year later (95% CI 3.9-8.8; *P*<.001). For cohort 3, the mean score obtained on the test conducted 1 month later was 5.6 points less than that obtained on the test conducted 1 year later (95% CI –8.7 to –2.5; *P*=.001) (Table 3 and Figure 2).

Time Spent

The time spent by cohorts 1 and 2 on the tests conducted 1 month and 1 year later did not differ significantly (cohort 1: 95% CI –77.5 to 794.9; *P*=.10; cohort 2: 95% CI –372.5 to 327.9; *P*=.31). However, a significant difference was observed for cohort 3, where the time spent on the test conducted 1 month later was 734.0 seconds shorter than that conducted 1 year later (95% CI –1149.9 to –318.0; *P*=.003) (Table 3 and Figure 3).

Discussion

Principal Findings

Historically, the process of learning RPD design is a potentially difficult part of dental education [21]. It requires that dental students first acquire a knowledge base and then use critical thinking skills based on evidence to apply that knowledge to a wide variety of clinical patient care situations. This characteristic suggests that a case-based learning mode is the most appropriate approach for RPD design learning. Case-based learning requires the use of real patient cases and scenarios to reflect realistic patient care situations, and students are asked to draw from their established foundational knowledge to make decisions about problems they may encounter in practice [22]. Previous studies have confirmed the effectiveness of case-based learning in RPD design learning [23]. These studies have typically used text and 2D sketches to describe structured clinical cases, but enhanced digital techniques are gradually being applied to transition from simple presentation documents to computer-aided teaching [11,24-27]. Some studies have further developed decision support systems for RPD design based on clinical case libraries to help trainee dentists complete RPD design by providing cases with similar task requirements [28,29]. More recently, 3D virtual casts and CAD software have been introduced to align with clinical cases and currently prevalent dental laboratory digital workflows [30,31]. Nevertheless, several challenges limit the application of these findings. First, many studies have only addressed students in clinical dental programs, ignoring the dental technology student populace, who, as future dental technicians, are key stakeholders for any RPD design education. Second, in assessing the validity of a training program, most studies have investigated short-term effectiveness without considering the effect on long-term retention of skills, which is the most important for translation to future practice. Our research approach fills these gaps.

When investigating relatively permanent changes in learning, the experimental design needs to incorporate a retention interval, which refers to a period without further practice. Following this interval, assessments can be conducted to evaluate learning outcomes. The inclusion of retention intervals aims to eliminate transient effects resulting from practice, such as fatigue or motivational factors [32]. Existing research lacks discussion on how to determine the length of the retention interval. In this study, the retention interval was determined using a combination of experience, design of relevant literature, and course scheduling. One month after the end of training is the latest time the participants can schedule a test before entering the semester vacation. One year after the end of training is the latest time the participants can schedule a test before graduation. Both time nodes are supported by relevant literature studies [33-35]. Within 1 year after completing the training, participants participate in a uniform dental laboratory internship, and the internship outline has uniform requirements for the design of RPDs with the same workload. At the same time, the user accounts of the participants were blocked in the RPD module, preventing the participants from using the module for additional training. However, participants may use paper and pencil for additional practice since they have different expectations for work content after graduation. Therefore, confounding factors related to different amounts of practice are inevitable.

We noted that the scores obtained on the test after 1 month for cohort 1 was significantly lower than the scores for cohorts 2 and 3, who received the D-RPD intervention. This finding reflects the higher efficacy of the D-RPD digital training approach compared to traditional training at improving short-term performance in RPD design. In addition, cohort 2 scored less than cohort 3, which was provided with the 3D virtual cast–based progressive intervention, albeit with no statistically significant difference, which is consistent with the results of Mahrous et al [30]. This finding suggests no significant short-term benefits of progressive digital training incorporating 3D virtual simulation over digital training using 2D sketches and text alone. However, the scores obtained in the tests conducted 1 year later showed that cohort 3 displayed significantly improved performance in comparison with the other cohorts, thus demonstrating improved long-term outcomes of the progressive digital training approach. Of note, added tacit knowledge from clinical practice gained during the internship curriculum that commenced soon after the first test, where students had additional opportunities to learn and participate in the process of RPD design, could have contributed to such an effect. Such practice enriches the experiential learning of students by allowing for case-based learning and greater practice [36]. The D-RPD module with the 3D virtual simulation–based intervention for cohort 3 was aligned with routine clinical production models to a large extent, which possibly facilitated higher competency over a period of time in cohort 3. These findings are in contrast to our short-term observations and those of Mahrous et al [30]. For the “time spent” evaluation dimension, the differences between the 3 cohorts were not significant at the 1-month test. The complexity of the RPD design process itself could account for this finding. After 1 year, a significant difference was notable, and cohort 3 showed the longest mean time spent on the test. It is feasible that the participants in cohort 3 took more factors into account in the RPD design after undertaking clinical practice in the intervening period and that the D-RPD process with 3D virtual casts was the most consistent with clinical practice; therefore, this effect was produced over a longer period of time. The longer time taken by cohort 3 in estimating more factors and spending more time could also have contributed to their higher score over time. These results indicate that the use of D-RPD, especially when incorporating the use of 3D virtual casts in a progressive mode, may facilitate an improvement in the RPD design competency of students compared with the traditional RPD design training approach.

The mean scores of cohorts 1 and 2 were less after 1 year compared to the scores after 1 month, showing a certain degree of loss of competency over time. In contrast, a significant increase was noted in the mean score of cohort 3. Before entering clinical practice, the participants in this cohort were exposed to experiential learning through virtual simulation that had similarities with clinical work, which might have produced a synergistic effect on improving RPD design competency. It is especially noteworthy that the scores and time spent at the 2 time points by cohort 1 showed very large SDs, indicating high variability in RPD design competency among the cohort 1 students. The opposite was notable in cohorts 2 and 3, which may be related to better teacher supervision, which D-RPD can facilitate. Moreover, previous research has shown that D-RPD design training has advantages that can be partly attributed to improved tracking of students' learning progress and their timely interactions with trainers [37,38]. D-RPD allows teachers to check the progress of the RPD design tasks of the students, make efficient corrections, and provide more frequent feedback. It is evident that this digital teaching mode can facilitate greater student engagement and problem-based learning compared to traditional paper-based teaching. These findings also reinforce that the approach involving D-RPD design combined with 3D virtual casts can provide students with more effective teacher supervision, while offering them virtual experiential learning consistent with clinical activity.

The intervention mode for cohort 3 was similar to the clinical CAD/CAM digital denture design process, which can improve the quality and efficiency of prosthesis design and facilitate improved management of design schemes [39,40]. Intraoral scanning produces 3D virtual casts that can improve precision, and it is readily accepted by the patient compared to the traditional impression method, producing models with higher accuracy [41,42]. The digital workflow allows dental technicians to design directly on these models and to perform postprocessing of multiple scanning data [14,43], thus rendering the entire workflow efficient and convenient. However, despite the rapidly increasing adoption of digital workflows in dental practices worldwide, preclinical education in dentistry and dental technology is typically lagging at imparting the relevant skills to students [12,44,45]. Taken together with our earlier research, this work proposes and validates a progressive digital teaching module for RPD design training that incorporates 3D virtual simulation, demonstrates greater efficacy for a digital training approach compared to traditional training, and provides evidence that a virtual 3D simulation–based progressive digital training module can enhance long-term learning outcomes of RPD design training.

Limitations and Future Work

The limitations of this study include a small sample size, a single center for recruitment, and a lack of randomization, which may have led to unaccounted differences in the inherent learning ability of students and their existing competency prior to participation in the experiment. In future work, bias may be avoided by using a randomized controlled study design to provide stronger evidence for this training module. In addition, there is a lack of data regarding the effectiveness of this training module for clinical dentistry students. Further studies are merited to enable more widespread adoption of 3D virtual simulation–based digital training approaches in dental education.

Conclusions

In this cohort study, we report in detail a major update to the D-RPD module and the design of an intervention experiment to observe the effects of traditional training, D-RPD training, and additional 3D virtual simulation–based digital training on the RPD design competency of students. Based on the results, we propose an effective, progressive, digital 3D virtual simulation workflow–based training module for RPD design, and we have preliminarily verified the efficacy of this novel training approach for facilitating improvement and long-term retention of RPD design competency among dental technology students. This training module should be further extended to clinical dentistry students, randomized controlled experiments should be designed, and feedback from students and teachers should be collected to enable its further optimization and eventual inclusion in curricula.

Abstract

Background: Health rumors arbitrarily spread in mainstream social media on the internet. Health rumors emerged in China during the outbreak of COVID-19 in early 2020. Many midelders/elders (age over 40 years) who lived in Wuhan believed these rumors.

Objective: This study focused on designing a serious game as an experimental program to prevent and control health rumors. The focus of the study was explicitly on the context of the social networking service for midelders/elders.

Methods: This research involved 2 major parts: adopting the Transmission Control Protocol model for games and then, based on the model, designing a game named “Fight With Virus” as an experimental platform and developing a cognitive questionnaire with a 5-point Likert scale. The relevant variables for this experimental study were defined, and 10 hypotheses were proposed and tested with an empirical study. In total, 200 participants were selected for the experiments. By collecting relevant data in the experiments, we conducted statistical observations and comparative analysis to test whether the experimental hypotheses could be proved.

Results: We noted that compared to traditional media, serious games are more capable of inspiring interest in research participants toward their understanding of the knowledge and learning of health commonsense. In judging and recognizing the COVID-19 health rumor, the test group that used game education had a stronger ability regarding identification of the rumor and a higher accuracy rate of identification. Results showed that the more educated midelders/elders are, the more effective they are at using serious games.

Conclusions: Compared to traditional media, serious games can effectively improve midelders’/elders’ cognitive abilities while they face a health rumor. The gameplay effect is related to the individual’s age and educational background, while income and gender have no impact.

serious game; COVID-19; health rumor; game communication; game TCP model; Transmission Control Protocol; gaming; misinformation; disinformation; rumor; health communication; false information; elder; older adult

Introduction

Background

In recent years, the arbitrary spreading of health rumors in mainstream social media on the internet has increasingly gained the attention of the public and raised concerns [1]. For health rumor researchers, a common concern is to propose a feasible and effective prevention and control program for current rampant rumors [2,3]. Furthermore, to prevent and control the spread of such rumors, it is necessary to strengthen the public's health knowledge to judge and identify the rumors [4]. The concept of a rumor involves a form of statement whose veracity cannot be quickly or ever confirmed. Generally, we have a "dream rumor" and a "bogie rumor," the former reflecting public desires and wished-for outcomes and the latter hiding some special purpose by somebody, both of them largely occurring during the early COVID-19 epidemic in Wuhan, China [4]. The traditional way of countering rumors often relies on media refutation, which can only be described as a "Band-Aid" solution. To fundamentally prevent and control COVID-19–related rumors and enhance the public's ability to resist them, we need to find a form of "information vaccine." Therefore, we chose serious games as a "vaccine" in this context.

The purpose of a serious game is to help people acquire knowledge by playing games. Serious games involve solving problems and studying via careful and thoughtful game ideas [5], while considering characteristics beyond gameplay (eg, purpose and scope [6]). In addition, game elements are used to improve information processing and identify relevant information, which is consistent with the purpose of health rumor prevention research [7]. COVID-19–related rumors are based on the content of serious games to experiment with health rumor prevention, mainly using the control variable method and the analysis-contrast method to apply serious game learning to health rumor prevention research. This paper explores how to help people acquire knowledge of health rumors and health commonsense from the prevention experiment using the relaxed approach of serious games [8].

Previously, serious games have provided a platform for education and business use. For instance, behavioral interventions can be carefully tested and designed to reduce risk-taking behaviors [9], where transmission risks and the usefulness of pandemic-like simulations were demonstrated in the laboratory to be safely and ethically comprehended at the initial state of a health crisis. In addition, other studies prove that serious games are used to accommodate informational and communication complexities in early warning disaster management to simulate and test how public information from social media is used in emergency operation centers to make (protective and communicative) decisions based on levels of trust, usefulness, and completeness [10,11]. Therefore, serious games as an "information vaccine" have certain feasibility, and this paper also explored this issue. Nevertheless, the prevention and control of health rumors have rarely been considered in the context of the social networking service (SNS) for elderly users.

Serious Games

Why are serious games chosen as a solution? Serious games refer to those electronic games whose main content is used for knowledge and skill development, professional training, and spreading culture. They are widely used in many fields. Compared to the limitations and congenital deficiencies of some communication models of traditional media, serious games have become an effective tool to address many social problems, because of their fast speed, wide range, and interactivity [12].

Abt [5] first defined the concept of serious games as follows: "These games have an explicit and carefully thought-out educational purpose and are not intended to be played primarily for amusement." Later, Sawyer [8], in his white paper titled "Serious Game 2 Initiative," redefined the concept of a serious game as being an entertainment game with nonentertainment goals. Several variants of the concept have also been proposed. Michael and Chen [13] defined serious games as games that educate, train, and inform. Meanwhile, Zyda [14] defined serious games as a mental contest played with a computer following specific rules. This situation led some analysts to describe serious games as the next wave of technology-mediated learning [15]. Although there is no single definition of the serious game concept, all the proposed definitions convey the same idea: using games to teach or transmit something [16].

Serious games are present in many areas. Westera et al [17] argued that serious games open up many new opportunities for learning complex skills, especially in the education and training domains [12,18-20]. Moreover, Yusoff et al [21] and Crookall [22] argued that good computer games are an excellent example of modern educational theory and that establishing simulation-based serious games as a discipline is a crucial endeavor that could benefit many other related disciplines.

Some early studies were systematically outlined by Connolly et al [23]. For instance, Ziebarth et al [18] and Diehl et al [19] adopted serious games to develop a prototype for the training and education of health students. Some scholars have emphasized the role of serious games in highly specialized skill acquisition (ie, drilling operation [24], mitigation of student dropout [25], improving the command performance of pilots [26]) and education (ie, medical surgery) [27,28], while providing the means to influence cognition and motivational driver [29].

Serious games are also being applied to pass on knowledge or expertise, which can be adopted for various purposes (ie, rehabilitation, psychotherapy, and brain disorders [30-32]). Sometimes, a serious game can also be used to increase risk awareness in the working area of the manufacturing floor [33]. The review by Abd-Alrazaq et al [34] showed that tools such as serious games are usable but are not replaceable options for rehabilitation and clinical intervention where long-term effects are required. Another review by Krath et al [33] revealed that serious games have also incorporated many theoretical foundations relevant to 3 significant landscapes: behavior, learning, and affect-motivation.

In research related to midelders/elders, several studies have demonstrated the potential of serious games to promote physical activity among older adults. For example, a randomized controlled trial conducted by Fu et al [35] found that a 6-month program of exergaming (exercise using video games) significantly improves the physical function of older adults. Similarly, a study by Jiménez-Pavón et al [36] showed that exergaming increases physical activity and cognitive performance in older adults with mild cognitive impairment.

Serious games have also been used to enhance cognitive training and disease management among older adults. For instance, a study by Anguera et al [37] found that cognitive training through a video game improves cognitive control in older adults. Additionally, a systematic review by Loerzel et al [38] indicated that serious games have the potential to improve self-management and quality of life among older adults with chronic diseases.

In COVID-19–related research, several studies have investigated the potential of gamification and serious games in promoting physical activity during the COVID-19 pandemic. For example, a study by Hall et al [39] proposed a project at a hospital's senior health center in Canada to discuss how health care can be addressed using serious games among middle-aged and older adults during the pandemic [39]. The study found that the game was effective in increasing physical activity levels and improving self-efficacy. Lau et al [40] demonstrated the potential use of serious game to improve physical activity, cognitive training, and mental health among the aging population during COVID-19 in Hongkong.

Similarly, a study by Suppan et al [41] developed a serious game designed to promote safe behaviors for infection prevention and control (IPC), with a specific focus on COVID-19 among health care workers (HCWs) and other hospital employees. Another study by Ferreira et al [42] explored the potential of gamification in promoting hand hygiene among HCWs during the pandemic. The study found that the game was effective in increasing hand hygiene compliance among the participants [42].

Overall, gamification and serious games have emerged as a promising tool to promote physical activity and health and well-being during the COVID-19 pandemic. These technologies have the potential to support health promotion initiatives and encourage people to adopt healthy behaviors in a fun and engaging way. Therefore, we believe serious games can also solve the issue of COVID-19–related rumors that existed among Chinese midelders/elders.

Health Rumor Analysis

Zhang et al [1] investigated all 453 features of health rumor data collected from a definitive online reference in China. A logistic regression model was adopted to determine the contribution of such features to true and false health rumors. There were measurable differences between true and false health rumors, where the length of a headline or statement and the presence of pictures were negatively correlated with the probability that a rumor was true. Meanwhile, a rumor was more likely to be true if it contained elements such as numbers, source cues, and hyperlinks. They also found that the dread health rumor is more likely to be true than a wishful one. Meanwhile, Chua and Banerjee [4] conducted a study on health rumors from 2015 to 2018. Users' trust in online health rumors was investigated using 2 factors: length and presence of an image. Additionally, 2 types of rumors were studied: pipe-dream rumor, which offers hope, and bogie rumors, which instill fear. A total of 102 people participated in the experiment, where the finding suggested that pipe-dream rumors are trusted when they are short and do not contain images, while bogie rumors are trusted when they are long and contain images.

Subsequently, Chua and Banerjee [3] investigated the role of epistemic belief in affecting internet users' decision to share online health rumors. The study focused on the characteristics of rumors—true or false, textual or pictorial, dread or wishful—shaping the decision-making among epistemologically naive and robust users separately. The study showed that epistemologically naive individuals are likelier to share online health rumors than epistemologically robust individuals. In addition, epistemologically robust participants were more likely to share textual rumors than pictorial ones. However, there were no differences between true and false rumors (or between dread and wishful rumors) among either epistemologically naive or robust participants. Meanwhile, Wu [43] modeled factors that predicted fake news sharing during the COVID-19 health crisis. Results showed that informational dependency and social dependency engender both positive and negative cognitive states, namely perceived information timeliness, perceived socialization, and social overload, which then invoke positive and negative affects. Considering that SNS dependency affects information-seeking behavior, it is important for individuals to be exposed to as much accurate information as possible and to build up rational communication against the spread of false rumors.

Ji et al [44] explored factors that influence people's engagement in scientific rumormongering of genetically modified (GM) food on the Chinese social media platform Sina Weibo at both the group and the individual level. In total, 9070 posts about GM food were obtained from 1 million users. Analysis using logistic regression of the effect of peer influence did not find that users would depend on their friendship network to spread rumors. Instead, results revealed that people with negative attitudes toward GM food and who are social media extroverts (ie, celebrities) are more likely to spread rumors. In contrast, social reputation did not influence the spread of rumors, overwhelming the voices of the scientific community and negatively influencing public attitudes and behaviors.

Meanwhile, Hui et al [45] conducted a study on the spread mechanism of rumors on social network platforms during COVID-19 and considered education as a control measure against the spread of rumors. A novel epidemic-like model was established to characterize the spread of rumors based on 2 dimensions of users (age and time), susceptibility based on education classes, control strategies to effectively restrain rumor propagation, and numerical simulations to verify the main theoretical results. The study concluded that improving education levels and conducting short-term online education are essential strategies for effectively controlling rumor spread. In addition, Pulido et al [46] focused on the social impact of research to identify types of false health information shared on social media (Reddit, Facebook, and Twitter) using the application of social impact in social media (SISM) methodology. The results indicated that messages focusing on fake health information are primarily aggressive, while those based on the evidence of social impact are respectful and transformative, and deliberation contexts promoted on social media overcome false health information. The findings provide insights into how public health initiatives can support the presence and interactions of evidence as an effective strategy to combat fake news.

A study by Kim and Kim [47] investigated the misinformation belief produced in the context of COVID-19 via 2 main factors: risk perception (psychometric paradigm) and communication. It was found that perceived risk and stigma positively impact belief in fake news, while source credibility and the quantity of information reduce it. Meanwhile, among communication factors, source credibility and the quantity of information reduce belief in fake news, while the credibility of information sources increases it. In addition, Zhao et al [48] used features of online health misinformation that were classified into central level (including topic features) and peripheral level (including linguistic features, sentiment features, and user behavioral features) to propose a health misinformation detection model using the elaboration likelihood model (ELM). Based on a data set collected from a real online health community (because of the lack of a labeled data set), the model correctly detected about 85% of health misinformation. Furthermore, the findings demonstrated the efficacy of behavioral features in health misinformation detection and offered suggestions for misinformation detection by integrating the features of messages and message creators. In COVID-19–related fake news research, Wang and Huang [49] found that although an official denial can initially reduce citizens' belief in unconfirmed information, later when the denial is revealed to be false, the citizens will have lower levels of belief, not just in the current denial, but also in the government's future denials of similar rumors. Moreover, the negative lasting effects will carry over to satisfaction with the authorities in the related policy area.

COVID-19 Background

This paper was initially written in 2020, and the experiment was conducted in the period from February to March 2020. Therefore, many things changed from then up to the Omicron strain of COVID-19. As such, we acknowledge that this paper has time constraints; however, the research still provides some valuable inspiration and conclusions on game studies, media development, and health care. Since the COVID-19 pandemic broke out in December 2019, the related health rumors also began to wreak havoc on the internet.

Rumor prevention is difficult in the case of rumors that rely on propaganda, and the educational means of traditional media are ineffective due to the lack of interaction and the complexity of information. On the internet, especially the midelders/elders were in a state of panic and information-blind obedience [50].

In China, an SNS group existed, in addition to many WeChat groups, similar to Discord and Facebook in the West. Therefore, we could easily find a target sample for our newly established experimental community, where any questions could be communicated at any time. Our experiment was conducted in early 2020, and some people could answer the questionnaire face to face, while others could not because of the lockdown. Therefore, some respondents were sent offline paper questionnaires, and we also requested them to fill in the online questionnaire. The Chinese midelders/elders were comfortable playing the game on their cell phones, so they easily believed the health rumor that the information communication channel is too fast. Some of them whom we could not meet face to face were contacted over a video call, and we confirmed their age and other personal information clearly to ensure accuracy in the experiment.

The original survey, questionnaire, and serious game are in Chinese, convenient for our non–English-speaking respondents, and all the concepts in this paper are the translated version. This means we just translated the statistical data and labels; during the experiment, there was no translation, and we followed the same steps for all the scales.

Elderly WeChat Users in China: Original Survey

According to our data collected in the original survey, the contemporary middle-aged and older adults, especially those aged 40-60 years, have a high frequency of use of WeChat; the number of elderly WeChat users with frequent use accounts for 66.09% of the total. According to interviews at different levels of the questionnaire survey process, middle-aged and elderly users of WeChat are aged from 50 to 65 years. They are also familiar with using the WeChat "circle of friends" function and other social media platforms (eg, TikTok). They often record their daily lives and travel through videos and pictures. Generally, this user group is also active in online social group chats, and their frequency of using online social media is no less than that of some young user groups. For example, 48.85% of middle-aged and elderly WeChat users said they occasionally read health information on WeChat, and only 16.67% said they had never received health information forwarded by relatives and friends (Figure 1).

The survey on the acquisition and dissemination of health information by elderly WeChat users was the focus of this study. Most people do not have the habit of reading health information regularly. It can be seen from the data that this depends to some extent on the frequency of obtaining information. People read health information only when it is forwarded to them by relatives and friends or when relevant health public accounts push this information or when it is in the form of characteristic health information news, as shown in Figure 2. Regarding access to health information, 62.07% of the respondents received health information from their WeChat friends. In addition, 83.33% of the respondents had the experience of forwarding health information to their children or parents, and 57.47% of those forwarded health information to their WeChat friends. Most respondents felt that the original intention of forwarding health information was to help others with a positive attitude.

Figure 1. Reading frequency of SNS health information by Chinese midelders/elders. SNS: social networking service.

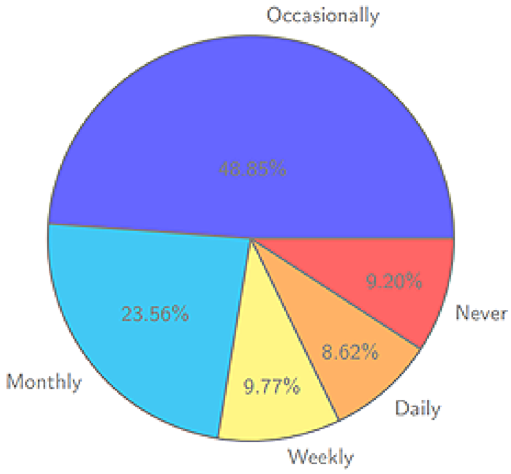

Figure 2. Receiving frequency of SNS health information by Chinese midelders/elders. SNS: social networking service.

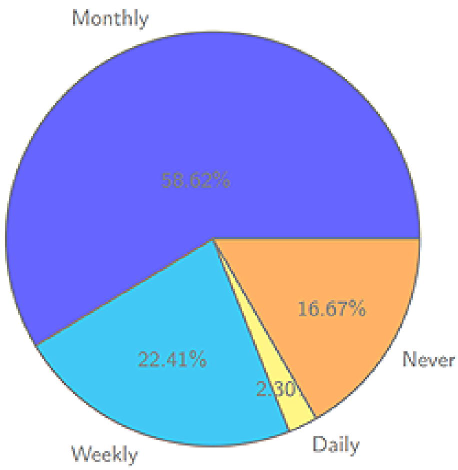

However, many midelders/elders received health information without any judgment and recognition and then spread the information with a “good intention” motive, which is also why the health rumor issue is rampant. The data also show that the failure to recognize and identify health rumors is more likely to be the reason than the motive for spreading them. In addition, according to the questionnaire, 86.78% of elderly WeChat users trusted health information forwarded by relatives and friends and 45.4% considered it very trustworthy. The trustworthiness of health information forwarded by colleagues wa 82.18%. These data show that WeChat has become a hotbed for health rumors among the midelders/elders.

Therefore, this paper used a serious game as a tool to test the effect of game media on the prevention of health rumors. Compared with other media, the serious game had a special communication model and effect that could improve this situation (see the *Results* section for more details). Therefore, using the COVID-19 pneumonia rumor was suitable as the target and content of the serious game, involving not only the elderly closely related to COVID-19 pneumonia but also COVID-19 rumor communication relying on WeChat. Finally, the number of health rumors that emerged during the COVID-19 epidemic was enormous, and enough rumor cases could be collected for experimentation.

Methods

The Transmission Control Protocol Model of the Game

There are many theoretical models concerning the communication effect of games as media [51]. The computer networking concept was adopted as the inspiration for this research based on the idea of engineering. Two main protocols exist in network communication: Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) [51]. TCP originated in the initial network implementation, complementing Internet Protocol (IP). TCP provides reliable, ordered, and error-checked delivery of a stream of bytes between applications running on hosts communicating via an IP network. Major internet applications, such as the World Wide Web, email, remote administration, and file transfer, rely on TCP because of the 3-way handshake mechanism (Figure 3) [52].

Having introduced the logical mechanism of UDP and TCP from the technical perspective of communication, we can see that all media communication models are suited to TCP and UDP (2 computer network theories). UDP uses a simple connectionless communication model, just from the information source to the information sink. For example, the newspaper provides information to readers without any interaction (request and response). However, for all current media, only games match the TCP model (Figure 4). In traditional media, no matter the newspaper, broadcaster, or television program, the audience only receives information; the UDP model does not have a feedback process, the timeliness is good, but transmission is unstable. As a result, users can refuse to accept information or hardly notice useful content. Therefore, serious games can help society to address health rumor issues. In this paper, we proved the effect on the health communication area [53].

Figure 3. Three-way handshaking in TCP. ACK: acknowledge; RTT: round-trip time; SYN: synchronize; TCP: Transmission Control Protocol.

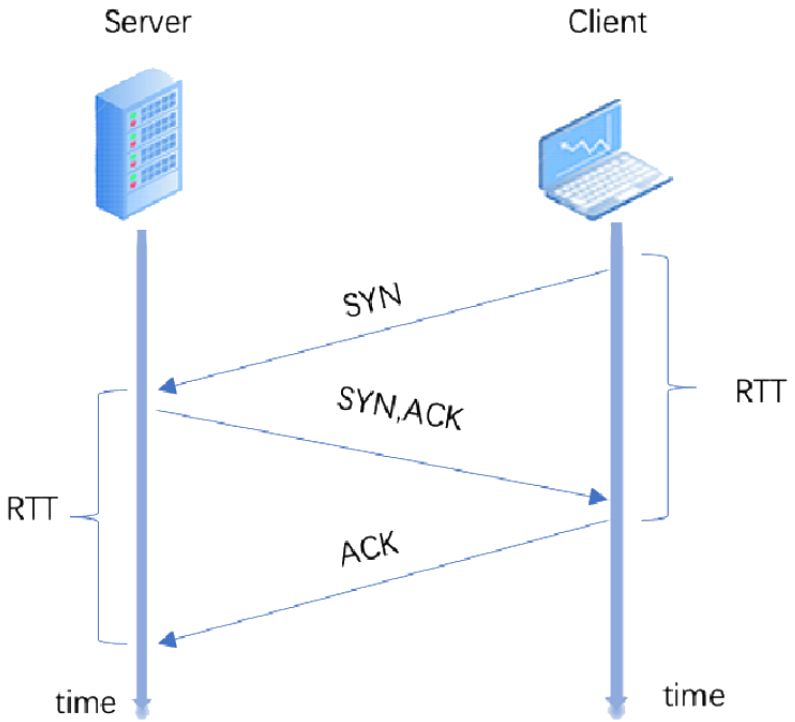

Figure 4. Serious game of TCP. RTT: round-trip time; TCP: Transmission Control Protocol.

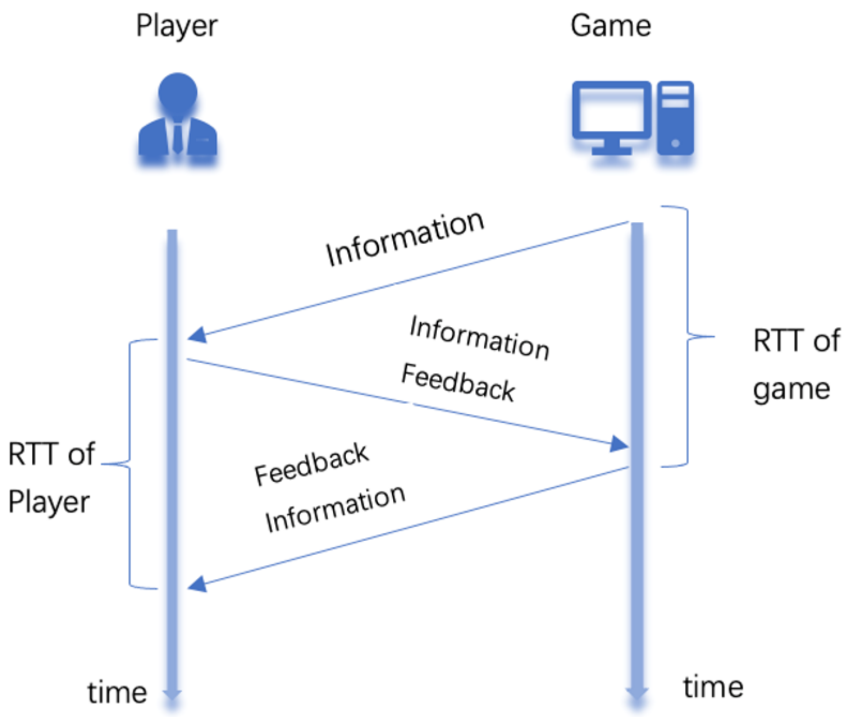

Study Design

This study investigated the prevention and control of health rumors in WeChat, as most elderly WeChat users are concerned about health information and are negatively affected by health rumors. Here, the term "elderly" in our paper is a macroscopic definition: it is not only a physiological age classification but also a description of the psychology or state. In China, people who believe a health rumor via the SNS in the age range of 40-60 years (midelders/elders) were considered. We recruited 200 midelders/elders in Tongren City, Guizhou Province, China, which did not have a serious spread of COVID-19 in early 2020. The participants got together for dancing and training in the city plaza, and then, we requested them to attend our game experiment.

The experimental program was constructed in 2 parts. The first part was developing a serious game based on the content of health rumors and health commonsense; we named it "Fight With Virus." The purpose was to apply this in a health rumor prevention experiment. The second part was developing a cognitive questionnaire with the theme of COVID-19 health rumor, with a 5-point Likert scale, which aimed to compare and analyze the prevention effects of traditional and serious game learning models on health rumors. Baishya and Samalia [54] extended the unified theory of acceptance and use of technology (UTAUT) into UTAUT2, incorporating 3 constructs into the original UTAUT: hedonic motivation, price value, and habit. Individual differences (ie, age, gender, and experience) were hypothesized to moderate the effects of these constructs on behavioral intention and technology use, thus affecting their learning of new technologies. Therefore, according to several past studies based on the UTAUT2 model [55,56], this study adopted the UTAUT2 model to analyze the effect of the serious game. We modified and added variables, which were analyzed using IBM SPSS Amos and IBM SPSS Statistics on factors influencing health information use and dissemination. On this basis, a suitable serious game experiment scheme was built.

The experiment was conducted in 4 steps. In steps 1 and 2, we selected the target participants (midelders/elders), while in steps 3 and 4, we designed the game for the experiment.

Step 1

The construction of the experimental program based on serious games and experimental research needed to be based on a full understanding of the use and dissemination of health information by the research participants. We analyzed the health information needs of the research participants, the frequency and channels of use and the dissemination of health information, and their ability to identify and judge health rumors.

Step 2

To investigate the phenomenon of the dissemination of health information in WeChat's midelder/elder user groups, we used a questionnaire designed in 3 parts: The first part involved a survey to collect personal information, such as gender, age, place of residence, income level, and education. The second part was a survey on the habit of using WeChat. The third part mainly involved the frequency, channel, and motivation of users to obtain and forward health information.

At the same time, 30 health rumor judgment questions were attached to this survey questionnaire, and respondents were asked to judge whether they were correct or incorrect. Through the correct rate of health rumor judgment, we determined the trust level and ability of the respondents to identify health rumors. We also popularized the 30 relevant health rumors, with the hope to popularize the degree of health rumor knowledge and also to strengthen the respondents' ability to recognize information. The questionnaire is shown in Multimedia Appendix 1.

Based on the cognitive ability determined through the questionnaire, 200 participants were selected and asked for their willingness to play the serious game.

Step 3

Based on the use and dissemination of health information by the research participants, the theme of the health rumor learning content was selected and a serious game experimental scheme suitable for this group was constructed through the design and production of serious game content. Considering the experimental length of the serious game and the understanding and acceptance level of the participants, the video game mode of a multiline plot was not applicable for our research, so a single-line plot and scenario was used in the design of the game.

The learning content of the serious game is mainly based on the theme of "a personal day," and the content of the game plot is a person's life from morning to afternoon, in the form of a single storyline. An explanation is provided at the beginning of the game to accurately communicate the theme, rules, and intent of the game to the players. In the learning content of the game, information such as health rumors and general knowledge about COVID-19 was selected, as shown in Table 1, and based on the selected content, failure/passing conditions were set for the game, which involved "risk of infection" and "psychological stress." Different scenarios are set up in a day's life, and questions are set up to interact with the game players to promote and increase the knowledge of COVID-19-related rumors in this interactive learning serious game. The main line design is shown in Figure 5, and the game logic is shown in Figure 6.

In this study, to achieve the effect of the serious game and the purpose of health rumor prevention, a feedback link of the serious game–based health rumor control prevention experiment was important. The feedback link was mainly achieved by setting up a feedback mechanism, which reflected the understanding of the research participants (players) of the game content (COVID-19 health rumor); by setting up the feedback mechanism, interactivity with the research participants could also be strengthened. At the same time, the feedback data were used to reflect the learning effect of the serious game.

The feedback mechanism of the serious game–based health rumor prevention experiment was implemented in the following 3 parts.

- The first part was to communicate the theme, rules, and intention of the game to the research participants by means of game instructions at the beginning of the game. This is an important step to quickly integrate the player into the learning process of a serious game and to let the player know what they will do next in the game.

- The second part was realized in the textual feedback of the gameplay process, where the player was provided with choices through interactive video scenarios, and instant feedback was provided. Instant feedback is an important part of the overall feedback process, which needs to be clearly communicated to the player. It is necessary to clearly communicate to the player whether their choices are correct and to strengthen the knowledge of health rumors and general health. The textual feedback content of the game process is shown inTable 2.
- The last part was to provide feedback after the player passed or failed in the game. At the end of the serious game, based on the player's overall understanding of COVID-19 health rumors and health knowledge, the feedback can strengthen the player's knowledge of health rumors.

The serious game created in this study used a COVID-19 health rumor as the learning content (see Figures 7 and 8). To achieve the purpose of preventing and controlling health rumors, a textual feedback mechanism was designed, involving 4 infection risks and 7 psychological stress settings. These were assigned to game failure or passing conditions, as shown in Figures 9 and 10. The game data reflected the performance of the research participant (player) in the game, with the settings shown in Table 3 to cater to the experiment's needs. The specific game data value settings and game passing/failure conditions are shown in Figure 11. Specifically, the story is as follows: The protagonist, a young person, suddenly finds themselves caught up in the COVID-19 pandemic in early 2020 in their city. Various pieces of information related to COVID-19 start to emerge around the protagonist, causing a massive explosion of fear and panic, particularly among many elderly people who turn to social media for information. They begin to demand that the protagonist follow their advice on preventing the pandemic. The goal of the game is to distinguish between real health knowledge and rumors throughout the daily life story, to use accurate knowledge to save the elderly citizens who are in a state of panic, and to slow down the spread of the virus. In the end, the game outcome is judged based on the actions and choices made by the protagonist.

Table 1. Selection of health rumors/health facts for the serious game content.

Time of day and COVID-19 health rumor/health fact	Setting
Morning	
R[a]1: Drinking plenty of boiled water at 60°C can prevent COVID-19.	Infection risk
R2: Domesticated dogs and cats can also spread COVID-19.	Psychological stress
R3: Putting used masks in a sterilizer can continue to provide protection and use.	Infection risk
The correct way to wear a mask (not an option).	General health knowledge
R4: Going out with ginger slices in the mouth can prevent COVID-19.	Psychological stress
R5: The government will use military aircraft to spread disinfectants in the sky.	Psychological stress
Noon	
R6: You should keep more than 1 m distance from strangers when you go out in times of an epidemic.	Infection risk
R7: Eye-to-eye contact may transmit COVID-19.	Psychological stress
R8: Shuanghuanglian Oral Liquid can effectively inhibit the COVID-19 virus.	Psychological stress
Afternoon	
R9: Disinfection is required for items after returning home from outside.	Infection risk
R10: High temperature can kill the virus, so hot blow-drying and hot water bathing can inhibit it.	Psychological stress
R11: Do not eat fish; pickled fish made from grass carp can transmit COVID-19.	Psychological stress

[a]R: rumor.

Figure 5. The game process. R: rumor.

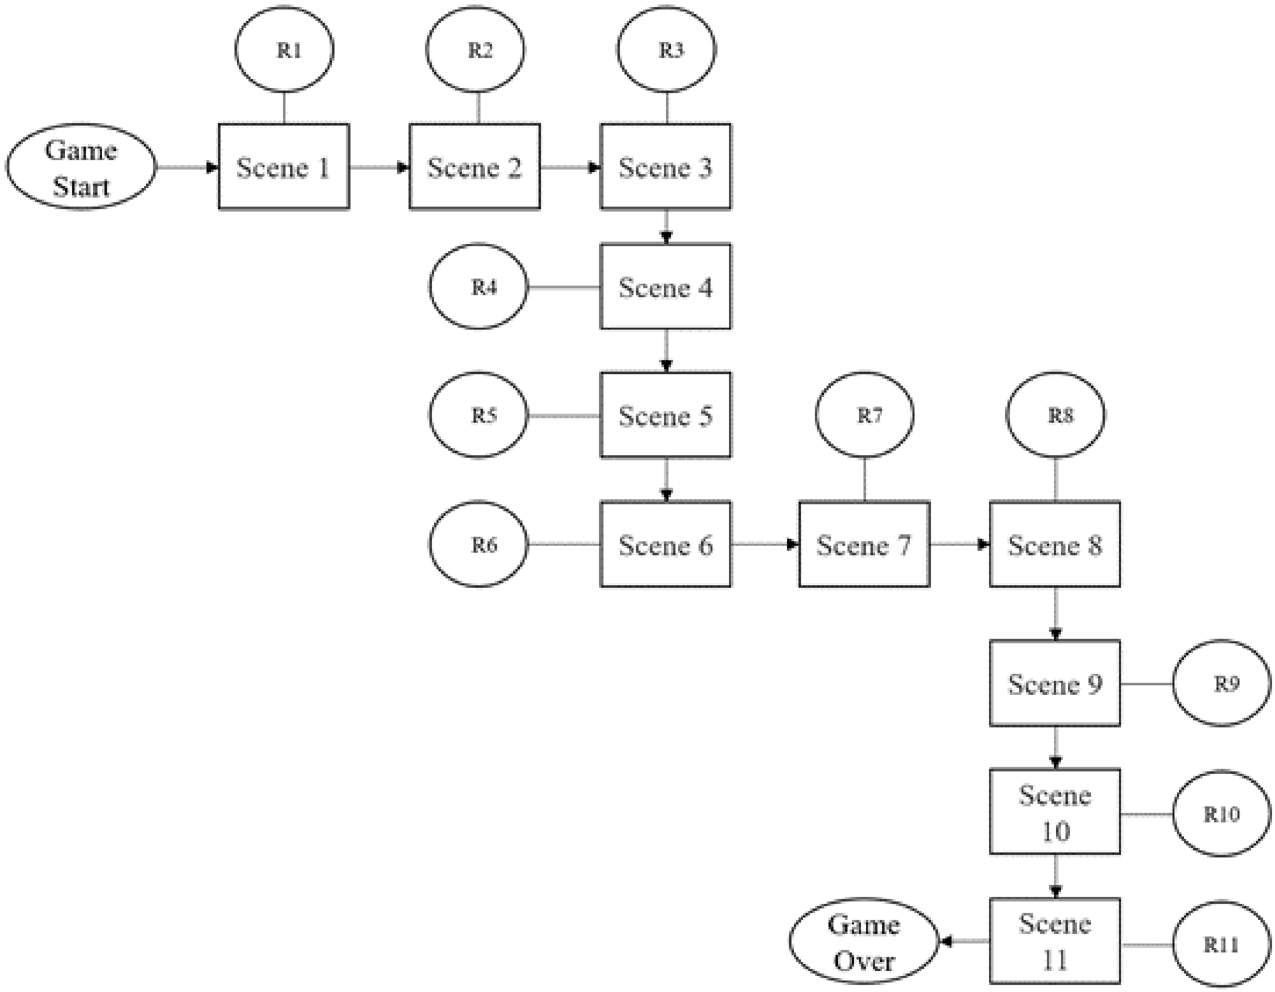

Figure 6. The game judgment logic. N: no; Y: yes.

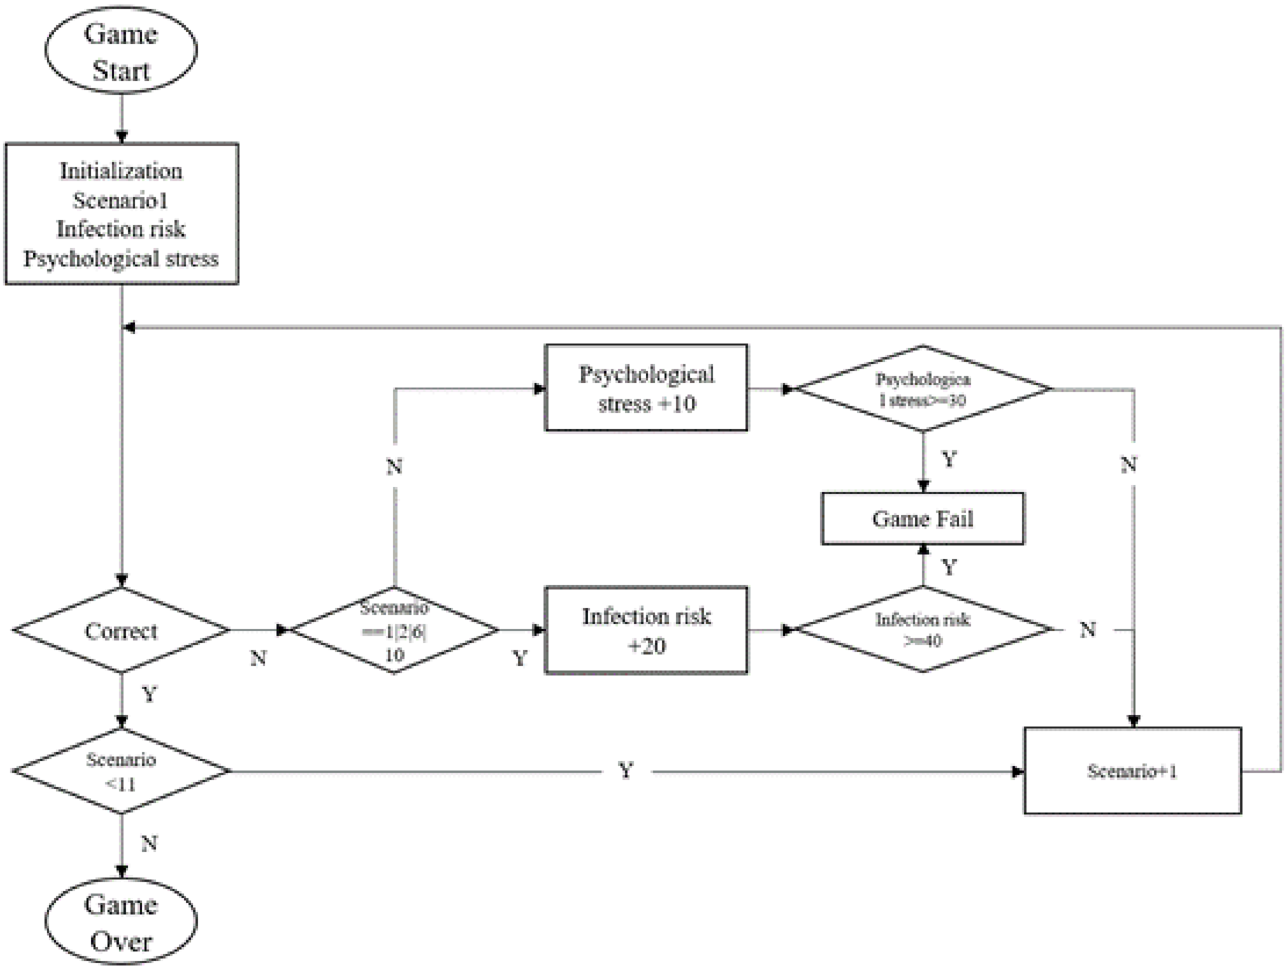

Table 2. Text feedback during gameplay.

Rumor number	Textual feedback (explanation and education) of scenario options during gameplay
R[a]1	Drinking water does not help, and scalding the mucous membrane of the mouth with hot water can increase the risk of infection.
R2	There is no evidence that COVID-19 can be transmitted to domesticated dogs and cats.
R3	Masks that have been used many times do not work to isolate droplets.
—[b]	Graphic feedback: follow the 3 steps (regulations) to wear the mask correctly.
R4	Ginger does not work to prevent the COVID-19.
R5	This is a rumor. There are no military aircraft to spread disinfectants in the sky; in addition, the local government has no right to do that. (This raises the players' sense of alertness and achieves the purpose of public education.)
R6	COVID-19 is spread via droplets and contact, and close contact increases the risk of infection.
R7	This is a rumor. The virus is transmitted through bodily fluids, droplets, and aerosols, not through the eyes. (This re-explains the mode of transmission of the COVID-19 virus.)
R8	Clearly inform that this is not yet clear information and should not be followed blindly.
R9	This is true. You should do that. (This provides possible contact transmission and health information on sterilization.)
R10	Dizziness and other symptoms can occur if you are exposed to bath bombs for too long or take a hot bath for too long.
R11	COVID-19 only infects mammals. Fish do not transmit COVID-19.

[a]R: rumor.

[b]Not applicable.

Figure 7. The experimental serious game's gameplay content 1 (Chinese version). Question: "Hi boy, do you know where one can buy Shuanghuanglian Oral Liquid (a Chinese medicine)? I hear it is useful for COVID-19 treatment!" Answer options: (A) "Really? I also want to buy some." (B) "We do not know the drug's action, so do not drink it by yourself!".

Figure 8. The experimental serious game's gameplay content 2 (Chinese version). Question: "Please come back to home soon; the government will use military aircraft to spray disinfectants!" Answer options: (A) "Really? I'm leaving right now." (B) "Fake news, Mom!".

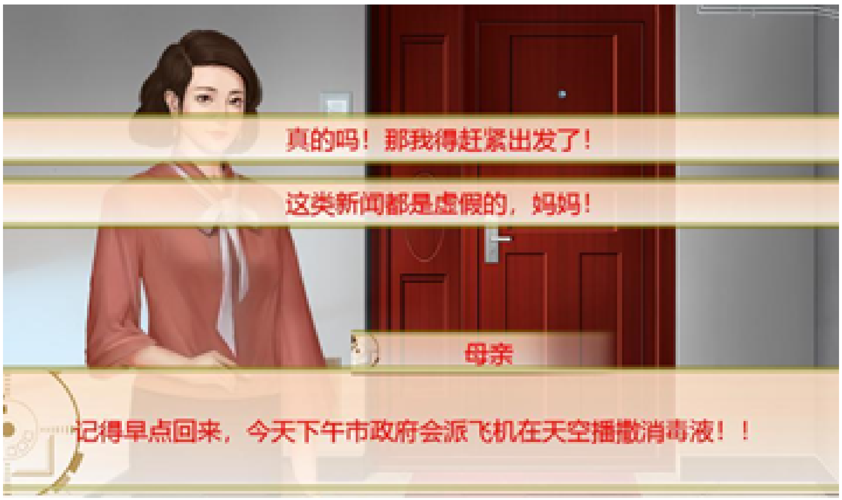

Figure 9. The experimental serious game: game over (Chinese version). Meaning: "The psychological pressure is 10, the risk of infection is 40, you are in a high-risk situation!".

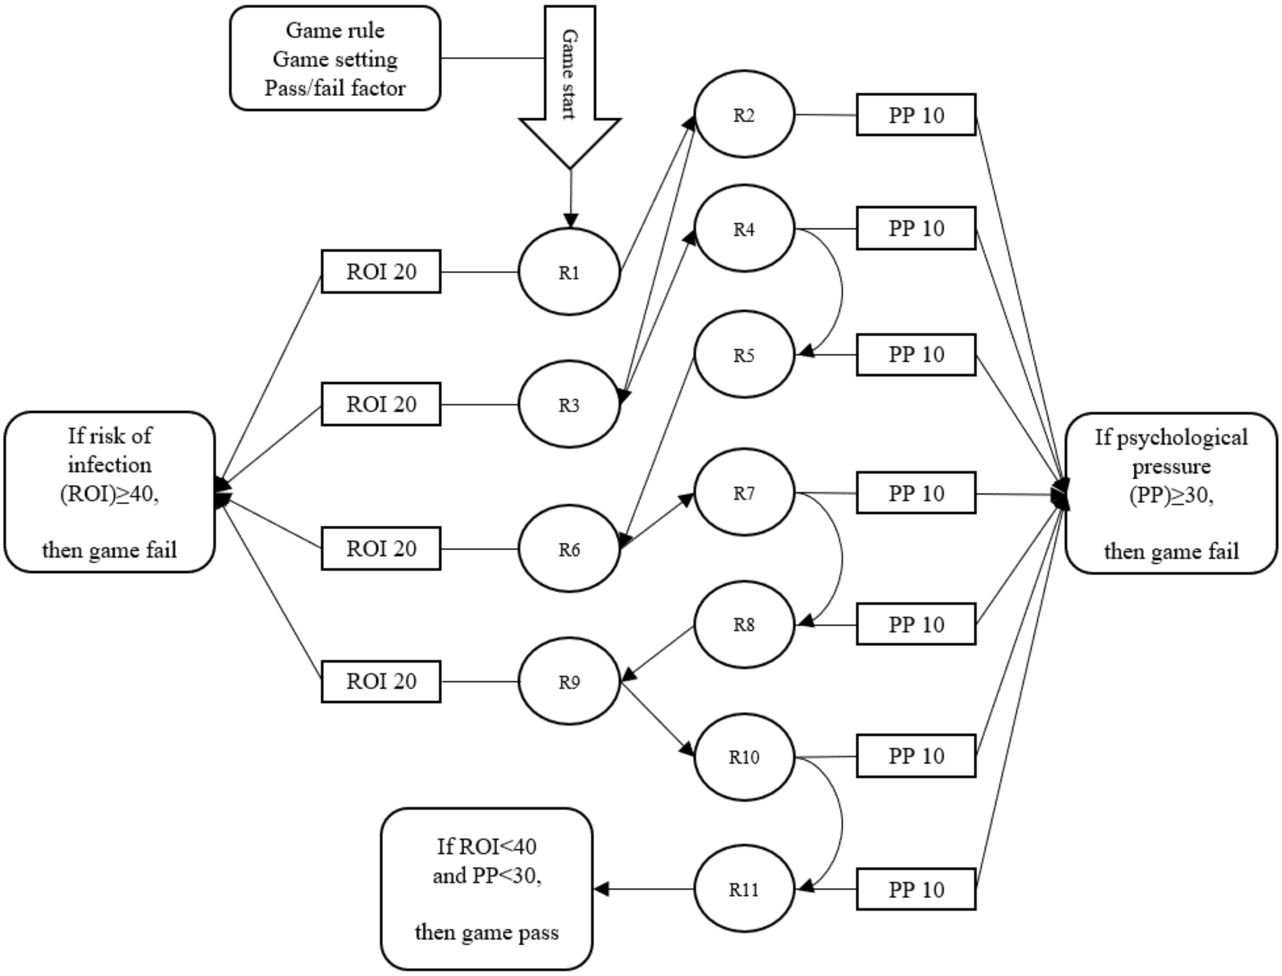
Table 3. Game data and game rating settings.

Game score	Error choice	Game failure	Game round
A	≤3	0	1
B	4-6	1	2
C	7-9	2	3
D	≥10	≥3	≥4

Figure 11. Game-related data values and failure/passing condition-setting thinking diagram.



Step 4

Finally, the data and feedback of the participants were obtained, and the effect of the serious game on health rumor prevention was analyzed through the data and feedback to determine whether serious games are useful to prevent health rumors.

Data Collected

This study compared and analyzed the differences between acquiring and understanding health rumor information through the learning modes of serious games and traditional media. A total of 100 people were selected to participate in the serious game experiment (G1 group), while 100 people who did not participate in the serious game experiment only studied by traditional media (G2 group). To ensure the objectivity of the controlled experiment, the educational background of the 200 participants was investigated before the formal study while keeping the 2 groups as similar as possible in terms of gender and age, as Table 4 shows. Next, we sent the testing questionnaire related to health commonsense and health rumors to G1 and G2.

Table 4. Demographic information of groups G1 and G2.

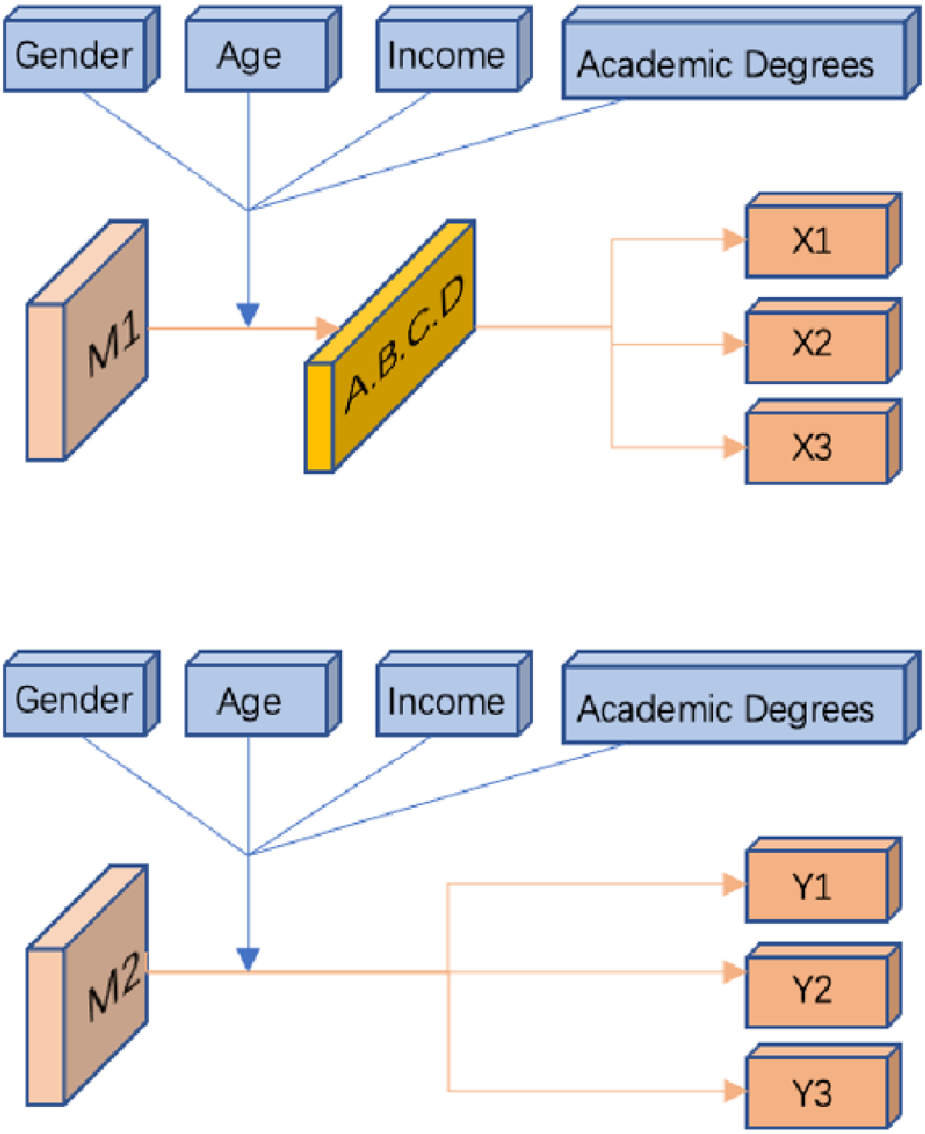
Characteristics	G1 (n=100), n (%)	G2 (n=100), n (%)
Gender		
Male	42 (42)	40 (40)
Female	58 (58)	60 (60)
Age (years)		
40-45	24 (24)	27 (27)
46-50	30 (30)	25 (25)
51-55	19 (19)	17 (17)
56-60	18 (18)	21 (21)
≥61	9 (9)	10 (10)
Educational background		
Less than high school	15 (15)	15 (15)
High school/technical secondary school	50 (50)	50 (50)
Junior college	20 (20)	20 (20)
Bachelor's degree and higher	15 (15)	15 (15)
Income		
Low	29 (29)	24 (24)
Average	48 (48)	55 (55)
High	23 (23)	21 (21)

Variables and Hypotheses

Based on the framework of serious games, a questionnaire was designed that included the following variable definitions:

- Independent variables: The learning mode refers to the way that information is obtained and knowledge learned; the variables were M1 (learning through serious games) and M2 (learning through traditional and new media). For gender, age, income, and education, in the preparation stage of the research, education was used as the main grouping basis, and the age distribution and gender ratio of the 2 groups of experimental objects were kept consistent.
- Intermediary variables: Game data for serious game experiments (A/B/C/D) refer to the player's performance data during the game, including the number of selection errors, the number of game failures, and the number of game passings. Personal performance was divided into 4 mediating variables: excellent (A), good (B), medium (C), and poor (D).
- Dependent variables: The variables were cognitive questionnaire (1) overall correct response rate of judgment and recognition of the COVID-19 health rumor (X1 for G1, Y1 for G2 [G2 did not participate in the serious game experiment]), (2) correct rate of judgment and recognition the COVID-19 health rumor part 1 (X2 for G1 [COVID-19 health rumor not included in the serious game experiment], Y2 for G2), and (3) correct rate of judgment and identification of the COVID-19 health rumor part 2 (X3 for G1, Y3 for G2 [COVID-19 pneumonia rumor included in the traditional media experiment for G2]).
- Intervening variables: The comprehension, cognitive level, learning ability, learning interest, and information attention of the G1 group affected the outcome of the dependent variables to a certain extent. The specific influencing relationship between various variables is shown in Figure 12.

Figure 12. Relationship between experimental study variables.



The following 10 hypotheses were proposed in this experimental study:

- Hypothesis 1 (H1): Serious game experiments can help research participants acquire and understand health rumor knowledge and health commonsense.
- H2: The serious game learning mode is more capable of inspiring the interest of research participants in their understanding of the knowledge acquired and their learning of health commonsense compared to the traditional learning mode.
- H3: The serious game learning mode is more impactful than the traditional learning mode.
- H4: In judging and recognizing the COVID-19 health rumor, G1 has a stronger judgment ability than G2 and a higher accuracy in identifying the rumor in the serious game experiment.
- H5: In judging the COVID-19 health rumor, for the rumor not included in the serious game experiment, without the influence of M1, the ability of G1 and G2 is not much different, and the accuracy rate of identifying the COVID-19 health rumor is roughly the same for both groups. The manifestation in the variable is X2≈Y2.
- H6: In judging and recognizing the COVID-19 health rumor, G1 has an overall stronger judgment ability than G2 and a higher accuracy rate of identifying the COVID-19 health rumor. The specific manifestation in the variable is X3>Y3.
- H7: Gender affects G1's and G2's judgment and recognition of the COVID-19 health rumor.
- H8: Age affects G1's and G2's judgment and recognition of the COVID-19 health rumor.
- H9: Income affects G1's and G2's judgment and recognition of the COVID-19 health rumor.
- H10: Academic qualifications affect G1's and G2's judgment and recognition of the COVID-19 health rumor.

Ethical Considerations

According to the guidelines of the People's Republic of China [57], this study met the conditions for exemption from ethical review.

Results

Analysis of Data Collected

According to the collected game data, 36% (72/200) of players received A, 41% (82/200) received B, 18% (36/200) received C, and the remaining 5% (10/200) received D. The accuracy rate of the judgment and recognition of the COVID-19 health rumor and health commonsense in the cognitive questionnaire of G1 and G2 groups are tabulated in Table 5. The overall accuracy was 84% for G1 and 78% for G2, with an average of 81%. The relationship of the parameters X1-X3 (G1) and Y1-Y3 (G2) are shown in Figures 13 and 14, respectively.

Table 5. Cognitive questionnaire data (judgment and recognition of rumor knowledge and health commonsense).[a]

Question number	Accuracy G1 (%)	Accuracy G2 (%)	Average accuracy (%), (G1+G2)/2
1	72	76	74
2	93	98	96
3	75	79	77
4	77	76	77
5	64	63	64
6	87	91	89
7	77	85	81
8	72	70	71
9	67	63	65
10	80	74	77
11	67	64	66
12	80	88	84
13	88	96	92
14	75	71	73
15	81	83	82
16	91	95	93
17	68	63	66
18	80	83	82
19	58	56	57
20	97	71	84
21	99	61	80
22	98	65	82
23	99	92	96
24	91	81	86
25	100	92	96
26	100	89	95
27	90	76	83
28	92	85	89
29	92	67	80
30	99	95	97

[a]All the correct rate values are kept to integer bits.

Figure 13. Comparison of corresponding dependent variables (G1).

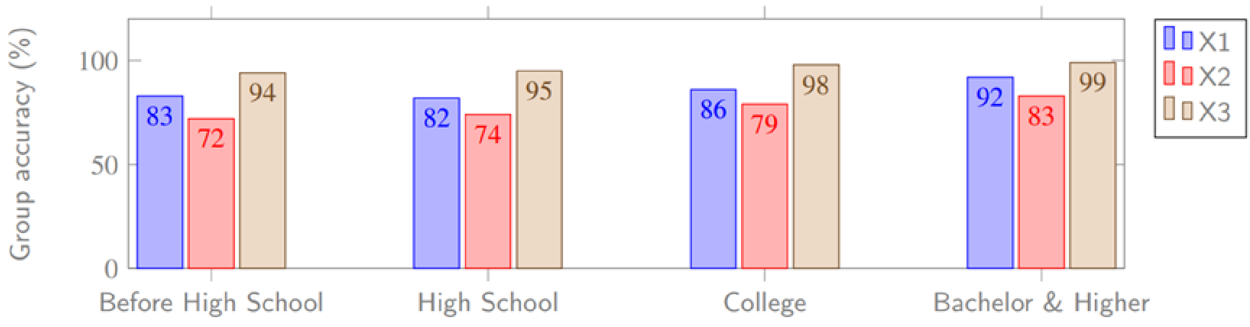


Figure 14. Comparison of two groups and corresponding dependent variables (G2).

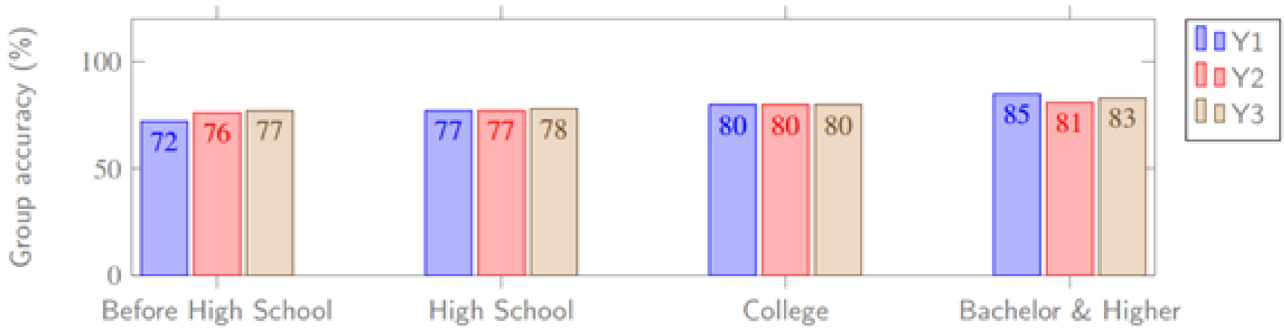

According to the data, the overall average correct rate of judgment and recognition of G1 and G2 was 84% and 78%, respectively. In addition, the related data collected showed that 76% of the participants believed that the serious game learning mode is more interesting than the traditional learning mode. This finding shows that G1 has good interest in games. Furthermore, 60% of the participants thought that the game learning mode is more helpful than the traditional learning mode, and 65% thought that the serious game learning mode makes a more profound impression. Therefore, from the perspective of the selection of participants, the serious game learning mode is more interesting, helpful, and impactful than the traditional learning mode. Therefore, H2 and H3 hold.

Analysis of Dependent Variables (X, Y) and Intermediary Variables (A, B, C, D)

According to the data of the dependent variables in Table 6, we could not directly prove that the impact of M1 on X1 was greater than that of M2 on Y1. At the same time, when the knowledge of health rumors and health commonsense was not included in the game content, the correct rate of judgment and recognition of G1 and G2 was almost the same, and even G1 had a relatively lower rate. However, X3 was 96%, which is much higher than Y3 (79%), and X3 exceeded X2 by up to 23 percentage points. This condition implies that the impact of M1 on X1 is greater than the impact of M2 on Y1. It not only shows that G1 had relatively strong learning ability but also that after the serious game learning model experiment, there was a significant positive effect on the accuracy rate of the judgment and recognition accuracy of the COVID-19 health rumor and health commonsense. At the same time, X1>Y1, X2≈Y2, and X3 >Y3. Therefore, H4, H5, and H6 are established.

The intermediary variables A, B, C, and D were sequentially observed, corresponding to the dependent variables X1, X2, and X3. It can be clearly seen in Table 7 that A-X1>B-X1>C-X1>D-X1, A-X2>B-X2>C-X2>D-X2, and A-X3>B-X3>C-X3>D-X3. The dependent variables corresponding to the intermediary variables showed a decreasing trend from A to D, indicating that M1 affected X1 and X3 through A, B, C, and D and the degree of influence was in the order of A>B>C>D. These data showed that the higher the average game score, the higher the correct rate of recognition and judgment. Therefore, combined with the previous analysis, H1 holds.

Table 6. Dependent variables X and Y.

Variable	Value (%)
X1[a]	84
X2[b]	76
X3[c]	96
Y1[d]	78
Y2[e]	78
Y3[f]	79

[a]X1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G1.
[b]X2: cognitive questionnaire correct rate of judgment and recognition part 1 for G1.
[c]X3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G1.
[d]Y1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G2.
[e]Y2: cognitive questionnaire correct rate of judgment and recognition part 1 for G2.
[f]Y3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G2.

Table 7. Intermediary variables (A, B, C, D) and dependent variables (X1-X3).

Intermediary variable	Dependent variables		
	X1[a] (%)	X2[b] (%)	X3[c] (%)
A	87	80	98
B	83	76	96
C	80	72	94
D	72	62	89

[a]X1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G1.
[b]X2: cognitive questionnaire correct rate of judgment and recognition part 1 for G1.
[c]X3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G1.

Analysis of Independent Variables

Gender

We grouped participants, ensuring the educational composition of the 2 groups was as consistent as possible. By observing and comparing the G1 independent variable (gender) and its corresponding intermediary variables (Table 8), we found that the game score reached A, where the male participants were better than the female participants but changed from B to D when the female participants were better than the male participants. This condition was especially true when the game score reached B, where the female participants were much better than the male participants. This situation may also be influenced by the unequal relationship of the overall gender. There was no gender difference in the numbers from game rating A to D.

Subsequently, by observing and comparing the G1 and G2 independent variable gender and the corresponding dependent variables (Table 9), we observed that regarding the dependent variables X1, X2, and X3, corresponding to the independent variable gender (female, male), the comparisons were female<male, female<male, and female>male, respectively. Regarding Y1, Y2, and Y3, corresponding to gender, the comparisons were female<male, female>male, and female<male, respectively. As such, there was no gender difference. Therefore, H7 does not hold.

Table 8. G1 gender and corresponding intermediary variables.

Intermediary variable	Gender		Comparison
	Female	Male	
A	16	20	Female<male
B	27	14	Female>male
C	12	6	Female>male
D	4	1	Female>male

Table 9. G1 and G2 gender and corresponding dependent variables.

Dependent variable	Gender		Comparison
	Female (%)	Male (%)	
X1[a]	83	84	Female<male
X2[b]	75	77	Female<male
X3[c]	97	95	Female>male
Y1[d]	76	81	Female<male
Y2[e]	79	77	Female>male
Y3[f]	71	88	Female<male

[a]X1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G1.

[b]X2: cognitive questionnaire correct rate of judgment and recognition part 1 for G1.

[c]X3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G1.

[d]Y1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G2.

[e]Y2: cognitive questionnaire correct rate of judgment and recognition part 1 for G2.

[f]Y3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G2.

Age

There were apparent differences in the age ranges between the 2 groups, as shown in Table 4. Therefore, random sampling in G1 and G2 was conducted, and 25 participants under 51 and 56 years old each were selected, with 50 participants in each group for comparative observation and analysis of the corresponding variable data.

First, by observing and comparing the high-age and low-age groups' independent and variable age groups and their corresponding intermediary variables (Table 10), we found that the number of people who achieved A and B game scores were all of low age. As a result, the number of people in the low-age group was greater than the number of people in the high-age group; among those with game scores C and D, the number of people in the high-age group was greater than the number of people in the low-age groups, indicating that to a certain extent, the independent variable age positively affects the intermediary variables A, B, C, and D. Second, by observing and comparing the high- and low-age groups of the G1 and G2 independent variable age with corresponding dependent variables (Table 11), the values of independent variables X1, X2, and X3 could be determined. The values of the low-age group were greater than those of the high-age group; the independent variables Y1, Y2, and Y3 also exhibited this behavior. Therefore, H8 holds.

Table 10. G1 and G2 targets of different ages.

Intermediary variable	Age	
	Low (n=25), n (%)	High (n=25), n (%)
A	8 (32)	13 (52)
B	6 (24)	8 (32)
C	8 (32)	3 (12)
D	3 (12)	1 (4)

Table 11. G1 and G2 age groups and corresponding dependent variables.

Dependent variable	Age	
	Low (%)	High (%)
X1[a]	76	87
X2[b]	69	80
X3[c]	88	98
Y1[d]	68	82
Y2[e]	66	80
Y3[f]	72	86

[a]X1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G1.
[b]X2: cognitive questionnaire correct rate of judgment and recognition part 1 for G1.
[c]X3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G1.
[d]Y1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G2.
[e]Y2: cognitive questionnaire correct rate of judgment and recognition part 1 for G2.
[f]Y3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G2.

Income

The relevant data collected are shown in Table 4. Nearly half of the participants in G1 and G2 believed that their income level was average, and the number of people who believed that their income was high or low was relatively small. By observing and comparing the high- and low-income subgroups in G1 and G2 with corresponding dependent variables, we found that the dependent variables corresponding to the 2 independent variable subgroups were not identical, as shown in Table 12. Therefore, H9 does not hold.

Table 12. High- and low-income groups and corresponding dependent variables of G1 and G2.

Dependent variable	Income	
	High (%)	Low (%)
X1[a]	84	84
X2[b]	82	78
X3[c]	88	94
Y1[d]	73	74
Y2[e]	69	72
Y3[f]	80	78

[a]X1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G1.
[b]X2: cognitive questionnaire correct rate of judgment and recognition part 1 for G1.
[c]X3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G1.
[d]Y1: cognitive questionnaire overall correct response rate of judgment and recognition of the COVID-19 health rumor for G2.
[e]Y2: cognitive questionnaire correct rate of judgment and recognition part 1 for G2.
[f]Y3: cognitive questionnaire correct rate of judgment and identification of the COVID-19 health rumor part 2 for G2.

Education

Based on the cognitive questionnaire, the independent variable education was divided into 4 segments, as shown in Table 4. First, 4 groups of the G1 independent variable education and corresponding intermediary variables were compared (Table 13). Through comparison and observation, we found that the higher the education level, the better the performance in the game, which demonstrates that the dependent variable education positively affects the intermediary variables. Second, the grouping and corresponding dependent variables of G1 and G2 based on academic qualifications are shown in Table 14. We found that education has a positive effect on the corresponding dependent variables. Therefore, H10 holds.

Finally, a thorough investigation of the selection tendency between the learning modes of serious games (M1) and traditional learning (M2) was conducted on G1 involving a comparison experiment of interest, help, and impression (Figure 15). The data showed that 76% (152/200) of the participants thought the serious game learning mode was more interesting than the traditional learning mode, indicating that G1 had a reasonable learning interest in games. Furthermore, 60%

(120/200) of the participants thought that the serious game learning mode was more helpful than the traditional learning mode, and 65% (130/200) thought that the serious game learning mode was more impressive than the traditional learning mode. Therefore, from the perspective of the selection tendency of the participants, the serious game learning mode is more interesting, helpful, and impressive than the traditional learning mode, which strengthens the hypotheses.

Table 13. Proportion of game scores in different education segments.

Segment	Intermediary variables			
	A (%)	B (%)	C (%)	D (%)
Less than high school	20	47	20	13
High school	28	44	20	8
College degree	45	40	15	0
Bachelor's degree and higher	59	23	13	0

Table 14. Education segments and corresponding dependent variables of G1 and G2.

Segment	Dependent variables					
	X1[a] (%)	X2[b] (%)	X3[c] (%)	Y1[d] (%)	Y2[e] (%)	Y3[f] (%)
Less than high school	83	72	94	72	76	77
High school	82	74	95	77	77	78
College degree	86	79	98	80	80	80
Bachelor's degree and higher	92	83	99	85	81	83

Discussion

Principal Findings

Based on a self-made serious game, this paper investigated the health rumor phenomenon, and a study on the user behavior and willingness to disseminate health information among Chinese elderly WeChat users (SNS) was conducted during the early COVID-19 pandemic. After a survey, participants were chosen, and a COVID-19 health rumor was selected as the study content and the experimental platform with the self-made game was established. The UTAUT2 model was upgraded by adding parameters, several hypotheses were proposed, and a control experiment was designed. The experiment results show that the serious game is useful for health rumor prevention.

After collecting game data and the correct response rates of G1 and G2 in the cognitive questionnaire for the judgment and recognition of the COVID-19 health rumor, the game data and the cognitive questionnaire data were combined to determine the relationship between specific variables. Finally, the experimental hypotheses were tested and evaluated, proving that H1-H6, H8, and H10 hold, while H7 and H9 do not hold.

The findings affirm that serious games are a powerful tool to enhance learning and commonsense against health rumors in the context of elderly users of SNS. As Wu [43] argued, perceptions of rumor credibility affect the users' desire to find accurate information (*cognitive gratification*) because they use SNS for verifying the contents of rumors and for acquiring more knowledge and information. Equipping oneself with better knowledge and commonsense against health rumors could have a profound effect on the stability and harmony of society [58], minimize the chance of being misinformed [35], and help create effective control strategies against rumor spreading [45]. Furthermore, as serious games provide the means for people to receive direct feedback relative to their judgment of health rumors, using these games is considered a more humane and emotional approach [47]. In addition, it also provides a suitable channel for health care providers to increase awareness [49] since tackling COVID-19 requires everyone to follow medical advice. Based on the verification of our hypotheses, we found that the effect of serious games correlates with parameters such as education, which suggests that the future rumor management for the youth is perfectly suited to the use of serious games, especially in China, where the education level of the youth is much higher than that of the middle-aged and older populations.

Limitations

Given the seminal findings of this study, it has some limitations. First, the cognitive questionnaire was administered offline, and the midelder/elder participants were reluctant in terms of their willingness to cooperate with the research. As such, there was a risk of the sample distribution being uneven or biased. Second, strict epidemic prevention and control have geographically limited experimental samples. Third, the serious game design was restricted to the COVID-19 health information and had limited interactivity.

Conclusion

This experimental study on preventing new health rumors via serious games proves that the serious game learning mode can help research participants understand and learn about health and rumors. Furthermore, serious games make a more profound impression on people than traditional learning modes, while providing fertile ground for more comprehensive research in the future. In addition, serious games could provide suggestions and support in future research on rumor prevention and detection. In particular, the Chinese government ended the zero-COVID policy in December 2022, and many new health rumors related to the Omicron variant were found on the internet in China. This study could provide a method of challenging the new issue and the game could be updated for the current situation. More importantly, we discovered that serious games can act as an "informational vaccine" against rumors (if rumors are considered a kind of "informational virus or bacterium"), and in the future, we can conduct further research in this direction.

Abstract

Background: Pressure ulcers (PUs) are a common and serious complication in patients who are immobile in health care settings. Nurses play a fundamental role in the prevention of PUs; however, novice nurses lack experience in clinical situations. Virtual reality (VR) is highly conducive to clinical- and procedure-focused training because it facilitates simulations.

Objective: We aimed to explore the feasibility of a novel PU management VR simulation (PU-VRSim) program using a head-mounted display for novice nurses and to investigate how different types of learning materials (ie, VR or a video-based lecture) impact learning outcomes and experiences.

Methods: PU-VRSim was created in the Unity 3D platform. This mixed methods pilot quasi-experimental study included 35 novice nurses categorized into the experimental (n=18) and control (n=17) groups. The PU-VRSim program was applied using VR in the experimental group, whereas the control group received a video-based lecture. The PU knowledge test, critical thinking disposition measurement tool, and Korean version of the General Self-Efficacy Scale were assessed before and after the intervention in both groups. After the intervention, the experimental group was further assessed using the Clinical Judgment Rubric and interviewed to evaluate their experience with PU-VRSim.

Results: The results compared before and after the intervention showed significant improvements in PU knowledge in both the experimental group (*P*=.001) and control group (*P*=.005). There were no significant differences in self-efficacy and critical thinking in either group. The experimental group scored a mean of 3.23 (SD 0.44) points (accomplished) on clinical judgment, assessed using a 4-point scale. The experimental group interviews revealed that the VR simulation was realistic and helpful for learning about PU management.

Conclusions: The results revealed that PU-VRSim could improve novice nurses' learning of PU management in realistic environments. Further studies using VR for clinical training are recommended for novice nurses.

Introduction

Pressure ulcers (PUs) refer to the skin damage caused by ischemia of the skin, subcutaneous fat, and muscles due to a continuous blood circulation disorder in a compressed body [1]. PUs result in a reduction of oxygen and nutrition delivered to the cells, which can contribute to the development of cancer and cardiovascular disease, ultimately amounting to high medical expenses [1]. The incidence of PUs is estimated at 12% in hospitals, representing a common but important health problem because it leads to high nursing burdens, increased medical costs, and mortality [2]. PUs are among the global health indicators and are included in the standard of nursing [3]. Most PUs are preventable by maintaining proper skin integration, and prevention is considered as important as treatment [3,4].

Nurses have a great responsibility in the well-being and safety of patients [5]. In addition, nurses are required to perform appropriate nursing for the prevention and management of PUs. However, they experience difficulties in performing clinical nursing and providing the necessary care to patients [6]. Novice nurses are those with less than 3 years of working experience based on the Benner novice-to-expert model; although they can recognize the basic order in nursing and take decisions, it is generally more difficult for novice nurses to establish priorities [7]. Particularly, novice nurses who have completed the regular curriculum do not have sufficient opportunities for practice during their training and thus experience difficulties in adapting to a new environment and changes in roles in the clinical field, leading to stress and anxiety [8,9]. Therefore, a program that can help novice nurses adapt to the clinical environment is needed.

Virtual reality (VR) is characterized by interaction, immersion, and imagination, and has been increasingly used in the curriculum for nursing with great potential for course development [10]. VR using a head-mounted display (HMD) provides the learning experience of communication between medical staff and patients, as well as simulations of standardized and controlled situations [11]. VR use has been easily accepted by learners in various medical environments and plays an essential role in improving their performance [11,12]. In nursing education, VR has been used in areas such as cardiopulmonary resuscitation, respiratory nursing, and delivery nursing, as well as for improving professional knowledge, clinical reasoning skills, and learning satisfaction [13,14]. In addition, as a learning method, VR meets the expectations and learning styles of the new generation of young learners [14,15].

In nursing education, teaching methods have shifted from traditional lecture-style education to simulation education [15]. Lecture-style education is effective in terms of knowledge transfer to novice nurses. However, there is a limit of this approach in improving nursing work skills in hospitals where various problems can occur [16]. Video-based education for novice nurses is a time-efficient and economically effective method owing to the heavy workload and lack of physical time; however, this format often lacks an appropriate feedback system [17]. Simulation education provides educational opportunities for clinical practice without putting patients or others at risk, and learners have the advantage of safely learning from experience [18]. VR is a representative technology for simulation education [15]. VR simulation can be used by novice nurses freely, which has been shown to improve their knowledge, critical thinking, and self-efficacy [13,18], thereby helping them transform into professional clinical nurses.

Simulation creates a learning environment in which learners can experience intervention and treatment in a safe manner, and various educational theories and structural models can be applied to achieve effective learning results [19].

The Analysis, Design, Development, Implementation, and Evaluation (ADDIE) instructional design model [20] is an effective and efficient development model based on the five steps of analysis, design, development, implementation, and evaluation. Kolb's experiential learning theory [21] states that learning is achieved through the process of "active experimentation," starting with a "concrete experience," "reflective observation," and "abstract conceptualization." Through the concrete experience of simulation, learners make reflective observations and abstract conceptualizations by trying and practicing new techniques in a safe environment, and they perform active experimentation to understand the patient's situation in an actual clinical environment and provide appropriate nursing practice.

This study aimed to develop a nursing PU management VR simulation program (PU-VRSim) and assess the feasibility of the novel virtual program for novice nurses. Toward this end, we applied the ADDIE instructional design model and Kolb's experiential learning theory. The first objective was to assess the feasibility of implementing PU-VRSim for nursing education on PUs. The second objective was to compare the effects of the VR program and video-based lectures on PU knowledge, self-efficacy, and critical thinking, and confirm the level of clinical judgment and experience of participants after undergoing PU-VRSim. The main research questions included: (1) Is implementing PU-VRSim for nursing education feasible? (2) What is the effect of PU-VRSim compared with that of video-based lectures? and (3) What are the participants' experiences with PU-VRSim?

Methods

Design

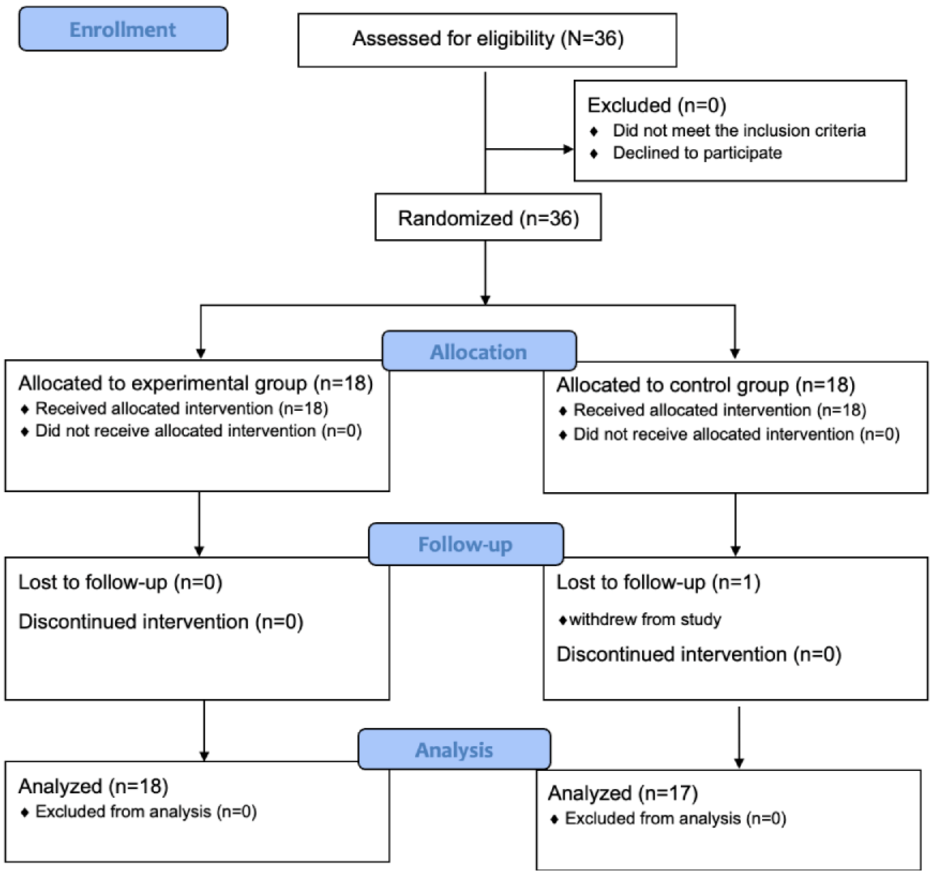
This study applied Kolb's experiential learning theory [21] based on the ADDIE model [20], which is a model of instructional design that was used to develop PU-VRSim for preventing and managing PUs using VR in a nursing education program. This was a mixed methods, pilot quasi-experimental study [22] including nurses with less than 2 years of clinical experience to confirm the effectiveness of PU-VRSim. PU-VRSim was created in the Unity 3D platform (Unity Technologies). Participants experienced the program through an HMD and hand controllers (HTC Corporation, VIVE pro).

Participants

For data collection, nurses with less than 2 years of clinical experience were notified of the purpose, period, conditions of participation, and benefits and disadvantages of participating in the study in the nurses' community bulletin boards. Recruitment for the preintervention survey, intervention, and postintervention survey was conducted through convenience sampling. Participants were categorized into the two groups based on the work schedule of the novice nurses, and participants were blinded to their group allocation. A total of 35 participants were recruited voluntarily from October 10 to December 31, 2022, with 18 assigned to the experimental group and 17 assigned to the control group from January 1 to March 31, 2023. In both groups, one researcher conducted a one-on-one survey and measured general characteristics, PU knowledge, critical thinking, and self-efficacy using preliminary questionnaires, which were sent to the two groups before implementing the program. Regarding the intervention, the experimental group participated in the PU-VRSim program in the simulation room, whereas the control group participated in a video-based lecture on the prevention and care of PUs. After the program, PU knowledge, critical thinking skills, and self-efficacy were measured in both groups. The effectiveness of the program was further assessed with participants in the experimental group via interviews and the Lasater Clinical Judgment Rubric (LCJR) (Figure 1).

The sample size required to compare variables between groups with the *t* test was calculated using the G*Power 3.1 program according to the method of Polit and Sherman [23], using a significance level of α=.05, effect size (*f*) of 0.80, and power (1–β) of .90 [24]. Considering that the sample size satisfying the above conditions was at least 16 people per group, 36 participants were selected, including 18 in the experimental group and 18 in the control group, prior to data collection. One participant in the control group dropped out of the study. Finally, 35 participants were included in the analysis.

Figure 1. Flow diagram of participants' enrollment, allocation, follow-up, and analysis.



Ethical Considerations

Data collection began after obtaining approval from the Institutional Review Board (40525-202204-HR-016-03) of Keimyung University in Daegu City for the protection of the research participants. The purpose of the study, procedures, guarantee of anonymity and confidentiality, and assurance that there are no consequences in case of withdrawal from the study were explained to the research participants, and they were allowed to respond to the questionnaire only when they agreed to participate in the research. The researchers conducted the preintervention survey, application of programs, and postintervention survey. All data collected during this study were anonymized. Participants were compensated for their contribution with a beverage coupon worth 10,000 KRW (~US $8) after the postintervention survey.

Instruments

PU Knowledge

The Pieper–Zulkowski pressure ulcer knowledge test (PZ-PUKT), a PU knowledge tool developed by Pieper and Zulkowski [25] and modified and supplemented by Park [26], was used in this study. The PZ-PUKT comprises 39 questions, including 19, 9, and 11 questions on PU stage confirmation, wound assessment, and dressing methods, respectively. Each question was answered "yes," "no," or "don't know," with 1 point for correct answers and 0 points for incorrect answers. The total score ranges from 0 to 39, with higher scores indicating greater knowledge of PUs. The Cronbach α value was 0.80 and 0.70 in the studies by Pieper and Zulkowski [25] and Park [26], respectively, and was 0.69 in our study.

Critical Thinking

The critical thinking disposition measurement tool developed by Yun [27] and modified and supplemented by Shin et al [28] was used for evaluating the impact of the intervention on critical thinking skills. This tool comprises 27 questions divided into 7 subdomains: intellectual passion/curiosity (5 questions), prudence (4 questions), confidence (4 questions), systemicity (3 questions), intellectual fairness (4 questions), healthy skepticism (4 questions), and objectivity (3 questions). Answers are rated on a scale of 1 point for "not so" to 5 points for "very much so"; a higher score indicates a stronger critical thinking disposition. The Cronbach α value was 0.84 in the studies of both Yun [27] and Shin et al [28] and was 0.83 in our study.

Self-Efficacy

The Korean version of the General Self-Efficacy Scale developed by Schwarzer and Jerusalem [29] and adapted by Schwarzer et al [30] was used to determine general self-efficacy. The Korean version of the General Self-Efficacy Scale comprises 10 questions rated on a 4-point Likert scale ranging from 10 to 40, with higher scores indicating higher self-efficacy. The Cronbach α value was 0.90 and 0.88 in the studies by Schwarzer and Jerusalem [29] and Schwarzer et al [30] and it was 0.86 in our study.

Clinical Judgment Rubric

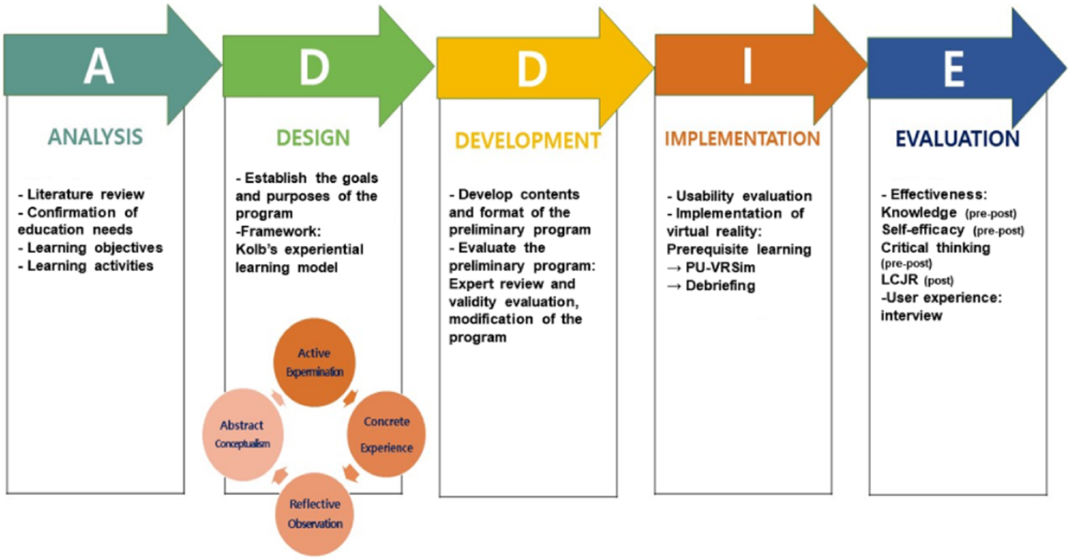
The LCJR, developed by Lasater [31], was used to evaluate the simulation experience. This rubric comprises 11 items based on the following four phases: noticing, interpreting, responding, and reflecting. The LCJR evaluates participants' performance as beginning (1 point), developing (2 points), accomplished (3 points), or exemplary (4 points). The total score ranges from 11 to 44, with a higher score indicating higher clinical judgment ability. The Cronbach α value was 0.83 in the study of Shin et al [32] and was 0.92 in our study.

Procedures

Development Overview

PU-VRSim was developed by applying Kolb's experiential learning theory to the ADDIE model (Figure 2).

Figure 2. PU-VRSim program development. LCJR: Lasater Clinical Judgment Rubric; PU-VRSim: pressure ulcer management virtual reality simulation.



Analysis Stage

The analysis stage identified learners' general and learning-related characteristics. Through a literature review [33], the importance of PU care, factors of PU occurrence, and prevention and management methods were confirmed, and the factors to be included in the development of the VR simulation were analyzed.

Design Stage

In the design stage, the teaching method for developing an effective educational program was determined. Kolb's experiential learning theory [21] was applied to the basic data collected during the analysis stage to determine the teaching method using the VR simulation (concrete experience) and debriefing (reflective observation). The design aimed to improve critical thinking, self-efficacy, and clinical judgment (abstract conceptualization). Using this approach, the learner would assist in performing PU prevention and nursing (active experimentation) well in actual patients.

Development Stage

In the development stage, a VR-based program was developed based on the educational topics selected in the analysis and design stages. A VR platform (Unity 3D, Unity Technologies) was constructed in collaboration with a professional company. A preliminary VR program was tested by five nurses with more than 5 years of clinical experience in scenarios and nursing care of patients with PUs. By checking and correcting errors in the VR program, operational problems were improved and addressed.

Implementation and Evaluation Stage

The implementation stage involved application and operation of the program completed in the development stage (Table 1).

Table 1. Core contents and images of the virtual reality system.

Main contents	Components	Image
Login	Registration of users	
Objectives	Identifying learning objectives: • Assess the degree of risk of developing PUs[a] in the patient. • Classify the PU stage of the patient. • Apply a proper dressing to the patient's PU. • Provide prevention education and care for PUs to the patient.	
Patient case	• Patient hospitalization history • Patient information: name, sex, age, diagnosis, past medical history, social history	
Patient information	Identifying data: vital signs, results of blood test, x-ray findings, physical exam, medication	
Nursing intervention		
Risk assessment for PU prevention	Braden scale score; a lower score indicates a higher risk of developing PUs.	
Assessment and evaluation of PUs	• Assessment of PUs: size and stage • Evaluation of PUs: writing a report	
Management of PUs	Dressing on PUs • Stage 1: film dressing • Stage 2: foam dressing	
Patient education	PU prevention and management education: • Skin care, urinary and fecal incontinence management • Support surfaces • Repositioning • Nutrition	
Final confirmation	• Running times • Feedback (recording)	

[a]PUs: Pressure ulcers

Assessments

Overview of Study Design

The program was used during the evaluation stage. PU knowledge, critical thinking, and self-efficacy in the experimental and control groups were measured once before the start of the study and then again after the program. For the experimental group only, assessment using the LCJR was performed after the program and the effect of PU-VRSim was evaluated through an interview.

Preintervention Survey

The preintervention survey of the experimental group was conducted from October 1 to November 30, 2022, and that of the control group was conducted from January 1 to March 1, 2023. After the participants signed a consent form to participate in the study, their PU knowledge, self-efficacy, and critical thinking were measured using structured questionnaires as described above.

Implementation

The experimental group received the VR simulation program, comprising a prebriefing session (15 minutes) where participants briefly learned about the definition, classification, prevention, and wound management of PUs. Participants were then exposed to PU-VRSim (10 minutes), including PU assessment, nursing care, and education to patients through VR. This was followed by a debriefing session (20 minutes), in which participants were assessed using the LCJR after the simulation.

The control group received a video-based lecture. The video format was selected to reduce the time burden on participants who work in shifts and to ensure safety from SARS-CoV-2 infection, according to the participants' hospital work. In total, 17 participants in the control group received lecture materials and a 30-minute video-based lecture on the definition, classification, prevention, and management of PUs.

Postintervention Survey

After the program, PU knowledge, self-efficacy, and critical thinking were assessed in both groups. The experimental group was further assessed using the LCJR and an interview was conducted to confirm their experience.

Interview

To discuss the experience of participating in PU-VRSim, which could not be verified using objective data, the participants were interviewed after the program. The interview included a self-introduction by the researcher and participant, recording of the interview, guaranteeing anonymity, and explaining that the research results were used only for research purposes and that the interviews were conducted with the participants' voluntary consent. One-on-one interviews were conducted in all cases in a quiet seminar room. Before conducting the interviews, the questions were drafted based on the purpose of the study and proceeded in the order of introduction, transition, and main questions, as shown in Textbox 1.

Textbox 1. Interview question structure.

Introduction question: Thank you for taking the time after work to participate in the virtual reality (VR) program. Can you briefly describe your feelings?

Transition question: Now, we would like to take the time to talk freely about the program's effectiveness and improvements.

Main question: What helped you with the program? What do you think about the content and methods of the VR program in which you participated? What do you need to improve or add to this program?

Data Analysis

The data collected in this study were analyzed using IBM SPSS 23.0, and a two-tailed test was performed at a significance level of .05. The normality of the dependent variable was verified using the Shapiro-Wilk test. The homogeneity of the data in the experimental and control groups was verified using the χ^2 test and independent *t* test. General characteristics and performance on the LCJR aspects of the participants were presented as means (SDs) and n (%), respectively. Wilcoxon signed rank and Mann-Whitney *U* tests were used to verify differences in PU knowledge, critical thinking, and self-efficacy between the experimental and control groups.

The data collected through the interviews were analyzed using an inductive approach, which is one of the content analysis methods suggested by Elo and Kyngäs [34]. For the data analysis, the researcher repeatedly read the transcripts of the interviews, interpreted the meaning of the key statements, and created categories by assigning titles. After data analysis, the authors discussed their interpretations to reach a consensus. Subsequently, the semantic units identified were grouped into higher-level categories, the properties were stated, and the keywords were derived by coding the contents accordingly.

Results

Feasibility of PU-VRSim

Our first objective was to assess the feasibility of implementing the PU-VRSim program for nursing education on PUs in the implementation and evaluation stages.

The general characteristics of the participants are presented in Table 2. The average age and work experience of the 35 novice nurses was 24.8 years and 14 months, respectively. The experimental group comprised 18 (100%) women, whereas the control group comprised 2 (12%) men and 15 (88%) women. We analyzed the homogeneity of the two groups in terms of general characteristics such as age, educational level, VR experience, and PU education experience; no significant difference was observed between the two groups (all *P*>.05) and thus homogeneity between the two groups was confirmed.

Table 2. Characteristics of participants (N=35).

Characteristics	Experimental group (n=18)	Control group (n=17)	χ^2 or t[a]	*P* value
Age (years), mean (SD)	24.11 (1.32)	25.53 (2.72)	–1.98	.06
Sex, n (%)			1.46	.16
Male	0 (0)	2 (12)		
Female	18 (100)	15 (88)		
Work experience (months), mean (SD)	14.06 (7.75)	14.65 (7.17)	–0.23	.82
Education, n (%)			1.852	.83
College	0 (0)	3 (18)		
University	18 (100)	14 (82)		
PU[b] education, n (%)			1.00	.33
Yes	17 (94)	17 (100)		
No	1 (6)	0 (0)		
VR[c] experience, n (%)			0.882	.38
Yes	3 (17)	7 (41)		
No	15 (83)	10 (59)		

[a]*df*=17 for the experimental group and 16 for the control group.

[b]PU: pressure ulcer.

[c]VR: virtual reality.

Effect of PU-VRSim on Outcomes

Our second objective addressed the effects of the VR intervention on PU knowledge, self-efficacy, critical thinking, and critical judgment.

As shown in Table 3, in the experimental group, the PU knowledge score increased by 2.88 points and the self-efficacy score increased by 0.56 points compared with those in the preintervention survey. In the control group, the PU knowledge score increased by 4.12 points, the critical thinking score increased by 4.0, and the self-efficacy score increased by 0.76 points. Each group showed significant improvements in PU knowledge after the intervention. However, there were no significant differences in critical thinking and self-efficacy in either group. There were no significant differences in the change in PU knowledge, critical thinking, and self-efficacy between the two groups.

The results for the clinical judgment assessment are summarized in Table 4. In the experimental group, after PU-VRSim, the overall clinical judgment of novice nurses was 3.23 points. When evaluated in the four phases to confirm whether all phases reached the level of “accomplished,” out of a total of 4 points, the mean scores for noticing, interpretation, responding, and reflecting were 3.27, 3.31, 3.32, and 2.91 points, respectively. The items “well-planned intervention/flexibility” and “skill proficiency” in the responding phase scored the highest, with 3.67 points, whereas “commitment improve” in the reflecting phase scored the lowest, with 2.78 points.

Table 3. Effect of the pressure ulcer management virtual reality simulation on outcomes.

Variable	Preintervention, mean (SD)	Postintervention, mean (SD)	*Z*	*P* value[a]	Difference		
					Mean (SD)	*Z*	*P* value[b]
Knowledge						–0.81	.42
Experimental (n=18)	24.39 (4.79)	27.28 (4.43)	–3.45	.001	2.88 (2.40)		
Control (n=17)	24.71 (5.42)	28.82 (3.41)	–2.78	.005	4.12 (4.74)		
Critical thinking						–1.51	.13
Experimental (n=18)	99.00 (10.70)	98.61 (8.51)	–0.13	.896	–0.39 (5.95)		
Control (n=17)	94.82 (7.24)	98.82 (9.36)	–1.40	.163	4.00 (9.01)		
Self-efficacy						–0.57	.57
Experimental (n=18)	29.11 (3.41)	29.67 (3.24)	–1.45	.148	0.56 (1.69)		
Control (n=17)	25.59 (4.18)	26.35 (3.98)	–1.16	.247	0.76 (3.40)

Qualitative Outcomes of the PU-VRSim Experience Among Novice Nurses

Overview of Themes

For the third objective, the interviews were grouped into five main themes: (1) realistic VR scenarios, (2) helpfulness of VR learning, (3) usability, (4) satisfaction, and (5) limitations of VR equipment (Table 5).

Table 5. Qualitative outcomes of the pressure ulcer (PU) management virtual reality (VR) experience in novice nurses.

Themes and subthemes	Description
Realistic VR scenarios	
Real environment	There was a sense of presence in the hospital
Real experience	Actual practice in nursing on PUs
Helpfulness of VR learning	
Improving knowledge	Remember the concept and care of PUs well
Improving skills	Perform overall practice (assess-evaluate-manage) for PUs
Usability	
Safety	Safe from infection due to low contamination
Accessibility	Able to participate freely regardless of time and place
Satisfaction	
Joy and fun	It was more like playing games than learning
New experience	It was a new and interesting learning experience
Limitations of VR equipment	Inconvenient to use equipment

Theme 1: Realistic VR Scenarios

The participants gained practical experience through VR scenarios. The subtopics related to this were "real field" and "real experience."

> *When I experienced it myself, it was lively and felt like a real clinical environment.* [S1, S8, S10, S16]

> *It was realistic to be able to assess and manage wounds about which I learned from books using VR* [S4]

> *Although it is VR for pressure ulcer nursing, which is difficult to understand only through lectures, it was good to apply it as a direct action* [S11]

> *I only practiced with lying mannequins, but it felt more realistic when I experienced it with patients in VR like a real clinical environment.* [S13]

Theme 2: Helpfulness of VR Learning

The participants expressed that VR was helpful for learning. Subtopics related to this theme were "improvement of knowledge learning" and "improvement of skills."

> *I was able to learn the stages of PUs and the types of dressings.* [S6]

> *I was able to learn about PU care.* [S8]

> *When applying nursing care to patients with PUs through VR, it seems to be more memorable.* [S9, S15, S16]

> *I was able to confirm the PU classification concept.* [S12]

> *There were no bedsore patients in the ward where I worked, and through this virtual reality program, I was able to evaluate, intervene, and evaluate PUs.* [S2]

> *I was able to perform overall nursing activities for patients with PUs.* [S6]

Theme 3: Usability

The participants expressed the feeling of using VR learning as "safe" and "easy to access."

> *There were times when the mannequins were dirty in nursing practice, but it was nice that the virtual patients were not contaminated.* [S13]

> *It was nice to be able to participate without the burden of time and place.* [S5]

Theme 4: Satisfaction

The participants expressed their satisfaction of using VR learning as "pleasure," "fun," and "new experience." They showed interest in VR and experienced fun and enjoyment through learning.

> *It feels more like playing a game than learning something. Enjoyed it.* [S4]

> *It was my first time using virtual reality, and I was able to enjoy it. I want to try again.* [S5, S13, S17]

> *It was a new experience, and I enjoyed it.* [S8, S14, S17]

Theme 5: Limitation of VR Equipment

The participants expressed limitations in terms of the equipment used in the VR program.

> *When I put the equipment on my head, I took off my glasses and put it on, so it was difficult to read the text because my vision was not clear.* [S5]
>
> *It was a bit heavy to wear on my head.* [S8]
>
> *The preparation for running the program was complex and took a long time.* [S12]
>
> *It took a long time when the focus was not good, and the text looked blurry and the controller was not recognized well in VR.* [S13]

Discussion

Principal Findings

In this study, we developed PU-VRSim by applying the ADDIE model and Kolb's experiential learning theory [20,21]. PU-VRSim was designed as a PU prevention and nursing simulation program for novice nurses with less than 2 years of clinical experience. The participants of the PU-VRSim group showed significant improvements in PU knowledge. They reached the accomplished phase of clinical judgment. They commented that it was realistic and helpful for learning about PU management.

PU-VRSim was developed by applying an analysis-design-development-implementation-evaluation method according to the ADDIE model [20]. In the analysis stage, a literature review [33] confirmed that PU care was an important indicator of the quality of nursing services, which is becoming increasingly important [35]. PUs are caused by immobility, pressure, and friction. Factors to be included in education were analyzed by evaluating the methods for preventing and managing PUs through support surface management, position change, and dressing application to relieve pressure on the skin surface. Previous studies [36,37] have confirmed the improvement in PU knowledge and nursing performance of nurses through PU nursing education, thereby suggesting that continuous education on PUs for nurses is needed.

Kolb's experiential learning theory [21] applied at the design stage of PU-VRSim connects theory and practice in VR simulation. Through concrete experience and reflective observation, an abstract conceptualization of theories in realistic situations can help to acquire the knowledge and skills that can be used in real situations. Kolb's theory has also been applied in simulation education in various health fields [38], and VR provides learners with experience-based learning in a real environment by which the learners make decisions and take appropriate actions in real situations [10]. Through PU-VRSim, novice nurses freely apply the theoretical knowledge acquired through existing knowledge and prior learning materials to the process of solving problems encountered by patients in a safe virtual clinical environment. Ultimately, positive results can be expected by applying the improved nursing capabilities in actual clinical trials.

After novice nurses underwent the program, they showed improvement in PU knowledge and reached the "accomplished" stage of clinical judgment. PU knowledge scores increased on average in both the experimental and control groups after the educational program. This shows that the effect of knowledge transfer [16] can be confirmed via both traditional teaching and lectures and with the new VR simulation method. According to Kolb's experiential learning theory, during knowledge transfer via VR, learners can improve their knowledge by reapplying it through concrete experiences and reflections, as well as learn how to utilize what they have learned and gain new knowledge. PU knowledge is the basis of PU care, and professional nursing can be performed through critical thinking and improvement of clinical performance skills. Furthermore, clinical judgment is a particularly important skill in nursing that has also received recent attention. VR has a positive impact on clinical judgment in nursing education [39]. Therefore, positive effects and acquisition of new skills can be expected if field-tailored simulation [40] is applied to nurses to reproduce clinical situations.

Interview contents were analyzed to confirm the experiences of the novice nurses participating in the PU-VRSim program. The analysis revealed that the realistic scenarios of PU-VRSim help in learning, with usability of safety, easy accessibility, and satisfaction being expressed as positive experiences. However, inconveniences in using the equipment to implement VR programs were expressed as negative experiences. This is consistent with the findings of Adhikari et al [41] on the experience of VR programs in terms of acceptability, applicability, areas of improvement, and limitations. VR can be safely and repeatedly applied in situations that can be dangerous to patients; however, it is expensive and has usage limitations [42]. VR was deemed to be a safe and effective educational method for use during the COVID-19 pandemic [43]. The development of a VR program that reduces the inconvenience and cost burden of equipment is expected to increase the use of VR in nursing education.

Our participants confirmed that PU-VRSim was helpful for learning because it could be used repeatedly to access disease-focused nursing problems. There is a need for education about various clinical situations in which nurses can apply nursing interventions according to the situation and an overall assessment of the patient [44,45]; PU-VRSim reflects the clinical situation of PUs and requires nursing education. In addition, it was confirmed as a positive experience, suggesting that improvement in nursing knowledge and clinical performance ability as well as repetitive learning are possible through the promotion of spontaneous thinking and immediate feedback of learners, which were evaluated as advantages of simulation in previous studies [46,47]. These results confirm the possibility of using PU-VRSim as an educational program in clinical practice.

In nursing practice using mannequins during the COVID-19 pandemic, the participants expressed concerns about infection via contamination of the mannequins from multiple contacts. Using VR, they felt safe as the risk of infection could be avoided. In previous studies, VR simulation was suggested and used as a nonface-to-face practice method when clinical practice was not possible due to the prevalence of COVID-19 [43,48]. In addition, participants did not feel the burden of time and space when participating in VR education. This is an advantage of VR, in which one can experience the actual medical field using only computers and equipment. Furthermore, individual learning is possible; therefore, it can provide optimal learning to individual learners and help them overcome obstacles in the physical environment [49]. VR may be an appropriate training method for shift workers, because nurses who work shifts can access the education without experiencing a time burden.

Novice nurses in this study regarded VR education as a new experience and evaluated it as enjoyable. A VR learning environment enhances immersion and activates learners' imagination to simulate the real world [50]. The VR program is a teaching method that incorporates the latest technology and meets the learning needs of a new generation. Educational programs are being developed on various topics for nursing students and novice nurses, and the effects of enjoyment and fun have been confirmed [13]. Learning satisfaction through the enjoyable and fun VR improves learners' learning motivation and confidence, and they experience reduced fear in real situations [14]. Because enjoyment and fun in learning are factors that stimulate learning motivation and interest, gamification can be applied when developing programs so that learners can enjoy various experiences in the virtual world.

When implementing the VR program, participants had difficulty in using an HMD; in particular, participants wearing glasses experienced inconvenience when wearing the device along with their glasses. As in previous studies, most of the participants experienced technical difficulties [41]. A VR program is typically executed using a computer program, an HMD, and a controller; however, the HMD and controller devices do not recognize the participants' fine movements, making it difficult to proceed [42]. In the future, the development of a convenient version of the HMD, with a clear field of view, ease of wearing, and usability, may lead to an increase in the use of VR education.

PUs are common health problems in hospitals, and novice nurses experience difficulties in treating PUs. Education of nurses has been regarded as an integral component of PU prevention [51]. VR is an ideal educational technology, and the number of educational programs applying VR in nursing education has been increasing recently [52]. For the VR education program, we confirmed the improvement in knowledge of the participants through the experience in prevention and nursing interventions for patients with PUs. Improvement in clinical performance can be expected with improved knowledge. In addition, the novice nurses in this study expressed satisfaction with VR education as a new experience and a safe learning method. Considering the limitations of VR equipment, it is necessary to develop and utilize a popular simulation program that is more user-friendly and can be manipulated easily. Based on this study, we suggest the development of VR nursing education programs focusing on the educational needs of novice nurses and including new technology such as artificial intelligence with the development of technology.

Conclusion

The PU-VRSim program developed in this study was found to be effective in improving novice nurses' knowledge of PUs and was positively evaluated as a pleasant experience conducive to learning in an actual hospital-like environment. Therefore, PU-VRSim can be used as an effective educational method for novice nurses, as well as for nursing students and clinical nurses. In addition, a synergistic effect can be expected when the content used incorporates various software programs, including VR simulation programs.

Limitations exist in understanding and generalizing the effects of nonrandomized control-group experiments targeting novice nurses. To supplement this, we propose a follow-up study that applies the PU-VRSim program to nursing students and clinical nurses, as well as a randomized control group experimental study of novice nurses. All participants in the experimental group were women; therefore, we propose a further study with a more heterogeneous group of participants by including male and female nurses. In addition, we suggest the development of a field-tailored VR simulation for health professionals, including novice nurses, and study of its educational effect. Finally, developing a program for VR simulation is expensive and wearing an HMD when implementing the program is uncomfortable. We propose the development of software and VR simulations using technology such as smartphone apps, which are inexpensive, comfortable, and easy to use. In conclusion, we propose the continuous development and improvement of VR nursing education programs for novice nurses applying new technologies.

Abstract

Background: Numerous reviews advocate using virtual reality (VR) in educational contexts. This medium allows learners to test experiences in realistic environments. Virtually supported scenarios offer a safe and motivating way to explore, practice, and consolidate nursing skills in rare and critical nursing tasks. This is also cited as one of the reasons why VR can significantly increase the knowledge acquisition of nursing students. Nevertheless, studies are limited in their significance owing to the chosen design. Despite great interest, this results in a low level of confidence in VR as a curricular teaching method for nursing education. Therefore, defining concrete design and didactic-methodological parameters that support teachers in the use and implementation of VR is more relevant.

Objective: This scoping review aims to provide an overview of significant design aspects for VR scenario conception and its transfer to generalist nursing education to generate value for the development of teaching scenarios and their sustainable implementation in teaching.

Methods: A comprehensive literature search was performed using the MEDLINE (via PubMed) and CINAHL databases, and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist was applied. The search was conducted from May to July 2022, using a specific search principle corresponding to the focus and the growing study corpus. A previously defined "population, concept, and context" scheme was employed as the basis for the double-blind review of all relevant international German and English publications released up to May 1, 2022.

Results: In accordance with the predefined selection procedure, 22 publications were identified. The identified aspects aided in the development of design, didactic, and research recommendations. The intuitive operation of realistically designed VR scenarios, which are standardized, reliable, and modifiable, as well as clear instructions and specific multimodal feedback functions were described positively. The same applied to the linear structure of the sequences with graduated demands and high image quality for increased immersion with low sensory overload. Changes in perspectives, multiuser options, dialogs, and recording functions can contribute to an interactive care practice. On the research side, it is advisable to define VR terminologies. In addition to considering larger samples, varying settings, and financial issues, it is recommended to conduct long-term studies on knowledge acquisition or improved patient outcomes.

Conclusions: VR scenarios offer high potential in the context of nursing education if teachers and learners develop them co-creatively according to design features and implement them by means of a well-conceived concept. VR enables trainees to develop practical skills continuously in a standardized way. In addition, its deployment supports the sensitization of trainees to digital nursing technologies and the expansion of their digital skills in a practical setting. Furthermore, it allows sustainability issues to be addressed.

Introduction

Background

Germany and the German health care system are facing enormous challenges. In addition to an increase in the need for care, demographic change is also leading to a blatant and increasing shortage of skilled nursing staff. Thus, the care gap in Germany is growing in all areas of care, and the need for nursing staff will rise alarmingly to 500,000 by 2035 [1]. However, in addition to the quantitative needs, the complexity of care is also increasing. A multimodal approach that considers other solutions in addition to human resources is required to counter the care crisis effectively [2]. Increasing technologization and digitalization in the health care sector can not only provide relief and additional security, but also strengthen the availability of current and person-centered (specialist) knowledge and skills in training and further education [3]. Accordingly, the educational pathways for the health care system in Germany are also changing. On the one hand, the academization of nursing education is being discussed and implemented in model study programs, while on the other hand, the new curricular orientation provides for generalist nursing education [4].

One recommendation therefore advocates transformative learning approaches that enable trainees and existing nurses to deal constructively and reflectively with the changing processes of an increasingly complex care reality.

Virtual Reality as a Transformative Learning Approach in Nursing Education

Gradually, more educational institutions of health care are making use of virtually supported teaching-learning scenarios [4], as they represent a suitable medium to train or support the skills of health care professionals.

One of the potentials is attributed to the immersive effect [5]. With the help of virtual reality (VR), users immerse themselves in a computer-generated synthetic environment [6] and perceive it via the senses of sight and hearing and increasingly via movement and touch as well. Therefore, immersion refers to the objective degree of sensory reality fidelity. According to Milgram et al [7], the degree of reality representation, which originally referred primarily to visual representation and has since been extended to haptic or acoustic experiences, can be classified on a “virtuality continuum” between the extremes of reality and VR.

As there is no standardized usage of the term VR yet, we applied the description of immersive virtual reality simulation (iVRS) according to Shorey et al [8] as a working definition, which was decisive for determining the study inclusion and exclusion criteria as follows: “The virtual world [also “virtual reality,” authors’ note] is a 3D computer environment that provides users with interactive experiences of an alternate reality in which they are avatars who can move, sense, touch, and act upon simulated objects that appear real [9]. There are 2 variations of virtual worlds, namely, desktop virtual reality simulation (dVRS) and iVRS [10]. dVRS, also known as non-iVRS, is where users interact with an environment displayed on a computer monitor using a mouse, keyboard, touchscreen, or joystick [11]. In contrast, iVRS provides a complete simulated environment where the user is equipped with several sensory output devices such as a head-mounted device, stereoscopic unit, audio device, and haptic device [10]. It involves a higher degree of interactivity compared to dVRS — by blocking out many visual elements of the real-world environment and inducing sensory stimuli that correspond with the virtual environment, it enables the user to immerse in the virtual environment [12].”

Nevertheless, both these varieties use the principles of interaction and user participation in addition to the characteristic of graduated immersion [13]. This characteristic enables nursing trainees to experience both routines and the complexity of rare or dangerous care tasks in an activating but safe and motivating environment [14].

In the last decade, various international studies have investigated the application of VR for educational purposes in nursing. As an interesting complement to traditional teaching methods, the use of VR to improve the teaching of basic nursing skills, communication, or teamwork [15] has increased. Here, above all, the possibility of conveying abstract and complicated content is used, as one’s actions and their effects are brought into focus and the learning content is perceived as more attractive [13] and is addressed via several sensory channels in parallel [16]. Beyond this, the procedure for learning and acquiring skills and competencies, which trainees can repeat as often as needed, promotes neuronal linkage [17,18] and the resulting confidence in action. In following this approach, ways of translating theoretical knowledge into practical skills and abilities emerge [19]. However, learners and teachers have described this theory-practice transfer as critical and inadequate if only conventional teaching methods are used [13]. This can lead to not only inadequate care but also dropouts from training as trainees demonstrate an excessive demand for the learning content and its transfer to concrete practical requirements [20], especially since the number and regularity of patient contacts during training are often insufficient.

Accordingly, technology-supported teaching-learning arrangements can provide multiple services as follows:

1. They can take up the changing range of professional tasks in nursing, depict them, and teach the competencies required for this in a situational and interactive way in a safe learning setting or support the acquisition by opening up opportunities for self-observation and self-reflection [5], particularly for complex action situations that occur rather rarely in care practice and cannot be guaranteed or practiced in the training phases.
2. They can increase the intrinsic motivation to learn and the attractiveness of training [18] and can make it more effective [21].
3. They can indirectly fulfill the demand for the inclusion of digital-related competence requirements in curricula [22].

In order to establish a connection between educational and care contexts and thus provide educational value, digital technologies should be used as a learning medium in a reflected and justified manner. This makes it more relevant to define concrete design and didactic-methodological parameters that support teachers in the use and implementation of VR in their teaching.

Despite the increasing number of publications on VR as a learning medium in the educational context of health care, there is still a lack of a merger between best practice experiences and recommendations for targeted use and specific design in generalist nursing education. To our knowledge, this didactic-methodological approach to VR-supported nursing education has not been applied yet. Based on this, our scoping review is intended to contribute to showing the potentials and indications of VR as a specifically selected and supplementary teaching-learning medium and to reveal the needs of this distinctive target group for an efficient design.

Study Objectives

The aim of this comprehensive literature review is to compile the findings and best practice examples of projects on VR-supported educational processes in nursing that have already been completed or are still in progress. With the help of this exploratory overview of the currently available evidence, it should be possible to make statements and recommendations as to which design aspects are relevant for the conception and use of didactically and methodologically significant virtually supported teaching-learning scenarios in the professional qualification of nursing specialists and to what extent these can be transferred to basic nursing training.

Methods

Overview

This scoping review, based on the JBI methodology [23], has obtained and mapped an overview of previous and current international research projects [24], and it is as broad and in-depth as possible [23]. With the help of the procedure described by Arksey and O'Malley [25], which comprises the steps of searching for and identifying relevant studies; selecting them; presenting the data; and compiling, summarizing, and reporting the results, it is possible to both make use of the research results already generated and identify the research gaps that still exist [25].

Search Strategy

From May to July 2022, a comprehensive search was conducted in 2 specialist databases (MEDLINE via PubMed and CINAHL via EBSCO) according to predefined inclusion and exclusion criteria, which are presented in Textbox 1. The search strings for the literature search in the databases are presented in Multimedia Appendix 1. In addition to publications identified in the reference lists that appeared to be suitable according to the keywords and were available as full texts, grey literature from other databases and websites available online was also taken into account and included in the screening of abstracts and full texts.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

Publications

- All publication types.
- Publications until May 5, 2022.
- Available full text (author request if applicable).
- German or English publications.
- International studies.

Population

- Trainees, students, and teachers in nursing care.
- Working nursing professionals participating in continuing education programs.

Concept

- Virtual reality (VR) applications in the professional qualification of nursing staff:
  - VR
  - Immersive applications
  - Use of a head-mounted display
- Outcome:
  - Effectiveness
  - Acceptance
  - Trust
  - Usability
  - Design features

Context

- Basic training as a nursing professional.
- Basic studies to become a nursing professional.
- Continuing education and training for nursing professionals.
- Interprofessional teaching-learning settings in which future nursing professionals also participate.

Exclusion criteria

Publications

- Publications after May 5, 2022.
- Full text subject to a fee.
- Non-German or non-English publications.

Population

- Exclusively students of human, dental, or veterinary medicine.
- Exclusively practitioners of human, dental, or veterinary medicine.
- Exclusively trainees of other health professions.
- Exclusively practitioners of other health professions.

Concept

- Other simulation-based teaching-learning forms without VR or immersive approaches.
- Programming aspects of VR applications only.

Context

- VR applications in medical-therapeutic settings without an educational purpose.
- VR applications in other educational or recreational contexts.

Study Selection

The online tool "Rayyan" [26] was used for the consolidation and further processing of internationally published German or English articles, which were initially selected on the basis of the title and abstract. With the help of this tool, the research team was able to process the data set independently and in a blinded manner on the one hand but still cooperatively on the other. In this way, articles published up to May 1, 2022, were checked for their suitability with regard to the research question, and relevant hits were identified and extracted in a structured manner. No selection was made with regard to the study design, but both the population involved and the technologies used were taken into consideration. Therefore, we included studies in which nursing trainees, students, and teachers or nursing professionals in further education or training tested the use of VR in the form of head-mounted displays as a medium in targeted teaching-learning arrangements or helped to shape the development process. Of relevance here were, above all, statements on questions of effectiveness; information on increases in knowledge, technology acceptance, and usability; and concrete information on the didactic design of scenarios.

For this reason, publications that focused on other forms of VR representation (eg, nonimmersive 2D representation on a screen or Cardboard app–based models) or use as an assistive technology in nursing or medicine, or focused exclusively on other health professions were not considered. Furthermore, studies that focused on technological details and programming issues, but did not address the educational context, were also excluded.

Data Extraction and Synthesis

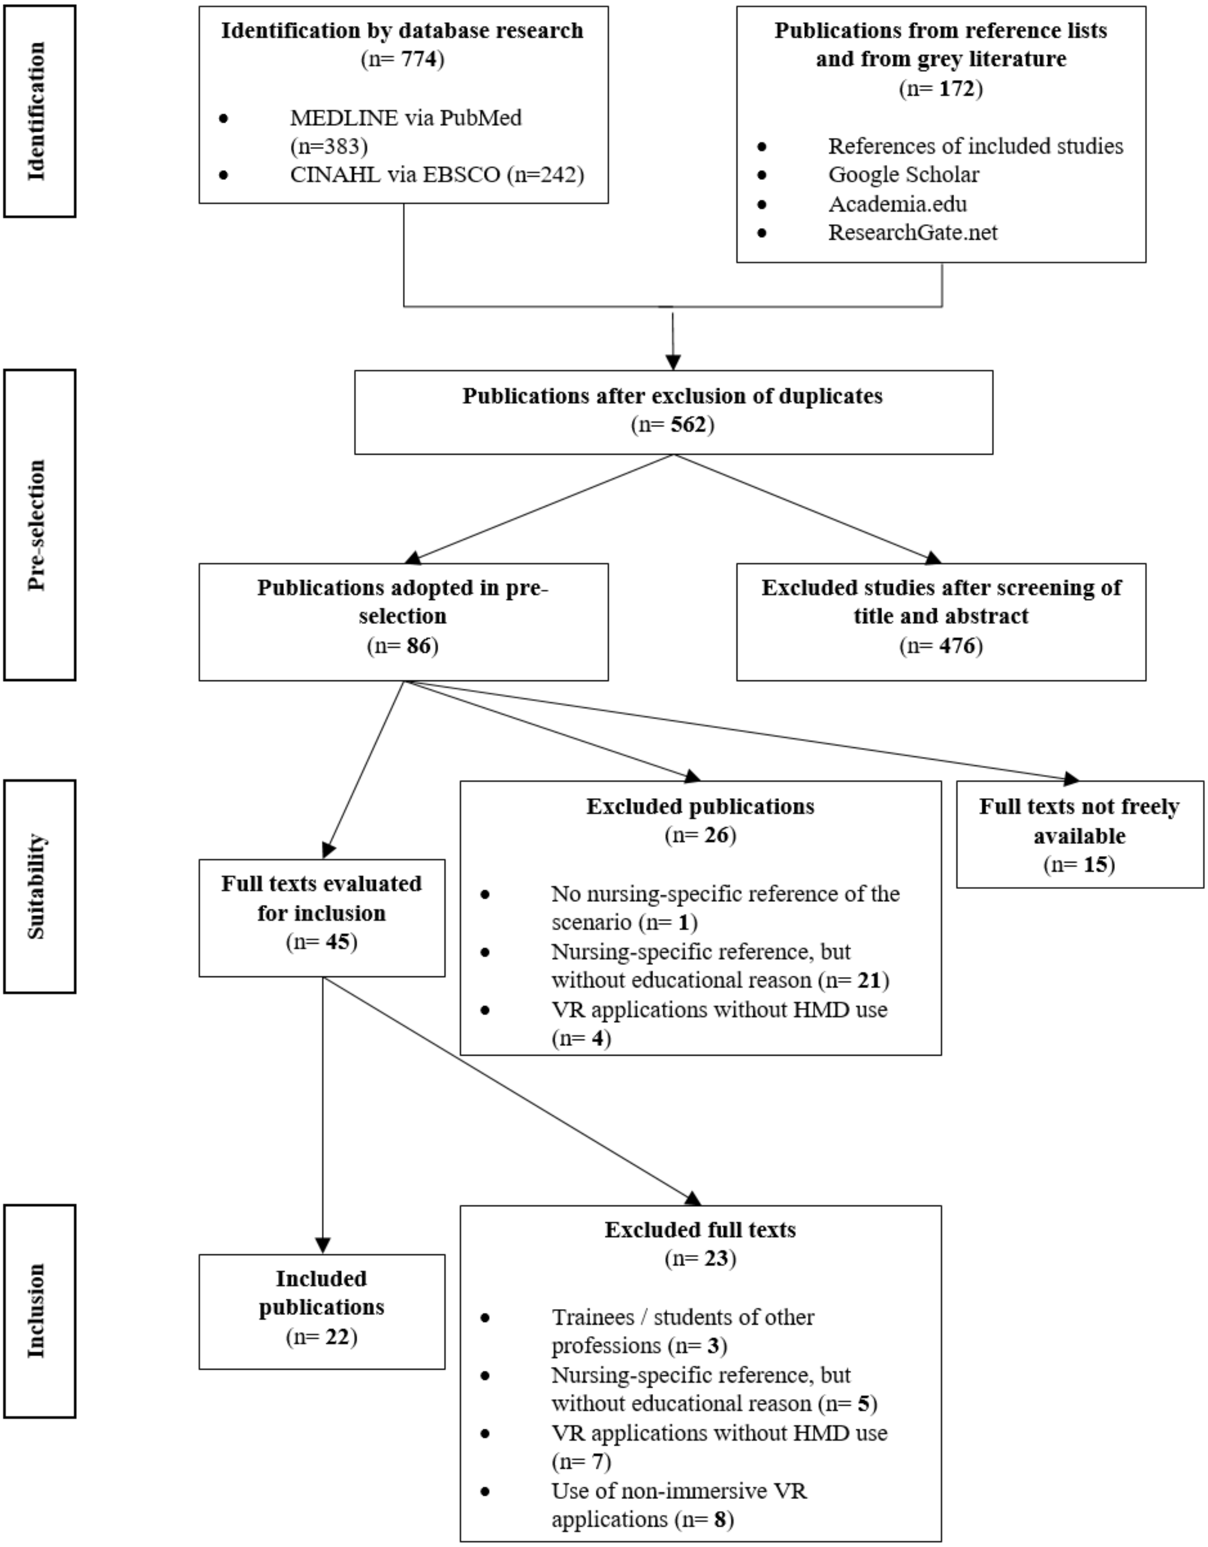
To systematically extract, summarize, and present the information on the current state of science that is relevant to answering the research question, the included studies were first processed narratively in a data table. The analysis and structuring of the data were carried out in terms of the study characteristics and the categories deduced in advance. Accordingly, the upper categories "creative design aspects," "methodological-didactic indications for use," and "research recommendations" served as a tabular and thematic structural basis for the present evidence synthesis (Multimedia Appendix 2 [8,27-47]). The category "general conclusions" included further relevant statements that did not fit into these categories.

Results

Research and Selection of Studies

Through a comprehensive database search, 774 potentially relevant studies were initially found. These were supplemented by 172 publications from a hand search. Studies automatically identified as duplicates by the program were only excluded after an additional manual cross-check, and 562 studies initially remained for the review process. The preselection of 45 articles, which was carried out by a double-blinded examination of the titles and abstracts according to previously defined criteria, led to the evaluation of the full text according to the inclusion criteria. Eventually, the data synthesis included 22 articles. There were no conflicts between the independent reviewers during this process. Figure 1 depicts this procedure graphically in the form of a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart [48].

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for literature selection. HMD: head-mounted display; VR: virtual reality.



Characteristics of the Studies Included in the Assessment

The 22 studies included in the assessment were from 14 different countries. Of the 22 studies, 8 were from the United States [31,33,35,36,40,42,46], with 1 co-authored by researchers from Australia [39]; 2 from Ireland [27,47]; 2 from Germany [29,45]; and 1 each from Switzerland [37], Belgium [43], Scotland [28], Norway [8], Canada [43], Brazil [30], South Africa [34], Singapore [8], South Korea [38], and Taiwan [32]. The publication language was mainly English, apart from 1 study, which was published in German. The date of release of more than 77% of the studies was between 2020 and 2022, and only 5 had been published between 2014 and 2019. This is probably due to the fact that VR technologies have become significantly more affordable in recent years through several manufacturers and have thus found their way into private households as well as practical application contexts, with accompanying research. With regard to the study design, the publications were very heterogeneous as is to be expected in a scoping review. Most of the articles involved mixed methods studies [28,30,34-38,40,41,43,45-47]. Moreover, there were 2 qualitative studies [27,32], 2 experimental studies [33,41], and 3 theoretical papers [31,39,42]. Some of these studies were also partially cited in 3 included systematic reviews [8,29,44]. Therefore, this review attempted to reveal aspects that provided hints and recommendations to the chosen categories for the development of virtually supported teaching-learning scenarios for nursing trainees from among different types of publications with regard to their divergent study objectives, settings, and populations. On the basis of this, the research team scanned and divided the publications into groups according to their contribution to one or more of the 3 predefined categories. However, this scoping review aimed to provide a summary of the results of interest and not an all-encompassing presentation of the results. Table 1 illustrates the contribution of the included studies to the deductive categories.

Table 1. Contribution of the included studies to the deductive categories.

Characteristics of the Study Participants

Of the 22 studies, 19 described the methodical approach in the empirical surveys (for the cumulative data from the 3 theoretical papers [31,39,42], reference is made here to the respective publication). Accordingly, these included a total of 1193 participants, consisting of 14 teachers, 1018 nursing students or trainees at different stages of their studies or training, and 112 learners from other study programs. The students were studying midwifery (52 participants) [47], emergency medical services (24 participants) [41], and medicine (24 participants) [41], and were participating in interprofessional courses with nursing students in which VR was used for study purposes. A total of 12 students from other nonmedical programs completed the virtual learning program as a control group [45]. One study included 49 participants from a conference, but their professions and levels of education were not explicitly stated [40]. Nevertheless, the study was included because it tested an application that is also explicitly aimed at nurses in training and practice. The sociodemographic data, which were not given in detail in all publications, showed that the participants in the learner group were predominantly female and in an age range of 18 to 36 years but were mostly younger than 25 years. Most of the studies were conducted at a single institution, while only

4 publications presented their results from multicenter studies [30,33,41,46]. Nevertheless, almost all researchers reported that the participants had heterogeneous experiences with VR at the time of the first surveys.

Potential of Implementing VR Into Nursing Education

The included studies depicted a variety of potentials and didactic contexts in which virtually supported teaching-learning scenarios can efficiently supplement conventional teaching methods.

Due to the almost unlimited scope for design, virtually supported teaching-learning scenarios offer a wide range of content-related practice areas for future nursing professionals. This can range from free practice and reflection of communication occasions to technology-assisted patient assessments and nursing actions [36].

The acquisition of knowledge with VR scenarios is based, on the one hand, on the theory of situated learning [8] in order to promote an active connection of didactic principles with clinical competencies [27,28,30,35,36,43,46]. The learning process in VR takes place in the context of specific action goals, competencies, structures, and rules of the simulated nursing action [49]. It also offers a way in which interactions can be experienced and practiced in the social context of a "Community of Practice (CoP)" [50]. On the other hand, VR offers a way for experiential and constructivist learning [8,27,33,37,43,47] by allowing learners to gain meaningful and realistic experiences, even in stressful, rare, and dangerous situations [28,30,37,38,40,41,47]. This comes into play especially when conventional teaching methods can only deficiently depict those situations or if it is important to control them more intensively than in the reality of care [39]. In this way, safe; low-risk; contactless; and shame-, stress-, and fear-free learning is possible [8,27,28,30,32,36,44] when the paradigm of experimental knowledge acquisition and the associated trial-and-error strategy [27,28,32] can be considered its basis. Learners thus perceive less direct pressure that can be exerted by teachers during exercise [32] and can acquire a better understanding of the relevance and effects of individual action steps through directly experienced and concrete consequences [38,46,47]. Combined with gamification elements, trainees enter into a playful learning experience with a positive culture of error [30,37], which, when used sensibly, is able to increase interest and engagement in learning as well as motivation and willingness to actively acquire and discuss the learning content [8,28,30,34,35,37,43,45-47]. While this indicates a positive added value for a better and more satisfying learning experience [27,34,38], the use of VR-supported scenarios can emphasize increased self-confidence and self-awareness from a didactic perspective [27,28,32,43]. The pride and perception of the enhanced competence of learners as well as the playfully conveyed pleasure in a challenge or a competition with fellow students can promote the attention and memorability of the content [27,28,47].

While traditional teaching methods (eg, teaching in the skills lab) require observation and subsequent assessment of performance by a teacher, VR allows learners to gather experiences and impressions unobserved but still in a kind of safe space [46] and to discuss and analyze them later with teachers. As an assistive teaching-learning tool that usefully expands and supplements existing methods [27,28,32,44], VR could replace up to 50% of the clinical hours in the conventional teaching of nursing students [36]. Thus, both novices and experts [30,44] can benefit from it during training (eg, improvement of soft skills such as empathy, interprofessional communication, and collaboration) [29,36,44,45]. Here, the function of the change of perspective or the location-independent multiplayer game option is suitable, which places learners in a realistically depicted setting of care in a targeted situation (eg, communicatively challenging situation of case discussion or family counseling) and thus extends conventional role play [44,45]. Similarly, in this environment, it is possible to expand competencies, such as observation and reflection, on a case- and action-related basis or to look at doubtful situations from different perspectives and then discuss them together with the teacher or in a class group [30,47]. Accordingly, the deliberate use of virtual scenarios in generalist nursing education is well suited to acquiring new knowledge for the first time in a multisensory way, consolidating it through repetition or different action requirements, and forming abstract concepts in an experience-based and feedback-supported way [27,28,32,46,47].

Above all, the option of applying theoretically taught content with the accompanying required practical skills and abilities of nursing in a situation-oriented manner and connected with virtual persons who require care enables learners to gather and reflect on practical experiences even before their first clinical assignments. This, in turn, can result in them being more courageous, motivated, and committed in their active engagement with real patients. On the other hand, they might also experience a feeling of greater competence and self-efficacy, which can reduce the theory-practice transfer that is often perceived as difficult [27,30,36,38,42-47]. Although the respective studies had some limitations with regard to design and generalizability, some research teams reported objectively ascertainable cognitive, procedural, and psychomotor gains, in addition to the rather subjectively assessed personal and affective added values.

However, VR is not suitable as a stand-alone teaching approach that can or should replace teaching without specific instructions and guidance [27]. Rather, it is a matter of meaningfully integrating the possibilities offered by immersive virtual simulations into the teaching of prospective nurses or into the continuing education and training of nurses who are already working.

Didactic-Methodological Recommendations for the Use of Virtually Supported Scenarios in Nursing Education

The possible values of virtually supported teaching-learning scenarios in generalist nursing education are numerous. Nevertheless, there is a need for some didactic-methodological considerations and measures to be able to use them.

The prerequisite for this, however, is the economic, intentional, systematic, flexible, and learner-centered concept that facilitates the use of this medium, which has been adapted to the respective groups of learners, their levels of skills and knowledge, their learning experiences, and previous methods [30,32,35,37,42]. According to the deliberate practice theory, exercises should be selected on the basis of clearly defined, specific, appropriate, and measurable learning objectives that correspond to the real requirements of nursing practice [29,30,35,37,38,42]. Thus, teachers face the task of didactically reducing the available virtual possibilities by focusing on single aspects and significant content [44,47]. Due to this and several other factors, VR is not an adequate substitute for experienced instructors to teach professional nursing [27].

Saab et al [27] emphasized that the core of the nursing values of care and compassion is still human interaction. Trainees cannot acquire these exclusively through simulations. Rather, the personal and professional experience of teachers should convey these values. Additionally, they have to stimulate an empathic curiosity to generate a greater willingness to put oneself in the situation of the person receiving care and to support an accompanying in-depth understanding of the respective situation [39]. Moreover, VR cannot replace the deepening practice with the person receiving care or those involved in care for the hermeneutic case understanding of learners, in which individualized or at least partially individualized decisions about interventions in particular cases should be made with direct communicative reflection on needs and requirements. Furthermore, the abovementioned group of authors stated that there is no adequate substitute for personal and continuous feedback from the teacher for the preparation, support, and reflection of the learning situation [27]. In addition to this reflected use in general, it requires a well thought-out concept to leverage the potential of virtually supported scenarios in nursing education.

Considerations on Implementing VR Into Teaching

The naive use of VR for self-purposes or entertainment should only be found in the leisure sector. However, in order to make a purposeful and targeted contribution to the acquisition of skills and abilities by nursing trainees, it is important to proceed in a planned and systematic manner. Thus, Dean et al [39] called for users to not become passive VR consumers but to continue to maintain a critical, analytical, and thoughtful attitude for transferability to the reality of care. This also reflects the basic attitude of caregivers. Since future nursing professionals should always adopt a critical and reflexive attitude in the course of the increasing use of technologies in nursing practice and should also be sensitized to this in their training, this applies equally to not only teachers but also learners with regard to the use of virtual scenarios.

This also presupposes that teachers organize optimal framework conditions. The International Nursing Association of Clinical and Simulation Learning (INACSL) Standards Committee [42] and Hardie et al [47] therefore recommended a detailed prebriefing for preparation and introduction to the handling of the technology. This includes concrete preinstructions [32,38,41,44], which involve the correct use of technical devices, such as the controller [30,37], and getting used to the glasses and the changing perception [30,32]. Instructions on the associated teaching material and learning content and the requirements of the scenario should also be part of the introduction. This can be done either face-to-face with tutors or instructors or via a video [28] or interactive tutorial. Good instructions and ease of use open up the potential for learners to use VR independently of teachers and thus of location [44,46], and possibly even use a multiplayer version [35,40,44]. A final debriefing in the form of feedback sessions or accompanying reflection tasks supplements meaningful usage. This can support teachers and trainees to identify learners' current strengths and weaknesses or to analyze and discuss discrepancies between the learning experience provided and the understanding of the nursing concepts presented or even the reality of care.

Accordingly, the use of virtual scenarios is recommended especially for smaller classes [27], so that trainers can handle the organization of the set-up of the simulations as well as the assignment and creation of rotation plans [36] in a manageable and efficient way. Under certain circumstances, the information or involvement of additional teachers should be considered [36]. Moreover, it should be considered whether specifically trained instructors or fellow students should provide support for the learners, for example, to secure the environment [43]. This also becomes relevant if trainees are given the opportunity to use or borrow VR headsets for voluntary practice in their free time in a separate room [27].

This, in turn, would not only enable the self-organized learning demanded by learners and the curricula [38] but also invalidate the argument that VR isolates users and show that it promotes social interaction [44], which is a highly relevant component in nursing.

In addition to the meaningful intention to implement VR in educational contexts, design aspects are crucial elements for using the various potentials of VR.

Overview of the Design Considerations of Virtually Supported Scenarios

With the exception of 2 studies [36,43], all included publications contained mostly experience-based hints and recommendations regarding the design of virtually supported teaching-learning scenarios for generalist nursing education.

To empower trainees to handle care situations, specific circumstances, and various settings, virtually supported scenarios should provide a realistic, plausible, and immersive learning environment [28,38,41,45,47], which should have consistent [31], clinically correct [34], and narrative story structures [47]. Due to this, multiprofessionally composed development and research groups [32,42] have to predefine concrete learning objectives [42] adapted to the current ability and knowledge level of learners [30], whereby learners come across the subjective relevance of the scenario they have experienced [51]. This forms the basis for the deduction of the most profitable specific means, details, and features. Authentic, motivating, and moderately challenging experiences should always be the goal. Thus, focusing on typical visual and auditory details relevant to the nursing process [44,46] is a major aspect. A basic prerequisite is high image and sound quality [27,34,38,41]. By observing the correct lens focus [28] and a high refresh rate, users can read text insertions [31] or recognize facial expressions and gestures [30] more easily. Moreover, this can increase the sense of immersion and perceived spatial presence within the chosen scenario [33,38,45] and prevent motion sickness [30]. Considering the cognitive load, the INACSL Standards Committee [42] recommends the selection of the type and degree of fidelity (eg, with regard to physical, conceptual, or psychological parameters). Therefore, trainees are able to draw their attention to the respective action demands [27] and challenges of different stress levels [29,37,38]. This could be supported by the targeted use of visual cues, including color markings, highlights, or animations [30,31]. The function of pausing during an exercise [31] in order to reflect on the next steps or to record the entire exercise [8] for later discussion can help to create a critical reflective attitude toward one's performance. In addition to realistic visual and auditory details, the integration of tactile stimuli in the sense of a mixed reality experience [46] and 360° views, which enable observation of one's performance from different angles [31], could be useful. The change of perspective [51] or modality of experience provides a basis for the reflection and discussion of actions and reactions demanded in specific situations. Since VR allows for slipping into other roles, it can promote essential nursing skills, such as empathy [52-54], which is particularly important for recreating other life perspectives and situations. The understanding of the needs and requirements of virtual people who require care on a physiological level can be supported by interactive models visualizing anatomical structures as well as regular or pathological processes [27,45,47].

Another essential recommendation for VR learning scenarios is the use of gamification elements [55]. The implementation of game-based details in the applications enables the strengthening of memory pathways [46,47], which in turn can positively influence learning outcomes [28]. This includes, for example, scores or rewards in the form of medals, congratulatory banners, or colored lights [30]. The given feedback can additionally motivate learners to perform practical nursing activities in VR [28] and support them in the development of problem-solving [27] and procedural skills [30]. Likewise, this can be supported by time limits for the execution of individual nursing actions.

Furthermore, if the application enables the collection of game-played data [41] and, for example, allows their visualization to both learners and teachers in the form of error rates [40], it can not only document but also promote intended learning outcomes, particularly when learners use this feature to analyze the learning gains according to performance [8]. Consequently, the scenarios, which rise in complexity in more challenging difficulty levels [35], should offer the possibility of the repetition of exercises [35,44] in order to achieve an increase in competence individually and in terms of one's responsibility. If a trial-and-error strategy [27] forms the basis for this procedure, the learning process can be positively reinforced.

However, virtually supported scenarios can only unfold their potential if the handling scenarios allow. On the one hand, uncomplicated and trouble-free handling and experience of technical possibilities can increase the learners' sense of presence in the situation [41]. On the other hand, it is an essential factor in the prevention of motion sickness [30]. Therefore, designers should pay attention to a high degree of correspondence between the image and the respective head movement, and the use of high-resolution graphics and the mitigation of technical overreactions, for example, can be useful when reaching for objects in virtual space [8,46].

Thus, design aspects should address the questions of handling and acceptance and the associated benefits for learning.

Research Recommendations

Owing to the greater availability of and interest in the use of VR as a teaching-learning medium, the corpus of studies in the field of nursing education has grown immensely in recent years. Nevertheless, the studies included in this review have stated the inconsistent use of VR terminology, indicating the need for an unambiguous definition in publications [29,44], and have mentioned the requirement for further research with larger samples and associated statistical analysis [27,29] with regard to various aspects.

On the one hand, this involves the investigation of technical parameters and interactive possibilities, such as stereognosis [32], motion tracking, and the integration of haptic devices, enhancing VR interface elements or social media and other mobile technologies to enable collaborative learning and effective distribution of educational content [45]. On the other hand, there is a demand for further investigation of the learning process itself by means of virtual simulations and the transferability of learned nursing-relevant content to real clinical practice [30]. Shah et al [36] recommended quantitative ethnography as a possible research method to take a closer look at associated emotions; ways of thinking and acting during immersion; and how, why, or when learning groups differ in this respect. If researchers use such comparative studies, for example, to analyze several sessions with the same and different instructors and assess learners' perceptions during the instructions in prebriefings and debriefings or with regard to different content [36], they should take care to pilot the study [42] and to provide comparable test conditions for participants in the control group so that they can, for example, walk through a real patient room in search of faulty aspects of patient and workplace safety [37]. They should ensure almost the same conditions when surveying individual learning experiences [42], learning gains [36], and long-term knowledge retention or improved patient outcomes [35]. Studies for examining and evaluating the use of VR scenarios in education in more detail should also survey possible previous VR experiences of users [41] to be able to consider possible influencing factors or risks of bias.

For the use and design of virtually supported teaching-learning scenarios for generalist nursing education, the integration of a best-practice simulation framework [47] (eg, INACSL criteria [42] and Jeffries' Simulation Theory [32]) for the consideration of not only microdidactic but also meso- and macrodidactic influencing factors is recommended. Thus, in addition to design and application aspects, questions about financial effects or the return on investment [35] also come into focus, and interprofessional cooperation [32] should take these into account, especially for continuous modification and optimization of scenarios. Targeted needs assessment [42] and continuous learner and teacher involvement in development [30] are critical factors for the appropriate and economic development of an effective teaching-learning medium.

Discussion

Implications and Aspects of the Use of VR Teaching-Learning Scenarios

Within the framework of the literature research and the results presented, it must be stated that there are various ways to define VR, and it can encompass different devices, degrees of immersion, and interactions. Uniform definitions of the terms used would therefore be desirable [35,50]. Nevertheless, this medium in its various manifestations is generating successively more interest not only within the private leisure sector but also as a supplementary teaching-learning instrument in both general education and medical and nursing education contexts, as VR can meaningfully expand the number of methods with regard to various teaching-learning outcomes [36,38].

On the one hand, a virtual change of perspectives, role plays, or teamwork tasks in authentically depicted nursing scenarios could support the learning, practice, and repetition of personal and social competencies, such as empathy, heuristic case understanding, and targeted observation, which are relevant in the relational profession of nursing [2,39]. On the other hand, learners can consolidate procedural skills and abilities in virtually supported care situations by means of demonstrations, step-by-step instructions, and various feedback mechanisms [8]. In this way, they can safely apply theoretical content before, during, or even after a practical assignment in a concrete action situation and thus consolidate or assess their knowledge. This has the potential to soften limiting framework conditions and facilitate theory-practice transfer [2,36]. Teachers can benefit from the targeted use of VR in that they can give trainees learning tasks that are not bound to time and place, and these trainees are in turn more motivated and committed to partly self-directed teaching [41,50]. In addition, teachers and trainees command content illustrated more practically for appropriate discussion and reflection together [48,53].

Beyond the possibility of enhancing practical skills continuously in a standardized way, the use of VR supports trainees' sensitization to digital nursing technologies and helps expand their digital skills in a practical setting. Even sustainability issues can be addressed in this way [38].

Nevertheless, it is important to note that almost all studies unanimously emphasized that virtually supported teaching-learning scenarios are still not an omnipotent substitute in teaching and that their use is rather critically reflected and well-considered at those points where conventional teaching methods reach their limits [40,46] to comprehensively prepare learners for the future role of a professionally acting nurse [38]. This scoping review offers an overview of the implications, considerations, and recommendations to develop and implement virtually supported scenarios reasonably and purposefully for educational demands in nursing education. An excerpt of the results is shown in Textbox 2.

This includes not handing out VR glasses to learners in an uncontrolled manner, but rather embedding the application methodically and didactically in the lessons in a meaningful way to ensure pre- and postdiscussions as well as parallel professional and technical support. Only then can the presented content effectively support individual learning [2,42,48].

VR is consequently highly recommended to complement the third location of learning, that is, the skills lab [50]. The complexity of the practice is only approximately representable owing to current restrictions, such as limitations in haptics or olfaction, which are of great relevance in the care sector, and the combination of these can lead to the high resemblance of daily nursing practice and the broad preparation of trainees [16,38]. In addition, technology in the field of VR will continue to develop in the future, and possibilities for realization may arise for those constraints. In the best case, this will happen based on the needs and requirements of respective target groups in multiprofessional teams and with co-creative participatory procedures [38]. Thus, further prospective research fields are emerging in addition to the current cost-benefit analyses, large randomized controlled studies in various teaching-learning settings, and surveys on improved patient outcomes [35,36,38,41], and these will offer further potential and provide focal points for investigation that need to be critically considered.

Textbox 2. Recommendations for the development and implementation of virtual reality scenarios.

Design recommendations

- Realism and plausibility
- Attractive playful design with high image and sound quality
- Dialog-based narration
- Adoption of perspective
- Direct feedback and tangible consequences of action
- Hierarchical structure
- Data collection and reproduction
- Clear handling, navigation, and instructions
- Pause, repeat, and record functions
- Location-independent multiplayer option

Didactic considerations

- Assistive, activating, and motivating
- Multimodal, learner-centered, and experience-based teaching concept
- Specifically formulated learning goals
- Secure standardized environment
- Consolidation of theoretical, procedural, and application knowledge
- One-to-one support including feedback
- Situational testing
- Independent and flexible in terms of time, and repeatable as often as required
- Heuristically reflexive decision-making and problem-solving processes
- Self-confidence in processes, expertise, and communication skills

Research recommendations

- Clear definition of terminology
- Cooperative and co-creative development processes
- Larger samples and statistical analysis
- Varying settings and conditions
- Evaluation of improved patient outcomes
- Longitudinal studies on knowledge
- Cost-benefit analyses
- Inclusion of additional interactive functions
- Consideration of theoretical frameworks
- Integration of best-practice simulation frameworks (eg, International Nursing Association of Clinical and Simulation Learning criteria)

Limitations

A methodological strength of this scoping review is the comprehensive and supplementary hand search conducted in parallel with the database search and the citation tracking to counteract the risk of excluding relevant hits. Furthermore, the research team used a tool for blinded analysis to avoid selection bias in the selection of studies as far as possible. Nevertheless, the initial decision for a sensitive search principle was changed in favor of a specific procedure, as there has been an enormous growth of extended reality (XR) applications in educational and medical contexts in recent years. Accordingly, there is a growing amount of research papers on a wide variety of focal points. However, these often only correspond to the previously defined inclusion criteria in individual points, and thus, they do not answer or inadequately answer the concrete underlying research questions for the selected target group or the corresponding application. This is also the reason for another limitation of the study. As nursing education in its generalist application in Germany is unique in a worldwide comparison, the largely international research results are only partly transferable to local framework conditions, teaching methods, and content, as well as the requirements in the initial training of future nursing professionals. Furthermore, the data protection regulations applicable in Germany should be taken into account. These can influence not only the choice of devices but also the processing and use of the generated data. Therefore, critical considerations are relevant in the reception and the attempt to generalize the results in other contexts, especially since the focus was on a selective collection of data and not on a dedicated analysis or detailed comparison of the studies with each other.

Comparison With Prior Work

This scoping review reveals the results of selected publications according to a specific search principle. Although the aim was not to compare the studies with regard to the respective design or the reported results, the latter could be summarized under the deductively created paragraphs that address recommendations and considerations.

Compared with previous studies, which were partly considered in this study, it was possible to generate a general overview of relevant aspects that fundamentally characterize virtually supported teaching-learning scenarios in initial nursing education. On the other hand, the basis for the identification was the very specific context of nursing education in Germany. However, a large number of studies published thus far have focused on other study populations from the medical and general education sectors or other definitions of VR in their surveys and explanations.

The inclusion and exclusion criteria used served primarily to provide those actors involved in German nursing education and training with information on the use and development of virtually supported teaching-learning scenarios, which corresponded to the international consensus and met the needs of the German context. Consequently, this publication can serve as a point of reference for both national and international recipients, provided that they critically evaluate it and, if necessary, supplement relevant aspects, which are related to the respective country, action, teaching, or study population background.

Conclusions

Flexible use, a positive error culture, and learning that can be individually controlled and adapted to the knowledge levels of trainees by means of virtually supported teaching-learning scenarios can increase learning motivation and satisfaction. Simultaneously and compared to other common teaching methods, VR can reduce time, personnel, and material resources, and future nursing professionals can specifically train, deepen, and consolidate the procedural, personal, and social competencies of professional nursing knowledge and actions in both theoretical and practical teaching sessions.

Nevertheless, VR cannot and should not replace experienced nursing teachers, especially to convey elementary nursing values such as care and compassion. Therefore, learners and teachers should be actively involved in the co-creative design and evaluation process of virtually supported teaching-learning scenarios for the acquisition of skills and competencies in a practical yet safe setting. This will help to reveal the needs of the target group from the beginning and to incorporate them directly into the development on an iterative basis. In addition, future users can identify weak points or errors in content or applications more quickly than nonspecialist developers who may focus on different aspects. This could also launch the systematic implementation of this medium in the curriculum. Moreover, trainees and teachers will be sensitized to apply it critically and reflectively owing to the deeper insights that accompany the process.

Acknowledgments

The study conducted as part of the DigiCare project was financed from funds of the Federal Ministry of Education and Research and within the implementation phase of the WIR! Programme – Change through innovation in the region (project duration: August 01, 2021, to July 31, 2024; funding code: 03WIR3106B).

Authors' Contributions

All involved authors equally contributed to all manuscript components.

Abstract

Background: Though the prevalence of diabetes is set to increase, most serious game solutions typically target patient self-management and education. Few games target health care professions education, and even fewer consider the factors that may increase their efficacies. The impact of facilitation, a prominent feature of health professions education, is examined in the context of a rehearsal-based diabetes management serious game.

Objective: In this mixed methods, open-label, superiority randomized controlled trial, we compare student performance, attitudes, and perceptions of a rehearsal-based diabetes management game for health care professionals.

Methods: Student participants were randomized into 2 groups to play a diabetes management game. The control group played the game alone, and the intervention group played the same game alongside a facilitator tasked to moderate overall challenge levels and address queries. Both groups were administered the Flow Short Scale, a 13-item measure rated on a 7-point Likert scale ranging from 1 (“not at all”) to 7 (“very much”) immediately after the game. Students were then invited to voluntary focus group discussions to elicit their attitudes and perceptions of the game. Findings were subject to between-group comparisons and inductive thematic analysis respectively.

Results: A total of 48 (26 control, 22 intervention) clinical-year undergraduates from the Lee Kong Chian School of Medicine in Singapore participated in this study, with 18 continuing to the focus group discussions. Flow Short Scale results indicated the superiority of the intervention group for overall flow (t_{46}=–2.17, P=.04) and the absorption subdomain (t_{46}=–2.6, P=.01). Qualitative results indicated students viewed facilitation as helpful and appropriate, and were able to identify improvable elements of the game’s theoretical foundations and overall design.

Conclusions: While serious games are efficacious means of rehearsing previously learned knowledge, facilitation allows for their efficiency to be greatly increased. Such increases are likely crucial in the coming years with the increased digitization of health care professions education and the prevalence of diabetes.

serious game; randomized control trial; facilitation; diabetes; diabetes management; flow; education

Introduction

Background

Diabetes is a chronic disease characterized by sustained high blood glucose and, when left unmanaged, is associated with severe health consequences and premature mortality [1]. Globally, an upward trend in the incidence of the disease has been noted in most regions, driven primarily by type 2 diabetes (T2D) and the prevalence of its associated risk factors [2-4].

This coincides with the increasing complexity of medicine and its need for a skilled workforce capable of taking up new knowledge in constrained time frames [5,6], necessitating the development of new methods to facilitate continuous health care professions education [7].

Digital Interventions

Despite numerous digital interventions developed in the wake of these needs, notable gaps remain. Educational interventions remain focused on patients with comparatively little for caregivers and health care professionals. Despite favorable outcomes, such interventions may have difficulties sustaining user attention and engagement [8-10]. Reviews of digital diabetes educational interventions suggest their full potential may be stymied by the absence of a human expert to guide the user [11], though it remains unclear if this is a consequence of the rapid uptake of digital technologies and the greater push toward self-reliance.

Jeon and Park [12] noted that self-care apps improve social motivation and behaviors, but not knowledge, behavioral skills, or personal motivation, which instead benefited from in-person interventions, while caregivers actively sought peer-to-peer support to alleviate concerns [13]. In continuous education, learners paradoxically reported great acceptance of distance learning methodologies, while also desiring face-to-face teaching [14,15]. Additional evidence suggests improving motivation and subject attitudes may be more important than enhancing knowledge [16], as observed in interactions with diabetes care services [16]. As a result, despite the student and patient-centered approaches used by modern developments [17-20], evidence of the exact benefits afforded by including a human expert, trainer, or facilitator in these interventions remains insubstantial.

Serious Games

Serious games may increase patient motivation [21-23], and the management skill of patients and caregivers [12,16,24], in the context of chronic diseases such as diabetes. They are usually defined as games designed for nonrecreational purposes such as education and therapy [25-27], and have enjoyed increasing uptake in both educational and clinical settings due to the ease by which they enhance motivation in their users [25-27]. They are distinct from gamification, which incorporates game-like elements into nongame interventions [28].

Such games are unable to replace qualified professionals, and instead support the promotion of exercise [29,30], deliver diabetes care education [31,32], and facilitate self-management [33,34]. Like their game-free counterparts, they are heavily focused on patients, with few health care professionals or caregivers. The majority appear to be gamified interventions as opposed to serious games, with literature reviews of the past decade returning only a nondigital escape room to improve diabetes management knowledge in pharmacy students and teaching insulin therapy to primary care physicians [35,36].

This dearth likely stems from early attempts to gamify existing methods, which failed due to poor game and instructional design [37,38]. Modern developments are understandably subjected to rigorous validation studies before implementation, and recent reviews of the literature suggest this remains the focus of a vast majority of game-based research—newly developed games are trialed against an established game-free control group, and efficacy is determined by the degree to which the game fulfills its intended purpose [25,39-42]. This user-centric focus, while meritorious, leaves unaddressed the key mechanisms of action responsible for a game's success, much less to what extent such mechanisms may be controlled to influence how players enjoy or learn from them.

Roles of Human Educators

Human educators provide emotional intelligence, empathy, and context awareness [43], key drivers of learner engagement and overarching educational outcomes despite advancements in intervention design [44]. With games, prior investigations suggest educators may facilitate learners transiting from passive knowledge retention and learning to encourage self-directed inquiry and active learning [43], as well as provide customized, empathetic, and learner-specific feedback that digital systems may not fully emulate [45].

Facilitation and Flow

Facilitation is considered by the Promoting Action on Research Implementation in Health Services framework as a process that supports and enables others' self-improvement and goal attainment [46,47]. In medical education, facilitators are credited for the success of collaborative [48], guided, yet autonomous learning experiences such as team-based learning [49,50]. Success may be attributed to facilitators exhibiting prosocial traits such as empathy, flexibility, authenticity, pragmatism, and credibility [51,52], as well as easing difficulties and keeping students invested in the activity [53-55].

Despite this, facilitation remains a broadly defined concept and the benefits of prosocial traits may not wholly translate to serious game-based interventions. Human experts introduced to games may assume multiple roles such as facilitators, instructors, and mentors [56], among others, with no role being universal due to the myriad roles games may play. Nonetheless, facilitation and moderation are the most likely drivers of success in serious games due to their means of adjusting a game activity to better meet the needs of individual learners.

The meeting of these needs is often a precursor of a flow state, a crucial yet often overlooked feature of serious games. Flow is a cognitive state characterized by absolute attention toward an optimally challenging task and the fluency of one's actions, seemingly without conscious thought [57-59]. Notably, high rates of flow are associated with a willingness to return and repeat an activity [25,59-61], critical in education where rehearsal facilitates the committing of new knowledge into long-term memory.

Understanding how much influence facilitation may exert on flow generation in serious games is thus key to increasing the efficacy of such games in medical education and further enabling the continuous education of health care professionals in the future.

Study Aims

To this end, this mixed methods study aims to identify and, where possible, quantify the benefits arising from human-assisted facilitation in digital game-based interventions. This will be accomplished via an open-label superiority randomized controlled trial, then a focus group discussion to elicit greater insight and provide additional context into participant perceptions and attitudes.

A rehearsal-based diabetes management game has been developed for this purpose and includes a special role for a human facilitator tasked with ensuring an optimal game environment for the player.

The quantitative aspect of this study hypothesizes that subjects assigned to a facilitated game group will report statistically significantly higher flow scores than subjects of the unfacilitated group.

Methods

Participants

Subjects were recruited from third-, fourth-, and fifth-year medical students undertaking their Bachelor of Medicine and Bachelor of Surgery degree at the Lee Kong Chian School of Medicine, Nanyang Technological University in Singapore, where this study also takes place. These students were selected due to their completion of the endocrinology segments of their internal medicine clinical postings and thus had basic familiarity with diabetes management in both clinical and community health care settings. Recruitment was performed by email advertisements and snowball sampling via word-of-mouth, and the completely voluntary and benefits-free nature of this study was repeatedly stressed. Exclusions included students who had not completed the endocrinology segments of their internal medicine postings, diseases of the eye not including myopia, noticeable psychosocial difficulties, and any other characteristics that may put them at risk while playing the game. All interested participants were instructed to read this study's information sheet, had the same sheet read to them before consent taking, and were repeatedly informed that they could ask questions and that participation in both the qualitative and quantitative aspects of this study was voluntary.

Ethical Considerations

Ethical approval was obtained from the Nanyang Technological University Institutional Review Board (IRB-2022-739).

Theoretical Bases

Before the formal study, informal focus group discussions with clinical-year medical students were conducted to gauge interest, elicit suggestions, and identify key features of the diabetes management game. Following this and subsequent literature reviews [62], it was determined the game intervention would best be developed based on self-determination theory (SDT), flow theory, and experiential learning theory.

SDT posits that an activity becomes intrinsically motivating when the needs of competence, autonomy, and relatedness are met [63]. Competence was addressed by mirroring the behaviors of both nonplayer characters (NPCs) and their ambulatory glucose profiles (AGPs) as closely as possible to case studies students would encounter as part of their education. To address the need for autonomy, players were permitted to manage NPCs in any manner. Relatedness was expected to be established by both the presence of the facilitator and the role the facilitator plays when checking in on the player's progress.

The facilitator's role also overlaps with flow theory, as they may adjust game difficulty based on real-time player feedback. Flow refers to a deep cognitive state wherein an individual directs absolute attention toward an optimally challenging task, simultaneously experiencing near-complete control over the activity and a total loss of awareness of the self [57-59]. Such states are associated with increased accomplishment across the breadth of the human developmental life span and, in the context of education and rehearsal, the willingness to return and repeat an activity [25,59-61].

Experiential learning theory stipulates that learning occurs when an individual partakes in the activity or task to be learned as opposed to receiving knowledge through instruction [64], and further overlaps with the aforementioned fulfillment of competence as defined by SDT.

Game Intervention

The digital diabetes management game is comprised of a single-player management game centered on a 2D community populated with NPCs who all have type 1 diabetes (T1D), T2D, or gestational diabetes (GD). NPCs work, consume meals, and partake in recreational activities within the game environment of their own accord and may not be directly controlled by the player. The player interacts with the game using the mouse and controls the administration of insulin, snacks, and oral medication. Upon clicking the respective buttons, players are presented with a dosage and may adjust it with further mouse clicks before confirming the action. NPCs do not partake in these activities of their own accord.

Each NPC possesses individually tracked blood glucose, visible to the player via an AGP, with changes simulated in response to stimuli, such as the physical intensity of current activities, insulin and oral medication dosages, consumption of meals or snacks, and phenotypic characteristics such as insulin resistance. Should extended or severe hyper- or hypoglycemia occur, NPCs will faint, be removed from the game, and the player will be informed that said NPC has been evacuated to an off-site hospital. Upon selecting an NPC, players may view their relevant clinical history, present symptoms, and all past actions they were administered (see Figure 1; a short technical demonstration is included in Multimedia Appendix 1).

Figure 1. Overview of the game world as viewed by the player, including sidebar display of relevant NPC details. NPC: nonplayer character.

Following a tutorial with actual gameplay, the player is given 12 minutes to play the game with 1 real-time minute corresponding to 1 in-game hour. They are tasked to keep the blood glucose levels of all NPCs in an ideal target range (subject to phenotype) as much as possible. With every real-time minute, each NPC's AGP is updated based on their in-game activities and the player's inputs to them thus far.

By default, the game begins with 10 NPCs comprising 7 T2D, 2 T1D, and 1 NPC with GD, reflective of the incidence of each phenotype. This number may change based on the actions of a human facilitator, who may access a game in progress from a separate machine. The facilitator is provided the same information as the player and may additionally create new NPCs for the player to manage, remove existing NPCs from play, or as an alternative to removal "freeze" the AGP of existing NPCs such that they need not be managed by the player until "unfrozen" (see Multimedia Appendix 2).

Due to the short duration of gameplay, the role of the facilitator was governed by a strict set of rules that they were not permitted to deviate from during this study. They were not permitted to offer knowledge a player has clearly forgotten (ie, administration of metformin to an NPC with compromised renal function) unless explicitly asked. They were to remind players of the function of game controls if asked, or if the player repeatedly made control-based mistakes (ie, trying to use the right mouse button or keyboard, which have no function). They were to succinctly explain to the player the reason behind an NPC fainting and being conveyed to the hospital should an instance occur (ie, too much bolus insulin 2 hours ago and NPC became hypoglycemic) to avoid disrupting the flow of the game. To minimize the influence of extraneous factors that may result from personal communication styles, the same facilitator was used for all games.

In the first 3 minutes of a facilitated game, the player will play the game solo with the facilitator remaining out of sight and taking no actions. On the third minute, and every 2 minutes after, the facilitator will approach the player and ask, "How are you faring?" The player would then indicate how well they are handling the present difficulty and if they desire a change in the number of active NPCs.

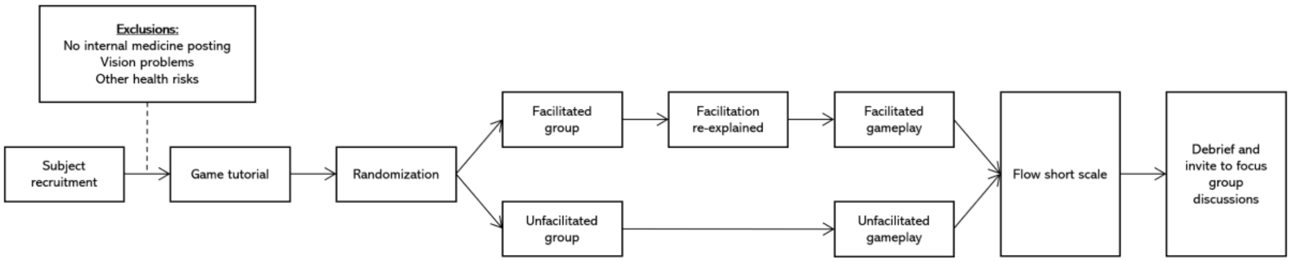
Study Design

This study used the CONSORT (Consolidated Standards of Reporting Trials) as guidelines and was conceptualized as an open-label, superiority randomized controlled trial (Multimedia Appendix 3). Following consent by the on-site member of this study's team, subjects were briefed on their objectives, given the tutorial, and allowed to familiarize themselves with playing the game until they had no further questions. Subjects were then randomized into either the facilitated intervention or facilitator-free control via simple randomization using Sealed Envelope, a secure web-based randomization service based in London, the United Kingdom [65], that allowed for allocations to be concealed from all parties until after a subject was enrolled and ready to partake in the intervention. Aside from the secure password to enable each randomization, subjects were permitted to view the result of their randomization.

Should the subject be randomized into the facilitated intervention group, the role of the facilitator would be repeated to them, and any last-minute questions answered. Otherwise, the facilitator would ensure the start of the game and then exit this study's site until the control's game had elapsed. The game itself was app-based and played on an internet-enabled university laptop belonging to this study's team, with the facilitator remotely joining from a separate laptop on the same network.

Upon conclusion of the gameplay, subjects were immediately administered the Flow Short Scale (FSS), issued an e-voucher as an inconvenience fee, and invited to the focus group discussion (see Figure 2). Subjects who attended the focus group discussion were reminded that the focus group discussions would be recorded for transcription by a third-party transcription company and any subject unwilling to consent again was allowed to leave. Subjects were then shown and allowed to refamiliarize themselves with the game through play. The guiding questions of the focus group comprised: (1) Do you recall becoming really immersed in the game? What were you doing just before? (2) What did the game do to capture and retain your attention for extended time periods? (3) If you could improve the game to make it clearer and more balanced, what would you do?

Figure 2. Overview of the study design.



Flow Short Scale

Following gameplay, subjects of both groups were administered the FSS. The FSS consists of 13 items on a 7-point Likert scale ranging from 1 ("not at all") to 7 ("very much") [66]. The FSS demonstrates good construct validity, psychometric properties, and a stable 3-factor structure comprising fluency of performance, absorption by activity, and perceived importance or outcome importance of said activity [67]. Flow itself comprises the first 10 items and the domains of fluency and absorption [66]. The scale is typically administered immediately after an activity as a retrospective measure of flow in said activity, and was, for this study, hosted on a university-secured Google Forms and transmitted to subjects via a QR code.

Power

Power calculations were performed via Sealed Envelope sample size calculations [68], with an α level of 5%, 90% power, and the anticipated control group means of 4 (0.5 above the mean of 3.5 due to games innately being conduits of flow) and anticipated intervention means of 5.05 (15% higher than the control), and an SD of 1. The increase of 15% was based on the results of prior studies comparing game-based interventions and established nongame controls on the results of the FSS [69,70]. An estimated 22 subjects per group for an overall 44 was expected.

Data Analysis

Quantitative analysis will comprise group comparisons of either discrete or continuous data drawn from FSS and in-game scores. If normally distributed, data will be analyzed via independent samples *t* tests (2-tailed across the board), with Welch correction performed should equality of variances not be observed. Data that are not normally distributed will be compared with Mann-Whitney *U* tests instead. Effect sizes will be calculated for FSS data to better visualize the degree of impact facilitation has on flow generation. Exploratory examinations of all data collected automatically by the diabetes management game will be performed to identify any notable differences between groups. The threshold for statistical significance is set for <.05 per convention, and will be performed using R (version 4.3.1; R Foundation for Statistical Computing).

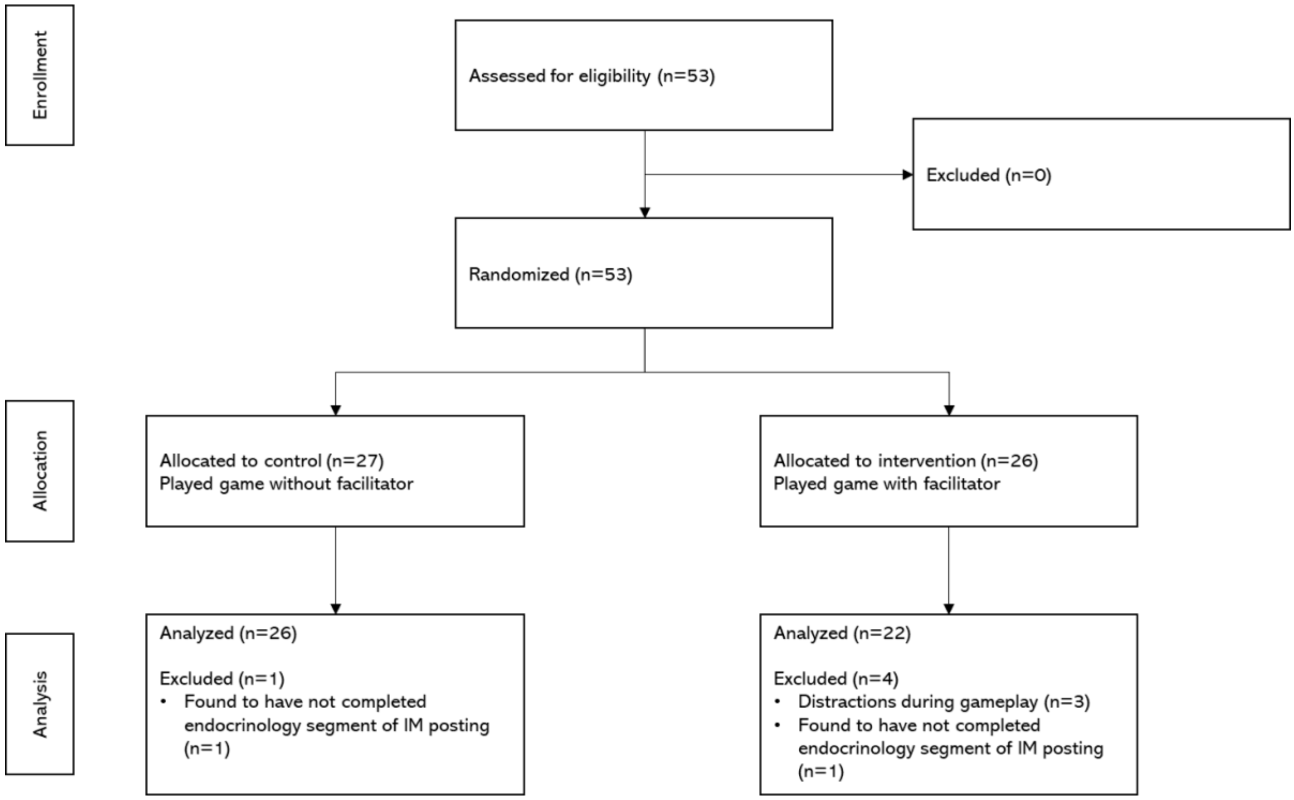
Due to the exploratory aspect of this study and the novelty of the proposed intervention design, transcribed focus group discussions were subject to inductive thematic analysis per the guidelines of Braun and Clarke [71,72]. A reflexive approach was adopted [72], with transcriptions performed by 2 authors (JWT and DKSC) with a third (SRM) acting as a referee. Of the 3, JWT and DKSC have prior histories of playing video games; only JWT plays recreational video games regularly, DKSC no longer plays video games, while SRM has a very limited history of playing video games. To minimize transference of bias, no communication or input was permitted during the initial stages of analyses. Both JWT and DKSC would first read the transcripts until familiarized, then begin a preliminary coding process and generate a series of initial themes. At this stage, prospective codes were deemed to be anything that appeared to be related to student perceptions of advantages afforded by facilitation, disadvantages resulting from its absence, and any other factor not accounted for by the research question but deemed serendipitous by the coders. Upon completion, these initial themes were then individually reviewed against previously identified codes and refined as necessary. Each analysis was then compared and discussed, with all differences highlighted for discussion and resolution with the referee. Themes were then cross-checked to ensure they represented clear patterns, and iteratively reviewed until each possessed a distinct scope with minimal overlap.

Results

Participants

Of the 53 subjects recruited into this study, 5 were eventually excluded due to being visibly distracted (ie, mobile phones) while playing the game or were found to have not actually completed the endocrinology segments of their internal medicine postings. A total of 48 subjects were thus included; comprising 26 control and 22 intervention randomizations (see Figure 3 for CONSORT flowchart).

Figure 3. CONSORT flow diagram for participant allocation. CONSORT: Consolidated Standards of Reporting Trials; IM: internal medicine.



Of the 48 analyzed subjects, there were 25 (52.1%) male and 23 (47.9%) female students aged between 21 and 25 (mean 22.44, SD 1.17) years. Control group subjects comprised 13 male and female students, while intervention group subjects comprised 12 male and 10 female students. The mean ages for both groups were 22.5 (SD 1.36) and 22.4 (SD 0.91) years respectively.

A total of 18 students continued on to the focus group discussions. Of these, 5 male and 5 female students were from the control group, and 5 male and 3 female students were from the intervention. Three sessions were conducted comprising 4 subjects (3 male, 1 female) with 1 control and 3 intervention assignments, 8 subjects (4 male and 4 female) with 6 control and 2 intervention assignments, and 6 subjects (3 male and 3 female), with 3 control and 3 intervention assignments. Table 1 presents an overview of participant demographics for each group in this study.

Table 1. Overview of participant demographics for both the randomized controlled trial and the focus group discussions.

Characteristics	Control	Intervention
Game randomized controlled trial		
Total participants (n)	26	22
Male, n (%)	13 (50)	12 (54.5)
Female, n (%)	13 (50)	10 (45.5)
Age (years), mean (SD)	22.5 (1.36)	22.4 (0.91)
Focus group discussions		
Total participants (n)	10	8
Male, n (%)	5 (50)	5 (62.5)
Female, n (%)	5 (50)	3 (37.5)
Age (years), mean (SD)	21.7 (0.48)	22 (0.76)

Between-Group Comparisons

Table 2 presents a summary of the performance of between-group comparisons. Normal distribution of data and homogeneity of variances were observed. Independent samples *t* tests were performed across FSS data, and results indicated superiority for overall flow (t_{46}=–2.17, *P*=.04), weighted primarily on the absorption subdomain (t_{46}=–2.6, *P*=.01) of the intervention group. No significant differences were observed between the fluency subdomain F and importance (t_{46}=–0.2, *P*=.84). These results suggest a moderate to high degree of flow for both the intervention and control groups, with notably high absorption for the intervention group, and are supported by the moderate to relatively high effect sizes of 0.63 for overall flow and 0.75 for absorption respectively.

Table 2. Summary of *t* tests and effect size calculations between the control (unfacilitated) and intervention (facilitated) conditions.

Variables	Control, mean (SD)	Intervention, mean (SD)	*t* test[a] (*df*)	*P* value	Effect size, Cohen *d*
Overall flow	4.4 (0.89)	4.95 (0.85)	–2.17 (46)	.04	0.63
Fluency	4.03 (1.16)	4.52 (1.06)	–1.5 (46)	.14	0.44
Absorption	4.96 (0.83)	5.6 (0.87)	–2.6 (46)	.01	0.75
Importance	4.26 (1.39)	4.35 (1.78)	–0.2 (46)	.84	0.06
Mean hours of ideal glucose	2.66 (1.36)	2.35 (1.09)	0.86 (46)	.4	N/A[b]
Metformin errors	2.77 (1.88)	2.73 (1.67)	0.08 (46)	.94	N/A
Number of evacuations	1.58 (1.94)	0.64 (0.95)	2.07 (46)	.04	N/A

[a]Two-tailed.

[b]N/A: Not applicable.

Gameplay analytics indicated no significant differences between hours NPCs spent at an ideal blood glucose level (t_{46}=–0.86, *P*=.4) and the number of NPCs administered metformin when contraindicated (t_{46}=0.08, *P*=.94). Ideal blood glucose was defined as 5 to 9 mmol/L for T1D and T2D, and 5 to 7 mmol/L for GD.

A significant difference was noted for the number of NPCs requiring medical evacuation, which occurs when they have extended hyper- or hypoglycemia and faint, in favor of the intervention group (t_{46}=2.07, *P*=.04).

Thematic Analysis

The focus group discussions elicited a broad range of student insights and perceptions, evidence in support of the theoretical foundations that afford such games their efficacy, perceived advantages of human-directed moderation of game difficulty, and suggestions on how to improve the intervention. Focus group discussion transcripts were anonymized to preserve the confidentiality of the research data and all mention of names were removed. Although the sessions were conducted in English, all participants were Singaporean and frequently communicated in Singlish—an English-based creole that, while comprising almost entirely of English words, uses a grammatical structure that deviates heavily from standard English. Sessions were transcribed verbatim to avoid accidental changes in meaning and retained Singlish terms such as “ya,” usually an analogue of “yes” but sometimes occurs as general affirmation, and the ubiquitous particle “lah,” typically found at the end of sentences that, when spoken with an appropriate tone, may modify an utterance akin to the use of adverbs in standard English.

Perceptions on Facilitation

Thematic analysis of the focus group discussions indicated facilitation was mostly helpful, and that students felt a sensation of safety and were more likely to undertake greater challenges as a result.

> *Yeah, I think it was quite… It was sort of like a safety blanket, you know?* [Student 1A]
>
> *I think I just felt like if anything happened I can go to the facilitator, like, hi, can you help? Can you take out one person? That would be like the guy over there.*
>
> *Yeah, same. [facilitator’s name] actually was basically my lifeline when I think about it.* [Student 1B]

Conversely, unfacilitated students experienced increased challenge and performance went down when this was too much for their skill levels, and desired facilitation when this occurred.

> *Okay, so it was challenging, but it was very frustrating, and I didn’t know what I could do to resolve it.* [Student 1C]
>
> *Yeah. I think a facilitator would have been good or at least there would be, like, instructions on the screen, lah.* [Student 1C]

Perceptions of Support for SDT

Support for SDT was deemed as features already present or features that if added would support the theory in the context of meeting the needs of competence, autonomy, and relatedness. Students who perceived themselves struggling with underperformance, actual or otherwise, requested additional modifications to the game beyond what the facilitator was capable of.

> *But yeah, it will be better if there’s, like, a tutorial or something from the easy levels to high levels, like that, yeah.* [Student 1C]

> *And then, after that, it's like, you're frustrated 'cause, like, your course is not really going well.* [Student 1B]

Feelings of autonomy were noted to already be present due to the numerous means of resolving problems and that actions were free of true consequences.

> *But because I didn't feel like there was any serious consequence, because it was a game, so I thought it was quite fun.* [Student 2D]

Perceptions of relatedness were most prevalent during attempts to involve peers as fellow participants and included comparisons to popular cooperative recreational games.

> *So, instead of it being confined to just the cafeteria and the outdoor exercise area, we could have the opportunity to explore more places…*
>
> *I'm thinking like an Overcooked kind of thing, like, different islands.* [Students 1A and 1B]

Perceptions of Support for Flow Theory

Discussions of the game activity suggested students who were facilitated were more likely to experience an altered perception of time despite there being a clock in the game.

> *I think for me, I didn't really care too much about the time. So, like, when [facilitator's name] stopped me, I eh 12 minutes already?* [Student 3B]
>
> *But it was a fun experience. I felt engaged, because every minute I would check everyone's [blood glucose]. So, I did not realise, like, that time had passed.* [Student 2D]

When queried, students were retrospectively aware of becoming completely absorbed in the activity to the point of forgetting about the facilitator's presence, despite the regular check-ins.

> *It's like I don't have the mental capacity to focus on anything else.* [Student 3C]
>
> *I think I completely forgot that I can ask the facilitator questions.* [Student 3A]
>
> *I just kept clicking around each patient to see where it was going, and the threads, and whatnot. I think that that's what really kept my attention most of the time…[Student 2C]*

Perceptions of Game Design Elements

Students generally perceived the game as fun, enjoyable, and an appropriate means of revising diabetes management knowledge. The intervention was perceived as both challenging and a safe space in which to commit mistakes harmlessly.

> *Especially fun cause there's the whole threat of them possibly dying in the hospital makes it, like, more exciting and more fun to play.* [Student 2C]
>
> *But because I didn't feel like there was any serious consequence, because it was a game, so I thought it was quite fun.* [Student 2D]

Student discussions frequently resulted in feedback and disagreements on the merits of said feedback were likely evidence of the specific needs of students playing the game.

> *I think they should stop moving. Like, moving doesn't help anything and it doesn't add anything.*
>
> *I like the moving though.*
>
> *The moving was fun lah you just keep chasing the guy around.* [Students 1B, 1A, and 1D]

Despite not being prompted, students were able to raise requests for changes to better align the game with SDT and flow theory. Changes in line with SDT from the game design perspective primarily focused on being able to play the game with other people and meet the need for relatedness.

> *Like, you can play with a friend… Unless, I don't know, there's some multi-player function introduced.* [Student 1A]

Changes in line with flow theory focused on how the game should have better-presented information to students, ranging from succinct to full and detailed explanations.

> *Maybe at the start, before you start playing, that there's a screen that shows everybody with all their conditions.* [Student 3E]
>
> *So, either working on a different way of showing they were thirsty, like maybe an icon that shows that they're thirsty instead…* [Student 2G]

Additional Findings

Although not the focus of this study, it was noted that certain student characteristics may exert some influence over the degree they engage with the game activity and facilitator. Further, 1 student indicated altruistic motives as a driver of engagement.

> *I was pretty immersed in the game, and especially with the fact when the people started dying and getting hospitalised. I think, like, when… Once that's happening, then, yeah, like, oh no, and then you feel more immersed in the game, because you want to keep everyone else alive.* [Student 3E]

Students who appeared more forgetful than their peers were also likely to express frustration that inhibits engagement.

> *…apparently the endocrinology emphasised that during multiple tutorials, but I don't have any recollection of that at all.* [Student 3B]

Discussion

Principal Findings

Results from the between-comparisons indicate support for the hypothesis; the facilitated group is superior, based on the moderate to fairly large effect sizes, to the control in terms of overall flow and the subdomain of absorption, but not fluency. Analyses of the focus group discussions suggest that, beyond flow, ideal conditions for flow were supported by the perception of safety and its related willingness to push oneself toward greater challenge. These findings were unlikely results of differing competencies between groups, evidenced by the nonsignificant differences in time NPCs spent at healthy blood glucose and the number of inappropriate administrations of metformin. Additionally, students of the intervention group almost universally forgot they were allowed to clarify the effects of medication and refrained from doing so as a result. This forgetting to ask for help renders the lower rate of medical evacuation to be most likely the result of the intervention group's difficulty adjustment as opposed to the facilitator reminding students of the effects of medication. This is likely the result of intense concentration on the game activity resulting from a high flow state as indicated by student reports of total attention being given to the activity. The higher flow scores of the intervention group also offer support to the notion that facilitation confers tangible benefits that result in increased engagement [56,73]. Due to substantial correlations between flow and intrinsic motivation [74], it is likely that students would be more willing to engage in a facilitated serious game due to interest and its enjoyability, and thus be more likely to re-engage in the activity without the need for an incentive [63].

Analyses of the focus group discussions have also indicated substantial support for flow theory and SDT as theoretical foundations of serious games in this design. Even when unprompted, students frequently requested the modification of game features that would circumvent a specific difficulty they experienced, only for other students to disagree with the merits of said requests. This both highlights the facilitator's role in helping students circumvent specific difficulties, and flow theory's need for a balance between the challenge of the activity and the learner's perceived skill [58]. Similarly, reports of feeling safe when paired with a facilitator likely stem from the need for relatedness as defined by SDT. Due to students' unfamiliarity with the facilitator, this is likely in the context of a mentor-mentee relationship as opposed to friendships [73,75] and is likely not observable in serious games featuring dynamic game balancing as the sole option for difficulty modulation [76]. While it could not be readily determined from the focus group discussions, there is a possibility that perceptions of safety stemmed from fulfilling the need for autonomy, due to a facilitated game affording students a means of exercising greater control over their learning environment [56,77].

While the use of games in medical education and training is not new, an embedded role for a facilitator remains uncommon even in nonmedical literature, with self-selected or dynamic game balancing remaining the common form of difficulty modulation [76]. As a result, the design of the present intervention appears unique to the best of the authors' knowledge in examinations of both gray and peer-reviewed literature. The inclusion of a facilitator remains beneficial particularly to beginners and players exhibiting low confidence, as evidenced by student perceptions of a "safety blanket." Comparable studies include a diabetes education and self-management study that paired young patients with mentors to alleviate the emotional stresses of adolescence and reduced the socioeconomic costs of the disease [75], a game-based learning tool for children with content that could easily be modified by an educator resulted in greatly increased student engagement and willingness to participate [78], and a qualitative study that suggested the facilitators required a mix of managerial and technical skills to blend away difficulties faced by students such that they may fully engage in a game-based activity [56]. This study's design nonetheless aligns with facilitation's role to support, give, and encourage learners as opposed to teaching the content in question, itself key to simulation and game-based interventions to which the diabetes management game belongs [79]. In addition, the results suggest some relation to the sociocultural theory of cognitive development as defined by Vygotsky, which posits that learning is a social process occurring primarily through interactions between a learner and an expert mentor [80]. Though the theory was not central to the development of the intervention, it may imply that learners used to learning with facilitators may be more receptive to the intervention than those used to learning on their own.

Serious games for diabetes management are almost universally directed at those affected by the disease and understandably target behavioral change as the ultimate goal of education [81]. This study presents one of the few serious games for use in health care education that includes an option for facilitation, itself understudied and uncommon to games even beyond the health care setting [56,79], but is limited by a lack of suitable comparators in the medical literature. In engineering education, it was noted that no 1-model decided the best means of facilitating a serious game, but that learning tended toward being experiential in nature [56], limiting its comparable applicability with the content of the diabetes management game, which falls primarily between the "Knows" and "Knows How" tiers of Miller's pyramid [82,83]. However, due to the clear distinction between the role of the facilitator and the game intervention itself, it should be possible for the facilitator's role to be generalized to other topics within health professions education. This may be further supported by the game's focus on the lower tiers of Miller's pyramid, and that the standalone game may be played relatively effectively without facilitation.

Finally, though the intervention was intended as a supplementary rehearsal tool, it appears to be a suitable means of formative assessment when played without facilitation [84], and for the rapid detection of learning gaps and their prevalence in a cohort.

Limitations

This study's inclusion of a dedicated role for a facilitator in a rehearsal-focused game-based intervention appears to be unique. This role, and its ability to moderate a learner's gameplay in real-time, does not feature in the recent literature and limits comparisons. This study's focus on ascertaining the benefits of facilitation in the context of a rehearsal-based game for diabetes management knowledge is itself a limitation, for the exact long-term effects on the topic cannot be determined without a follow-up long-term study involving a version of the game refined after player feedback. Though sufficiently powered and based on a strong theoretical foundation, this study nonetheless presents a sample drawn from a single institution and cohort of students.

Similarly, triangulating the findings via studies involving the same methods of facilitation, but with different topics within health professions education, will help determine the long-term effects of facilitation and its benefits to medicine. The semiexploratory nature of the intervention, and the use of a one-to-one facilitator-student ratio means the intervention cannot be sustainably upscaled without first determining an optional means of increasing the ratio, limiting its deployment to smaller scales. Finally, an element of self-selection bias favoring students with preexisting interests in video games may have been present due to the voluntary nature of this study.

Conclusions

The inclusion of a facilitator in a rehearsal-based medical serious game can increase the degree to which a student may engage in an activity and elicit sensations of safety with the corresponding willingness to embrace greater challenge. The benefits appear particularly notable for participants who are beginners or unconfident in their abilities and are likely to be the result of facilitators easing difficulties to greater align the participant with the conditions of flow and SDT.

Acknowledgments

This project was supported by the Games for Health Innovations Centre (ALIVE) Serious Games Grant. We would like to thank Dr Han Siew Ping and Dr Olivia Ng Xie Wei for their assistance with the focus group discussions.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

JWT, RD, and SRM were involved in the conceptualization of this study, its methodology, and funding acquisition. JWT, GT, XL, RD, and SRM were involved in the design of the software. JWT and DKSC were involved in the data curation and analysis with supervision from SRM and PR. All authors were involved in writing the original draft, and reviewing and editing this paper.

Conflicts of Interest

SRM is the Associate Editor for *JMIR Medical Education*. All other authors declare no conflicts of interest.

Multimedia Appendix 1
Technical demonstration of the diabetes management game's control system. All participants will interact with the game in this manner.
[MP4 File (MP4 Video), 32725 KB - games_v12i1e54703_app1.mp4]

Multimedia Appendix 2
A sample video demonstrating the freezing, unfreezing, removal, and addition of a non-player character (NPC) by a facilitator. Participants assigned to the facilitated gameplay will experience these.

Abstract

Background: Virtual reality (VR) modules are commonly used for health care training, such as adult advanced cardiac life support (ACLS), due to immersion and engagement. The metaverse differs from current VR serious gaming by enabling shared social connections, while current VR modules focus on computer-based content without social interaction. Educators in the metaverse can foster communication and collaboration during training sessions.

Objective: This study aimed to compare learning outcomes of VR-based, machine-guided training with educator-guided, VR-based training in the metaverse environment.

Methods: A total of 62 volunteered students from Acibadem Mehmet Ali Aydinlar University Vocational School for Anesthesiology were randomly divided into 2 groups of 31 participants each: one group received VR-based training with machine guidance (MG), and the other received VR-based training with educator guidance (EG) in the metaverse. The members of both groups undertook VR-based basic training for ACLS. Afterward, the MG group was trained with a VR-based advanced training module, which provides training with full MG, whereas the EG group attended the VR-based, educator-guided training in the metaverse. The primary outcome of the study was determined by the exam score of the VR-based training module. Descriptive statistics defined continuous variables such as VR exam scores and time spent on machine- or educator-guided training. The correlation between training time and VR exam scores was assessed with the Spearman rank correlation, and nonnormally distributed variables were compared using the Mann-Whitney *U* test. Statistical significance was set at $P<.05$, with analyses executed by MedCalc Statistical Software (version 12.7.7).

Results: Comparing the VR test scores between the MG and EG groups revealed no statistically significant difference. The VR test scores for the EG group had a median of 86 (range 11-100). In contrast, the MG group scores had a median of 66 (range 13-100; $P=.08$). Regarding the correlation between the duration of machine-guided or educator-guided training and VR-based exam scores, for the MG group, =0.569 and $P=.005$ were obtained. For the EG group, this correlation was found to be =0.298 and $P=.10$. While this correlation is statistically significant for the MG group, it is not significant for the EG group. The post hoc power analysis (80%), considering the correlation between the time spent on training and exam scores, supported this finding.

Conclusions: The results of this study suggest that a well-designed, VR-based serious gaming module with MG could provide comparable learning outcomes to VR training in the metaverse with EG for adult ACLS training. Future research with a larger sample size could explore whether social interaction with educators in a metaverse environment offers added benefits for learners.

Introduction

Serious games are now widely used for training as an additional modality to simulation-based education by various industries [1-5]. Training using serious gaming modules can be conducted through various platforms, such as personal computers; tablet personal computers; virtual reality (VR); or mixed reality systems, such as augmented reality or augmented virtuality. Due to the immersive effect and enhanced student engagement, VR and mixed reality modules are currently favored for health care training, such as advanced cardiac life support (ACLS) training [6-8]. The COVID-19 pandemic has also accelerated the process of digital learning [9]. The shift from conventional in-person classrooms to online education has been expedited by the global pandemic, underscoring the importance of maintaining physical distancing during these training sessions [10-12].

The portability and increased affordability of VR and mixed reality systems in recent years have contributed to a significant growth in VR-based learning. A notable advantage of a VR-based serious gaming module is its compatibility with wireless VR headsets, eliminating the need for a personal computer and an expensive cable-based VR headset [13,14].

Due to advancements in the internet connection speed, the organization of VR-based multiplayer training sessions has become feasible. This facilitates learners' collaborative interaction within a group setting to solve medical cases [10,15,16].

Online education stands as one of the potential application areas of the metaverse. The metaverse, which is an immersive, 3D, computer-based, and multiuser online environment, serves as an optimal platform for orchestrating multiplayer training sessions [17,18]. The metaverse merges the physical and computer-based environments by integrating the internet, the web, mixed reality, augmented reality, and VR [10].

The metaverse offers shared social connections, thus differentiating it from existing VR-based serious gaming modules, which primarily focus on presenting computer-based content and environments without fostering communal interaction [19]. This facilitates interaction between learners and educators during metaverse-based training sessions, allowing educators to guide the learners and provide feedback [19,20]. The presence of the educators fosters communication and collaboration during training sessions, thereby enhancing the motivation and engagement of the learners [16,21]. While the metaverse has the potential to provide collaborative and individualized learning experiences, the presence of an educator is crucial in guiding and enhancing the learning process [20,22]. Educator-guided learning in the metaverse has the potential to be superior compared with machine-guided learning, as educators can provide personalized feedback, facilitate discussions, and adapt the learning experience to the unique needs and preferences of each student, whereas machine-guided learning can be particularly beneficial for self-learning, where a fixed learning content is available [10,22].

In our university, a VR-based multiplayer training module within the metaverse environment specifically designed for advanced cardiac life support (ACLS) training has been developed [23]. This module serves as an additional training tool to simulation-based training, enabling learners to receive guidance either from machine algorithms or educators within the metaverse. In light of the limitations of machine-guided learning in VR for collaborative learning and the time constraints associated with educator-guided training in a metaverse environment, a comparative analysis of these methods has been deemed necessary [10,22,24]. The hypothesis of this research is to evaluate and contrast the learning outcomes achieved through VR-based, machine-guided training against educator-guided, VR-based training within the metaverse setting.

Methods

Recruitment

The study was advertised to fourth-semester (2023-2024 Spring Semester) students at the Vocational School for Anesthesiology at Acibadem Mehmet Ali Aydinlar University, and volunteers were accepted for participation. In total, 62 participants volunteered for the study, including 36 female participants and 26 male participants between 20 and 22 years of age. Participants were randomized into 2 groups based on their university ID numbers, with students being assigned to one group if their ID number was odd and to the other group if their ID number was even. By using this randomization process, the participants were divided into 2 groups, each consisting of 31 individuals: one group received VR-based training with machine guidance (MG), and the other group received VR-based training with educator guidance (EG) in the metaverse. All participants read and signed an informed consent document outlining the study flow. The study took place at the Center of Advanced Simulation and Education of Acibadem Mehmet Ali Aydinlar University. Exclusion criteria included previously experienced VR-induced motion sickness; previous ACLS training; and other medical conditions, such as episodes of vertigo or being on medication that causes vertigo-like symptoms.

Study Flow

From this point forward, the group trained with VR-based training with MG will be referred to as the MG group and the group trained with VR-based training with EG in metaverse will be referred to as the EG group. A total of 2 educators with more than 10-year experience in medical simulation guided the participants in metaverse during the study.

The members of both groups undertook VR-based basic training for ACLS. Afterward, participants of the MG group were trained with a VR-based advanced training module, which provides training with full MG, whereas the EG group attended VR-based, educator-guided training in the metaverse.

Serious Gaming Module

The VR-based serious game used in this study, named "3DMedsim ACLS VR," was developed in line with the ACLS standards of the European Resuscitation Council (ERC) and American Heart Association (AHA) [25,26]. The development process was reviewed by clinicians to ensure adherence to crisis resource management and the criteria of the latest AHA and ERC guidelines [27-29].

The serious game is combined with a learning management system along with a learning record store (LRS), allowing the storage of credentials of the users within a shared database [30-32]. In addition, it incorporates a 3D visualization engine integrated with the LRS, enabling the tracking of user interactions and the generation of experience application programming interface (xAPI) calls for each action taken [31]. When users engage in predefined interactions with significant objects within the computer-based environment, corresponding xAPI events are automatically generated [30,33]. This functionality is made possible through the development of a Unity extension software library making necessary xAPI web service calls to the LRS servers through the HTTP protocol [34]. User actions are defined in terms of actor, verb, and object parameters, with the library automatically creating xAPI calls for each action, subsequently recorded by the LRS. The library is also capable of automatically creating xAPI calls for actions not performed within specified time limits or in the correct sequence. Security measures and user authentication features essential for record-keeping are also included in this library, using the basic access authentication method inherent in the http protocol standard.

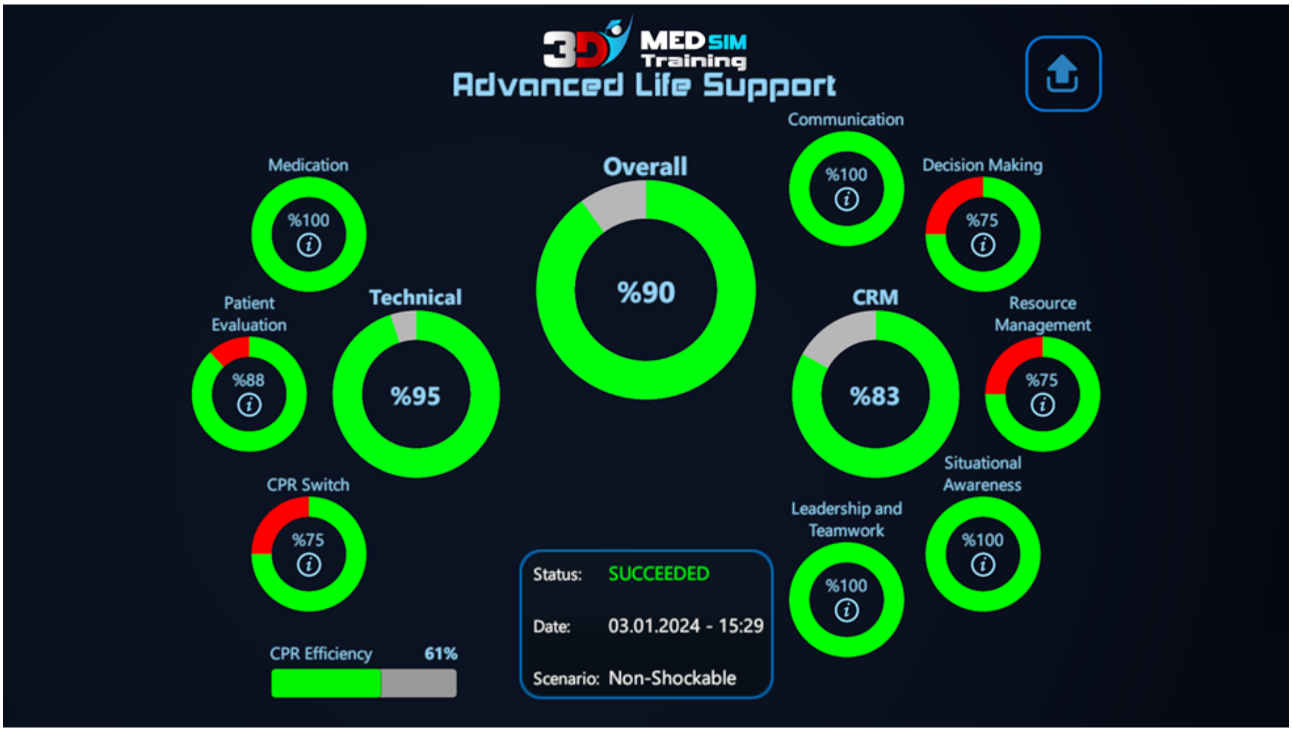
The ACLS serious game includes 4 different stages: basic training, advanced training with machine support, advanced training with educator support in the metaverse environment, and test mode. All of these stages take place in a computer-based hospital room setting to increase immersion, as shown in Figure 1. This serious game also allows users to create a multiplayer lobby and invite others as observers to join the training. These multiplayer lobbies include a voice chat for communication between the observers and the player [13].

In the first stage, basic training is developed with complete beginners in mind. This stage aims to walk the player through the ACLS algorithm step by step with visual and audio cues for each interaction. The user is only able to interact with correct objects in this stage, with no time limits, until they felt ready for advanced-level training mode. The removal of timings and wrong choices removes the stress element and allows the user to familiarize themselves with the ACLS algorithm [13].

In the second stage, advanced training builds on top of basic training. In this stage, visual and audio help for each step is removed. The user is also able to interact with any object or button, which means making mistakes is a possibility at this stage. However, if the user makes a mistake, they are warned by MG. The system monitors each action performed by the player and generates verbal warnings when errors are detected or if time limits are exceeded. In the study, the MG group played this mode independently with MG, while the EG group played the mode in the metaverse environment, accompanied by an educator, as depicted in Figure 2. In educator-guided mode, the system disables machine-guided warnings, enabling educators to provide real-time guidance during training in the metaverse [13].

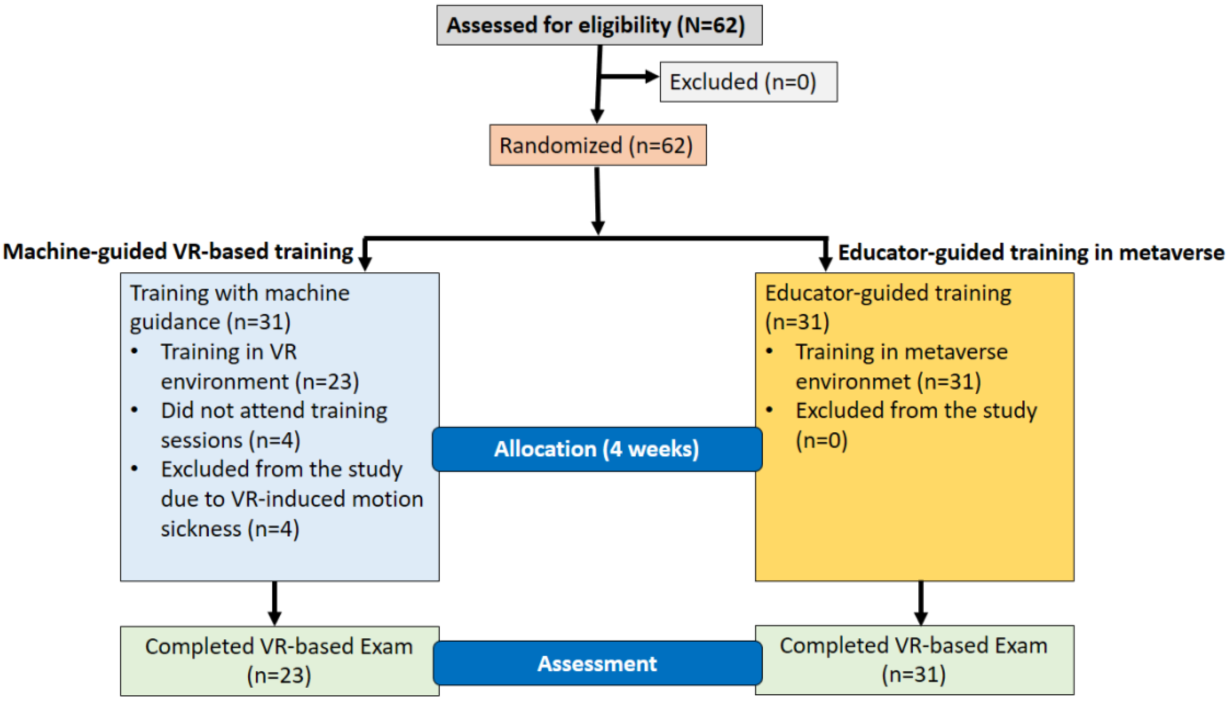
Figure 1. A computer-based hospital room setting in the serious gaming module, including selection options for the next step in the advanced cardiac algorithm. CPR: cardiopulmonary resuscitation.

Figure 2. The score screen of the advanced cardiac life support serious game exam mode, including separate scores for technical skills, nontechnical skills, and the total score. CPR: cardiopulmonary resuscitation.



The final stage is the VR-based exam mode, which was completed by participants immediately following the MG and EG training modes on the same day. In this mode, each action taken by the user is graded according to its timing, order, and accuracy. Contrary to the advanced training mode, there was no guidance for the users. The final score consisted of 2 categories. In total, 70% (70/100) of the total performance score is derived from ACLS assessments, with the remaining percentage (30/100, 30%) calculated from crisis resource management performances of the participants. The primary outcome of the study was determined by the total score obtained through the exam mode of the VR-based training module [13]. A sample test score report can be seen in Figure 3.

Figure 3. Randomized controlled trial flow diagram of the study. VR: virtual reality.



Data Collection

The mean test scores obtained by participants in the VR-based training module exam, along with the duration of machine-guided or educator-guided training (in minutes), were chosen as key indicators for the outcomes if the study. The correlation between exam scores and time spent on training was investigated.

Statistical Analysis

Descriptive statistics were used to define continuous variables, that is, VR exam scores and time spent for machine- or educator-guided training (minutes; mean, SD, median, and range). The correlation between time spent for machine- or educator-guided training and VR exam scores that did not show normal distribution was evaluated using the Spearman rank correlation. The comparison of MG and EG groups that did not show normal distribution in terms of VR exam score and time spent for machine- or educator-guided training was performed using the Mann-Whitney *U* test. The statistical significance level was set at *P*=.05. Analyses were conducted using MedCalc Statistical Software (version 12.7.7) [35].

Ethical Considerations

This study was approved by the Scientific Ethical Committee of Acibadem Mehmet Ali Aydinlar University (approval 2023-20/672). All participants read and signed an informed consent document outlining the study flow. No secondary analysis was performed using these data (Multimedia Appendices 1 and 2).

The data used in the research do not contain any information that can identify individuals. Each participant was assigned a unique code that replaced personal identifiers. The key linking codes to personal information were securely stored separately from the research data. Only essential research team members have access to the deidentified data. Participants did not receive any financial compensation. The participants were informed with the consent form that the results of this research may be used in scientific and professional publications or for educational purposes, but the identities of the participants will remain confidential. The relevant consent form (Turkish or English) can be seen in Multimedia Appendices 1 and 2.

Results

Overview

There were 4 dropouts from the MG group because they did not meet the inclusion criteria. In addition to this, 4 participants from the MG group did not attend the training sessions. Therefore, the EG consisted of 31 participants, whereas the MG group consisted of 23 participants (Figure 3 and Multimedia Appendix 3).

After undertaking a VR-based basic training for ACLS, the participants were divided into 2 groups, MG (n=23) and EG (n=31). The participants of the MG group were trained with a VR-based advanced training module with full MG. The participants of the EG group attended a VR-based, educator-guided training in the metaverse environment. In order to evaluate the knowledge level of the participants, the exam mode of the VR-based training module was used.

As shown in Table 1, the average score was 53 (SD 33) out of 100 for the MG group participants and 68 (SD 35) out 100 for the EG group participants. When comparing the VR test scores, no significant difference was found between the MG and EG groups. The average VR test scores for the EG group were 68 (SD 35), with a median of 86 (range 11-100), whereas MG group scores were 53 (SD 33), with a median of 66 (range 13-100; *P*=.08), as seen in Table 1.

Table 1. Mean and median scores of educator guidance and machine guidance group participants.

Virtual reality exam score (total 100 points)	Machine guidance group	Educator guidance group	*P* value[a]
Mean (SD)	53 (33)	68 (35)	.08
Median (range)	66 (13-100)	86 (11-100)	_[b]

[a]*P*<.005 for all exam scores.

[b]Not applicable.

Mann-Whitney U Test

After comparing the time spent (in minutes) for machine-guided training and educator-guided training for each participant, a significant difference was found between the MG and EG groups. The time spent in the EG group had a median of 21 (range 14-62) minutes. In contrast, the MG group had a median of 15 (range 5-30) minutes (*P*=.002).

Correlation Between VR Test Scores and Duration of the Training

Regarding the correlation between the duration of machine- or educator-guided training and VR test scores, for the MG group, =0.569 and *P*=.005 were obtained. For the EG group, this correlation was found to be =0.298 and *P*=.10. While this correlation is statistically significant for the MG group, it is not significant for the EG group.

Spearman Rank Correlation Test

If the power analysis is based on the exam scores of the 2 groups, the type I error rate was found to be 40% at a 5% significance level. However, when a post hoc power analysis was conducted, considering the correlation between the time spent on training and exam scores, the type I error rate increased to 80% at the same significance level [36,37].

Discussion

Principal Findings

This study focuses on comparing the learning outcomes of machine- versus educator-guided, VR-based training in the metaverse environment. Participants of the EG and MG groups were evaluated using the exam mode of the VR-based training module, which was defined as the main outcome indicator of this study. The findings of the study revealed that there was no statistical difference between the VR-based exam scores of the MG and EG groups. Although these values are statistically significant, the post hoc power analysis based on the exam scores of the 2 groups indicated a power of only 40%. Since this is a preliminary study, a power analysis was not conducted beforehand. While the results are statistically valid, they might be influenced by insufficient power. From an educational perspective, however, the observed difference appears relevant. In addition to this finding, the participants of the EG group spent more time during the advanced training compared with the participants of the MG group (*P*=.002). The correlation between the duration of machine- or educator-guided training and VR-based exam scores is statistically significant for the MG group (=0.569, *P*=.005), but not significant for the EG group (=0.298, *P*=.10). These findings indicate that dedicating additional time to VR-based, machine-guided training holds promise for boosting exam scores of the participants. The post hoc power analysis (80%), considering the correlation between the time spent on training and exam scores, supported this finding.

Using well-designed, VR-based serious gaming modules for specific tasks can enhance learners' motivation, resulting in improved learning outcomes [9,10,16,19,22,38]. The serious gaming module used in this study, specifically designed for adult ACLS training, has proven its capability of improving the knowledge level during our previous study [13].

Numerous studies have demonstrated that VR-based training within the metaverse environment enhances learning outcomes, attributed to its immersive effects and interactive features [15,20,38-41]. Interactivity enables users to engage and communicate through avatars, enhancing embodiment, immersion, and user engagement within the metaverse [9,10,20,39]. The training module used in this study provides different real-life hospital environments to enhance the immersive effect and multiplayer mode to enable users to interact with each other.

A gamified interaction may experience insufficient supervision. The presence of an educator in the metaverse has the potential to enhance learning outcomes, particularly for learners who struggle with self-regulation [9,21]. Introducing multiplayer features within the metaverse can address this limitation, fostering social interaction and potentially enhancing learning outcomes further [19,20]. However, performance data gathered during this study indicated that there was no statistical difference in the exam scores between the MG and EG groups, suggesting that EG did not provide any additional advantage in terms of achieving better learning outcomes.

According to previous studies, an important limitation of metaverse-based learning is the lack of sufficient metaverse literacy among both learners and educators, revealing the importance of familiarization with effective metaverse usage [19,24]. As VR-based serious gaming modules have been embedded into the curricula of training programs of our university for the last 6 years, the students and educators, who have participated in this study, did not encounter any issues with the usage of VR hardware.

Widespread adoption of VR hardware is still restricted among a notable portion of the population. This problem is exacerbated by the lack of high-speed internet connectivity in certain regions of the world. [11,42]. As the same problem also exists in our country, this study was performed on the university campus with high-speed internet access and the VR headsets were provided by the simulation center of our university.

Limitations

The first limitation of the study was the small sample size, which was attributed to the challenges faced in recruiting volunteers. The second limitation of the study was the limited processing power and graphics capability of the headsets used in this study. Therefore, only the heads of the avatars were displayed during the game, leading to a decreased level of immersion. The third limitation of this study was the potential for selection bias. Participants were recruited from a specific population, which may not represent the broader demographic. This can limit the generalizability of our findings. In addition, the voluntary nature of participation may attract individuals with particular characteristics or interests, further skewing the results. Future studies should aim for a more diverse and random sample to mitigate this bias.

Conclusions

Based on the findings of this study, a properly designed VR-based serious gaming module with MG could potentially offer similar learning outcomes to VR-based training in the metaverse with EG. Future research with a larger sample size could explore whether the effect of social interaction with educators in the metaverse environment may provide additional benefits for learners.

Acknowledgments

The authors express their gratitude to the biomedical support team at the Center of Advanced Simulation and Education of Acibadem Mehmet Ali Aydinlar University for their invaluable support during this study. This research did not receive any specific grants from public, commercial, or not-for-profit funding agencies.

Data Availability

All data generated or analyzed during this study are included in this published paper and Multimedia Appendix 4.

Abstract

Background: Firefighters face stressful life-threatening events requiring fast decision-making. To better prepare for those situations, training is paramount, but errors in real-life training can be harmful. Virtual reality (VR) simulations provide the desired realism while enabling practice in a secure and controlled environment. Firefighters' affective states are also crucial as they are a higher-risk group.

Objective: To assess the impact on affective states of 2 simulated immersive experiences in a sample of healthy firefighters (before, during, and after the simulation), we pursued a multivariate approach comprising cognitive performance, situational awareness, depression, anxiety, stress, number of previous adverse events experienced, posttraumatic stress disorder (PTSD) severity, and emotions. The efficacy and ecological validity of an innovative VR haptic system were also tested, exploring its impact on performance.

Methods: In collaboration with the Portuguese National Fire Service School, we exposed 22 healthy firefighters to 2 immersive scenarios using the FLAIM Trainer VR system (neutral and arousing scenarios) while recording physiological data in a quasi-experimental study. Baseline cognitive performance, depression, anxiety, stress, number of adverse events, and severity of PTSD symptoms were evaluated. Positive and negative affective states were measured before, between, and after each scenario. Situational awareness, sense of presence, ecological validity, engagement, and negative effects resulting from VR immersion were tested.

Results: Baseline positive affect score was high (mean 32.4, SD 7.2) and increased after the VR tasks (partial η^2=0.52; Greenhouse-Geisser $F_{1.82,32.78}$=19.73; P<.001). Contrarily, mean negative affect score remained low (range 11.0-11.9) throughout the study (partial η^2=0.02; Greenhouse-Geisser $F_{2.13,38.4}$=0.39; P=.69). Participants' feedback on the VR sense of presence was also positive, reporting a high sense of physical space (mean score 3.9, SD 0.8), ecological validity (mean score 3.8, SD 0.6), and engagement (mean score 3.8, SD 0.6). Engagement was related to the number of previously experienced adverse events (r=0.49; P=.02) and positive affect (after the last VR task; r=0.55; P=.02). Conversely, participants reported few negative effects (mean score 1.7, SD 0.6). The negative effects correlated positively with negative affect (after the last VR task; r=0.53; P=.03); and avoidance (r=0.73; P<.001), a PTSD symptom, controlling for relevant baseline variables. Performance related to situational awareness was positive (mean 46.4, SD 34.5), although no relation was found to metacognitively perceived situational awareness (r=–0.12; P=.59).

Conclusions: We show that VR is an effective alternative to in-person training as it was considered ecologically valid and engaging while promoting positive emotions, with few negative repercussions. This corroborates the use of VR to test firefighters' performance and situational awareness. Further research is needed to ascertain that firefighters with PTSD symptomatology are not negatively affected by VR. This study favors the use of VR training and provides new insights on its emotional and cognitive impact on the trainee.

Introduction

Background

Over the last few years, gamification and serious games applied to nongame settings have become a visible theme, promoting knowledge acquisition, user engagement, and strategic skills [1]. More precisely, virtual reality (VR) serious game training systems have been showing high potential for many purposes, especially in the professional instruction field [2,3]. Simulated situations under high stress levels have been gaining greater interest for some time. As an example, Keitel et al [4] examined endocrine and psychological stress responses in medical students during 2 simulated stress scenarios (a stress situation induced at a laboratory and a simulated emergency situation) compared to a rest condition.

For firefighters, this assumes special importance in relation to the idiosyncrasies of their strenuous everyday duties [2]. Their functions require a repetitive and continuous preparation to acquire and preserve skills and refresh expertise, which can be potentially facilitated through VR tools. These systems present direct advantages compared to traditional in-person training as a cost-effective and safer realistic alternative to perform dangerous or complex tasks and train decision-making and related abilities in secure environments, replicating similar conditions to those in real life with less time and consumption of resources or other constraints.

Furthermore, VR applications make available a plurality of training scenarios with high ecological validity [2]. Ecological validity can be defined as "the ability to generalize experimental results to different populations, situations, and variables" [5] and is related to the cues contained in an experiment that permit the generalization from the laboratory to real life. VR settings have been successfully used to increase the ecological validity of several experiments [6] as well as enhance participants' daily activities, be it rehabilitation for older adults [7], improving cognitive function of children with attention-deficit/hyperactivity disorder [8], or simply shopping in a virtual supermarket [9].

The high ecological validity of VR scenarios allows for customized realistic immersive scenarios fit to the training purpose [10] without putting the workers' lives or properties in danger [11]. These systems present several other advantages, namely, being an observer [12]; repeated practice; and promotion of the users' engagement and motivation regarding the training tasks and, consequently, the retention of competencies and transference of knowledge [2,13]. VR experiences also encourage post–training session discussions and member collaboration [14]. This is critical because coordination and cooperation are essential between firefighters. Furthermore, VR technology provides user insights into simulated experiences and gains into real-life situations and can be applied to a wide range of personnel categories (eg, trainees and commanders).

As presented by Narciso et al [15], the ideal VR training system should reproduce with the best accuracy possible the real-world situations such that the user can be immersed in the virtual environment and perceive it as close to reality. Thus, the effectiveness of the VR system and its ability to mobilize the user are crucial points to consider regarding firefighting training. Moreover, these workers have to manage critical and dangerous incidents, operate in intense and stressful unpredictable conditions, face hazardous scenarios, deal with human suffering, and handle one's own and colleagues' emotions.

In the last years, some studies have applied simulated tasks [16] and VR systems using several devices and tools (eg, game engines using 3D graphics, software, and VR equipment) for the purpose of firefighter instruction [10,13,17-22]. Reis and Neves [23,24] presented a list of guidelines for simulation in training contexts using VR tools, namely, physical and psychological fidelity, interaction, immersive features, and realism. In addition, Saghafian et al [25] highlighted the importance of realism to increase the acceptance level of the users, effectiveness, and transfer of knowledge, as well as the role of emotions in VR contexts, for example, when using a VR fire extinguisher training tool for several companies from the industrial sector.

From our perspective, developments have been made in this area, with studies focused on VR for firefighting training purposes [15,23,26-28]. In a specific study by Narciso et al [29], virtual environments were used to investigate the effects of multisensory stimuli in 6 different methods—audiovisual or audiovisual combined with smell, or heat, or weight, or uniform, or mask, or a combination of these—on stress (using heart rate and self-report measures), fatigue, cybersickness, presence, and knowledge transfer. This study was conducted in the context of firefighter training and involved a sample of 91 individuals who were not firefighters. Another pilot study revealed the positive effects of resorting to VR tasks for firefighter training purposes, namely, in decision-making abilities during emergency actions [24].

Notwithstanding the existing literature, a clear gap remains in this area, including studies using multimodal experiments capable of integrating realistic immersive scenarios, neuropsychological measures, and biological parameters. The study by Andrews [16] called attention to the ecological and content validity issues of simulated emergency tasks for firefighters, aggregating findings from 60 protocols. The author also highlighted the lack of empirical studies concerning simulating tasks. Indeed, there is a clear need for in-depth ecological experiences, and VR systems might be a valid solution with high application potential.

Some explicit attempts have been made to increase realism in firefighter training [15,16,30]. For example, the study by Butler et al [30] has sought to integrate a multicomponent method including behavioral and biological parameters in a sample of incident commanders to investigate standard operating procedures and decision-making during simulated events. However, the technology used was scarcely immersive (the study used moving images and did not resort to VR technology). In addition, another study [31] investigated decision-making in a sample of Portuguese trainees who became certified for the job using a realistic VR system coupled to a haptic thermal device. The impact of VR was analyzed, but neither physiological measures nor the emotional and neuropsychological components were included.

Other studies have addressed firefighters' situational awareness [12,32-34], defined as the "knowledge or how well the individual discriminates true (signal) from false (noise) information" [32]. However, the literature is still scarce in studying the potential of including this variable applied to firefighter training from a broader perspective, as argued by Chiu [12], namely, combined with VR methodology.

Despite the aforementioned body of work, further research is still needed regarding the effectiveness of VR training applied to firefighter instruction. For example, recently, in their study, Narciso et al [35] applied a heart rate variability measure and self-reported questionnaires to a sample of Portuguese firefighters in this VR context. Although the authors found promising results related to stress, sense of presence, cybersickness, and transference of knowledge, training in real environments showed superior results compared to the VR setting. This is unsurprising and does not preclude the use VR in transfer situations in which learning in real settings is not practical.

To successfully perform their duties, firefighters need flexibility for diverse tasks and operations and have to act immediately, make critical decisions in adverse conditions, deal with fatigue, and control their emotions. After interventions, it is central for their mental health to return to a homeostatically appropriate state to carry on with their lives. In this regard, a systematic review [36] found some mental health issues within firefighter groups, namely, posttraumatic stress disorder (PTSD), anxiety, and depression. Oliveira et al [37] also investigated this issue and replicated these findings.

Emotions play a crucial role in the mental health of firefighters [38]. Findings from Godfrey et al [39] revealed that difficulties in emotion regulation mechanisms were positively associated with the severity of PTSD symptomatology in a sample of firefighters and might be a valuable target considering the vulnerability of this population. Stanley et al [40] highlighted greater levels of distress tolerance as a key trait for firefighting, defined as a capability to deal with negative emotional and physical states. Specifically, firefighting is emotionally challenging work, being cognitively demanding and physically overloading, with implications for the decision-making process [41]. In this regard, Robinson et al [42] found some impairments in cognitive functions among nonfirefighter participants (namely, in the visual declarative memory and working memory domains immediately after the exposure and 20 minutes after) in response to the threat during a simulated firefighting emergency. Furthermore, a study found that shift workers have a higher propensity to show cognitive impairment due to sleep deprivation [43].

This state might affect fundamental cognitive abilities that are crucial to guarantee the success, effectiveness, and safety of firefighting operations. Previous research has indicated that firefighters require higher cognitive function during their hazardous activities [44,45]. Some examples of this higher-order cognition are attention (as a broad construct)—the ability to maintain focus over the time; vigilance—the capacity to maintain continuous attention to specific stimuli, helping in information discrimination; processing speed—the ability to acquire and process information rapidly and, consequently, execute [46]; analytical thinking—the ability to solve problems by virtue of understanding logical principles and assessing the evidence [47]; accurate decision-making ability as a complex process that includes making difficult choices, weighing potential risks and rewards, taking actions, and analyzing the effects [48,49]; working memory—the capacity to maintain information accessible while performing other complex tasks [50], involving temporary storage and manipulation of information; cognitive flexibility—the ability to respond readily, changing selectively according to the environment's demands [51]; and awareness of the situation—the ability to continuously extract information from the surrounding dynamic environment [52], among other executive functions.

Considering the state of art, this study used an Australian VR realistic training system, the FLAIM Trainer, which uses immersive technology for firefighter training and learning. This simulator comprises several cutting-edge characteristics, including various immersive virtual fire scenarios, using a multisensory interface with several customized and haptic components (eg, heat suit, hose line, and a nozzle). For the purpose of this work, a multimodal approach was implemented using realistic training tasks combined with psychological and physiological measures, including evaluation of executive functions and firefighters' performance regarding situational awareness.

Objectives

The main goal of this work was to assess the impact of 2 simulated experiences on positive and negative emotions in a sample of healthy Portuguese firefighters pursuing a multivariate approach and, ultimately, investigate affective aspects of the immersive performance in the following two virtual environments: (1) a neutral scenario (exploration of the surrounding area of a rural residence, including preventive tasks) and (2) an arousing stressful scenario (extinction of a residential fire, including victim rescue actions). The relationship among cognitive performance; reported levels of anxiety, depression, and stress; PTSD severity; adverse events witnessed as a firefighter before the experiment; and affective states before, during, and after the VR task was also analyzed. Another aim was linked to this latter question and concerned evaluation of the impact of an innovative and haptic VR system (the FLAIM Trainer) on firefighter training and daily duties. The ecological effectiveness and the direct and indirect effects of these immersive scenarios were tested, including evaluation of firefighters' situational awareness fit to firefighter demands. These aspects have direct implications for firefighting work and performance in relation to firefighter training and the role of emotion regulation mechanisms in the daily duties of these workers.

Methods

Overview

The sample comprised 22 healthy firefighters from several fire stations in Portugal (n=17, 77% from Lisbon and the Tagus Valley area) recruited in collaboration with the Portuguese National Fire Service School at Sintra (Portugal). The exclusion criteria were the presence of a severe psychiatric or physical condition affecting the brain and behavior—including PTSD, drug or alcohol addiction, significant vision and hearing problems, and pharmacological treatment with effects on brain mechanisms—and never having participated in firefighting campaigns. The Results section presents a detailed description of the sample.

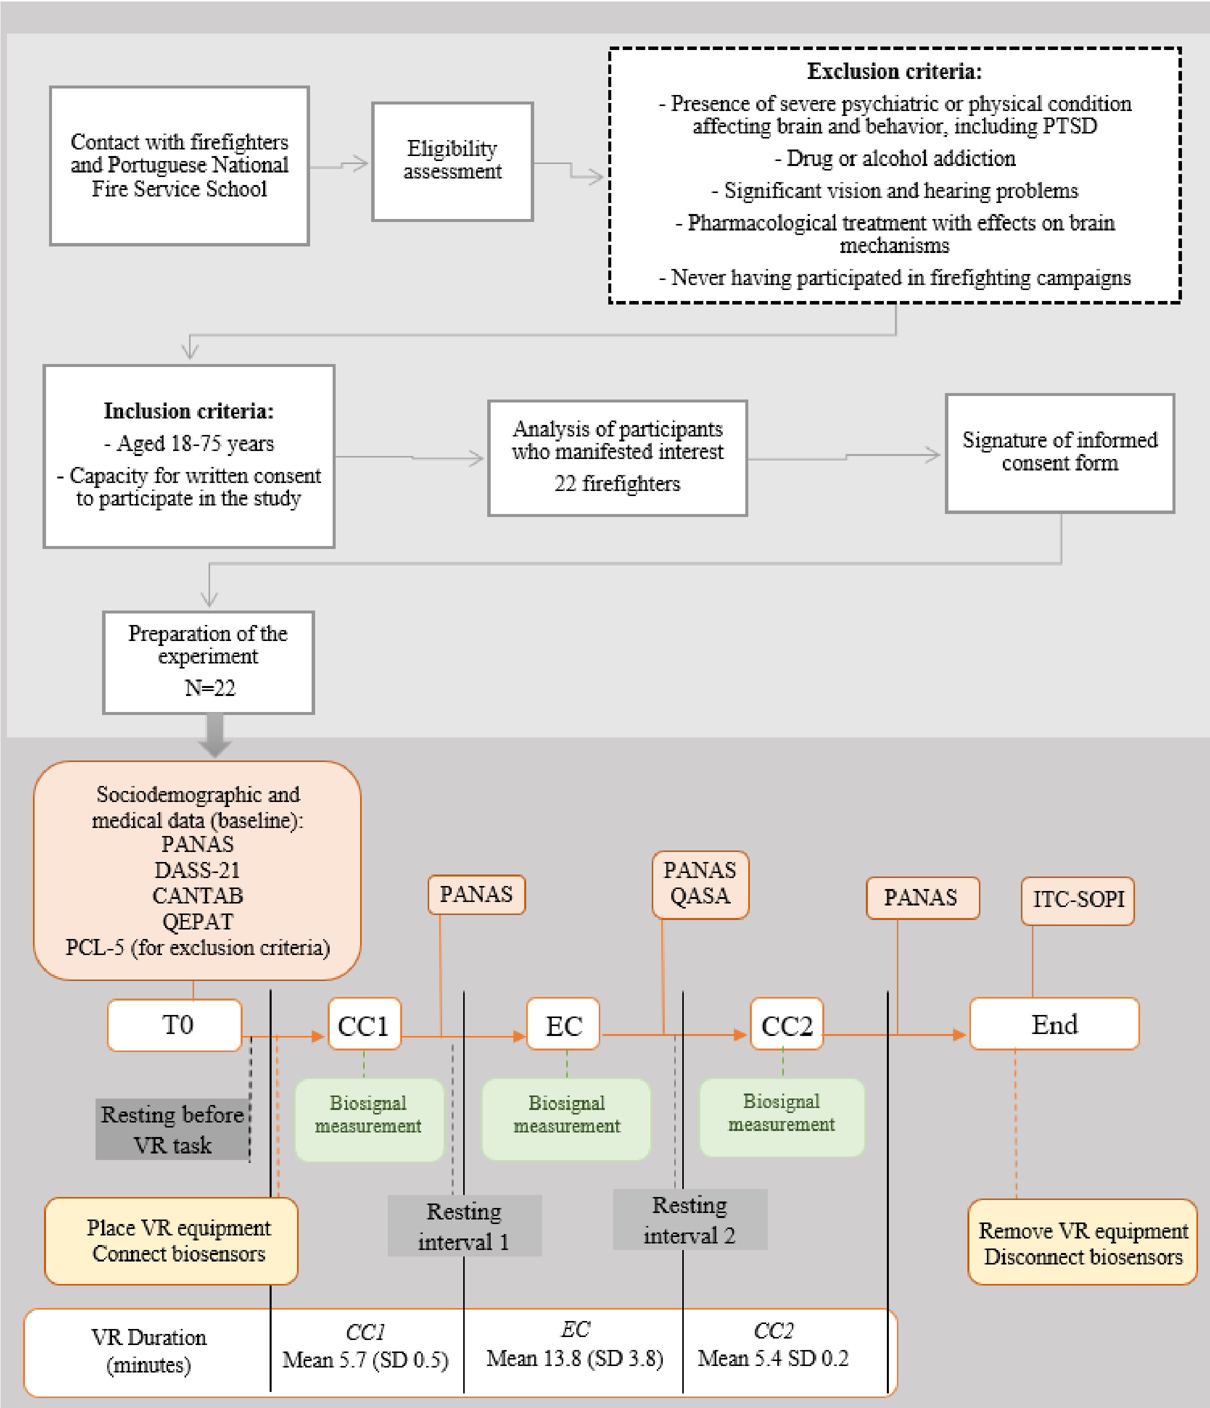
Protocol Procedure

The experiment was conducted at the Portuguese National Fire Service School facilities at Sintra (Portugal), except in the case of 9% (2/22) of the participants, who performed the tasks at the Institute for Nuclear Sciences Applied to Health, University of Coimbra (Portugal), using a quasi-experimental study design. Data collection at the Portuguese National Fire Service School occurred during daytime with participants who were at the school attending a course or called up from nearby fire brigades to participate in the study. Data were also collected during daytime at the Institute for Nuclear Sciences Applied to Health with 9% (2/22) of the firefighters, who purposely went to the institute to participate in the study on a day off from work. Collection at both sites took place during the participants' time off from work. All participants underwent an individual session, including a comprehensive semistructured interview regarding sociodemographic information and self-reported medical history followed by a psychological assessment comprising self-report measures and a battery of computerized tests to assess cognitive function. The total duration of the psychological assessment session was approximately 1 hour. Each participant was then conducted to a separate room to take part in the virtual experience session, including measurement of biosignals and filling out the self-report questionnaires immediately after undergoing each experimental scenario to evaluate their experience in the VR environment at various moments in time (Figure 1).

It was determined that the participants should complete the psychological assessment first and the VR experience afterward due to the consideration that performing the VR task first could elicit a particularly positive or negative mood and, thus, lead to mood-congruent memory recall bias [53,54] and inaccurate reports during the subsequent psychological assessment. To prevent the psychological assessment from having the opposite effect on the VR task performance, it was ensured that the participants had at least 25 minutes to rest between the psychological assessment and the VR task.

During all VR experiments (including during the filling out of the self-report measures), firefighters wore urban-standard fire combat equipment, comprising protective clothing and boots, to accurately simulate a real situation.

CANTAB: Cambridge Neuropsychological Test Automated Battery; CC1: control condition 1; CC2: control condition 2; DASS-21: 21-item Depression, Anxiety, and Stress Scales; EC: experimental condition; ITC-SOPI: ITC–Sense of Presence Inventory; PANAS: Positive and Negative Affect Schedule; PCL-5: Posttraumatic Stress Disorder Checklist for the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition; PTSD: posttraumatic stress disorder; QASA: Quantitative Analysis of Situation Awareness; QEPAT: Questionário de Exposição e Perturbação dos Acontecimentos Traumáticos (a Portuguese questionnaire related to the exposure to and disturbance of traumatic events); T0: baseline.



Outcome measures

We collected sociodemographic and self-reported medical data, and the measurement instruments used were: (1) the Positive and Negative Affect Schedule (PANAS [55,56]); 2) 21-item Depression, Anxiety, and Stress Scales (DASS-21 [57,58]); 3) Questionário de Exposição e Perturbação dos Acontecimentos Traumáticos (QEPAT; a Portuguese questionnaire related to the exposure to and disturbance of traumatic events [59]); 4) Posttraumatic Stress Disorder Checklist for the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (PCL-5; [60]; [61]); and 5) Cambridge Neuropsychological Test Automated Battery (CANTAB) [62].

The following selected tests were administered in this sequence before the VR tasks: motor screening task (MOT), spatial working memory (SWM) task (extended version), rapid visual information processing (RVP) task (3-target version), intra/extradimensional set shift (IED; lines-first-repeated version), the 6) Quantitative Analysis of Situation Awareness (QASA; instrument created for this study following the methodology proposed by Edgar et al [63]), and the 7) ITC–Sense of Presence Inventory (ITC-SOPI [64,65]).

More detailed information about the outcome measures used in this study and the internal consistency of the scales can be found in Multimedia Appendix 1.

All scales' descriptive statistics, Cronbach α values, and detailed information about the duration of the experiment (conditions and resting intervals) can be found in Multimedia Appendix 2.

VR Session: Setup

The FLAIM Trainer VR technology was designed for firefighter training and learning, presenting a wide range of simulated fire environments (150 available scenarios in 28 languages) [66], which faithfully reproduce dangerous situations usually faced in fire duties (eg, highway, national park, and warehouse fires) or rarer events (eg, fire in a petrol station or engine fire on an aircraft). The system was developed in an attempt to fit the needs regarding fire duties and integrated professional feedback; instructors can monitor in real time and review and track trainees' performance. The simulator was acquired for research purposes within firefighter training.

Some case studies have been reported using the FLAIM Trainer VR system with positive results [67]. Higher levels of acceptance and usability of this VR system were found among 91 Brazilian military firefighters during a firefighting specialization course [68].

The simulator incorporates feedback and outcomes to assist firefighters in decision-making, along with a proprietary virtual fire behavior technology that mimics real fire. This technology aims to improve high-level skills such as risk assessment and dynamic thinking and practical abilities such as muscle memory, radio messaging, and hose and nozzle handling [69]. The hardware was designed considering user-friendliness and immersiveness. The user can explore and navigate the scenes freely, which is facilitated by a teleport mode, and interact with objects.

The hardware setup includes customized components, namely, a self-contained breathing apparatus kit where the VR computer is housed with a built-in HTC Vive Pro VR headset, a half facemask and lung demand valve to capture respiration and reproduce sounds of breathing, and a thermal imaging camera, as well as a fire proximity heat suit technology and a mobile hose line apparatus with haptic technology reproducing a realistic jet and nozzle force; the pump pressure and the suppressant type can be controlled and customized at any time by the instructor. Support equipment includes an instructor tablet, HTC Vive Tracker Puck, charging systems, cables, peripherical hardware, tripods, tracking hardware with base stations (Vive Lighthouses), and Vive Controller [69,70]. In this experiment, the half facemask, thermal imaging camera, and heat suit were not used. Figure 2 shows 2 firefighters performing the VR tasks.

During the VR sessions, biosignals were recorded simultaneously through noninvasive superficial sensors to study autonomic arousal related to firefighters' emotions and behavior and its impact on decision-making under stressful conditions. The parameters measured were electrodermal activity, photoplethysmography, electrocardiography, electroencephalography, and respiration. These data will be reported in a separate study.

The VR experience was divided into 3 moments with 2 different experimental scenarios. The experiment started with a brief tutorial for the user's familiarization with the interaction with the VR system and the use of the hose and the teleport mode. Then, the neutral scenario (*Property Emergency Prepare* scenario; Figure 3) was presented—control condition 1. The firefighters were instructed to explore the scenario for 5 minutes and clean the terrain and the nature around a rural property as a prevention and safeguard measure against potential bushfire risks. In this environment, it was not possible to enter the house, but there were several elements outside with which the participant should interact (eg, cleaning inflammable debris from the nearby zone, ensuring the safety of the animals, and preparing the area for a potential fire).

The experimental condition consisted of a residential fire in the first floor of a house inserted in an urban zone (Bedroom Fire scenario; Figure 4). The scenario ended when the firefighter extinguished the fire and rescued all human victims. The experiment ended with another immersion in the neutral scenario (Property Emergency Prepare scenario; Figure 3)—control condition 2—for 5 minutes, effectively acting as a postbaseline assessment. The firefighters were instructed to act as in a real situation during all conditions. A total of 14% (3/22) of the participants did not complete the last scenario (control condition 2) for health-related reasons (ie, shortness of breath caused by the physical demands of the experimental condition), due to technical issues (ie, system crashed due to lack of battery during the task), or because they did not wish to continue participating in the experiment.

Participants took a mean of 34.1 (SD 8.6) minutes to complete both the control and experimental conditions, also accounting for resting time between the conditions. While a 5-minute time limit was established for the control conditions, some participants needed more time to familiarize themselves with the VR headset and nozzle, so additional time was provided. This also had the aim of ensuring that the participants were engaged and motivated to perform the experimental condition. The first control condition had a mean completion time of 5.7 (SD 0.5) minutes, whereas the second control condition had a mean completion time of 5.4 (SD 0.2) minutes. No time limit was imposed for the experimental condition. Instead, it was determined that the participants had finished the experimental condition once they had completed the 2 objectives of putting out the fire and saving the victims or when they themselves decided to terminate the task. Even though participants were encouraged to complete the objectives, they could quit at any time. Only 5% (1/22) of the participants abandoned the experimental condition after not being able to complete it after 20.5 minutes. Furthermore, it was ensured that the participants had resting time between conditions to avoid fatigue, although the specific interval duration between conditions was determined by the participants. The mean resting times were 4.3 (SD 3.3) minutes between control condition 1 and the experimental condition and 6.5 (SD 1.6) minutes between the experimental condition and control condition 2.

Figure 3. Scenario of control conditions 1 and 2 (provided by FLAIM).

Figure 4. Scenario of the experimental condition (provided by FLAIM).

Statistical Analysis

Statistical analysis was performed using SPSS (version 28; IBM Corp), and a significance level of 0.05 was established. Detailed information about the statistical analysis performed can be found in Multimedia Appendix 1.

Ethical Considerations

Participants provided written informed consent. This study was approved by the local research ethics committee of the Faculty of Medicine of the University of Coimbra (approval number: CE_Proc. CE-047/2020) and was guided by the Declaration of Helsinki of 1975 and its latest updates. All data were handled under rigorous protective measures in place to safeguard participant information; specifically, an alphanumeric code was assigned to all participants following a deidentification process to preserve participants' confidentiality and privacy. No compensation was provided for participation in the study.

Results

Participants

Most participants were male (15/22, 68%), with a mean age of 39.1 (SD 9.7; median 42.0, range 23-56) years, and had completed the mandatory education in Portugal (secondary education; 17/22, 77%). In addition, 91% (20/22) and 82% (18/22) of the sample reported consuming alcohol and coffee, respectively, and 36% (8/22) smoked regularly. Regarding their history of psychological help, 59% (13/22) of the firefighters reported having sought psychological assistance in the past. Concerning their activity as firefighters, the sample was equally distributed between professional (12/22, 55%) and volunteer (10/22, 45%) firefighters working primarily in shifts (19/22, 86%) for a mean of 36.8 (SD 17.5; median 42.0, range 7-60) hours per week. The participants had worked for a mean of 18.9 (SD 10.6; median 18.0, range 4-40) years as firefighters. Detailed sociodemographic data can be found in Multimedia Appendix 3.

Characterization of Psychological Measures

DASS-21 Results

Participants' scores in the 3 scales of the DASS-21 were low as they all had normal depression scores (0 to 4), 9% (2/22) had mild anxiety scores (4 to 5), and only 5% (1/22) had mild stress scores (8 to 9). The sample mean was 1.1 (SD 1.3; median 1.0, range 0-4) for the depression scale, 1.2 (SD 1.5; median 0.5, range 0-5) for the anxiety scale, and 3.7 (the highest; SD 2.6; median 3.5, range 0-8) for the stress scale.

QEPAT Results

Regarding the number of adverse events in the context of firefighting activities, participants had experienced a mean of 31.9 (SD 4.5; median 33.0, range 23-40) event types out of 42. No additional events were described by any participants.

The most frequently experienced adverse events were participating in firefighting activities in which goods and properties were at risk (mean 2.7, SD 0.8; median 3.0, range 1-4) and aiding or seeing injured and/or fragile older adults (mean 2.7, SD 0.7; median 3.0, range 2-4), with 59% (13/22) of the sample indicating experiencing each event many times or frequently. In addition, 50% (11/22) of the sample indicated having seen or aided gravely injured adults many times or frequently (mean 2.6, SD 1.1; median 2.5, range 1-4).

While analyzing the level of disturbance, we considered only the events the participants had experienced. The events that obtained the highest mean disturbance score were witnessing the death or grave injury of a firefighter colleague while in active duty (mean 3.4, SD 0.7; median 4.0, range 2-4) and having aided a firefighter colleague who died or was gravely injured while in active duty (mean 3.2, SD 0.7; median 3.0, range 2-4). Both of these events were experienced by 41% (9/22) of the participants. One other event type that obtained a high disturbance score and was experienced by all but 1 participant (21/22, 95%) was hearing through radio communications that firefighter colleagues were in danger, injured, or dead (mean 3.3, SD 0.7; median 3.0, range 2-4). Of the events experienced by all participants, having seen or helped injured children was the one with the highest level of disturbance (mean 2.2, SD 0.9; median 2.0, range 1-4).

PCL-5 Results

None of the participants surpassed the PCL-5 full-scale thresholds or fulfilled the *Diagnostic and Statistical Manual of Mental Disorders*, *Fifth Edition*, criteria for possible PTSD diagnosis, yielding a sample mean score of 3.9 (SD 4.5; median 2.0, range 0-12). The subscales had similar low mean scores. In the Intrusion Symptoms and Avoidance subscales, the sample held a mean of 1.0 (SD 1.5; median 0.0, range 0-5) and 1.0 (SD 1.9; median 0.0, range 0-8), respectively, similar to that of the Negative Alterations in Cognitions and Mood (NACM; mean 1.1, SD 1.7; median 0.0, range 0-6) subscale and slightly lower scores on the Alterations in Arousal and Reactivity (AAR) subscale (mean 0.9, SD 1.3; median 0.0, range 0-4).

PANAS Results

Participants had low negative affect scores for all 4 moments of administration of the PANAS, ranging from a mean of 11.0 after both control conditions (SD 1.3 for control condition 1 and SD 1.8 for control condition 2) to 11.9 (SD 3.2) after the experimental condition. All mean scores were <12 although higher than the minimum score of 10 ($P<.05$ for all comparisons). Conversely, the scores on the positive affect scale were moderate to high. At the baseline measure (T0), the sample had a mean of 32.4 (SD 7.2), close to the middle point of 30 (Cohen d=0.33; t_{21}=1.53; P=.14). The highest mean score was obtained for the measure after the second control condition (mean 40.7, SD 6.6), although it was lower than the maximum score of 50 on the scale (Cohen d=–1.42; t_{18}=–6.18; $P<.001$). Detailed results can be found in Multimedia Appendix 4.

CANTAB Results

All participants excelled in the MOT, concluding the assessment trials with 0 mistakes.

In the SWM task (more detailed information about the outcome measures used in this study can be found in Multimedia Appendix 1), the mean was –0.6, measured in normalized z scores (SD 1.3; median –1.0, range −1.9 to 2.3), which is only slightly lower than the norm mean of z=0 (Cohen d=–0.47; t_{21}=−2.22; P=.04). Only 18% (4/22) of the participants had values higher than the mean, with 14% (3/22) obtaining the highest possible score of z=2.3 (percentile 99). These 3 participants never made the mistake of revisiting a box in which a token had previously been found. The sample's median percentile was 15.5 (range 3-99), with only 23% (5/22) of the sample in percentile 42 or higher. In total, 36% (8/22) of the participants were in the lower range (percentile 10).

In the RVP task, both the z scores of how good the participants were at detecting target sequences (RVP A', prime; RVP prime, the accuracy to detect correctly the targets [RVPA}) and the probability of false alarm (RVP probability of false alarm; RVPPFA) were relatively low (RVPA: mean –0.5, SD 0.6 and median –0.5, range –1.4 to 1.2; RVPPFA: mean 0.3, SD 0.9 and median 0.1, range –1.5 to 2.3). While the frequency of false alarms was similar to that of the norm (Cohen d=0.30; t_{21}=1.41; P=.17), our participants were slightly worse at detecting the target sequences (Cohen d=–0.81; t_{21}=–3.80; P=.001). Another 14% (3/22) of the participants had a probability of false alarm of 0 (percentile 99). In both measures, only 5% (1/22) of the participants were in a percentile of <10 (8 for the RVPA and 7 for the RVPPFA) who were also in percentile 5 in the SWM task. The sample's median percentile for the RVPA measure was 29.5 (range 8-89), indicating that half (11/22, 50%) of the sample had equal or worse capability to detect target sequences than the bottom 29.5% in the CANTAB normative data.

Finally, the sample's mean efficiency in performing the IED task (more detailed information about the outcome measures used in this study can be found in Multimedia Appendix 1) was not different from the norm mean z scores (mean 0.0, SD 0.7; median 0.1, range –1.3 to 0.8; Cohen d=–0.06; t_{21}=–0.28; P=.78). However, the participants' performance was heterogeneous, with a median percentile of 49.6 (IQR 28.8-68.5). In total, 9% (2/22) of the participants were in percentile 9, which indicates that only 9% in the normative data made more errors in this task than these participants.

No correlation was found between the CANTAB z scores and any relevant sociodemographic data (ie, sex, age, number of children, failing in school, alcohol and caffeine consumption, years in service, and hours worked per week as a firefighter; sex: CANTAB_SWM: P=.81; CANTAB_RVPA: P=.499; CANTAB_RVPPFA: P=.31; CANTAB_IED: P=.50; age: CANTAB_SWM: P=.46; CANTAB_RVPA: P=.29; CANTAB_RVPPFA: P=.49; CANTAB_IED: P=.75; number of children: CANTAB_SWM: P=.57; CANTAB_RVPA: P=.55; CANTAB_RVPPFA: P=.73; CANTAB_IED: P=.60; failing in school: CANTAB_SWM: P=.34; CANTAB_RVPA: P=.19; CANTAB_RVPPFA: P=.84; CANTAB_IED: P=.12; alcohol: CANTAB_SWM: P=.37; CANTAB_RVPA: P=.61; CANTAB_RVPPFA: P=.37; CANTAB_IED: P=.17; caffeine consumption: CANTAB_SWM: P=.31; CANTAB_RVPA: P=.44; CANTAB_RVPPFA: P=.66; CANTAB_IED: P=.43; years in service: CANTAB_SWM: P=.496; CANTAB_RVPA: P=.63; CANTAB_RVPPFA: P=.84; CANTAB_IED: P=.998; hours per week: CANTAB_SWM: P=.42; CANTAB_RVPA: P=.82; CANTAB_RVPPFA: P=.49; CANTAB_IED: P=.20).

ITC-SOPI Results

The results for the ITC-SOPI scales were as expected. The highest mean was obtained for the Sense of Physical Space scale (mean 3.9, SD 0.8; median 3.8, range 2.9-6.4) followed by the Ecological Validity scale (mean 3.8, SD 0.6; median 3.8, range 2.8-4.8) and the Engagement scale (mean 3.8, SD 0.6; median 3.8, range 2.2-4.7). These scores were higher than the middle point of the scale (3) for all subscales ($P<.001$ for all comparisons).

Finally, the Negative Effects scale had the lowest scores, with a mean of 1.7 (SD 0.6; median 1.7, range 1.0-3.0). This mean, although small, was higher than the lowest possible score of 1 on this scale (Cohen *d*=1.25; t_{20}=5.71; *P*<.001). The most frequently mentioned negative effects were "feeling tired" (mean 2.1, SD 1.1; median 2.0, range 1-5) and "feeling disoriented" (mean 2.1, SD 1.0; median 2.0, range 1-4), followed by "ocular fatigue" (mean 2.0, SD 1.0; median 2.0, range 1-4).

Correlations Between Measures

At baseline (T0), stress as measured using the DASS-21 correlated positively with the NACM (*r*=0.44; *P*=.04) and AAR (*r*=0.43; *P*=.04) subscales of the PCL-5 but not with the full-scale scores (*r*=0.21; *P*=.34). In addition, the stress scale correlated positively with the negative affect scale of the PANAS at baseline (T0; *r*=0.42; *P*=.049) and after the second control condition (*r*=0.46; *P*=.05). On the other hand, the depression scale of the DASS-21 correlated negatively with the positive affect scale of the PANAS at baseline (T0; *r*=–0.51; *P*=.01) and after each condition (control condition 1: *r*=–0.63 and *P*=.002; experimental condition: *r*=–0.54 and *P*=.009; control condition 2: *r*=–0.70 and *P*<.001). The anxiety dimension of the DASS-21 did not show any correlation with the PANAS for any of the moments measured.

Posttraumatic stress symptoms, as measured using the PCL-5, did not correlate with affect measures (PANAS) except after the arousing experimental condition. Participants who held higher full-scale (*r*=0.43; *P*=.047), intrusion symptom (*r*=0.53; *P*=.01), and avoidance (*r*=0.71; *P*<.001) scores (measured using the PCL-5 at baseline [T0]) had increased negative affect scores measured using the PANAS after the experimental condition. A partial correlation controlling for anxiety, depression, and stress scores (DASS-21) confirmed this result (*r*=0.49 and *P*=.04, *r*=0.51 and *P*=.03, and *r*=0.75 and *P*<.001, respectively). Conversely, even though it appears that there is a negative relation between NACM (as measured using the PCL-5) and positive affect (as measured using the PANAS) after the experimental condition (*r*=–0.48; *P*=.02), this relationship dwindles after controlling for the 3 DASS-21 scales (*r*=–0.45; *P*=.06). A similar result is found when correlating the Avoidance subscale (PCL-5) and the number of adverse events experienced (as measured using the QEPAT). While there appears to be a correlation (*r*=0.44; *P*=.047), it becomes nonsignificant after controlling for the DASS-21 scales (*r*=0.43; *P*=.08).

There was no significant correlation between any of the CANTAB and QASA measures.

Direct Impact of the VR Training Task

Impact on Affect

Performing the VR task had a positive impact on positive affect compared to the baseline (partial η^2=0.52; Greenhouse-Geisser $F_{1.82, 32.78}$=19.73; *P*<.001). Baseline (T0) positive affect was lower than that measured after control condition 1 (*P*=.004), the experimental condition (*P*<.001), and control condition 2 (*P*<.001). The negative affect scores remained consistent throughout the experiment, with no differences found between or after the VR tasks (partial η^2=0.02; Greenhouse-Geisser $F_{2.13, 38.4}$=0.39; *P*=.69). The results found for positive and negative affect remained true after controlling for PCL-5 (full-scale) and DASS-21 scale (depression, anxiety, and stress) scores.

Impact on Sense of Presence

The mean results on the ITC-SOPI scales were positive, as mentioned previously. These positive results are highlighted when related to the affect felt throughout the VR tasks and after the experiment ended, controlling for positive and negative affect at T0 (baseline).

When considering the positive affect reported after all VR tasks were completed (ie, at the end of the experiment, after the second control condition) and its relationship to the ITC-SOPI scales, a positive correlation emerges solely with the participants' reported engagement (*r*=0.55; *P*=.02). Contrarily, the negative affect reported correlated positively and significantly with the negative effects of the VR task as measured using the ITC-SOPI, both after the first nonarousing control condition (*r*=0.61; *P*=.01) and at the end of the experiment (ie, after control condition 2; *r*=0.53; *P*=.03). This is in accordance with the correlation found between the negative effect scale of the ITC-SOPI and other scales. Specifically, a positive and moderate correlation was found between the negative effect and avoidance scores (*r*=0.73; *P*<.001) controlling for baseline levels of depression, anxiety, and stress (DASS-21) and for the number of adverse events experienced (measure obtained using the QEPAT questionnaire). No significant correlations were found between any ITC-SOPI scale and the positive or negative affect reported after the arousing experimental condition. We recognize how idiosyncratic differences in baseline affect could bias results, and therefore, all the aforementioned results do represent partial correlations.

Another noteworthy correlation found was between the number of adverse events that the participants reported having experienced (QEPAT) and the engagement subscale (ITC-SOPI; *r*=0.49; *P*=.02). It appears that participants who experienced more adverse events while in active duty also considered the VR setting more engaging.

Impact on Situational Awareness

Regarding the QASA tool, the sample had overall positive results, obtaining a mean rate of correct responses (ie, hit and correct rejections) of 68% (SD 14.6%; median 64.3%, range 43%-93%). This mean rate was similar for the hits (mean 68.2%, SD 21.1%; median 71.4%, range 29%-100%) and correct rejections (mean 67.5%, SD 12.6%; median 71.4%, range 43%-86%). In accordance, the mean rate of incorrect responses was relatively low at 32% (SD 14.6%; median 35.7%, range 7%-57%) for the rate of both misses (mean 31.8%, SD 21.1%; median 28.6%, range 0%-71%) and false alarms (mean 32.5%, SD 12.6%; median 28.6%, range 14%-57%).

Comparably, the mean actual situational awareness, as measured using A' was relatively high (mean 46.4, SD 34.5; median 45.0, range –25.0 to 92.9), with only 5% (1/22) of the participants having an A′ value of <0 (A′=–25). This indicates that the overall sample had a good situational awareness regarding the elements present in the VR task simulation and was able to distinguish true from false information (with the exception of 1/22, 5% of the participants).

These results were in tandem with the perceived confidence of the participants in their answers (perceived situational awareness

[PSA]). The sample's mean PSA was 47.2 (SD 25.0; median 47.6, range 0-100). All but one participant (21/22, 95%) had confidence in their ability to detect the correct response as they obtained positive values, and only 5% (1/22) of the participants reported not being very confident (ie, PSA value of 0).

When comparing the difference between A′ and PSA scores, it is possible to see that, although no difference between the means was found (mean difference=–0.8; Cohen *d*=–0.02; t_{21}=–0.08; *P*=.94), there was a great amount of variation between participants (SD 45.0; median –12.6, range –61.9 to 83.3 in this difference between A' and PSA). A total of 59% (13/22) of the participants perceived their situational awareness as being higher than it was (reflected by a negative difference), whereas 41% (9/22) had higher situational awareness than they themselves perceived having (as reflected by the positive difference).

The sample presented a slight information acceptance bias, with a mean of –13.6 (SD 30.3; median 0.0, range –100.0 to –9.1). In total, 9% (2/22) of the participants had B″ values of –100, indicating a great tendency to accept information as true even if it was false. A total of 36% (8/22) of the participants did not have any bias as they had a B″ value of 0.

Concordantly with the aforementioned results, no correlation was found between the actual situational awareness (A′) and the PSA (*r*=–0.12; *P*=.59). The same result was found when controlling for experience (ie, years as a firefighter; *r*=–0.11; *P*=.63). PSA values did not correlate with the bias scores (B″; *r*=0.19; *P*=.41) either. The only correlation found was between A′ and B″ scores (*r*=–0.51; *P*=.02) even after controlling for years in service (*r*=–0.50; *P*=.02).

A summary of the main findings of this study can be found in Multimedia Appendix 5.

Discussion

Principal Findings

This study showed the viability of a VR firefighter training tool as a valid serious game approach to act as an alternative for in-person real-life training, which can endanger a firefighter's life and is subject to limitations in the training situations available. Furthermore, the VR setup used in this study allows for ecologically valid and immersive scenarios, which is an advantage for realistic training that prepares for real-life situations.

Participants' level of acceptability is a crucial aspect to consider for VR use. Many reasons can explain the low tendency to integrate VR settings, namely, skepticism, vulnerability, insecurity, lack of ease of interaction with the equipment [71], or absence of realism [25]. Kari and Kosa [72] presented an interesting model joining hedonic and utilitarian or inconvenience measures to explain use and acceptance of VR games supported by the participants' behavioral intention to use that was influenced by curiosity and enjoyment. Another relevant aspect is that perceived ease of use was positively correlated with perceived usefulness, curiosity, enjoyment, and control and negatively associated with discomfort; in turn, utilitarian health and well-being factors were less significant aspects in terms of use of VR game applications.

In this study, the VR task was well received by the participants, in concordance with a previous study using the same VR apparatus [68]. Positive affect increased compared to the baseline just by performing the VR task. This was independent of the type of scenario. That is, it appears that being immersed in the VR setting itself improves positive affect, whether the scenario was neutral and did not require immediate action (preparing the surroundings of a house for a forest fire) or required urgent action and was arousing (putting out a house fire). This is corroborated by the relationship found between positive affect and engagement, both reported at the end of the overall VR task and both yielding highly positive mean scores. This reflects that engagement with the overall VR task increased as positive affect increased, and vice versa. This is true regardless of idiosyncratic differences in baseline positive and negative affect. For VR training to be successful, firefighters have to be engaged with the task, which could be related to positive rather than negative affect. Indeed, a recent systematic review and meta-analysis demonstrated the positive impact of VR environments on positive and negative affect measured using the PANAS [73].

Another aspect of the success of the VR firefighter training is the positive feedback from participants regarding the simulation itself. At the end of the study, participants reported that the simulations were perceived as real and similar to the real world, which was reflected by the high mean scores regarding the sense of physical space and ecological validity, as well as the reported usefulness for training and learning purposes. This adds to the existing literature that has demonstrated how VR increases the ecological validity of experiments [6] and allows for the transfer of skills from VR to real-world scenarios [7-9].

In this study, the realness (measured using the ecological validity scores) of the VR simulations was independent of both the positive and negative affect felt by the participants, which attests to the validity of the simulation being independent of the participant performing it. Similar results were found with VR applied for higher-education purposes in another study. The study showed that the level of immersion is crucial for students' sense of presence and positive affect (also measured using the PANAS). Our results contribute to the generally accepted premise that VR has a positive impact on users' learning and training outcomes [73]. In the same vein, Shafer et al [74] presented a model explaining how enjoyment is generated in VR applications. The authors argued that participants' perceived interactivity predicts spatial presence and realism in the task, whereas realism independently predicts spatial presence and, in turn, spatial presence predicts enjoyment; cybersickness was included as a covariate influencing enjoyment, and previous experience using VR or similar experiences had a weak impact on cybersickness.

Another point to consider regarding the viability of VR firefighting training is the dampening of negative effects. It could be argued that these might surpass positive effects if the use of VR leads to greater distress or discomfort or puts into question the health of the participants. In this study, we found no validation for this tenet. On the contrary, participants' negative affect remained low at baseline and throughout the VR task, with no impact of the arousing, urgent house fire scenario. These results (demonstrated by the firefighters' positive feedback and low negative emotions) are congruent with the principal dimensions highlighted in a very recent study—usability, usefulness, fun, and joy—as critical aspects to the adoption and recommendation of VR experiences [75].

Nevertheless, a positive correlation was found between the participants' avoidance, a symptom of PTSD, and the negative affect reported after the arousing scenario. Similarly, participants who reported experiencing symptoms of avoidance more frequently were also the ones who indicated having felt more negative effects due to the VR simulation. This is true regardless of the number of adverse events experienced and of depression, anxiety, or stress symptomatology. This finding should be further explored to ensure that even firefighters who demonstrate some PTSD symptomatology can perform the VR task and are not vulnerable. In addition, while one might expect that experiencing a greater number of adverse events would deter firefighters from engaging in a VR-simulated firefighting environment, the opposite was found. The participants who reported feeling greater engagement with the VR tasks were those who had experienced an increased number of adverse events. Some explanations can be posited in this regard. Indeed, having experienced stress levels during firefighting activities and confrontation with adversity could lead to greater motivation to improve this state of affairs and mobilize participants to act and manage situations, suggesting specific coping strategies and resilience mechanisms [75]. This topic gains importance with respect to implications for intervention strategies, namely, the relevance of including approaches to boost mechanisms of emotion regulation in firefighters, for example, stress buffer interventions or improving distress tolerance programs, as proposed by Stanley et al [40], who highlighted the positive role played by distress tolerance in occupation stress and suicide risk among 831 firefighters.

Nevertheless, the participants reported feeling scarce negative effects due to the VR task alone. The most frequently mentioned effect was "feeling tired," which might be attributed to the complex implementation of this study itself. Due to the plurality of physiological and psychological measures taken throughout the VR task, the participants had more equipment on them than they would in other VR training contexts and expended more time than usual between scenarios to complete questionnaires. Moreover, this negative effect can be reduced by not performing several VR scenarios in a single training session, thus diminishing fatigue. Regarding "ocular fatigue," the second most mentioned negative effect, it is something that is expected to subside as technology improves. As expected, negative *affect* measured after most of the VR tasks (control conditions) was related to the negative *effects* reported, both being minute.

The positive and negative emotional experience found in this study was congruent with the results found in a sample of trainees using a VR training system for fire extinction [25].

To further explore the reliability of VR training, it is relevant to assess firefighters' performance in this task. For this purpose, the QASA tool was developed. It has a 2-fold objective: it both allows for the assessment of whether firefighters are aware of and attentive to the elements present in the simulation and validates that the firefighters are really attentive to the VR task as if it were a real-life scenario. Participants were successful in this task as they managed to correctly identify most of the elements that were true (ie, hit) and most of the elements that were false (ie, correct rejections). However, this alone does not allow us to infer their awareness of the simulation situation. To assess their actual situational awareness, the emphasis should be on the A′ measure, which can be interpreted as a measure of "an individual's knowledge of the situation as compared to the 'ground truth" [63]. The participants' situational awareness was high, indicating that the overall sample was attentive to the simulation and could identify which statements addressing the simulation were true and which were false. This supports the fact that the participants were paying attention to the simulation. However, were the participants aware of their own situational awareness? Although the sample's mean PSA was similar to their actual situational awareness, there appears to be no correlation between the two, suggesting that performance self-appraisal is not accurate in this setting. In fact, approximately half (11/22, 50%) of the participants overestimated how good their awareness was, whereas the other half (11/22 50%) underestimated it. This is especially surprising considering how all but one participant (21/22, 95%) were confident that most of their responses were correct, some even indicating that all their responses were correct. This result, although expected, has major implications as awareness of the situation is a necessity when it comes to firefighting. Not being attentive to the details of a situation can be the difference between life and death in a real-life scenario. Finally, most participants (11/22, 50%) showed almost no bias in information acceptance. That is, they were considerate when responding to the questions and did not simply accept all the information provided as being true or false.

Concerning the firefighters' emotional and cognitive characterization, a few depressive, stress, and anxiety symptoms showed some correlation with other measures. For instance, stress levels were correlated with some PTSD symptoms. Participants who had higher values of NACM and AAR also had higher stress values, which was to be expected. Indeed, in the systematic review conducted by Jones [36], a plurality of studies found high comorbidities in firefighters.

Furthermore, participants with higher stress scores additionally reported increased feelings of negative affect (when the study started, before the VR task, and after the VR task was finished). While anxiety scores appear to not have any correlation with any of the other measures, the depression level reported had an inverse correlation with positive affect throughout the experiment. That is, the more the participants felt depressed, the less positive their emotional state was. However, this seems to reflect more on the participants' typical emotional state than on the VR task's success and impact. Nonetheless, our sample showed few indicators of psychopathology (as measured using the DASS-21 and PCL-5), which is in concordance with results from a sample of 312 Portuguese firefighters who reported low scores of depression, anxiety, and stress using the same measure used in this study and high levels of happiness [76]. The mental health of firefighters is an issue of particular relevance [37], which cannot be neglected and is emphasized by the aforementioned findings.

In this regard, serious games applied to interventions have revealed promising results in clinical settings, namely, by promoting treatment of and recovery from serious mental illness [77]. Regarding trauma, a recent study presented a contribution toward showing increasing users' awareness of psychological trauma, their sense of security, and promotion of seeking specialized help, using a serious game combined with psychological principles as theorical frameworks [78]. Another study using a computer game showed potential to reduce intrusive memories of a traumatic event [79]. Positive results using a VR simulator were exhibited by 2 truck drivers with PTSD [80]. This literature suggests a high potential for PTSD treatment using the innovative elements of VR.

Regarding the participants' cognitive performance, none demonstrated having any sensorimotor deficits or lack of comprehension, measured using the MOT as recommended [62]. Regarding their performance on the remaining cognitive tasks, the capability to not be swayed by false alarm sequences in the RVP task (RVPPFA measure) and their ability to shift between the intra- and extradimensions of a stimulus (IED test; ie, the ability to discriminate between visual set formation and maintain or shift attention in accordance with environmental clues) were no different than those of the sample norm. On the other hand, on average, the firefighters performed worse on the SWM task (ie, remembering which boxes were previously searched) and the ability to detect rapidly shown number sequences (RVPA measure) during the RVP task.

These measures were explored as they convey cognitive functions that are at play when putting out fires. SWM, strategic planning capacity via trial and error, attention and rapid visual processing, abstract thinking, and cognitive flexibility, as the ability to shift attention between elements of a stimulus following environmental clues through an organized search, are all competencies needed when firefighting as rapid decision-making and problem-solving are required. Although questions could be raised regarding the ecological validity of transposing this concise cognitive assessment to a real-life situation, it also brings into deliberation the need to assess a firefighter's strengths and vulnerabilities when appointing them to a position in action. Questions of ecology are highlighted by the fact that no correlation was found between any of the CANTAB and QASA measures.

Comparisons With Prior Work

According to previous work, VR serious game systems have high potential for training purposes, giving the possibility to customize them directly in accordance with the users' needs [2]. In this study, 2 realistic scenarios (and widely related to the daily duties of firefighters) were selected to ascertain the impact on induced positive and negative affect, on the one hand through neutral and nonurgent duties (preventive tasks) and, on the other hand, through urgent, stressful, and arousing activities, namely, extinguishing a house fire and rescuing victims.

During these tasks, firefighters had the opportunity to practice and develop their skill set (eg, dynamic thinking, stress management, decision-making under pressure, risk assessment, fire control, hose handling technique, and nozzle control) and learn in and experience a safe immersive environment, which might not be possible to replicate in real life. These are advantages of VR compared to traditional training according to several authors [2,10,11]. Other features of these systems demonstrated during this study were the capacity to maintain motivation and user engagement [13]. Indeed, participants reported adequate levels of physical presence, ecological validity, and engagement at the end of the experience and residual negative effects, in accordance with previous studies with Portuguese firefighters [15,35]. Furthermore, while performing the tasks, several firefighters provided additional feedback, which supported the system's similarity to real-life work, as recommended in the literature [15,23], and reinforces its acceptability and usefulness, in agreement with other studies [72,75]. In addition, emotions, a crucial dimension to consider in VR experiences as argued by Saghafian et al [25], were monitored at baseline, between scenarios, and immediately after, showing consistent effects. Collectively, these results demonstrate the reliability of the experiment.

Regarding cognitive performance, some studies have shown the negative impact of a shift work regimen on cognitive functions, which is frequent among Portuguese firefighters (19/22, 86% of our sample were shift workers). In general, our sample revealed normative performance across most tests, which is in line with the considerations of another study conducted with firefighters [44]. These authors assessed cognitive functions using 3 different tests (paired-associate learning, reaction time, and spatial span) of the CANTAB software in simulated hot conditions and further noted that some of these tasks were probably quite easy for their healthy sample of wildland firefighters.

Finally, another key aspect in the firefighters' performance was their actual situational awareness and how good they perceived it to be, that is, their performance self-appraisal (a metacognitive ability). As Edgar et al [63] note, the correlation between the actual situational awareness and PSA is inconsistent in the literature, sometimes being negligible, as in this study. They further highlight several studies that show that performance is moderated by how good the participants believe their situational awareness to be independently of whether their assessment is correct. They hypothesize that the inconsistency between studies might be explained by a lag between the measurement of actual situational awareness and PSA. This explanation does not fit this study as both measures were collected in the same moment. Nevertheless, efforts should be made not only to improve the actual situational awareness of firefighters but also to align their perception with their actual awareness.

Limitations and Future Work

This experiment was conducted for research purposes. Although precise instructions were provided for participants to act exactly as in real-life firefighting, these findings should be viewed with this caveat. Despite the greater levels of ecology and presence revealed by the experiment, fighting a fire and rescuing victims in simulated situations will never be exactly the same as in a real-life situation. In the same vein, although the cognitive dimensions assessed are valuable skills for performing fire duties, some caution is needed when transferring these outputs to real practice as they were obtained through computerized abstract tasks. In addition, considerations should be taken regarding the experimental setting itself. As previously mentioned, the experiment involved performing a complex set of diverse tasks (neuropsychological session followed by 3 moments of immersive VR scenarios with simultaneous measurement of biosignals) requiring that participants wear nonusual equipment (eg, electrocardiography, electroencephalography cap, and respiration band) during task performance and involving a wide range of resources. These constraints may challenge ecological transposition to real firefighting activity and could cause fatigue among participants. Despite this limitation, these were requirements of the experimental design, and pauses between procedures were implemented. However, to reduce this potential concern, future work should consider reviewing the duration of the experiment, including the duration of the simulation.

The impact of the psychological assessment on the participants' performance on the VR task should also be considered in future work. Although the protocol was designed to avoid bias due to mood-congruent memory recall [54], completing the PCL-5, DASS-21, and CANTAB before the VR task could induce fatigue and negative associations from past experiences and have impacted the participants' VR experience. It is recommended that this interplay between the psychological assessment and VR task is further explored in future research.

One other aspect not accounted for is the level of experience the firefighters had with VR specifically and gaming in general. In our case, participants had a moderate level of experience with immersiveness. Previous research has found that the level of experience and age of the participants influences their immersion in the VR setting [81]. Work on Outcome Measure instruments and Statistical analysis are reported at the Multimedia Appendix 1 [82-91]. Even though this was not the focus of this study, it is an aspect that could lead to a heterogeneous experience for individuals of different experience levels and, thus, should be further investigated in future research.

A final aspect that is worth mentioning is that many firefighters have stated that within a firefighter brigade, each member has a specific role assigned inside the team when deployed in field operations has a specific role assigned inside the team when deployed in field operations. In future work, this issue might be mitigated by including multiplayer tasks to achieve the most realistic situation, similar to a prototypical VR system using a multiuser training application among maritime firefighters [19]. Collaboration between members, communication skills, and collaborative work could also be addressed even more as target abilities of being a firefighter. These are skills easily promoted by opting for VR training settings [14] rather than in-person methodologies.

Conclusions

An innovative multicomponent approach was applied to a sample of Portuguese healthy firefighters considering psychological variables and cognitive indicators including situational awareness ability combined with a haptic realistic VR training system and simultaneously coupled with physiological measures. Considering that firefighters are a population at high risk, negative affective states of depression, anxiety, and stress were considered, as well as the severity of PTSD symptoms and adverse events witnessed as a firefighter. This is relevant because Portugal is a country annually ravaged by wildfires, with uncalculated costs at various levels.

Promising results were found as participants were engaged during all tasks, revealing high levels of motivation and acceptance related to the VR software. The ecological validity of both immersive scenarios was supported (irrespectively of facing neutral or arousing stress-inducing conditions), with a positive impact (positive affect was higher after the experiment) that could buffer the minor negative effects reported when PTSD symptom severity and anxiety, stress, and depression were controlled for. In general, the sample demonstrated adequate cognitive abilities and awareness of significant elements of the situations even though they did not correspond exactly with their perception.

These results attest to VR translatability to the real world as a valid cost-effective alternative to traditional in-person training closer to the specificity of firefighter activity. The use of innovative technologies such as the haptic and immersive VR software used in this study was attested for firefighter training and learning purposes and complemented prior work, combining several methodologies in a multicomponent approach. In addition, serious games and VR immersive tools might be put at the disposal of professional corpora to improve work conditions.

Valid contributions to this field of study emerged. Implications for real-world practice are important in relation to the impact of being a firefighter as well as the consequences of daily duties and identification of variables that have to be considered for improving training programs fit to the demands of firefighting work and the daily challenges faced.

Acknowledgments

This study was supported by grants from the Foundation for Science and Technology (in Portuguese, Fundação para a Ciência e Tecnologia) cofinanced by the European Regional Development Fund, PCIF/SSO/0082/2018, DSAIPA/DS/0041/2020, and FCT/UIDB&P/4950/2020. The authors would like to thank the Portuguese National Fire Service School (Sintra division) team and all firefighters who collaborated on this study, as well as the multimedia and reporting team, authors of the 2 images of firefighters' performance during the experiments, which were included in this work. The authors are grateful to Ana Dionísio (a former Coimbra Institute for Biomedical Imaging and Translational Research collaborator) who collaborated in experiments and supported the team during the initial virtual reality experiences. Also worthy of mention are psychologist Salomé Caldeira, PhD, and psychiatrist João Redondo, MD, from the Centre for Prevention and Treatment of Psychological Trauma, Coimbra University Hospital Centre, who provided expertise in the stress and trauma field. The authors also thank the Portuguese authors who gave permission for using the instruments used in this study. Finally, the authors would like to acknowledge the FLAIM systems team, who provided technical support for the FLAIM Trainer simulator system, in particular to James Mullins and Martijn Boosman. No generative artificial intelligence was used in any portion of manuscript writing.

Data Availability

The datasets generated during and analyzed during this study are not publicly available due the use of personal psychological evaluation data but are available from the corresponding author on reasonable request.

Authors' Contributions

VR and RP were responsible for recruitment by contacting the fire stations and scheduling participants' sessions at the Portuguese National Fire Service School. JO, JAD, RC, MS, and MC-B designed the study with validation from VR and RP. JO designed the neuropsychological protocol with direct collaboration from JAD. JO, JAD, RC, DS, and DA collected the data. JAD organized the database with direct collaboration from JO. JAD performed the statistical analysis. MC-B, JO, and JAD wrote sections of the manuscript. All authors contributed to manuscript revision and read and approved the submitted version.

Abstract

Background: Incentive salience processes are important for the development and maintenance of addiction. Eye characteristics such as gaze fixation time, pupil diameter, and spontaneous eyeblink rate (EBR) are theorized to reflect incentive salience and may serve as useful biomarkers. However, conventional cue exposure paradigms have limitations that may impede accurate assessment of these markers.

Objective: This study sought to evaluate the validity of these eye-tracking metrics as indicators of incentive salience within a virtual reality (VR) environment replicating real-world situations of nicotine and tobacco product (NTP) use.

Methods: NTP users from the community were recruited and grouped by NTP use patterns: nondaily (n=33) and daily (n=75) use. Participants underwent the NTP cue VR paradigm and completed measures of nicotine craving, NTP use history, and VR-related assessments. Eye-gaze fixation time (attentional bias) and pupillometry in response to NTP versus control cues and EBR during the active and neutral VR scenes were recorded and analyzed using ANOVA and analysis of covariance models.

Results: Greater subjective craving, as measured by the Tobacco Craving Questionnaire–Short Form, following active versus neutral scenes was observed ($F_{1,106}$=47.95; P<.001). Greater mean eye-gaze fixation time ($F_{1,106}$=48.34; P<.001) and pupil diameter ($F_{1,102}$=5.99; P=.02) in response to NTP versus control cues were also detected. Evidence of NTP use group effects was observed in fixation time and pupillometry analyses, as well as correlations between these metrics, NTP use history, and nicotine craving. No significant associations were observed with EBR.

Conclusions: This study provides additional evidence for attentional bias, as measured via eye-gaze fixation time, and pupillometry as useful biomarkers of incentive salience, and partially supports theories suggesting that incentive salience diminishes as nicotine dependence severity increases.

Introduction

Automatic appetitive motivational processes are emphasized as critical components in the development and maintenance of substance addiction (eg, dual-process theories [1,2], incentive salience theory [3,4], Tiffany's model [5], and incentive-habit model [6]). Preclinical and human investigations frequently rely on the use of cue exposure paradigms to elicit these motivational processes in the laboratory. The cue exposure paradigm is largely grounded in associative learning principles, which posit that repeated pairing of specific stimuli and substance consumption produces conditioned reinforcement such that the stimuli become conditioned cues capable of eliciting motivational or incentive salience for the substance [7]. Incentive salience can be a conscious or unconscious process and is defined as the motivation for a reward resulting from the integration of one's current physiological state and previously learned associations about the reward cue [8]. Subjective craving for substances is thought to reflect the conscious product of high levels of incentive salience [3,4].

Despite this conceptual coherence, a lack of ecological validity in traditional cue exposure paradigms limits our ability to accurately test and interpret incentive salience outcomes. Attempts have been made to improve the potency of cues and the ecological validity of cue-reactivity designs (eg, [9,10]), yet cue exposure studies typically present the cues in isolation, outside of the context of usual use in natural environments (eg, 2D images or single cigarettes). This isolation of cues limits the ability to invoke a *true* craving state in the lab [11,12] and potentially contributes to poor generalization to the real world [13]. Through greater immersion and interaction within typical contexts of use (eg, the presence of others within a setting where the substance is commonly taken), paradigms using virtual reality (VR) technology have greatly enhanced our ability to elicit craving for various substances in the laboratory [12,14-18], including tobacco [19-22]. Further, VR cue exposure paradigms show great promise as treatment platforms by promoting individualized and accessible care, and allowing for the experience of social immersion and reaction to cues within relevant contexts [23]. Thus, VR cue exposure paradigms represent generalizable tasks with substantial potential for utilization within addiction-related research and clinical settings.

Recent technological advances in VR implementation also allow for precise inline assessment of eye-related measures during cue exposure. The integration of eye-tracking technology into the VR headset is a substantial improvement from previous eye-tracking applications that require inadequate camera placement for precision eye tracking, resulting in partial blockage of the field of view. With this improved technology, it is possible to extract several eye-related measurements that are theoretically related to automatic appetitive motivational processes such as incentive salience and subjective craving; these are attentional bias, pupillary responses, and spontaneous eyeblink rate (EBR).

Attentional bias, or the allocation of a disproportionate amount of time attending to substance-related stimuli relative to neutral stimuli, is thought to either cause or index critical processes responsible for substance-seeking behavior [24]. Several theoretical models suggest that cue-induced subjective craving and attentional bias reflect closely linked underlying processes [3,25,26], such that the degree of attentional bias toward reward cues correlates with the motivational, as opposed to the hedonic, qualities of the reward [27]. Clinically, attentional bias to smoking cues is linked to relapse following smoking cessation [28,29] and was found to be even more predictive of relapse than withdrawal symptoms, subjective craving, and low mood during acute abstinence [29]. Recently, the use of direct eye-tracking indices of attentional bias has shown substantial improvements in bias estimate reliability [30-33]. Assessment within naturalistic settings has also independently improved the reliability [34] and validity [35] of attentional bias measurement, yet the naturalistic constraints of these methods prohibit advanced clinical application. Thus, eye-tracking indices of attentional bias within naturalistic, yet clinically feasible settings, may be especially useful as biomarkers of the incentive salience/craving phenomenon in substance addiction.

Pupillary responses and EBR represent two lesser-studied eye characteristics with theoretical ties to incentive salience processes that warrant further study as potential biomarkers of addiction. Pupil diameter has been associated with engagement of cognitive resources [36], sensitivity to rewards [37], and reward processing broadly [38]. Pupil diameter changes indicate fluctuations in attention allocation and are suggested as a measure of attention-related constructs that do not reach the threshold of overt behavior or conscious appraisal [39]. Only one study has investigated pupillometry as a measure of response to substance cue exposure in humans and found that pupillary bias toward alcohol versus neutral cues, but not subjective craving reports, predicted relapse to alcohol use in a sample of detoxified patients with alcohol dependence [40].

EBR has been linked with striatal dopaminergic function in preclinical models and has been advanced by some as a reliable alternative to the assessment of dopaminergic functioning via positron emission tomography [41]. Dopamine release in the basal ganglia is theorized to inhibit the spinal trigeminal complex, consequently triggering increased EBRs [42]. Given the observed modulation of striatal dopamine during cue exposure [43], it may be possible to detect these dopaminergic fluctuations through EBR measurement. Yet, outside of our preliminary report on this sample [44], this hypothesis has not yet been tested.

This study sought to investigate the validity of these eye characteristics as markers of incentive salience acquired during a novel real-world VR nicotine and tobacco product (NTP) cue exposure paradigm across NTP users with varying degrees of use. An initial report was published by our group early on during data collection (N=31) [44] that described the development of the NTP cue VR paradigm and provided preliminary results supporting the potential of this paradigm as an effective lab-based cue exposure task, including its ability to elicit subjective craving and a sense of presence in the virtual world. The present study provides an update to this preliminary report with a larger sample of daily and nondaily users of NTPs (N=108). It was hypothesized that eye-based markers of attentional bias, pupillometry, and EBR would be greater in response to NTP cues compared with control cues presented during the VR NTP cue exposure paradigm and that these measures would correlate with subjective craving and measures of past NTP use.

Methods

Participant Recruitment and Screening Procedures

As previously described [44], participants were recruited through flyers and social media posts (eg, Facebook, Craigslist, and San Diego Reader) targeting the San Diego community. A brief telephone screening interview was used to determine initial eligibility. Inclusion criteria for the study were ages ≥18 years, at least weekly NTP use during the past 3 months, and NTP use history ≥1 year. Exclusionary criteria were nonfluency in English, medical or psychiatric history affecting brain development (ie, current severe *Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition; *DSM-5*] psychiatric disorders other than tobacco use disorders, severe head trauma with loss of consciousness >2 minutes, or history or treatment of neurologic disorders), and (3) visual problems that interfere with task completion (eg, severe motion sickness and blindness). NTP use was defined as use of any tobacco (eg, cigarette, cigar, or hookah) or electronic nicotine delivery system (eg, e-cigarette or vaporizer). NTP use groups were defined as daily users (average use of 7 days per week in the past 3 months) and nondaily users (average use of 4 - 27 days per month in the past

3 months). The distinction between daily and nondaily users is supported by the literature, confirming that regular, voluntary, nondaily users of tobacco do not smoke often enough to regulate nicotine levels and evince less tobacco dependence and cue-induced craving as compared to daily users [45-47].

Eligible participants were invited into the laboratory and instructed to bring their NTPs with them for use immediately after the visit to control for effects related to expectations of imminent substance availability [48]. Participants were asked to abstain from NTP use for at least 1 hour prior to their visit, resulting in VR testing at least 2 hours post use (the average half-life of nicotine in body tissues [49]), and all other substance use (including alcohol and cannabis use) for at least 24 hours prior to testing. Abstinence was self-reported as COVID-19 restrictions did not allow for biological verification.

Ethical Considerations

Participants received a detailed explanation of study procedures and provided written informed consent consistent with the University of California, San Diego Institutional Review Board policies upon arrival to the laboratory (UCSD IRB #180719). Participant data were deidentified. Participants received US $50 cash for completing the in-person session and up to US $60 in gift cards for completing the follow-up portion of the research (not presented here).

Psychological and Substance Use Measures

Prior to undergoing the NTP cue VR paradigm, participants underwent a clinical interview to assess psychological health (Mini International Neuropsychiatric Interview for *DSM-5* [50]) and completed self-report questionnaires encompassing basic demographic information, previous VR experience, and other measures of psychological functioning not reported here.

The 90-day timeline follow-back (TLFB) [51] and Customary Drinking and Drug Use Record [52] interviews were administered to assess substance use history (including recency since last NTP use in minutes). The TLFB has high test-retest reliability for intervals ranging from 30 to 360 days prior to the interview date, with an intraclass correlation coefficient of 0.92 for "Total number of cigarettes smoked per interval" [53]. The Population Assessment of Tobacco and Health (PATH) tobacco dependence index [54], with a range of 0 - 80, was administered to assess nicotine dependency across nicotine products. Subjective craving before and after the VR paradigm was assessed via the Tobacco Craving Questionnaire–Short Form (TCQ-SF) [55], modified to reference participants' preferred nicotine product (eg, e-cigarettes and tobacco cigarettes). The TCQ-SF has demonstrated reliability (Cronbach α coefficients >0.69 across subscales) and validity, and has been shown to reliably measure the same multidimensional aspects of tobacco craving as the original TCQ when tested following overnight abstinence and during ad libitum smoking [55]. Pre- and post-VR TCQ-SF scores and previous 90-day NTP use episode count from the TLFB (logged transformed due to skewness) were used in the quantitative analyses presented below. REDCap electronic data capture tools hosted at the University of California, San Diego were used for interview and self-report data collection.

Following completion of the NTP cue VR paradigm, participants were assessed on VR presence (Igroup Presence Questionnaire [IPQ] [56]) and VR-related simulator motion sickness (Simulator Sickness Questionnaire [SSQ] [57]). The IPQ total score was calculated using a simple averaging method to obtain a perceived presence score ranging from 0 to 100. The SSQ was scored in concordance with procedures outlined to assess VR-specific sickness (Virtual Reality Sickness Questionnaire) [58], involving a simple averaging method to obtain a score ranging from 0 to 100.

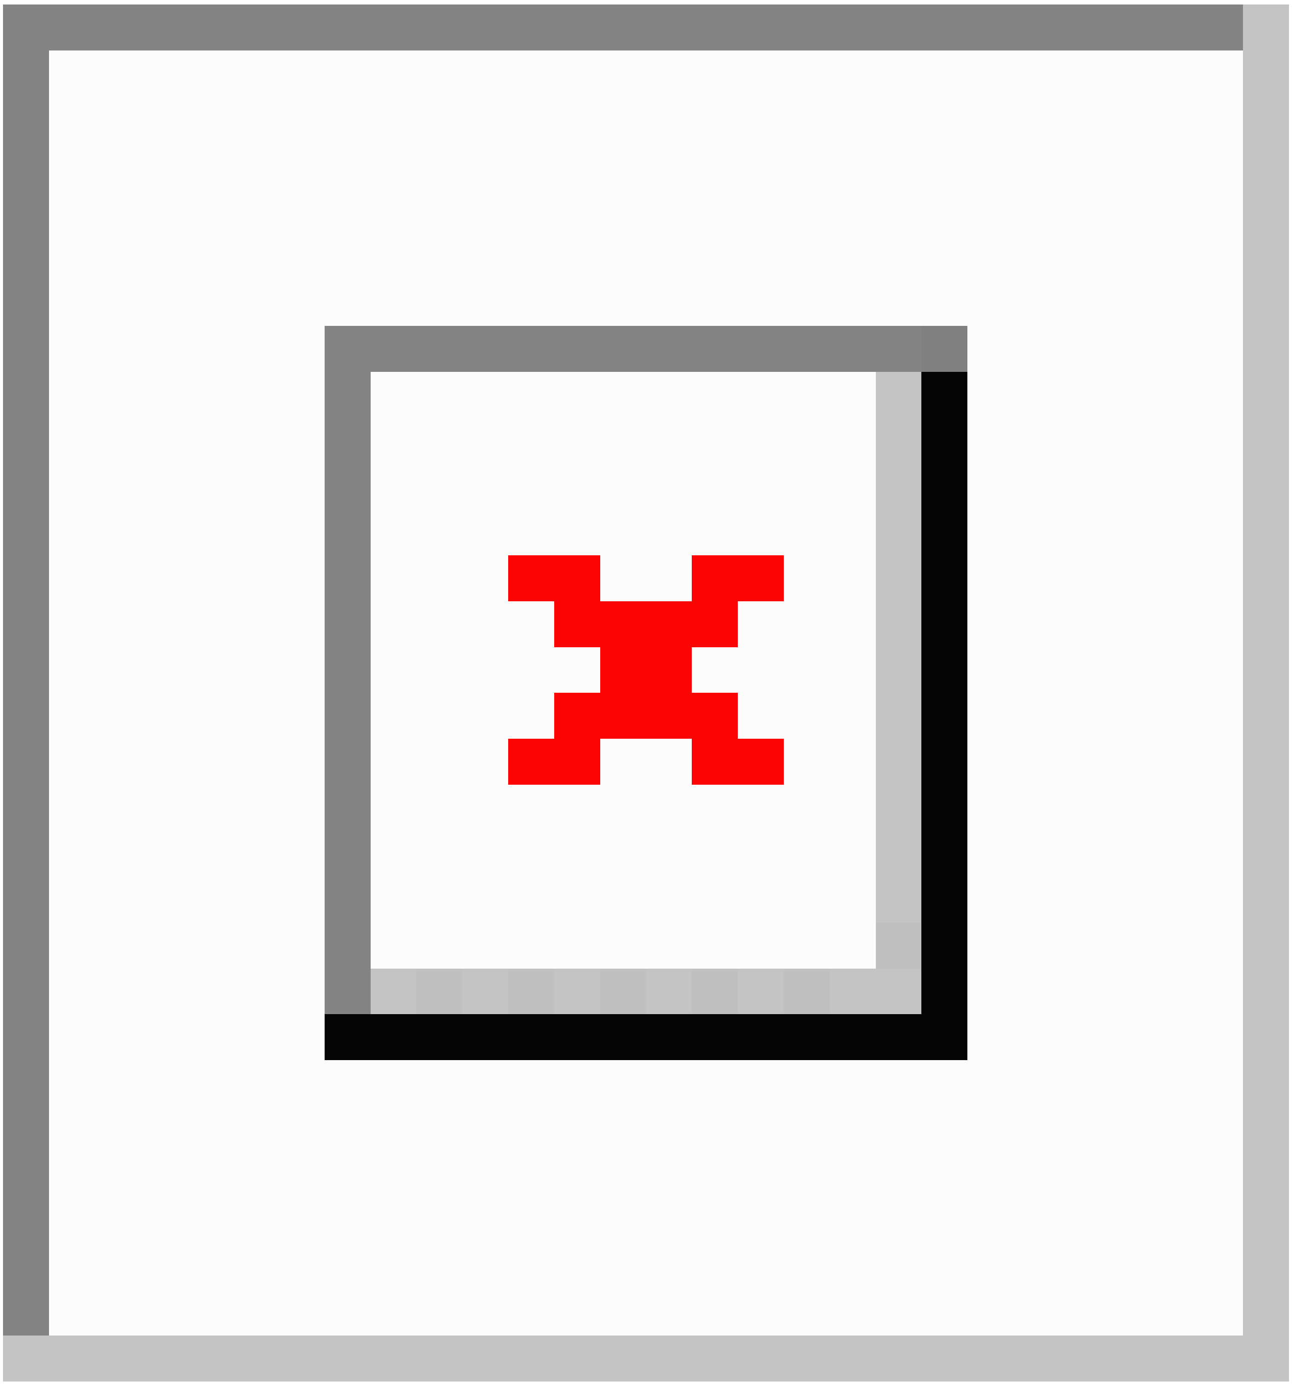
NTP Cue VR Paradigm

As previously detailed [44], the HTC VIVE Pro Eye VR headset (HTC, Taoyuan City, Taiwan) was used to enable VR capabilities and collect eye-related data during the NTP cue VR paradigm (built in Unity). HTC's SRanipal SDK [59] was used in conjunction with Tobii's XR SDK (Tobii Technology, Stockholm, Sweden) to provide access to data from the eye tracker. Specifically, Tobii's XR SDK and Gaze-to-Object-Mapping (G2OM) algorithm were applied to determine object selections, while the remaining data were retrieved from the SRanipal SDK.

Initially, 3 active scenes containing control and NTP-related cues (driving, patio, outdoor BBQ) and 3 neutral scenes containing only control cues (bus, waiting room, library) were developed. However, after preliminary testing of the paradigm, 1 active and 1 neutral scene were removed due to inconsistent eye-gaze effects and increased VR-related sickness (driving, bus; see Liu et al [44] for additional details). All active scenes contained multiple types of NTPs (see Liu et al [44] for a detailed description of the scenes). Thus, the data presented below are derived from the remaining 2 active (patio, outdoor BBQ) and 2 neutral (waiting room, library) scenes (Figure 1). Importantly, the selection of the study outcomes was done prior to any data acquisition and thus was not affected by removal of the scenes.

During the paradigm, participants were encouraged to move around in the virtual scenes via teleportation and interact with cue objects using two handheld VIVE controllers. Virtual visual analog scales assessing subjective craving ("How much are you craving nicotine right now?") and scene relevance ("How relevant was that scene to your own life?") were presented between scenes, and responses were made by adjusting a slide bar using one of the controllers. Participants were instructed to "Just explore everything around you until the scene changes."

Figure 1. Screenshots of the four final scenes from the nicotine and tobacco product cue virtual reality paradigm. Neutral scenes include the (A) library and (B) waiting room. Active scenes include the (C) outdoor BBQ and (D) patio. The figure is adapted from the initial task development report [44], which is published under Creative Commons Attribution 4.0 International License [60].



Gaze Statistics Calculation

A combination of the G2OM algorithm provided by Tobii's XR SDK, a machine learning–based mapping algorithm that aims to improve small object and fast-moving object tracking, and naive ray-casting was used to enable object selection in the direction of the gaze [61]. Specifically, to ensure adequate performance without detrimentally affecting the frame rate, the G2OM algorithm provided by Tobii's XR SDK was used only for the detection of the interactable objects (including all NTPs and control cues), and the naive ray-casting was used for the detection of background and other nonmovable large objects. In addition, when a virtual object was interacted with via the controllers, the object selection was "locked" until the object was released, thus reducing eye-gaze errors due to rapid movement and microsaccades.

Given the complexity of the dynamic virtual environment, eye fixations were defined based on functionality—the duration of eye gaze intersection with the selected object of interest. The total object fixation number and total object fixation time (dwell time) were summed within each cue category (NTP and control) for each scene. Mean fixation time (total fixation time/object fixation number) indices were then created within each cue category for each scene and averaged across the scenes. Mean NTP versus control cue fixation and fixation time contrast scores from the active scene metrics were calculated for use in the exploratory analyses described below.

Pupil Diameter and Blink Detection

Pupil diameter was recorded continuously throughout the paradigm and mapped to each object identified via Tobii's G2OM algorithm. Pupil diameter was summed within each cue category (NTP and control) for each scene. Mean pupil diameter indices were then created by averaging over the mapped pupil diameter samples within each cue category for each scene and averaged across the scenes. Mean NTP versus control cue pupil diameter contrast scores (mean NTP cue diameter – mean control cue diameter) from the active scene metrics were calculated for use in exploratory analyses.

Consistent with previous studies, an eyeblink was defined as complete eyelid closure (or missing pupil diameter) with the pupil covered for 50 - 500 milliseconds [62,63]. Total EBRs were summed within each scene and averaged within scene type (active and neutral). Mean active versus neutral scene EBR contrast scores (mean active scene EBR – mean neutral scene EBR) were calculated for use in exploratory analyses.

Statistical Analysis

Statistical analyses for demographic differences between NTP use groups were conducted using one-way ANOVA models. Analyses for the main outcomes were conducted using repeated measures ANOVAs, followed by analyses of covariance controlling for age and sex. Interactions between NTP use group and cue/scene type as well as their main effects were estimated. Estimated marginal means (EMMs) are reported for the main effects that control for the other variable of interest (ie, NTP use group or cue/scene type) in the model. Analyses of preliminary reliability estimates across scenes were conducted using Pearson correlations. A significance threshold of $P<.05$ was set for all primary analyses.

Exploratory investigations of relationships between the objective outcomes (ie, total fixations, mean gaze fixation time, pupil diameter, and EBR) and subjective craving (pre-VR, during VR, post-VR), recency of NTP use (minutes since last NTP use at time of testing), and previous 90-day NTP use utilized Pearson correlations and partial correlations. Bonferroni-corrected *P* value thresholds that corrected for the tests of the 3 subjective craving and 2 NTP use variables per objective outcome were calculated ($P_{corr}<.01$). Follow-up analyses computed correlations within NTP use groups, transformed the *r* values into *z* scores using Fisher *r*-to-*z* transformation, and compared the *z* values by determining the observed *z* test statistic. SPSS Statistics for Windows, version 28 (IBM Corp) software was used for all analyses.

Results

Study Sample

A total of 303 phone screenings were completed, with 193 individuals deemed eligible. The primary reasons for ineligibility were low/no NTP use (32 screenings) and severe psychiatric comorbidity/psychotropic medication use (39 screenings). Many eligible screenings were not enrolled due to COVID-19 restrictions/cancellations at the time. Of the 115 participants who completed the protocol, 108 participants had usable eye fixation data, 104 had pupillometry data, and 106 had EBR data (excluded participants had calibration or technical issues with the eye-tracking hardware/software).

Demographic information for the sample of 108 with eye fixation data is presented in Table 1. In general, the sample contained slightly more male participants (n=61, 56.5%) and predominately self-identified as White (n=60, 55.6%), and 58.3% (n=63) had no or very limited (one time) previous experience with VR. Of the full sample, 56.5% (n=61) were predominately e-cigarette or nicotine vaporizer users; however, 68.5% (n=74) of the sample reported smoking a tobacco cigarette, and 77.8% (n=84) reported use of any combustible tobacco product (cigarette, cigar, pipe, or hookah) within the previous 6 months. Daily and nondaily NTP use groups were not found to differ in type of NTP use (*P* values >.25).

Table . Sample demographics by nicotine and tobacco product (NTP) use group and total sample.

Variable		NTP use group		Total (N=108)
		Nondaily (n=33)	Daily (n=75)	
Age (years), mean (SD)		30.76 (12.58)	31.92 (12.75)	31.56 (12.65)
Sex, n (%)				
	Female	14 (42.4)	33 (44.0)	47 (43.5)
	Male	19 (57.6)	42 (56.0)	61 (56.5)
Ethnicity: White, n (%)		21 (63.6)	39 (52.0)	60 (55.6)
Education: college level, n (%)		31 (93.9)	63 (84.0)	94 (87.0)
Previous VR[a] experience, n (%)				
	Never	17 (51.5)	26 (34.7)	43 (39.8)
	Once	5 (15.2)	15 (20.0)	20 (18.5)
	A few times	7 (21.2)	27 (36.0)	34 (31.5)
	Many times	4 (12.1)	7 (9.3)	11 (10.2)
Combustible tobacco product user (predominately), n (%)		18 (54.5)	29 (38.7)	47 (43.5)
NTP use days (previous 90 days)[b], mean (SD)		33.91 (21.57)	89.79 (0.76)	72.71 (28.43)
NTP use episodes (previous 90 days)[b], mean (SD)		161.82 (180.85)	2145.92 (2633.99)	1539.67 (2376.99)

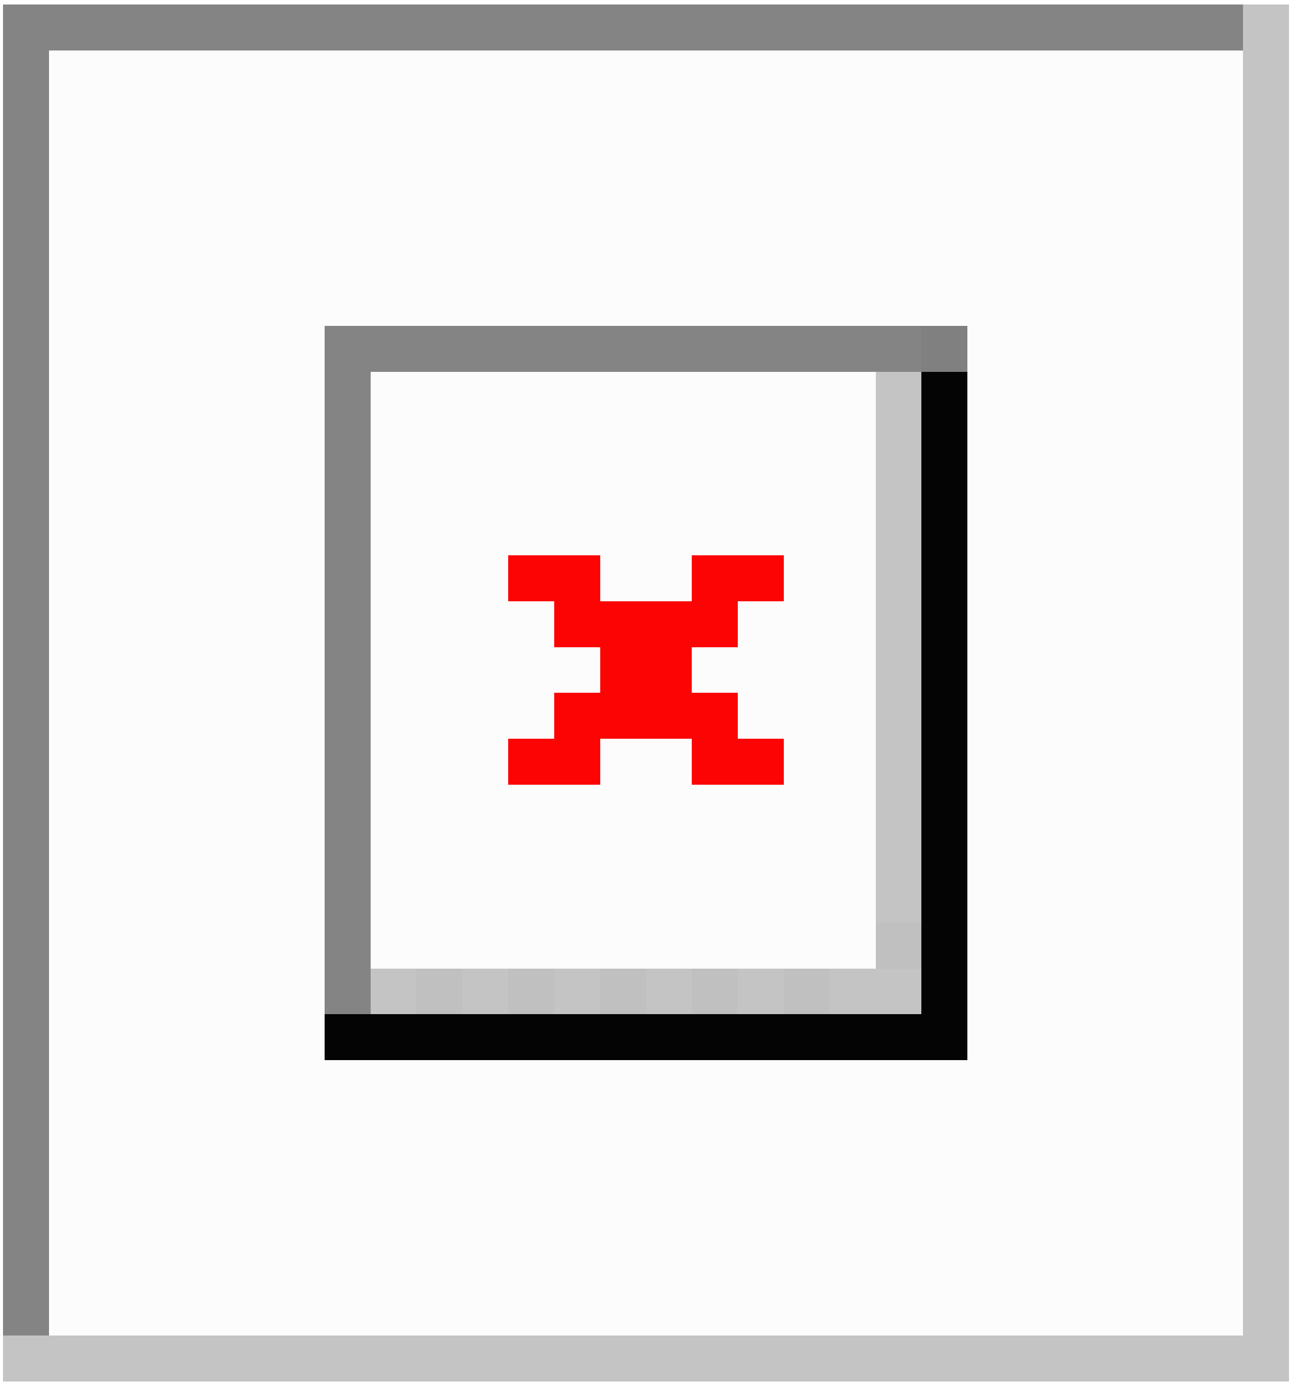
Subjective Craving

Results of the ANOVA investigating subjective craving during the paradigm revealed significant effects of scene condition ($F_{1,106}$=47.95; P<.001; η_p^2=0.31) and NTP use group ($F_{1,106}$=16.91; P<.001; η_p^2=0.14) on craving. No interaction between scene condition and NTP use group was observed ($F_{1,106}$=0.03; P=.87; η_p^2<0.001). Specifically, active scenes (EMM 46.50, SE 3.11) elicited greater subjective craving than neutral scenes (EMM 31.89, SE 2.92; Figure 2), and daily users reported greater subjective craving across scenes (EMM 50.81, SE 3.12) than nondaily users (EMM 27.59, SE 4.70). Controlling for age and sex in this analysis reduced the main effect of scene condition ($F_{1,104}$=4.16; P=.04; η_p^2=0.04) but not NTP use group ($F_{1,104}$=17.63; P<.001; η_p^2=0.15). Age and sex were not found to be significant predictors of subjective craving either via direct effects or interactions (*P* values >.05). Subjective craving ratings were found to positively correlate between the ratings following the 2 active scenes (r=0.844; P<.001) and between the ratings following the 2 neutral scenes (r=0.816; P<.001).

Figure 2. Mean subjective craving ratings averaged across active and neutral scenes by NTP use group. Error bars indicate a 95% CI. NTP: nicotine and tobacco product.



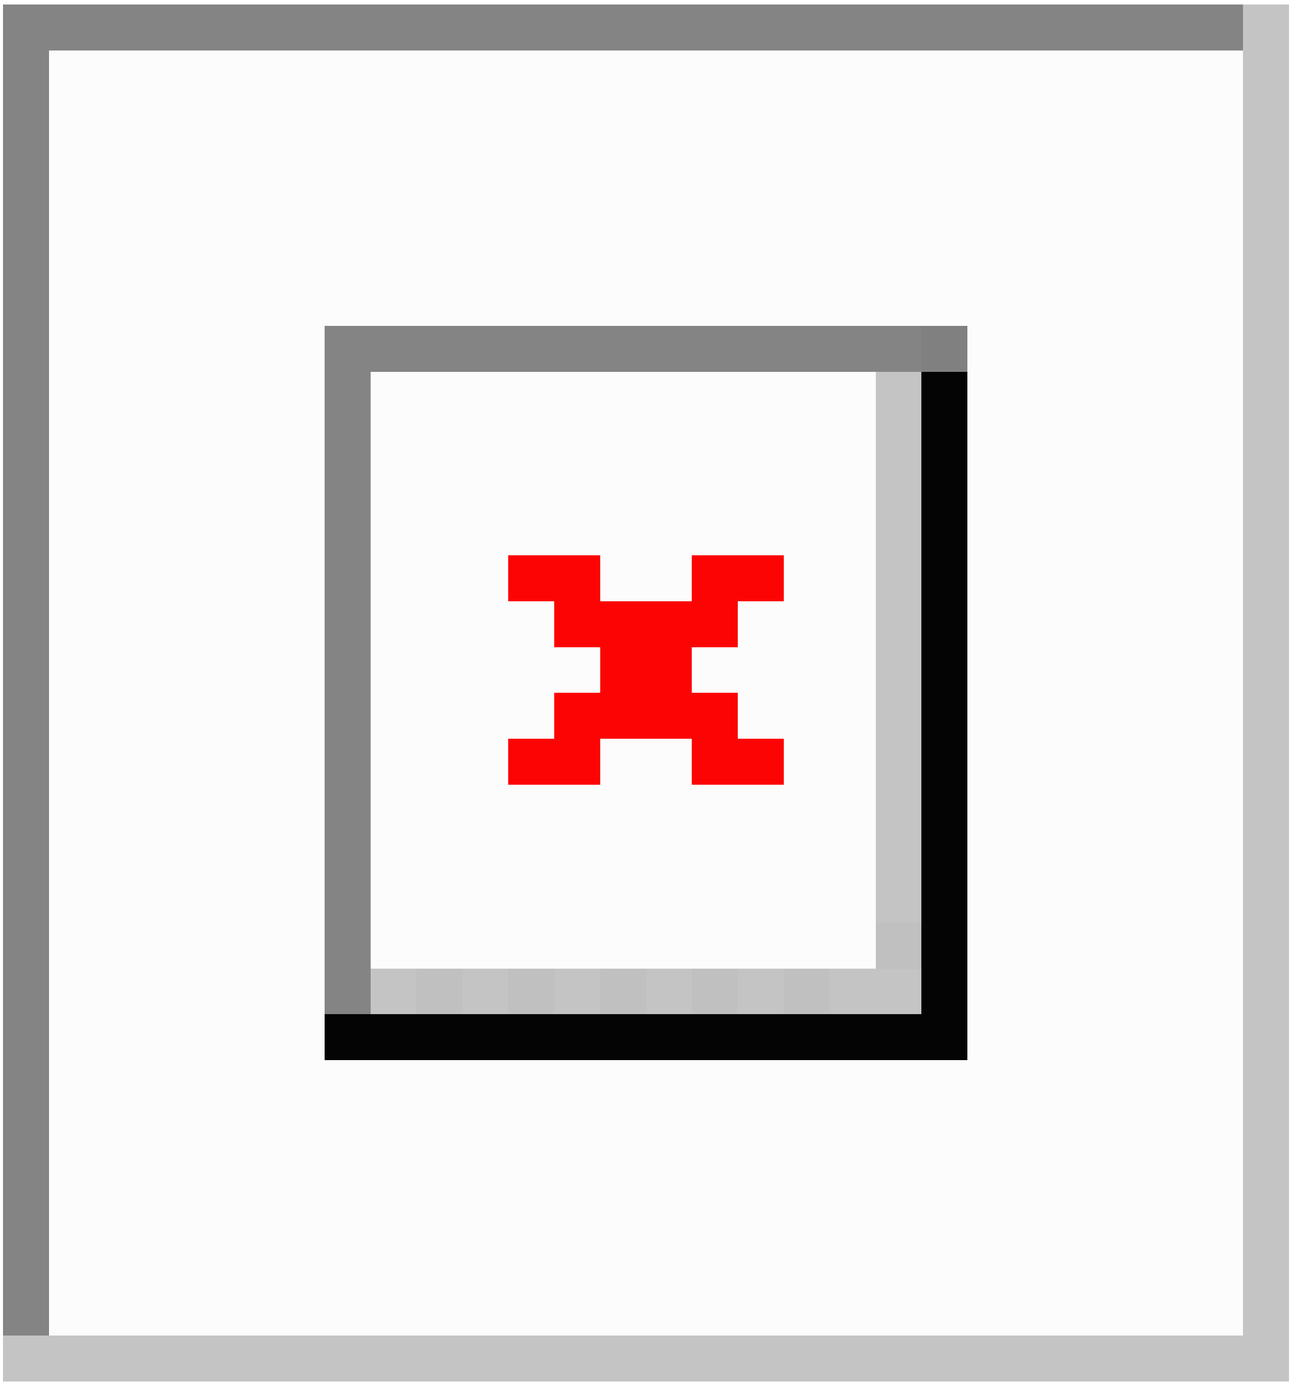
Total Cue Eye-Gaze Fixations

Results of the ANOVA investigating total cue eye-gaze fixations during the paradigm revealed a significant effect of cue type on number of fixations during the active scenes ($F_{1,106}$=1353.18; *P*<.001; η_p^2=0.93). No effect of NTP use group ($F_{1,106}$=0.03; *P*=.85; η_p^2<0.001) or interaction between cue type and NTP use group ($F_{1,106}$<0.001; *P*=.98; η_p^2<0.001) were observed. Specifically, NTP cues were associated with fewer total fixations (EMM 12.91, SE 0.21) as compared to control cues (EMM 48.11, SD 1.00). Controlling for age and sex in this analysis reduced, but did not eliminate, the main effect of cue type ($F_{1,104}$=175.04; *P*<.001; η_p^2=0.63). Further, there was a significant interaction observed between cue type and sex ($F_{1,104}$=8.40; *P*=.005; η_p^2=0.07), whereby male participants engaged in more total fixations toward control cues (EMM 50.07, SE 1.19) as compared to female participants (EMM 45.67, SE 1.35), yet their total fixations toward NTP cues were similar (male participants: EMM 12.69, SE 0.24; female participants: EMM 13.28, SE 0.28). Borderline main effects of age ($F_{1,104}$=3.69; *P*=.06; η_p^2=0.03) and sex ($F_{1,104}$=3.81; *P*=.05; η_p^2=0.03) were also observed. When comparing the 2 active scenes, total cue eye-gaze fixations were found to positively correlate for the NTP cues (r=0.347; P<.001) and control cues (r=0.657; P<.001).

Mean Eye-Gaze Fixation Time (Attentional Bias)

Results of the ANOVA investigating mean eye-gaze fixation time (attentional bias) during the paradigm revealed a significant effect of cue type on fixation time during the active scenes ($F_{1,106}$=48.34; P<.001; η_p^2=0.31) and some support for a NTP use group effect ($F_{1,106}$=3.31; P=.07; η_p^2=0.03; Figure 3). No interaction between cue type and NTP use group was observed ($F_{1,106}$=0.31; P=.58; η_p^2=0.003). Specifically, NTP cues were associated with greater mean fixation times (EMM 3557.79, SE 163.36 ms) as compared to control cues (EMM 2225.54, SE 87.34 ms), and daily users demonstrated greater mean fixation times across cue type (EMM 3054.09, SE 98.75) as compared to nondaily users (EMM 2729.24, SE 148.87). Controlling for age and sex in this analysis reduced, but did not eliminate, the main effect of cue type ($F_{1,104}$=14.32; P<.001; η_p^2=0.12), and the NTP use group effect was largely unchanged ($F_{1,104}$=3.53; P=.06; η_p^2=0.03). Age and sex were not found to be significant predictors of mean eye-gaze fixation time either via direct effects or interactions (P values >.05). When comparing the 2 active scenes, mean eye-gaze fixation times were found to positively correlate for the NTP cues (r=0.261; P=.006) and control cues (r=0.462; P<.001).

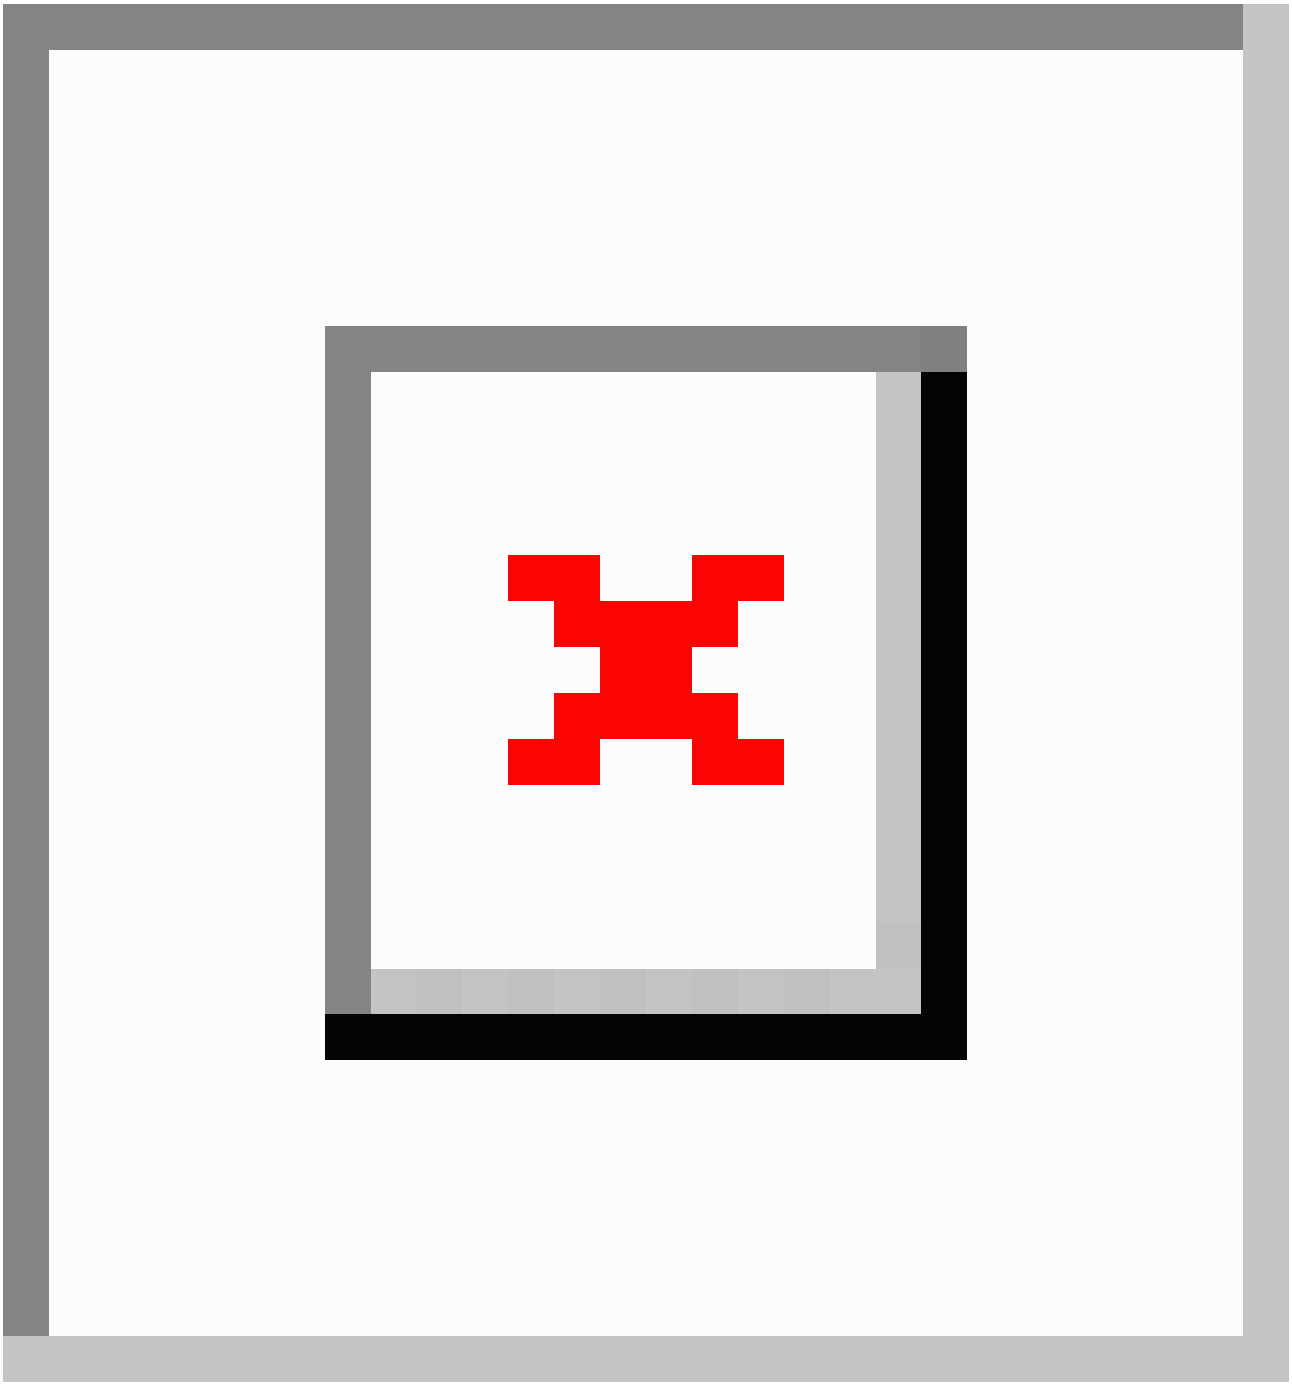
Figure 3. Mean eye-gaze fixation time averaged across NTP and control cues by NTP use group. Error bars indicate a 95% CI. NTP: nicotine and tobacco product.



Pupil Diameter

Results of the ANOVA investigating mean pupil diameter during the paradigm revealed a significant effect of cue type on mean pupil diameter during the active scenes ($F_{1,102}$=5.99; *P*=.02; η_p^2=0.05) and some support for an interaction between cue type and NTP use group ($F_{1,102}$=3.38; *P*=.07; η_p^2=0.03; Figure 4). No NTP use group main effect was observed ($F_{1,102}$<0.001; *P*=.99; η_p^2<0.001). Specifically, NTP cues were associated with greater pupil diameter (EMM 3.86, SE 0.07 mm) as compared to control cues (EMM 3.81, SE 0.07 mm) across groups, but only the nondaily use group displayed a significant difference between cue types (nondaily mean difference 0.09, SE 0.03; *P*=.01; daily mean difference 0.01, SE 0.02; *P*=.57). Controlling for age and sex in this analysis reduced the main effect of cue type ($F_{1,100}$=2.25; *P*=.14; η_p^2=0.02) and the interaction between cue type and NTP use group ($F_{1,100}$=3.26; *P*=.07; η_p^2=0.03). A main effect of age on pupil diameter was also observed ($F_{1,100}$=18.36; *P*<.001; η_p^2=0.16). When comparing the 2 active scenes, pupil diameters were found to positively correlate for the NTP cues (*r*=0.793; *P*<.001) and control cues (*r*=0.765; *P*<.001).

Figure 4. Mean pupil diameter averaged across NTP and control cues by NTP use group. Error bars indicate a 95% CI. NTP: nicotine and tobacco product.



Spontaneous Eyeblink Rate

Results of the ANOVA investigating mean EBR found no significant differences between EBR during active and neutral scenes ($F_{1,104}$=0.50; *P*=.48; η_p^2=0.005) or between NTP use groups ($F_{1,104}$=0.17; *P*=.68; η_p^2=0.002), nor a significant interaction ($F_{1,104}$=0.37; *P*=.54; η_p^2=0.004). Controlling for age and sex in this analysis resulted in no change to the relationships. Age and sex were not found to be significant predictors of EBR either via direct effects or interactions (*P* values >.05). EBRs were found to positively correlate between the 2 active scenes (*r*=0.635; *P*<.001) and between the 2 neutral scenes (*r*=0.567; *P*<.001).

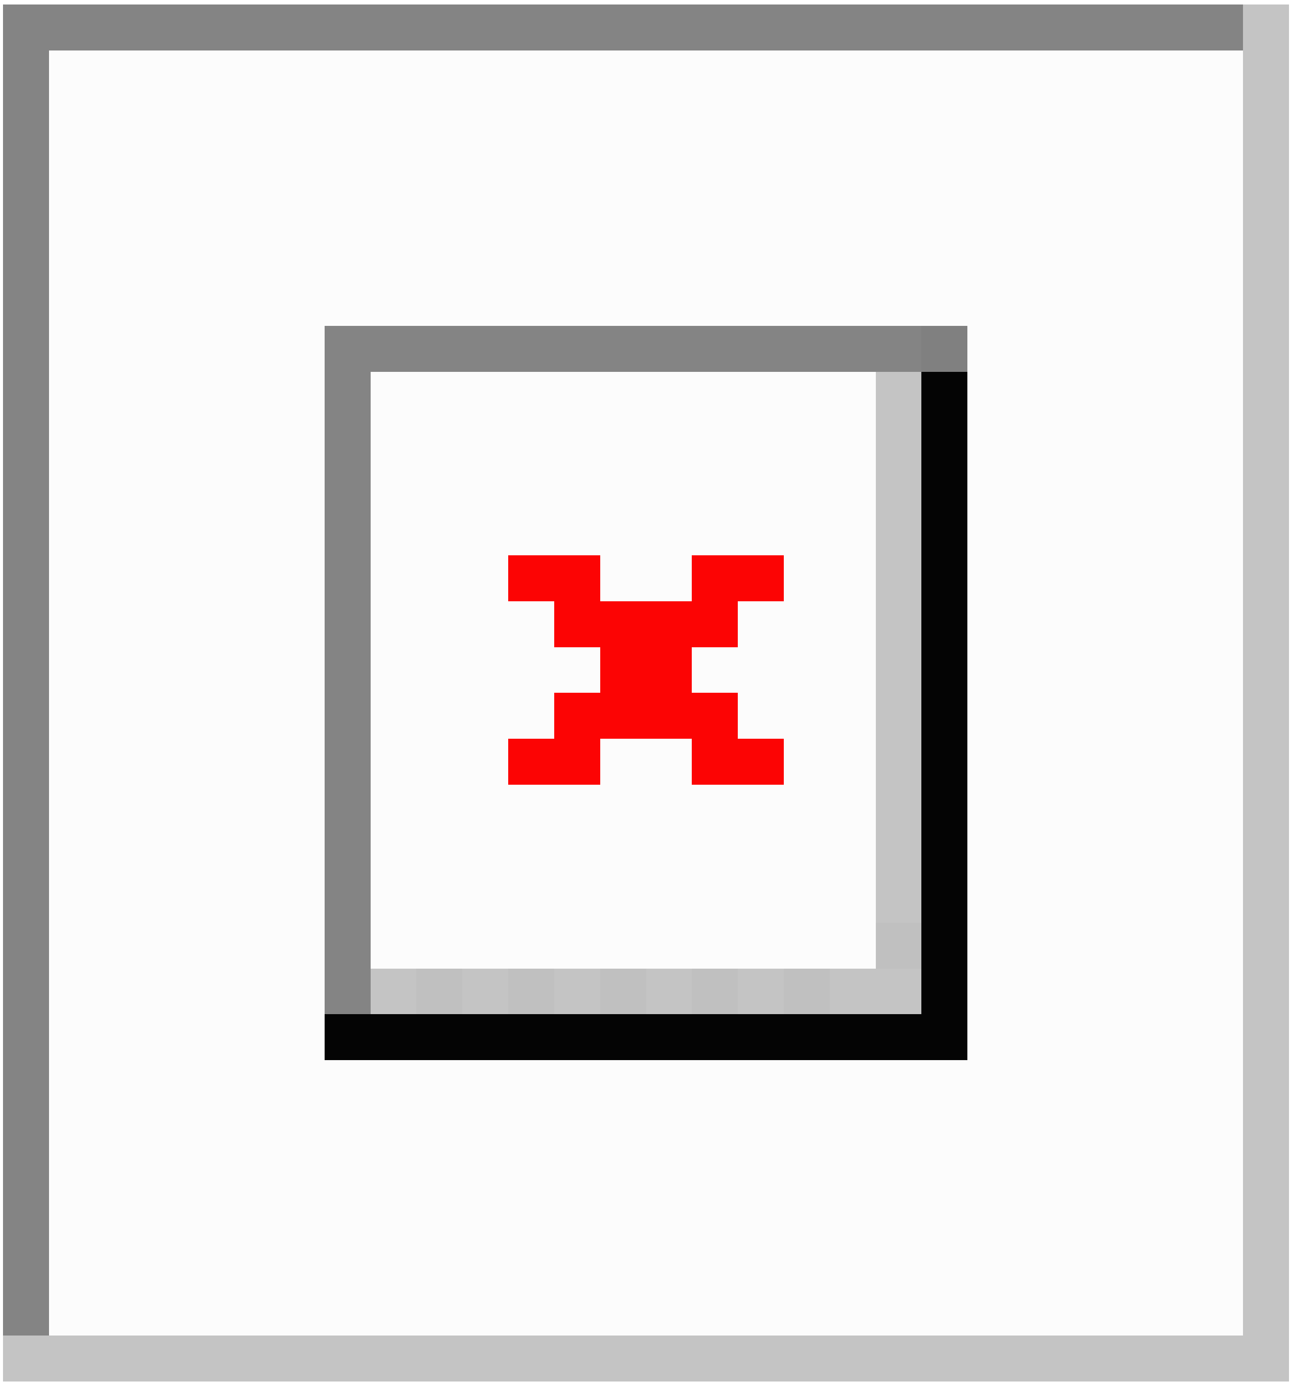
Relationship to NTP Subjective Craving and Use

Mean NTP versus control cue fixation time contrast scores (attentional bias scores) were found to positively correlate with subjective craving assessed within the paradigm (*r*=0.19; *P*=.04) and with the TCQ-SF administered pre- (*r*=0.18; *P*=.06) and post-VR paradigm (*r*=0.22; *P*=.02). Comparison of correlations between NTP use groups demonstrated a significant group difference (Z_{obs}=2.48; *P*=.007), with the nondaily group demonstrating a stronger positive correlation (*r*=0.57; *P*=.001) compared to the daily group (*r*=0.10; *P*=.38) in TCQ-SF scores post-VR paradigm (Figure 5). Similar group relationships held for the other craving metrics. Follow-up analyses investigating mean cue fixation time separately by cue type (NTP and control) in the full sample revealed that the positive correlations with all three subjective craving ratings were driven primarily by mean NTP cue fixation times (*r* values=0.21-0.28; *P* values <.03), as opposed to control cue fixation times (*r* values=0.02-0.03; *P* values >.76). The mean NTP versus control cue fixation time contrast score (attentional bias) was not found to correlate with previous 90-day NTP use (*r*=0.05; *P*=.58), yet significant positive correlations with previous 90-day NTP use were observed for mean NTP cue fixation time (*r*=0.20; *P*=.03) and control cue fixation time (*r*=0.26; *P*=.007) when analyzed independently.

Mean NTP versus control cue pupil diameter contrast scores were not found to correlate with subjective craving measures across the full sample (*P* values >.20) or NTP use groups independently (*P* values >.07). Mean NTP versus control cue pupil diameter was found to negatively correlate with previous 90-day NTP use (*r*=–0.20; *P*=.04), yet no significant correlations with previous 90-day NTP use were observed for the NTP (*r*=0.09; *P*=.37) or control cue (*r*=0.15; *P*=.12) pupil diameters independently.

Partial correlations controlling for age and sex resulted in similar estimates for all analyses described above except for the correlation between mean NTP versus control cue pupil diameter contrast scores and previous 90-day NTP use, which was eliminated when age and sex were controlled for ($r_{partial}$=−0.05; *P*=.64). Total cue fixations and eyeblink rates were not found to correlate with any subjective craving measures or previous 90-day NTP use (*P* values >.05). None of the objective measures significantly correlated with recency of NTP use (*P* values >.05). None of the first-level correlations survived multiple comparison correction (Bonferroni-corrected per objective measure *P* values <.01) and, as such, must be interpreted with caution.

Figure 5. Scatterplot depicting the linear relationships between mean NTP versus control cue eye gaze fixation time contrast scores (in milliseconds) from the active scenes and subjective craving from the TCQ-SF administered post-VR paradigm by NTP use group. NTP: nicotine and tobacco product; TCQ-SF: Tobacco Craving Questionnaire—Short Form; VR: virtual reality.



Discussion

This study provides updated results on the utility of a novel VR NTP cue exposure paradigm to index incentive salience via three eye characteristic markers: eye-gaze fixation time (attentional bias), pupil diameter, and EBR in response to NTP versus control cues. Overall, the results are largely consistent with our preliminary report [44] and support two of our initial hypotheses, suggesting that measures of eye-gaze fixation time and pupil diameter, but not EBR, during VR cue exposure could be useful objective indicators of the incentive salience process in nicotine addiction.

Consistent with previous VR cue exposure investigations across a variety of substances [14-21], active VR scenes with NTP cues elicited greater subjective craving compared to neutral control scenes. Further, daily NTP users endorsed greater overall levels of subjective craving compared to nondaily users across scenes. Together these findings suggest the VR NTP cue exposure paradigm elicits subjective phasic craving in response to NTP cues and can discriminate by frequency of NTP use on this metric.

Given that the intention of the paradigm was to provide a more naturalistic and translatable context of use than standard cue exposure and attentional bias paradigms, it follows that more control versus NTP cues were present in the active scenes. As a result, greater total eye-gaze fixations toward control versus NTP cues were observed. Yet, the average gaze fixation time was found to be 1.33 seconds longer for the NTP cues compared with the control cues across the full sample, thus demonstrating attentional bias toward the NTP cues regardless of NTP use frequency. The attentional bias contrast score (mean NTP vs control cue fixation time) was also modestly, yet consistently, associated with measures of subjective craving assessed before, during, and after the VR paradigm. This was primarily driven by response to the NTP cues, as opposed to the control cues, supporting the previously established link between attentional bias, as indexed by fixation time, and subjective craving [10,30,64-66]. The culmination of fixation time results also supports the validity of the VR NTP cue exposure paradigm as suitable for measuring attentional bias toward NTP cues in a free-viewing, translatable, and ecologically valid context.

Interestingly, although no interaction between NTP use group and cue type was observed, the daily NTP users were found to fixate on all cues (NTP and control) longer (325 ms) than the nondaily users. Furthermore, no association was observed between the attentional bias contrast score and previous NTP use frequency, yet greater mean gaze fixation time to NTP and control cues were *independently* associated with greater NTP use in the previous 90 days. These results are somewhat contradictory to the findings by Mogg and colleagues [67], where greater smoking versus control fixation times were inversely associated with nicotine dependence. This discrepancy could relate to differences in tasks, as Mogg et al [67] used a visual probe task to assess eye-gaze fixation time, which presented cues in isolation, devoid of context and additional competing cues. Additionally, independent associations between cue types and dependence severity were not reported in their paper; thus, it remains unknown whether a similar relationship would have been observed in their data. Regardless, our results suggest that in the presence of additional naturalistic context and the absence of any researcher-directed task demands, individuals with varying levels of nicotine dependence evince attentional bias toward NTP cues and more frequent/dependent NTP users demonstrate prolonged attentional engagement with all salient visual cues present.

Consistent with Mogg and colleagues [67] and with subjective craving associations broadly [68], we observed stronger correlations between the attentional bias contrast score and subjective craving levels within the nondaily NTP users, as compared to the daily users. Relatedly, greater pupillary diameter was observed in response to NTP cues compared to control cues, particularly within the nondaily users. Interestingly, the NTP versus control cue pupillary response contrast was found to be negatively associated with previous NTP use, although these effects were essentially eliminated after controlling for age, a known correlate of pupil size [69]. These findings are in line with theories suggesting that appetitive motivational processes (ie, incentive salience) reduce in importance as addiction becomes more severe and habitual [5,6,67].

Taken together with our attentional bias and NTP use data, there may be additional nonselective attentional processes occurring in individuals with more severe nicotine dependence that are not routinely captured by traditional subjective and procedural tasks of attention. For example, our results may reflect an effect of prolonged nicotine use on general attentional processing in the absence of task demands and trial durations, whereby individuals with more prolonged NTP use may have delayed disengagement from any salient cue in their visual environment. These correlations appear to hold even after controlling for total number of cue fixations, suggesting this is not a product of orientation bias. Traditional tasks used to investigate attentional bias (eg, Stroop and visual probe tasks) are thought to index the delayed disengagement of attention; yet their ability to do so is limited by trial carryover effects, short durations of stimulus onset asynchrony (SOA), and task demands (eg, to shift attention based on cue location [24]). Even with tasks thought to explicitly measure disengagement, the SOA is often only 500 - 2000 milliseconds [24], yet our data suggest that when free-viewing a complex scene with many cues present, individuals spend on average 2955 milliseconds engaged and attending to one object cue irrespective of NTP use history and cue type. Thus, further investigations using these paradigms to assess attentional disengagement may benefit from increasing SOA beyond 3000 milliseconds to ensure they are capturing the entire disengagement process. Given that acute nicotine administration facilitates attention disengagement from a cued location [70], it may be possible that the reverse effect is occurring during the state of acute withdrawal in heavier users of NTPs.

This study has several strengths and limitations. Strengths include the inline assessment of eye characteristics during a translatable real-world VR NTP cue exposure paradigm with no imposed task demands, thus more accurately indexing naturalistic attentional and incentive salience processes. The inclusion of light to heavy users of various NTPs and ages increases the generalizability of the findings to the majority of current nicotine users. Limitations include the absence of biological verification to confirm self-reported NTP use due to COVID-19–related precautions, absence of prospective NTP use data, and the short duration of abstinence at the time of testing. However, substantial variability in abstinence was reported and abstinence time was not found to substantially impact the results. Still, studies investigating these effects at much longer durations of abstinence and in treatment-seeking populations may observe differing results as the salience of cues may change based on extended abstinence. Given that the active scenes differ in the amount and nature of the cues (both NTP and control), additional studies with multiple identical administrations and with prospective NTP use data are needed to adequately assess the reliability and validity of these eye-tracking indices. Lastly, given the relationship between increasing age and potential for greater addiction severity (eg, allowing for greater years of use with increasing age), future studies are needed to identify the independent contributions of age and eye-related variables (especially pupil size [69]) on NTP use outcomes.

In summary, this study represents an update to our initial paper [44], provides validation of the utility of the VR NTP cue exposure paradigm for the assessment of attentional bias as measured via eye-gaze fixation time and pupillometry, and highlights areas for further consideration in other attentional bias paradigms (eg, increasing SOA). Given that attentional bias has been shown to predict relapse following smoking cessation [28], these markers may prove useful in clinical settings by facilitating the matching of individuals who exhibit greater attentional bias with interventions targeting incentive salience processes (eg, varenicline [16,18] and mindfulness [71]). The validation of reliable biomarkers of addiction such as attentional bias could also greatly benefit treatment development by providing an earlier identification of treatment efficacy (a "fast fail" marker) in clinical trials. Broadly, markers such as attentional bias and pupil diameter have the potential to provide much needed objective measures of addiction phenotypes, thus reducing error associated with phenotyping and outcomes measurement based solely on subjective assessments.

Abstract

Background: The COVID-19 pandemic has had a severe impact on students' mental health. Interventions are needed to promote their psychological well-being and prevent mental illnesses in the aftermath of this unprecedented situation. Digital escape games can be an effective tool to support students' mental health. A cocreation approach can improve the acceptability of these interventions by involving different stakeholders (eg, end users, game designers, and health professionals) to obtain audience-specific games.

Objective: This study aims to describe the process of testing and optimizing the game "EscapeCovid" on students' mental health, to serve as a model for the cocreation of future similar interventions.

Methods: The PRODUCES (Problem, Objective, Design, End Users, Cocreators, Evaluation, Scalability) framework was used. Cocreation steps (test and optimization) were detailed for replicability. A total of 45 students tested a pilot version of the game, with 10 undergoing a semistructured interview. Meetings with a group of stakeholders and brainwriting were organized to optimize the game.

Results: We produced a new version of the game incorporating the suggestions provided by student testers and following the stakeholders' guidelines. Improvements were made to both the content and the form of the new version of the pilot game. The storyline, including the protagonist and the scenes, was adapted to the student population.

Conclusions: Our results suggested that cocreation can contribute to the design of more widely accepted interventions aimed at promoting mental health and preventing psychological disorders. Results also suggest that an end user–centered approach can facilitate intervention tailoring. When conceiving a health-related escape game for students, we recommend using the cocreation approach to enhance players' experience, thus positively influencing their learning process and overall well-being.

Introduction

University Students' Mental Health and the COVID-19 Pandemic

University students are often likely to experience serious mental health problems during their studies because they are exposed to several stressors including academic pressure, taking on more adult-like responsibilities, or having limited financial resources [1].

The COVID-19 pandemic has exacerbated students' mental health, as demonstrated by a skyrocketing incidence of mental health disorders during the repeated lockdowns between 2020 and 2021 [2,3]. Shifting to online courses, uncertainty about academic and professional future, and a dramatic reduction of social interactions have largely contributed to compromising the mental health of the student population [4]. Restrictive measures, in particular, were associated with high levels of depression, anxiety, and stress in students [5-7]. In 2020, nearly one-fifth of students experienced suicidal ideation as a result of COVID-19 [8]. The prevalence of these mental health problems was more than 50% higher among students than in the general population [9]. Students' mental distress due to the COVID-19 pandemic persisted in the aftermath of the peak of the pandemic [10].

Against this background, there has been a high demand for mental health prevention programs addressed to students during and after the lockdowns [11]. Several studies have described the development and application of interventions aimed at supporting students during the health crisis. In particular, digital psychological interventions have produced positive effects on students by promoting resilience and well-being [12]. During the lockdowns, when face-to-face contact was limited, digital interventions had the advantage of reaching a larger audience with no time or space limit. Examples of interventions were video clips, online booklets, mobile applications, virtual doctor appointments, etc. University students, in particular, actively sought this type of online help and interventions, probably because they are digital natives [13].

Gamification in Mental Health–Related Interventions

To optimize interventions, gamification is considered an essential strategy, including in the mental health field [14]. Gamification relies on the full involvement of the player and exploits several psychosocial determinants affecting the learning process (eg, self-efficacy, social interaction, and a positive learning environment) [15]. Enhancing these factors can facilitate the recall of abstract concepts, such as the concept of mental health [16]. Introducing gamified elements (eg, step-by-step sequencing, rewarding systems, and puzzle-solving activities) in a health promotion and prevention tool can influence the aforementioned psychosocial determinants and, consequently, stimulate participants' learning loop and their cognitive capacity [17].

Over the last few years, increasing attention has been paid to the possibility of games improving well-being [18]. Games can engage players, especially young target populations, in understanding and retaining information in a more attractive and acceptable way [19]. This means that they can increase their mental health literacy and their knowledge of both the symptoms of psychological problems and the different solutions to overcome them. By providing tips and skills to face psychological difficulties, games might also contribute to positive changes in individuals' behaviors and attitudes.

Escape Games as a Tool to Improve Psychological Well-Being and Prevent Mental Disorders

Escape games are a type of digital intervention based on gamification where players collaborate to find clues, complete tasks, and solve puzzles with the aim of achieving a specific, time-bound goal, which is usually to escape from a room. Previous research corroborated the constructive impact of escape games in improving health-related knowledge in players [20,21] using a learning-by-doing approach [21].

Escape games can contribute to delivering health-related messages by fostering motivation for behavioral change through an enjoyable and playful approach, according to the PRIME (Plan, Response, Impulses, Motives, and Evaluation) theory of motivation [22]. Based on this theory, a decision to engage in an activity will not result in action unless it generates the desire and the impulse to do it at the relevant moment. Thus, the stimuli generated from the act of playing a game—including different tasks, lights, sounds, and colors—trigger feelings, ideas, and brain activities for positive decision-making. In other words, the game gives the input to change.

Additionally, gamification has the potential to increase motivation, engagement, and self-awareness, and even diminish symptoms of diseases such as depression and anxiety [23]. Indeed, gamification stimulates several components of good mental health. As an example, achieving goals in a game can result in a sense of satisfaction, accomplishment, and increased self-esteem, all of which improve overall well-being. Furthermore, game enjoyment is associated with positive well-being and social and emotional support [24].

The Cocreation of Escape Games

Cocreation occurs when end users and service providers, often along with other participants, work together in the early phases of the development of an intervention cycle [25]. Cocreation is a process facilitating the acceptability of an intervention because it primarily considers the needs and preferences of end users during the intervention development. Thus, the benefits of gamification tend to increase when cocreation is used [26], and cocreating an escape game can foster its adoption [27]. Based on this approach, game producers and end users must first exchange views to achieve a shared goal [28,29]. Indeed, when developing a public health–related game, players' experience and needs are relevant for enhancing its effectiveness in promoting health and prevention. Ideally, players work alongside designers, health professionals, and researchers, to produce the intervention. The cooperation of players and other stakeholders is therefore essential to maximize end users' acceptability and adherence to the game. As a result, cocreation is usually recommended to produce a successful game, including in the mental health field. Accordingly, sensitive topics and taboos should be addressed using players' words and taking into account the levels of empathy and sympathy players display during the cocreation process. Including end users with lived experience of mental health disorders promotes a deeper understanding of the game topic [30].

The PRODUCES Framework

PRODUCES (Problem, Objective, Design, End Users, Cocreators, Evaluation, Scalability) is among the different existing frameworks facilitating the cocreation of health-related interventions [27]. It is well-known for using a systemic approach to participatory methodology. According to this framework, the *problem* is a narrowed-down behavioral issue that the researchers and the designers wish to address. The cocreation process has an *objective* (“what” and “how”) and follows a specific predefined *design*, engaging *cocreators* who represent end users (ie, a specified target population). For the latter, all characteristics must be considered, from age to socioeconomic status, to tailor the intervention coherently. Cocreated interventions can also be *evaluated* and their *scalability* can be assessed. The satisfaction of the end user as well as the effectiveness of the intervention are elements to consider for the final evaluation. A successful intervention can be scaled up to reach a wider public. Thus, the PRODUCES framework helps to guide the participatory methodology by providing specific instructions.

Objective

The objective of this study was to describe the process of cocreation of the escape game “EscapeCovid”. The end goal of the game was to promote university students’ mental health literacy, their beliefs about mental health, management of emotions, and positive coping strategies during the COVID-19 pandemic. An applied methodology is presented here to be used as a model for cocreating an acceptable gamified mental health intervention addressed to young people. Providing this example also has the aim to illustrate one cocreation process for the benefit of other researchers and designers.

Methods

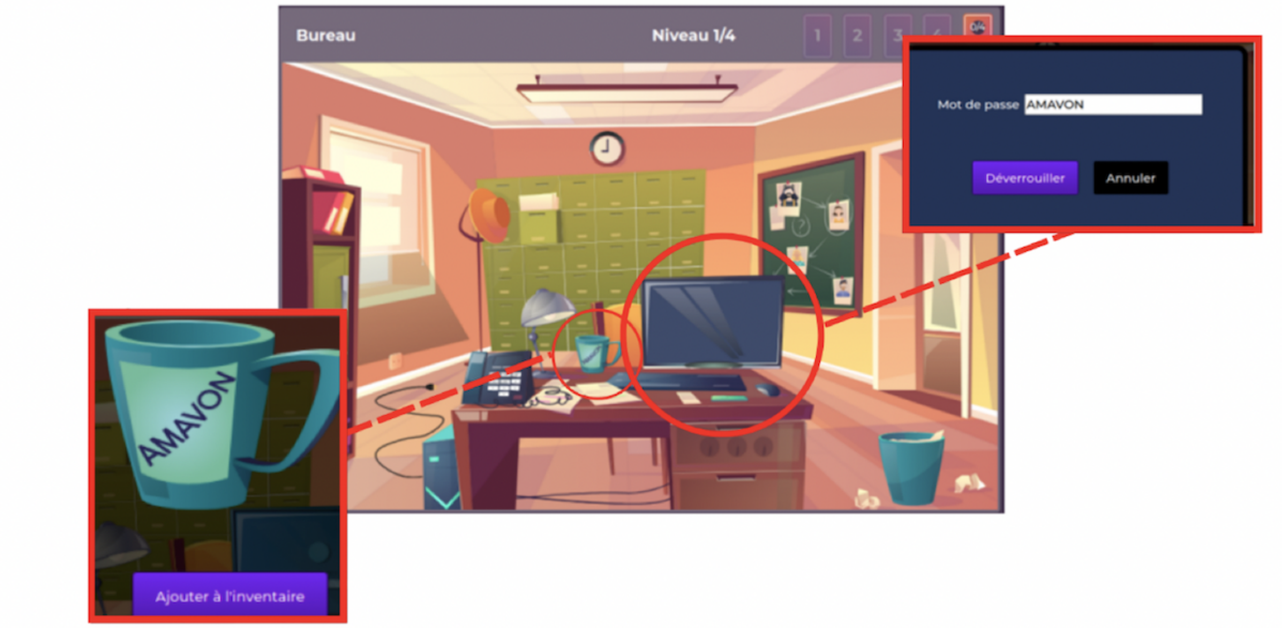
The First Pilot Version of “EscapeCovid”: The Escape Game “Manage Your Emotions”

“EscapeCovid” was based on an existing escape game that was used as the skeleton of the final game. “Manage Your Emotions” was created in 2021 during the pandemic by a start-up based in Bordeaux, France, specializing in producing both real-world and online escape games. Creators were game designers, programmers, and health care professionals aged under 35 years.

The game “Manage Your Emotions” is set in Tony’s room, a fictional university student living in a shared flat and experiencing the difficulties of the first lockdown. The goal of the game is to collect several tools to disclose emotion cards and combine them. The game session involves 4 players and a game guide. The role of the game guide is to coordinate the whole game, to give clues if the players are stuck, and to animate the debriefing session. The game lasts in total 2 hours: 45 minutes of play and 1 hour and 15 minutes of debriefing. During the debriefing, the game guide and the players discuss in more detail the concept of emotions (ie, how to identify and manage them). The game guide follows a predefined plot facilitating the interactions between participants.

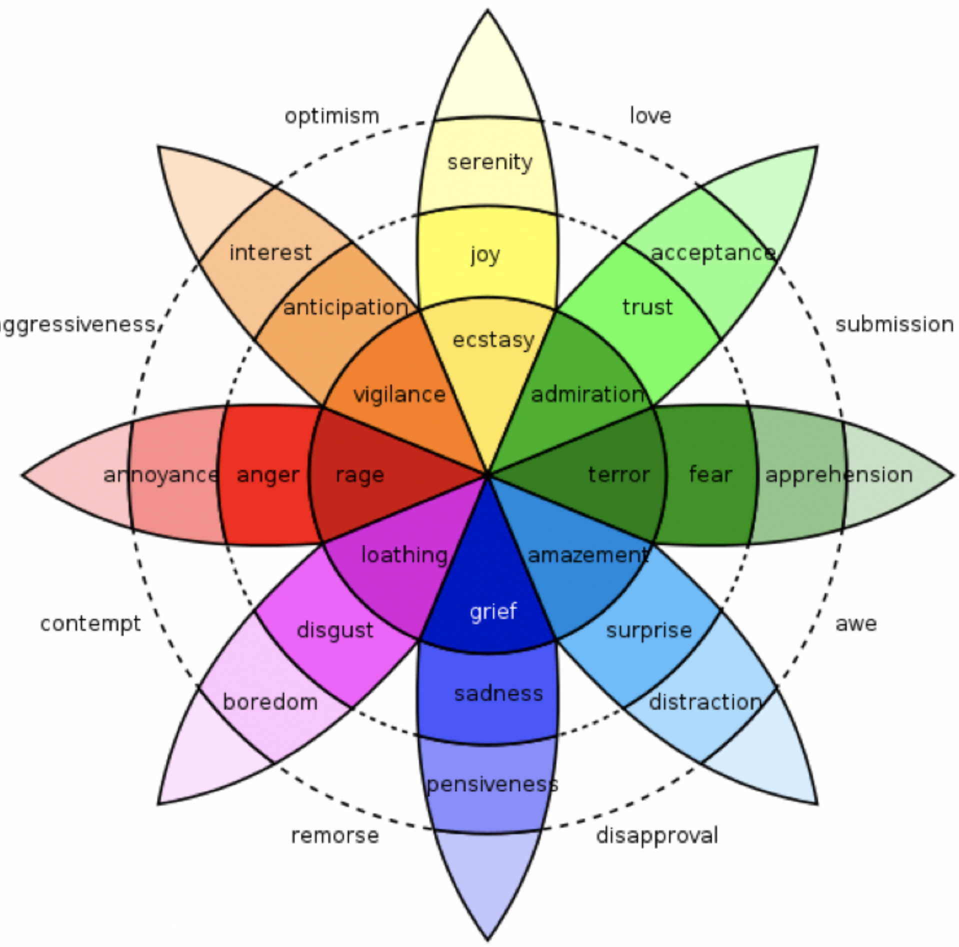
During the game, players follow Tony during a typical day through 3 rooms of his apartment (his home office in the bedroom, living room, and bedroom). By doing so, players discover his emotions and their consequences on his daily life. Figure 1 illustrates Tony’s home office in the bedroom with a set of clues for the players.

Figure 1. Tony's office in the escape game "Manage Your Emotions."



Players solve puzzles by clicking on the elements on the screen to uncover emotion cards. The definition of the different emotions is based on Plutchik’s wheel of emotions [31] (Figure 2) which is the theoretical framework of the game.

Figure 2. Plutchik's wheel of emotions.



Plutchik's wheel of emotions covers 8 primary emotions: joy, trust, fear, surprise, sadness, anticipation, anger, and disgust. They can be combined into more complex secondary emotions—for example, the combination of joy and trust can result in love. In the wheel, darker colors correspond to more intense emotions. All combinations and intensities are explained in the cards. Plutchik's theory posits that the more we know about emotions, the better we understand how various emotions are interlinked and how they can change over time. Plutchik's wheel of emotions has been used in several studies as a scientific instrument to interpret emotions [32,33]. In this escape game, playing cards had to be associated to identify Plutchik's emotions.

As the name suggests, the game "Manage Your Emotions" exclusively focused on emotions and therefore did not cover the full range of features of mental health (eg, mental health literacy and positive coping strategies). Furthermore, the software presented several bugs and the scenarios did not reflect the real-life conditions of a student during the pandemic.

Cocreating "EscapeCovid": Test and Optimization

Our cocreation process followed the PRODUCES framework [27]. The problem we chose was students' mental health during the COVID-19 pandemic. We particularly focused on mental health literacy, beliefs about mental health, management of emotions, and positive coping strategies as the levers to act upon for increasing students' psychological well-being. We addressed all types of mental health problems, but specifically anxiety and depression, among the most common troubles in young people [34]. These problems were exacerbated during the repeated COVID-19–related lockdowns [35].

Our objective was to develop the "EscapeCovid" game. The project was born during the third lockdown in France (from April 3 to May 3, 2021 [not included], ie, 29 days), where students were especially penalized because all educational institutions, but universities, were open. At that time, the plight of university students was prominently featured in the French media, which in turn heightened the pressure on French politicians [36].

As for the design aspect, we used a 2-step participatory methodology approach (test and optimization), as described below. Both steps involved students as players of the game before and during its improvement. Thus, through direct experimentation, cocreators were a sample of students representing all university students referred to as end users.

The evaluation was performed through questionnaires and semistructured interviews using a mixed methods approach. Students reported their opinions on the game allowing for an assessment of its qualities and defaults. In this sense, the design and the evaluation were strictly related.

In terms of scalability, our objective was to distribute the new game among additional universities catering to French-speaking students (eg, France, Africa, and Québec).

Table 1 reports the components of our study corresponding to the PRODUCES framework, including the phases and steps of the project.

Table 1. The PRODUCES[a] framework applied to the "EscapeCovid" study.

PRODUCES framework	Application in "EscapeCovid"	Corresponding element/phase
Problem	To address students' mental health during the COVID-19 pandemic	N/A[b]
Objective	To develop the "EscapeCovid" game	N/A
Design	Participatory methodology approach	Cocreation (test + optimization)
End users	Students	Optimization
Cocreators	45 health care students + 2 game guides + 1 developer + 1 project manager + 1 student intern + 1 designer+ 1 developer + 1 medical doctor + 1 researcher	Cocreation (test + optimization)
Evaluation	45 questionnaires and 10 semistructured interviews (mixed methods)	Test
Scalability	Disseminate the new game to other French students	Optimization

[a]PRODUCES: Problem, Objective, Design, End Users, Cocreators, Evaluation, Scalability.

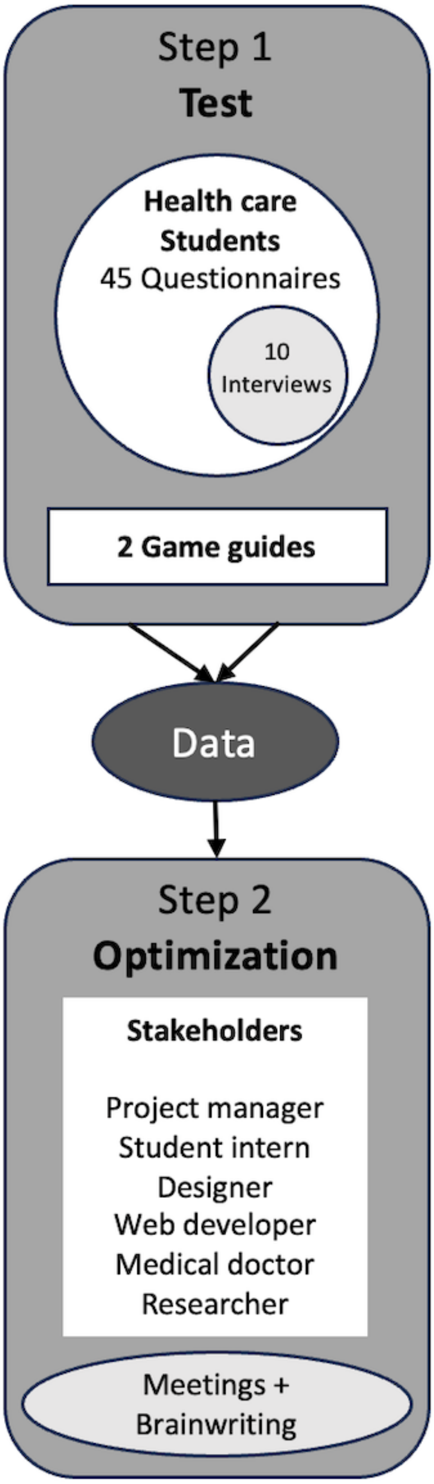
[b]N/A: not applicable.

In practice, referring more specifically to design, cocreation was implemented following 2 steps: the test and the optimization. In the first step, the escape game "Manage Your Emotions" was tested by a sample of health care students, 2 game guides (both public health experts), and 1 developer (a computer scientist). Game guides trained with colleagues and friends to annotate their first impressions of the game flow. They commented on the difficulties encountered while animating the game, including interactions with players and technical issues. The collected information was used to improve the debriefing and to solve bugs in collaboration with the developer.

Then, the official test was launched. Health care students played the game in groups of 3 or 4, each group supervised by 1 game guide. At the end of the game session, health care students were asked to complete an online questionnaire to rate their experience and provide feedback for improvement. Semistructured interviews were conducted with some voluntary respondents to obtain more in-depth advice (for improving the game).

In the second step, the game was optimized using the data collected from the test with the collaboration of a group of stakeholders. The latter included 1 project manager from a public health research center, 1 student intern completing a degree in cognitive engineering, 1 game designer, the developer of the test step specialized in computer science, 1 medical doctor, and 1 psychology researcher. Meetings were organized to reshape the pilot game and brainwriting techniques were used to collect ideas and pass them on to stakeholders. The brainwriting technique involves the written generation of ideas by different individuals on separate sheets, which are then collated by the project manager in the same shared file. Ideas are categorized and synthetized in the shared document where stakeholders can discuss them with written comments and paragraphs. Then, the team meets in person to agree on a common solution. Meetings and brainwriting were done in an iterative loop [37]. Figure 3 illustrates the cocreation process we adopted.

Figure 3. The cocreation process.



The Testers of "EscapeCovid"

The students testing the game were included exclusively if they were health care students registered at the University of Bordeaux (France). We accepted all specific health-related fields of study (eg, medicine, midwifery, speech therapy), genders, and ages. We opted for health care students to assess the relevance of the contents of the game given their expertise in medical and paramedical care. Furthermore, previous studies have shown that health care students are a population at risk of mental illness [38] and, as a consequence, tend to be more sensitive to this topic. Recruitment was conducted from April 27 to May 17, 2022. We used a snowball sampling approach starting with health care students doing their internship at the public health research center where the study was based. Additionally, health care–related student associations were asked to post a recruitment announcement on their social media pages. We aimed to recruit between 30 and 50 health care students, as this number would guarantee the feasibility of the study and the interactions required during the game. Thus, the recruitment was stopped when we reached a sample of 45 health care students and the recruitment strategies seemed to be no longer efficient (ie, no further responses). The final number of health care students who took part in the study was 45.

Through an email or by clicking on a link on the association's social media posts, participants in the study were directed to a form to schedule the game session and then randomly allocated to a session including 4 players each.

All 45 health care students received a €20 (US $22) gift card. Among them, 10 also volunteered to take part in a semistructured interview and received a supplementary €20 (US $22) gift card.

In addition to health care students, testers included 2 game guides and 1 developer employed by the start-up producing the game. No inclusion or exclusion criteria were considered for these testers who were all females and aged between 25 and 30 years.

The overall aim of the project was to coproduce a game and not to measure its impact on the mental health of health care students playing the game. Students were in charge of testing the intervention, as opposed to being on the receiving end. In other words, they were not the research sample but were actively engaged in designing and implementing the research process [39]. Nonetheless, they were provided with a list of mental health care services they could refer to if needed. The medical doctor and the researcher in psychology from the stakeholders' group were also available upon request. Finally, respondents were asked to electronically sign a consent form stating that their answers were completely anonymous without tracing. Interviewees also signed a form assuring that the recording of the interview would be deleted after 5 years until the final report and the last published paper, according to the policy of the involved research center.

Data Collection Instruments and Analysis During the Test

A mixed methods approach was applied using both questionnaires and semistructured interviews which were administered to our sample. The satisfaction questionnaire was sent by email to students 1 day after having played the game. It was created ad hoc by IM for this study and tested with 3 public health interns at the research center where the project was conducted. The interns played the escape game and answered the questions reporting to IM if they were adapted and appropriate, and whether it was easy to answer them. Some adjustments to the original items were made after this pilot testing. The final satisfaction questionnaire included 12 items on the degree of appreciation and relevance of the intervention. On a visual analog scale from 0 (not at all) to 10 (a lot), students had to rate the game in terms of how enjoyable it was, the quality of its content, its level of difficulty, the graphics, and the clarity and relevance of the objective. Students were also asked to state to whom they would recommend the game, whether they would pay to play it, whether they had understood the importance of talking about mental health, whether the game increased their knowledge about mental health, whether the game helped them speak more freely about mental health, and whether they felt the game destigmatized mental health. Participants were also asked to rate the game from 1 (very bad) to 5 (very good) stars. We included these specific questions because they provided concrete hints for improving the game. The start-up appraised the features with the lowest scores as the most important to consider when reshaping the game. For instance, they chose to work first and foremost on the graphics if players rated them low (ie, <5 points). Some questions helped understand if the game could have its own business model, with players advising and paying for it. Finally, the questions were aimed at assessing the impact the game had on students' mental health literacy, ranging from destigmatization to readiness to seek help [40]. The items of the satisfaction questionnaire are available in Multimedia Appendix 1. Sociodemographic characteristics were also collected, including students' gender, age, and year of study. Variables were described as counts and percentages. The questionnaire allowed us to obtain a large number of answers in a short time from a young population that is often difficult to reach [41].

Semistructured interviews were based on a grid composed of 3 macro themes and related 13 subthemes. The first macro theme, called "General Description of the Participant" included the following 3 subthemes: students' profile (sociodemographic characteristics), any previous experience with escape games, and the reason for participating in this study. The second macro theme was a "Brief Account of Participants' Experience" during the game session of "Manage Your Emotions," focusing on 5 subthemes: whether students enjoyed it, their satisfaction with the design and scenarios, the feasibility of the game, the learning outcomes, and any advice to improve the game. The last macro theme, "The Impact of the Game," included questions on the effectiveness of the game in teaching 5 topics (each corresponding to a specific subtheme): mental health, stigmatization, understanding and managing emotions, the importance of help-seeking, and techniques for mental health promotion. All subthemes were applied deductively, meaning they had been determined before the interviews.

Then, individual students' speeches were generalized to obtain an overall assessment of the game. Interviews were recorded, fully transcribed, and analyzed through qualitative coding. The framework method was used to cross-check results among individuals and within individuals to report common and consistent concepts [42]. This approach allowed us to list the guidelines for the optimization step.

Ethics Considerations

As the goal of the project was to collect satisfaction data with no repercussions on participants' health, no ethical approval was needed, in line with the French law for health-related research (Délibération n° 2018-155 du 3 mai 2018).

Results

Sociodemographic Characteristics

The quantitative sample of 45 students was purposely limited for a small-scale test. Among them, 34 were female students, 10 male, and 1 nonbinary. Their average age was 22 years (range 18-27 years). The years of study ranged from first-year students to PhD candidates, with the majority attending their fourth year (n=16). The qualitative sample (n=10) was composed of 7 female students and 3 male students. In the qualitative study, one-half of the sample declared having experienced a mental health problem and having seen a mental health specialist.

Students' Gaming Experience

The sample of 45 students who answered the questionnaire and the sample of 10 students interviewed reported enjoying the game session.

> *We discuss between us, why and how it is this emotion and not another [...] it was really good.* [B, female PhD candidate, Public Health, first year]
>
> *Yeah, I really liked the associations of emotions [...] frankly, we spoke with people we didn't know, so frankly it went well, it was cool.* [D, male students, Pharmacy, fourth year]

The majority of the sample (30/45, 67%) gave a high score (between 8 and 10) when asked whether they enjoyed the game. For 34/45 (76%) it was interesting (scores from 8 to 10). Twenty-one students considered that the game was easy. The most frequent overall score given to the game was 4 out of 5 stars (25/45, 56%).

In line with this finding, 21/45 (47%) respondents gave a positive score between 8 and 10 regarding the appeal of the graphics. Concerning the visual staging of the game, 1 student declared that the storyline was not coherent:

> *Tony's apartment is too big for being a student flat.* [MA, female student, Speech Therapy, second year]

Tony's character was also discussed, with some students questioning his relatability:

> *When Tony was talking, I didn't really get into the thing, in the end I found it very tricky, too tricky, a bit like a fake student.* [L, female student, Speech Therapy, third year]

Regarding the overall content of the game, 27/45 (60%) participants found the objective of the game clear (scores from 8 to 10) and 30/45 (67%) considered the content of the game suitable for students (scores from 8 to 10).

Half of the sample (24/45, 53%) would recommend the game to their close friends and family, especially their friends attending university (43/45, 96%). However, the vast majority of students (36/45, 80%) would not pay to play it.

The Knowledge Acquired During the Online Game Session

For 27/45 (60%) of the respondents, the game made them understand the importance of talking about mental health and 38/45 (84%) thought that the game was likely to increase their knowledge about mental health. However, interviewed students reported that knowledge about mental health was addressed in an unsuitable way.

For students, the game enabled users to better understand and identify different emotions, but the general concept of mental health was missing:

> *It was really more about identifying emotions, and self-reflection.* [L, female student, Speech Therapy, fourth year]
>
> *There would be a wealth of important information to address on mental health.* [A, female student, fourth year of international health]

The Development of the "EscapeCovid" Game

Quantitative and qualitative data from the test (step 1) informed the optimization of the game "Manage Your Emotions" (step 2) to produce the new game "EscapeCovid". Data were collated and analyzed by the stakeholders working on the development of the game. All results were considered to reshape the new escape game accordingly. The results of the mixed methods analyses were shared among stakeholders. This group of experts met 3 times to summarize the most important suggestions provided by the testers. Each meeting lasted from 3 to 4 hours. Then, 1 shared document was prepared and the stakeholders were asked to provide solutions for each suggested change. This was the beginning of the brainwriting process, where stakeholders updated the document once per week and met regularly every other week. Ideas were incorporated into a new working document, which was the basis for a new round of discussions (ie, five 2-hour meetings). Once consensus had been reached, the web developer revised the game following the guidelines written by the stakeholders on an online document and Figma (Figma, Inc.), a collaborative web application for interface design. Both the contents and the designs were discussed and modified.

Table 2 reports the modifications made from the first version of the game to the final one (also see Textboxes 1 and 2 for the topics addressed and educational content of versions 1 and 2).

Table 2. Comparison of features from the 2 versions of the game.

Features	Version 1: "Manage Your Emotions"	Version 2: "EscapeCovid"
Objectives	• To teach players to name, identify, and manage their emotions.	• To increase students' knowledge of mental health by familiarizing them with a range of emotions and symptoms of depression and anxiety.
Game flow	• 45-minute game session (3 rooms: home office in the bedroom, living room, and bedroom) + 45-minute debrief.	• Alternating game/debrief sessions in each room (home office in the bedroom, living room, and bedroom) and evaluation questions.
Topics addressed and educational content	• See Textbox 1.	• See Textbox 2.
Character(s)	• Tony, a confined student.	• Thomas, a confined student. • Thomas' roommate, "Hana." • A researcher who appears on the screen to give instructions and clues if the players need them.
Team competition	• Accumulation of points assigned according to the speed with which the player solves puzzles.	• Accumulation of points based on different criteria: speed in solving a puzzle, number of clicks used, time spent in each room and in the entire game, and correct answers to evaluation questions. Teams can also lose points if they choose to access clues to solve puzzles or if they answer assessment questions incorrectly.
Storyline	• Tony is a student living confined in his shared flat during the first lockdown. Game users follow him and the emotions he felt throughout lockdown. • Players must solve puzzles to access emotion cards.	• The same story plot as version 1. The presence of a new character changes the transition from 1 room to the other. • Players must solve puzzles to access emotion cards.
Game setting	• The graphics of the game are similar to an apartment of a young worker and not a student. • The vocabulary used by Tony is not adapted to the target audience.	• A student flat share; instead of having a home office in the bedroom and a separate 2-bedroom flat, the home office in the bedroom is on one side of Thomas' room. • Thomas' voice and vocabulary have also been adapted to meet the expectations/requests of the target audience.

Textbox 1. Topics addressed and educational content of version 1: "Manage Your Emotions."

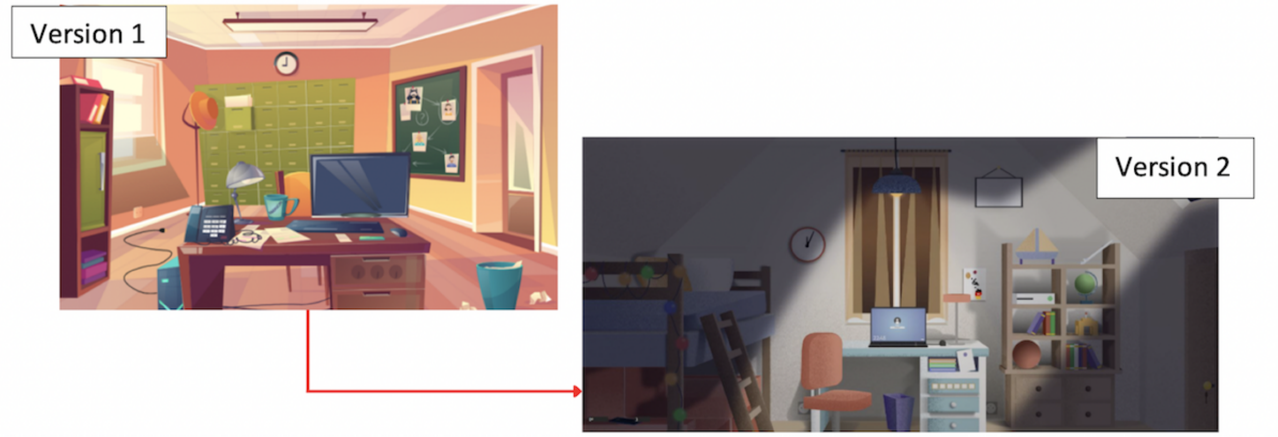
1. Game
   - This involved knowledge, identification, and management of emotions.
2. Debriefing Session
   - This involved tips and resources to identify and manage emotions.
   - In addition, the emotions felt during the examination period were discussed.

Textbox 2. Topics addressed and educational content of version 2: "EscapeCovid."

1. Game (examining symptoms of depression through emotions):
   - Stress and anxiety: other emotions, fear.
   - Anhedonia: sadness.
   - Self-devaluation: disgust.
   - Other topics related to mental health that were addressed, including the following:
     - Names of some mental health illnesses.
     - Stigmatization of mental health and mental illness.
     - Resources
2. Debriefing session
   - Room 1: Home office in the bedroom within the bedroom
     - Stress and anxiety: definitions and differences. Link with depression.
   - Room 2: Living room
     - Relationship between mental health and anhedonia. Link with depression.
   - Room 3: Bedroom
     - Relationship between mental health and self-devaluation. Association with depression.
3. Debriefing/end of the game
   - Emotions not previously addressed during the game.
   - Experienced symptoms and depression.
   - Stress on the importance of having good mental health.
   - Resources available in the case of a mental health problem.

In particular, substantial modifications concerned the introduction of mental health–related information in the game. Students had confirmed that the first version of the game was exclusively oriented toward emotions and their management. There were no specific elements of mental health described as either mental diseases or psychological well-being. In "EscapeCovid," the terms "depression" and "anxiety" were used by the main character. The symptoms and consequences of these mental health diseases were presented in the story. Depression and anxiety were selected because they are the most frequent psychological issues among young adults [43]. Players were supposed to learn more about mental health problems (mental health literacy), to destigmatize them (positive beliefs about mental health), and be able to tackle them (positive coping strategies). Puzzles and enigmas were used to teach these concepts with debriefing sessions to reinforce the learning process. Given their expertise in the field of health care, interviewees (health care students) helped with the writing of the plot, from the enigmas to the summary sheets. An example of a cocreated scenario within the story is available in Multimedia Appendix 2. Thanks to a cocreation approach, the game content could be revised by all public health stakeholders who were experts in public health and psychology. The graphics were also modified as shown in Figure 4.

Figure 4. Evolution of the graphics of the first room of "Manage Your Emotions" versus "EscapeCovid".



Playing the “EscapeCovid” Game

The escape game takes place in Thomas’ apartment which he shares with another student, Hana, during the first COVID-19 lockdown. Thomas is a university student and is taking his classes remotely. Throughout the game, we follow him during a typical day in lockdown. There are 3 rooms in Thomas’ apartment—a home office in the bedroom, a living room, and a bedroom. To move from 1 room to another, players must solve all the puzzles by clicking on the objects spread out in Thomas’ room. When players click on an object, a riddle appears and must be solved to move on to the following riddle. Players can only move to another room if they have solved all of the enigmas by uncovering clues or cracking the codes hidden in the sofa, among books, on the floor, etc. There is a limited number of clicks per participant.

At the end of each room scenario, a set of cards is shown, with each card containing a mental health–related message linked to the puzzles. For instance, in the living room, Hana is sleeping on the sofa in the dark and the books around her have titles containing the words “depression,” “pain,” etc. By solving clues and clicking, players can switch the light on and tidy up the room to make her recover strength. The cards synthesize the messages transmitted through the puzzles in the room. In this case, they explain the symptoms of depression and give tips for coping with distress.

“EscapeCovid” can be played in groups of 4-6 players who help each other and discuss using their computer cameras and headphones. This encourages team spirit and mutual aid, which can be the reflection of real life in the case of mental suffering. All along the game, the group of players is guided by a game guide who explains the rules and answers any questions. The same guide concludes the game session with a final debrief where all participants share their experiences. This final stage is essential for understanding and retaining the mental health–related takeaway messages.

Discussion

Principal Findings

We described the process we used to cocreate a digital game promoting students’ mental health during the COVID-19 pandemic. We followed a 2-step procedure. First, we collected quantitative and qualitative data from a manageable sample of students testing a preexisting game. Second, a group of stakeholders used these data to refine and optimize the game to obtain the final user-centered version.

The cocreation approach was very informative for developing the “EscapeCovid” game. In particular, during the test, students felt free to express their opinions openly and give feedback. They mostly appreciated the fact that they could support the development of an intervention addressed directly to them and their peers. Students were also motivated to cocreate the game because it was in line with their values. Students’ contribution to the design process nurtured new ideas following a collective creative approach [44] from the testing phase to the final optimization phase. Stakeholders’ work was facilitated by students’ guidelines while being creative and innovative.

The Rationale and the Usefulness of “EscapeCovid”

During the COVID-19 crisis, several mental health diseases emerged in the young, and digital games were among the most accepted solutions to overcome psychological difficulties [45]. With this rationale, we conceived "EscapeCovid". This game was designed to alleviate anxiety and depression by encouraging interaction with peers and fostering empathy. Participants in this study also confirmed the usefulness and appreciation of digital games during and after the COVID-19 crisis. Previous studies have shown that playing games is helpful in dealing with trauma and improves well-being [46]. This has also been observed in the context of the pandemic [47]. For this, "EscapeCovid" combines the pleasure and the entertainment of games, with a positive psychological effect. This might be due to teamwork, engagement, learning of coping strategies, and creativity, which are all at the root of our game. Indeed, the objective of "EscapeCovid" was to trigger the need to speak out about mental health after having experienced the psychological difficulties of COVID-19. "EscapeCovid" pioneered the discussion of mental health, making it a common topic, and provided advice on how to improve one’s mental health, especially in the aftermath of the crisis.

Guidelines for Successful Escape Games on Young’s People’s Mental Health

First, we confirmed that students enjoy playing escape games, which are linked to mental health. This was also found in other studies where health-related serious games were proven to facilitate experiential learning through an entertaining approach [21,48]. Thus, resorting to this type of intervention could be a good strategy to convey messages aimed at improving players' mental health. Engaging in playing games has been reported to promote the potential to enhance life satisfaction and improve individuals' mental well-being [18].

We observed that the plot was essential in capturing players' attention. During the game, testers were attracted by the messages and the scenario, feeling interested in following Thomas' story. They considered this aspect as crucial to transmit educational content, helping to convey new health-related topics, as shown in a previous study [21]. A meta-analysis on the gamification of learning confirmed that the use of personified narrative components is particularly effective in promoting behavioral learning [49].

Playing in groups was also a strategy to make connections and combat isolation, particularly experienced during the COVID-19 lockdown. The notion of interrelationship and mutual aid is a component to consider when developing games, even if they have a digital format.

According to testers, the "EscapeCovid" game had to be user-friendly, fun, and pedagogical. It had to present supplementary contents on mental health, with more specific details on mental health disorders and advice for preventing or treating them. We recommend that future game creators use precise and detailed content, providing accurate and uncensored mental health information and avoiding stigmatizing psychological disorders.

The Challenges of Cocreating Mental Health–Related Games With and For Young People

The involvement of end users entails a large proportion of subjectivity. This is especially true when handling topics such as mental health where feelings and emotions are at stake. End users give their opinions without any specific framework [50]. To mitigate this issue, the sample answering the questionnaire should be large enough to be representative of the target population. However, for the sake of feasibility in terms of time and financial efforts, it is not always possible to question more than 50-100 people. Qualitative interviews are meant to provide further information corroborating the quantitative data, but they still imply subjectivity. Per se, interviews cannot be representative [51]. The limited number of stakeholders has its share of arbitrariness. Nonetheless, regardless of their number, cocreators are the bridge between the whole target population and the stakeholders [27].

Cocreation is time-consuming. The 2-step development demands at least twice as long as the standard time to produce a game. Data collection and analysis add work to the producers who need to incorporate the results into their creative process. Discussions among stakeholders and brainwriting also slow down the production process. This is a limit of cocreation which cannot be overcome while being the best solution for producing an intervention that is well-tailored to the needs of the end user. Qualitative interviews in particular require time and effort, but they are a crucial tool for an in-depth analysis.

Technological issues should also be considered. Players' expectations might not be easily met because of software limitations. This could result in frustration from both parties and decrease adherence to the game. Start-ups and game industries should therefore keep up with new technologies and continuously update their services.

The Advantages of Cocreation

Cocreation has the advantage of considering the viewpoint of the end user, which might not be the case in classical processes of game development using a top–down approach. Collecting students' opinions before the development of the game allowed us to obtain several inputs and ideas that a limited number of web developers and project managers could not provide. The filter of expert health care professionals was also essential during the process. New knowledge was produced through sharing among parties.

The consultation with students having experienced mental health disorders allowed us to address the escape game's topic through a different lens. By considering their opinion, the game could be made more realistic and engaging. The disclosure of emotions and opinions can be facilitated through anonymous questionnaires and qualitative interviews, with students knowing that they are contributing to an intervention beneficial to them and their peers. The feeling of being useful to the community is another added value in the cocreation process [52].

Two different teams—one from an academic environment and the other from a start-up—collaborating to develop the game was also an asset. Indeed, researchers' scientific point of view informed the business goal of the start-up with the common will of creating an evidence-based marketable product.

Finally, cocreation provided useful information for the improvement of both the content and the format of the game. The latter was more contextually specific, adapted to a young population, namely, students, and bridging the gap between the preconceived ideas held by the start-up team and the real-world implementation of the game.

Recommendations for Researchers and Designers

The "EscapeCovid" game is an example of a digital game on mental health, which could be cocreated with young users. The guidelines we present might be applied to other similar interventions.

A 2-step approach is recommended with (1) an initial collection and analysis of combined quantitative and qualitative data, followed by (2) the integration of these data into the reflective and creative work of a group of experts and stakeholders. This approach, similar to a market survey, allows us to obtain clearer game instructions and broader insights, resulting in a more targeted and audience-specific final product.

We suggest basing the coconstruction process on an already existing pilot version because it facilitates the development of the final game. Although the game can be completely re-created, preliminary mock-ups will allow to save time and money. In our study, students were not required to design the game from scratch, and working on the first version of the game was an advantage for providing relevant, concrete, and realistic comments based on an existing version.

Stakeholders are also advised to take into account testers' opinions seriously and implement them accordingly. Testers represent the end users and their preferences must be carefully considered to obtain a fully satisfactory end product. For this reason, it is essential to collect as much information as possible during the testing stage.

We suggest to try out the game again once it has been modified. An iterative loop of test-optimization-test will increase the quality of the game. However, it must be pointed out that this process is expensive and time-consuming, despite being extremely informative. It is therefore recommended to end the loop once the comments are saturated, which effectively means limiting the number of additional changes suggested by users and resulting work for developers. This approach can serve as a blueprint for future work on creating gamified interventions on health-related topics addressed to students. Successfully cocreated games can have a wide outreach and improved scalability.

Study Limitations

Testers were mostly student interns at the research center where the study was conducted. This might have biased the results because participating students were already made aware of the project and willing to contribute to its progress as members of the same research laboratory. The test was performed by health care students, meaning that the modifications of the game might be relevant to them and not to students of other subjects. This particular student population also faces specific forms of stress not experienced by their peers. However, we considered their opinion to be of paramount importance in terms of the contents of the game, which benefited from their skills and experience with stress. The game was more realistic and other students could relate to Thomas' story imagined by young people their age.

Another limitation is that the students participating in the study were rewarded with a gift card, which could have significantly influenced the answers due to desirability bias. This phenomenon was even more likely in the case of interviewees who had received 2 gift cards. The gender balance among the participants was skewed in favor of female students, which may have influenced the results of the test.

Finally, we were not able to retest the game after its modification. Because of money and time constraints, we only produced a new version of the game without further refinement.

Conclusions

Our results suggest that cocreation contributes to improving the suitability of a health promotion and disease prevention intervention and that an end user–centered approach can facilitate intervention tailoring. When conceiving a health-related escape game, we recommend using a 2-step approach, including an initial collection of quantitative and qualitative data from end users testing the game (test), followed by the integration of these data into the development of the game by a restricted number of experts (optimization). This approach can serve as a model for future work on creating gamified interventions on health-related topics addressed to students.

Acknowledgments

The authors acknowledge and thank all the students who took part in the study. The authors are also indebted to the university student associations for helping recruit participants. Finally, the authors wish to thank Sara Garfield for revising, proofreading, and editing the paper. The project was funded by the French National Research Agency (ANR; grant number ANR-21-CE36-0011-02). IM was supported by the Digital Public Health Graduate Program within the framework of the PIA3 (Investment for the Future; Project reference: 17-EURE-0019). Further support was given by the AUF CO//ectif (DREO-7450).

Authors' Contributions

DL was responsible for conceptualization, investigation, and writing—reviewing. CV performed data curation and writing—original draft preparation. DT collected and analyzed the quantitative data. HH and CT took part in data curation and writing. IM contributed to conceptualization, methodology, investigation, writing—reviewing and editing, and supervision.

Conflicts of Interest

DL, HH, and DT are employees of the start-up Tricky, which developed the game described in this paper. Their jobs are paid by other projects, and they did not take any financial benefit from the development of "EscapeCovid." The game was developed for business, but data collection, analysis, and observation for this manuscript were conducted by CV, CT, and IM who are totally independent from Tricky. The study results are completely transparent and based on scientific integrity.

Abstract

Background: Traditional serious game design methods often overlook stakeholder needs. This study integrates stakeholder theory and enterprise architecture (EA), along with the Architecture Development Method, to propose a novel framework for serious game design. Crafted to aid practitioners, researchers, and specialists in leveraging resources more effectively, the framework is validated through a design science research methodology. Expert reviews have further refined its features, making it a robust tool for enhancing serious game design and implementation.

Objective: This paper introduces a framework for designing serious games, covering stakeholder analysis, requirements gathering, and design implementation planning. It highlights the importance of expert review in validating and refining the framework, ensuring its effectiveness and reliability for use in serious game design. Through critical assessment by experts, the framework is optimized for practical application by practitioners, researchers, and specialists in the field, ensuring its utility in enhancing serious game development. The next step will be to validate the framework empirically by applying it to a serious game development project.

Methods: We developed and validated a conceptual framework for serious game design by synthesizing stakeholder theory and EA through literature review, concept mapping, and theory development by way of a design science research approach. The framework is iteratively refined and validated via expert review, drawing on insights from professionals experienced in serious games, stakeholder theory, and EA. This method ensures the framework's practical relevance and effectiveness in addressing real-world design challenges.

Results: An expert review by 29 serious game practitioners validated the framework's success in stakeholder management, confirming its stakeholder-centered effectiveness. Although the experts praised its structured approach, they suggested clearer guidance for game design elements. In addition, the experts, while acknowledging the framework's complexity, saw its depth as valuable for efficient management. The consensus calls for a refined balance between detailed functionality and user-friendly design, with the framework's impact on stakeholder capabilities revealing a spectrum of professional needs.

Conclusions: This paper presents a framework for creating effective and organizationally aligned serious games. Evaluated across execution, practical, and EA levels, it is logical but varies in ease of understanding, with experts calling for more accessibility at the EA level. It enhances stakeholder efficiency and management but is criticized for rigidity and a need for flexibility. Recommendations include streamlining the framework, enhancing clarity, reducing administrative tasks, and incorporating clear guidelines on technology use, motivational elements, and operational tools. This aims to help stakeholders produce more targeted and adaptable game designs. The next iteration will be developed after application to a project and team feedback.

(JMIR Serious Games 2024;12:e48099) doi:10.2196/48099

KEYWORDS

serious games; stakeholder theory; enterprise architecture; serious game development; design framework

Introduction

Background

This paper articulates a stakeholder-centered framework for serious game design in various stages before, during, and after various methods have been applied to develop it. The research presents the framework—informed by stakeholder theory and enterprise architecture (EA)—as it evolved through various stages of development. It underscores the need for a structured approach that focuses on stakeholders throughout the design process to enhance the success of serious game production efforts. This research reflects 3 cycles of the design science research (DSR) paradigm, aiming to balance domain-specific needs with generalizable solutions. The framework emphasizes alignment with stakeholder needs and effective communication among different groups, recognizing the complexity of serious games and the importance of their relevance to users.

This work also presents findings from an expert review questionnaire that used a qualitative methodology to assess the framework's effectiveness. The review gathers feedback from practitioners and specialists in the field, guiding enhancements to the framework's clarity, structure, and usability. The paper concludes with insights into the framework's current state of development and recommendations for its refinement, emphasizing the need to simplify its complexity and communicate its components more effectively for real-world application.

Framework Requirements

Several key requirements for the initial framework emerged from a comprehensive integrative literature review. A conceptual framework is indispensable for comprehending the complex phenomena explored because it provides a structured and systematic method for organizing, analyzing, and interpreting data. Several essential components of a conceptual framework contribute to its efficacy, including clarity, relevance, coherence, simplicity, testability, and generalizability. As such, the following characteristics of the framework that has been developed serve as guiding principles. First, a conceptual framework should be clear and straightforward for its intended audience to comprehend. It should define its key concepts, variables, and relationships as well as provide a thorough overview of the subject under investigation. Second, the framework should be pertinent to the research problem or question being addressed. It must thus be tailored to the context and objective of the study. Third, the framework must have logical coherence, a clear structure, and internal consistency. The framework's concepts, assumptions, and relationships should be logically connected and consistent with one another. Fourth, a good conceptual framework should be as simple as possible while capturing the essential characteristics of the studied phenomenon. Fifth, the framework must be susceptible to empirical testing, with testable hypotheses and predictions that can be evaluated through observation and data analysis. Sixth and last, such a framework should be applicable to other settings or situations and be generalizable beyond the specific context of the study. It should therefore serve as a foundation for the development of broader theoretical insights and generalizations about the subject of study.

Our framework prioritizes stakeholder engagement and management within serious game design, addressing a gap often overlooked in conventional design literature. While incorporating established design elements—such as learning objectives [1-4], game mechanics [5-9], narrative [10,11], user interface and experience [12], and evaluation [13,14]—the framework's novelty lies in its stakeholder-centered approach. It is tailored to align with educational or training standards, drive engagement, and provide meaningful feedback. However, the primary focus is not solely on game design; instead, the framework is rooted in stakeholder theory and EA, which have been the fulcrum of our extensive literature review. By doing so, we address the intricacies of organizational and stakeholder dynamics, ensuring that serious games are developed within a context that appreciates the diverse roles and impacts of various stakeholders.

Products of the Integrative Literature Review

Overview

The integrative literature review presents a taxonomy of serious games; the phases of serious game production; the stakeholders involved in serious game production; stakeholder identification, analysis, and management procedures; and The Open Group Architecture Framework (TOGAF) Architecture Development Method (ADM). These concepts are briefly outlined in the following subsections because they inform the construction of the conceptual serious game framework.

What? Classifying Serious Games

Serious games are edifying artifacts, tools, and games created by development teams that use ludic activity for a specific purpose, format, genre, interaction style, and application area. Serious game taxonomies classify games by *purpose*. This classification can help identify the functions of a serious game and guide the selection and development of educational and training games. The following are some serious game categories:

- Simulation games simulate real-world situations to give learners practical experience and practice in complex or high-risk situations (eg, flight simulators for pilot training and medical simulators for surgery [15]).
- Educational games teach specific knowledge or skills, such as language, math, or history. Game mechanics such as rewards and feedback encourage learning and participation [16].
- Training games teach practical abilities such as customer service, leadership, and teamwork. To track progress and facilitate learning, they may include simulations or role-playing scenarios as well as feedback and assessment [17].
- Health games promote healthy behaviors such as exercise, healthy eating, and disease management. Game mechanics such as rewards and challenges may encourage behavior modification and participation [18].
- Persuasive games aim to influence players to adopt certain behaviors, such as environmental conservation, social

justice, or political activism. Story elements often emotionally engage and motivate players [19].

By classifying serious games by their intended function, a functional taxonomy can help find the best games for learning or training needs and guide their development. These serious game classifications are relevant to this research and accepted under the serious game banner.

Serious games, gamification, and game-based learning differ greatly. These terms all refer to using games or game elements in learning or training, but serious games are games with a specific goal. They usually teach players a skill [20]. Serious games differ from entertainment-focused commercial games. Gamification, by contrast, uses game elements such as points, badges, and leader boards to motivate and engage nongame users [21]. A fitness app, such as *Strava*, that rewards users for reaching fitness goals uses gamification. Game-based learning uses games to teach or train, but, unlike serious games, its main goal is not to achieve a learning outcome [22]. *Civilization* may be used by a history teacher to teach about historical events and civilizations, but it is not meant to teach history. Game-based learning uses games to teach or train without a specific goal.

Who? Serious Game Production Stakeholders

Different stakeholders from varying fields are involved in serious game production and development. Common stakeholders include the following [16]:

- Game developers are responsible for designing and developing the game. They create captivating game mechanics, visuals, audio, and more.
- Subject matter experts (SMEs) are knowledgeable about the serious game topic. They provide content and knowledge for game accuracy and effectiveness.
- Teachers and trainers can use serious games as a teaching or training tool for students or employees. They demonstrate how the serious game can meet learning goals.
- Game publishers distribute serious games to a wider audience. They market, distribute, and sell the game.
- Players are serious game consumers. They play the game and give feedback to improve it.
- Funders and sponsors are individuals or organizations that provide financial support for the development of the serious game (eg, government agencies, private foundations, or businesses).

When? Phases of Serious Game Production

Serious game production follows a similar process to traditional game development but with educational or training goals. The following are the five main serious game development phases:

1. The first step in serious game development is to identify the game's learning objectives, audience, and context. This usually involves a needs assessment or curriculum analysis to identify gaps or areas where game-based learning could be beneficial [15].
2. A detailed plan for game mechanics, story, user interface, and learning content is created during the design phase. This phase may include storyboarding, prototyping, and playtesting to ensure that the game is engaging and meets learning objectives [16].
3. Development includes creating the serious game, including programming, artwork, audio, and multimedia assets. Game developers, instructional designers, SMEs, and other stakeholders work together to ensure that the game meets educational or training goals [23].
4. After creating the serious game, it is tested and evaluated to ensure that it meets its learning objectives. User testing, focus groups, and other student and stakeholder feedback methods may be used [24].
5. The serious game can be deployed for use in educational and training settings in the deployment and maintenance phase and should be supported and updated to ensure that it remains relevant and effective over time.

Serious game developers use the aforementioned steps to create outcome-aligned educational and training games. Such a framework supports agile game development and various development methods.

Where? TOGAF ADM

Serious games can make use of TOGAF ADM. Serious games with multiple stakeholders and complex systems require a structured EA development process. TOGAF ADM can also be customized for different industries and organizations. Such a broad view ensures that the game aligns with organizational goals, making it a good choice for serious game creators. TOGAF ADM is a nine-phase, sequential process for EA [25]:

1. Architecture vision: the EA team creates a high-level vision of the organization's desired future architecture state. This phase determines the architecture development's business drivers, stakeholders, and scope.
2. Business architecture: phase 2 involves understanding the organization's business processes, objectives, and strategies. This phase produces business architecture artifacts that describe the organization's business capabilities, value streams, and structure.
3. Information systems architecture: this phase focuses on understanding the organization's information systems and technology infrastructure. This phase creates architecture artifacts for the organization's application, data, and technology architecture.
4. Technology architecture: phase 4 focuses on selecting and defining technology components for implementing the organization's architecture. This phase creates architecture artifacts for the organization's technology infrastructure's hardware, software, and networks.
5. Opportunities and solutions: phase 5 evaluates architecture solutions that meet business goals and objectives. This phase creates architecture artifacts that describe proposed solutions and their organizational impact.
6. Migration planning: in this phase, a plan is created to transition the organization's architecture to its desired future state. This phase produces architecture artifacts that describe transition activity sequence and timing.
7. Implementation governance: phase 7 oversees the implementation of architecture solutions and ensures alignment with organizational objectives and goals.

Governance framework architecture artifacts are produced in this phase.

8. Architecture change management: this phase manages ongoing changes to the organization's architecture, aligning them with its goals and objectives. This phase produces architecture artifacts that describe change management.
9. Architecture evaluation: this phase evaluates the effectiveness of the architecture solutions and ensures that they meet the organization's goals and objectives. This phase creates architecture artifacts that describe the evaluation process and results.

Interest groups can create EA solutions that meet their business goals by following TOGAF ADM. Moreover, TOGAF application to serious game development requires several crucial steps. First, an architecture vision is created to describe the game's goals, objectives, target audience, and learning outcomes. Stakeholder analysis is then performed to identify the game development stakeholders and their needs and expectations. This ensures that the game is designed with stakeholders in mind. Architecture requirements describe the game's functional and nonfunctional needs. The architecture development phase designs the game's architecture based on the previous step's requirements. This includes game mechanics, visual and audio assets, user interface, and layout design, that is, build, code, integrate visual and audio assets, and test the game's usability and efficacy. To ensure stakeholder satisfaction, the game is monitored and evaluated over time. This may involve player feedback, game performance data analysis, and adjustments. Specifically, this work references the application of an ADM to serious game development and highlights how it can assist organizations in creating the desired strategic resource game. Doing so emphasizes that the ADM not only assists in the development of the serious game but also identifies organizational capabilities, methods, and processes that can be leveraged in future projects, thereby enhancing the team's effectiveness.

Why? Stakeholder Identification, Analysis, and Management

Serious game design requires a stakeholder-centered conceptual framework for the following reasons:

- A stakeholder-centered approach considers various stakeholders' needs and expectations during design. This may lead to more effective, engaging, and audience-relevant games (Bopp, J, A, unpublished data, December 2020).
- A stakeholder-centered approach ensures that the game is designed for the end user, improving usability and effectiveness. This improves player engagement, learning, and game performance [26].
- A stakeholder-centered approach can involve stakeholders in the design process, facilitating participation and acceptance. By increasing stakeholder confidence and ownership, serious game adoption and implementation can succeed [27].
- To improve serious game sustainability and scalability, a stakeholder-centered approach can be used to design games that meet the evolving needs of stakeholders. This can help the serious game stay relevant and effective as stakeholders' needs change [28].

Serious game development relies on stakeholder identification, analysis, and management. This process begins with stakeholder identification. Stakeholder analysis prioritizes their needs and interests, while surveys, interviews, and focus groups help understand them. Stakeholder management involves planning how stakeholders will be engaged, their needs met, and their feedback incorporated into the serious game. Serious game development can use stakeholder management techniques such as regular meetings, an engagement plan, a registry, the prioritization of needs, feedback, and data analytics. Developers can create more effective, engaging, and audience-relevant games by managing stakeholder needs and expectations. A stakeholder-centered framework is needed for serious game design to ensure that stakeholders' needs are met and to improve game effectiveness, usability, and sustainability.

How? Stakeholder Identification, Analysis, and Management

Stakeholder identification, analysis, and management are crucial to project success, including serious game development. Stakeholders are people or groups who care about the project's outcomes and can influence them. Successful stakeholder identification, analysis, and management follow these four steps:

1. Identify internal, external, primary, and secondary stakeholders. Stakeholder analysis maps stakeholders and identifies key players [29].
2. Analyze stakeholders' interests, needs, expectations, and influence on project outcomes. A matrix that maps stakeholders by power and interest can do this [30].
3. The project team can develop strategies to manage stakeholder relationships based on stakeholder analysis. This involves prioritizing stakeholders by influence and interest and creating stakeholder-specific engagement strategies [31].
4. Implement stakeholder management strategies through ongoing communication and engagement, such as project updates, meetings, and consultations. Stakeholder interests must be monitored and the stakeholder management plan adjusted [32].

These steps for identifying, analyzing, and managing stakeholders can help serious game developers maximize project success and build long-term relationships. When a new serious game project begins, the organization or team will already know the relevant stakeholders from stakeholder management and EA. Thus, each project improves the organization or team.

Methods

Framework Development

Overview

This section discusses how the integrative literature review revealed relevant theories, determined its limits, found relevant sources, collected terminology, defined its theoretical pillars, and provided practical approaches to the stakeholder-centered framework. Moreover, this section assesses the framework's evolution over time; and it also theorizes future representations; reviews design processes; suggests improvements; and states the artifact design's aggregate, iterative, and consistent impacts.

Variant 1: Informed by Literature

The preliminary snapshot of the stakeholder-centered framework is a compilation of ideas for a flexible, general-purpose framework to aid in the design of serious games. Initial concepts included generating, developing, and visually communicating the system's fundamental elements, with a focus on user needs and empathy for the target demographic of serious game design stakeholders. Existing serious game literature, models, and approaches inform the framework variant, and an early exploration of these works provides a knowledge base for further consideration. Understanding the methods used in previous research on the same or similar issues assists in determining which methods will be most beneficial to advancing the topic and can aid in the evaluation of prior studies.

Various sources are represented in this formation because serious games' content, definition, sources, liminal works, methods, and existing frameworks are investigated. As such, a substantial portion of this work is theoretical in nature and largely represents the efforts to seek and collect literature on the nature of serious games.

Textbox 1 shows how theoretical and experiential exploration shaped our initial project impression. First, because serious game projects require people and management, stakeholder theory was added to the framework. Second, early EA readings may help organizations achieve their goals. The framework's third pillar, serious game design theory, positions the research and establishes its context. From this early stage, the framework must be applied and evaluated to determine its value for practitioners in the given milieu. This variant was extensively developer (self) reviewed. These steps close the DSR cycle loop and indicate that each variation is evaluated, even if reflectively.

Textbox 1. Sources that informed the first variant of the framework.

Sources and detail with explanation

- Deterding et al [21]
  - The authors define "gamefulness" and "gamification." This influential work examines the differences between full-fledged games, serious games, pervasive games, extending games, game elements, and playful interaction. Even if not adopted, their definitions of "gamification" and "gamefulness" in contrast to serious games and playful interaction refine discourse and enable researchers to better understand and analyze the phenomena.
- Annetta [33]
  - The author has presented a nested model of educational game design elements. Serious games have 6 elements, ranging from identity to instruction. This paradigm is hierarchical, with identity as the foundation for serious game design.
- Garris et al [23]
  - A model by the authors shows the learning approach used in educational game research and its results. First, the main goal of any instructional content is to create a game-like educational program. Second, these qualities trigger a loop of user perceptions or responses such as interest or delight, user behaviors such as perseverance or concentration, and system input. If designers can match educational content with game elements, this cycle creates repeatable and self-motivated play. Third and last, game participation achieves training goals and learning outcomes.
- Ferdig [34]
  - The authors define the "heart of serious game design" as theory, content, and game design. Serious game success requires emergent theory, content, and game design knowledge. Managing disciplinary conflicts and agreeing on serious game design is a major challenge for serious game teams.
- Marne et al [35]
  - The authors list 6 serious game design aspects. This serious game design methodology shows the importance and distinction of pedagogical and game design expertise and their role in serious game development. This model's main benefit is selecting the right experts for each design area.
- Rooney [36]
  - The author proposes a triadic serious game design framework that considers pedagogy, play, and fidelity to create media.
- Vanden Abeele et al [37]
  - The authors advocate the player-centered, iterative, interdisciplinary, and integrated (P-III) serious game design framework. This prominent framework provides a way for creating serious games that hinges on 4 conceptual pillars: player-centered design (from user testing during development to participatory design workshops during the design phase, projects start with inquiries that are influenced by ethnographic research), iterative development (the team establishes multiple milestones, and user testing culminates in a final prototype that can be evaluated), interdisciplinary teamwork (collaboration between instructional and game designers), and integration of play and learning (seamless blend between the game vision and core mechanics on the one hand and learning principles on the other hand).
- Yussof et al [38]
  - The authors propose a serious game conceptual framework. The suggested outline combines gaming requirements with learning and pedagogy theory to provide a conceptual framework for serious game designers and educators.
- Gee and Hayes [39]
  - The authors adapted the mechanics, dynamics, and aesthetics (MDA) framework into the design, play, and experience (DPE) framework. The extended DPE framework shows serious game layers for storytelling, learning, game play, and user experience. Every layer includes design, play, and experience.
- Roungas and Dalpiaz [40]
  - The authors created a conceptual model of serious games to reduce misconceptions in serious game design teams by specifying a standard terminology that stakeholders can accept. The conceptual model also guides serious game design to address Game Design Document and other record keeping and administrative process inconsistency. Combining educational and game elements is the main challenge. Completed conceptual models are displayed in unified modeling language (UML) class diagrams.
- Breuer and Bente [41]
  - The authors examine how serious games relate to e-learning and game-based learning. Serious games may use different learning strategies than edutainment and e-learning, according to them. According to the authors, many serious game definitions and typologies are limited.
- Ferdig [34], Rooney [36], and Deci and Ryan [42].

- Our novel synthesis combines the DPE framework, the serious game design framework proposed by Rooney [36], and self-determination theory (SDT). The idea emphasizes the importance of theory (pedagogy), content (fidelity), and game design (play) in serious game design. Effective serious game development is said to be central to these elements. In the DPE framework, SDT principles such as relatedness (the desire to connect with others), autonomy (the desire to choose one's own paths), mastery (the desire to develop skills and master them), and purpose (the desire to connect actions with greater reason) are proposed to clarify or distinguish the connections between human psychological patterns and game features, mechanics, and dynamics to argue that gaming approaches and thinking can be successful. All 3 theories are combined to create a new serious game development strategy. The final stakeholder-centered framework partially incorporates these theories, but much of it leads the authors of this study to literature on game design.

Variant 2: Position, Activity, and Specialization

The next stakeholder-centered framework revisits unknowns and defines user problems to generate problem statements for subsequent design phases. Recordkeeping is stressed to avoid future issues. Stakeholder theory is emphasized, and how to identify and analyze serious game stakeholders is a key question. These stakeholders include experts, developers, and consumers, whose power and interest are analyzed using stakeholder analysis methods such as the power-interest grid. In the initial framework visualization, the EA pillar influences responsible, accountable, consulted, and informed matrices; Gantt charts; and business process model and notation swimlanes. In addition, variant 2 introduces 2 phases, idea validation and conceptualization, which continue in subsequent variants. We also discuss the 4 main serious game stakeholders from a previous stakeholder management approach: development team, publishers, context-related staff, and supplemental staff. Consumer stakeholders are consulted during development, but only the 3 (or 4) main categories are relevant to core game production.

As shown in Table 1, serious game production stakeholders often play multiple roles in smaller teams due to constraints. Variant 2 of the framework includes idea validation and conceptualization. The former evaluates the team's serious game development prospects, while the latter starts project ideation. The framework has 3 levels: *execution*, *inquiry*, and *practical*. Serious game design stages include idea validation, conceptualization, development, and iteration in the execution level. Academic research and inquiry on serious game manufacture, participatory design, and more occur at the inquiry level. Stage-specific requirements and outcomes are listed in the practical level checklist.

The 3 levels are necessary due to the complexity of serious game development. The variant 2 framework shown in Figure 1 [43] also includes TOGAF ADM, DSR design, and the agile software development life cycle. Collaboration, adaptability, and rapid prototyping are hallmarks of agile software development. Rapid prototyping, customer focus, flexibility, and serious game development improvement are promoted by this approach. Serious game development levels include TOGAF ADM, DSR design, and the agile software development life cycle.

Table 1. Serious game stakeholder categories, positions, activities, and specializations.

Category	Positions	Activities	Specializations
Development team	Programmer, artist, designer, producer, tester, composer, sound designer, and writer	The different tasks that game designers may perform during game development include coding, developing AI[a] systems and camera systems, drawing characters and environments, designing UI[b] elements, populating levels, managing the development team, managing schedules and resources, testing the game for bugs, creating music and sound effects, writing character dialogue, and setting up game objective prompts. Designers may also distinguish good from bad games and explain why, as well as ensure that the game achieves its goals and maintains its vision.	Over time, professionals specialize in 2D or 3D graphics, physics, mathematics, particle systems, UI, AI, input devices, and computer networking. Storyboard artist, concept artist, 3D modeler, environmental artist, texture artist, visual effects artist, UI artist, animator, technical artist, art director, level designer, game designer, system designer, scripter, combat designer, creative director, executive producer, associate producers, and assistant producers can specialize. Some positions are hired later in the development process and may be considered freelance rather than full time.
Publishing team	Product manager, project manager, creative manager, art director, technical director, marketer, and players and users	Publishing team members set priorities, review project milestones, set and meet targets or deadlines, provide feedback on improvements, collaborate with marketing to develop packaging and other visual assets, and promote the game. They also mediate between the studio and the publisher’s legal department, work with licensors and the ESRB[c] to secure a rating, and provide technical support. They may also cooperate with marketing and PR[d] on press materials, co-design the game, and improve its visual language.	These positions may or may not affect the game’s content and aim to streamline development and maintain quality within budget and time constraints. Game designers or writers in publishing usually fill these positions, which may vary in involvement depending on the publisher. In addition to programming, they may handle management issues and work with media outlets and advertising firms with different needs and capabilities.
Context-related team	Subject matter expert, educational theorist, scholar, and research director	They consult with teams on game content and requirements, provide educational material, maintain educational aspects, investigate and test game features, and manage or supervise scholars and data collection. They also propose, choose methods, supervise, budget, and report.	In all serious game design projects, these stakeholders must provide sufficient materials to address serious issues and express them through gameplay. Although they may not be educators, they focus on game curriculum and syllabus development. They may be specialists in a research field or pursuing specialization.
Supplementary team	Business developer, lawyer, brand manager, PR manager, quality assurance manager, talent recruiter, human resource officer, game reviewer, licensor, and funding entity	They create business opportunities, secure funding, and invest in games. They also provide legal advice, review contracts, and handle licensor negotiations. In addition, they maintain brand representation in the game and work with marketing on packaging, create marketing strategies, contact gaming publications and blogs, and organize press events. Moreover, they manage the test department, send developers bug sheets, and ensure quality, as well as recruit, manage, and train new hires.	Their responsibilities include building relationships with teams, reviewing game demonstrations, negotiating contracts, generating marketing strategies, managing the employment process, playing and reviewing games, and securing funding for serious game projects. Game producers run the test department, organize press events, recruit talent, and invest in serious game projects. These people play games, write reviews, and suggest improvements. In addition, they license IP[e] and may work with licensors to get ratings. Moreover, they financially support serious game projects and crowdfund.

[a]AI: artificial intelligence.

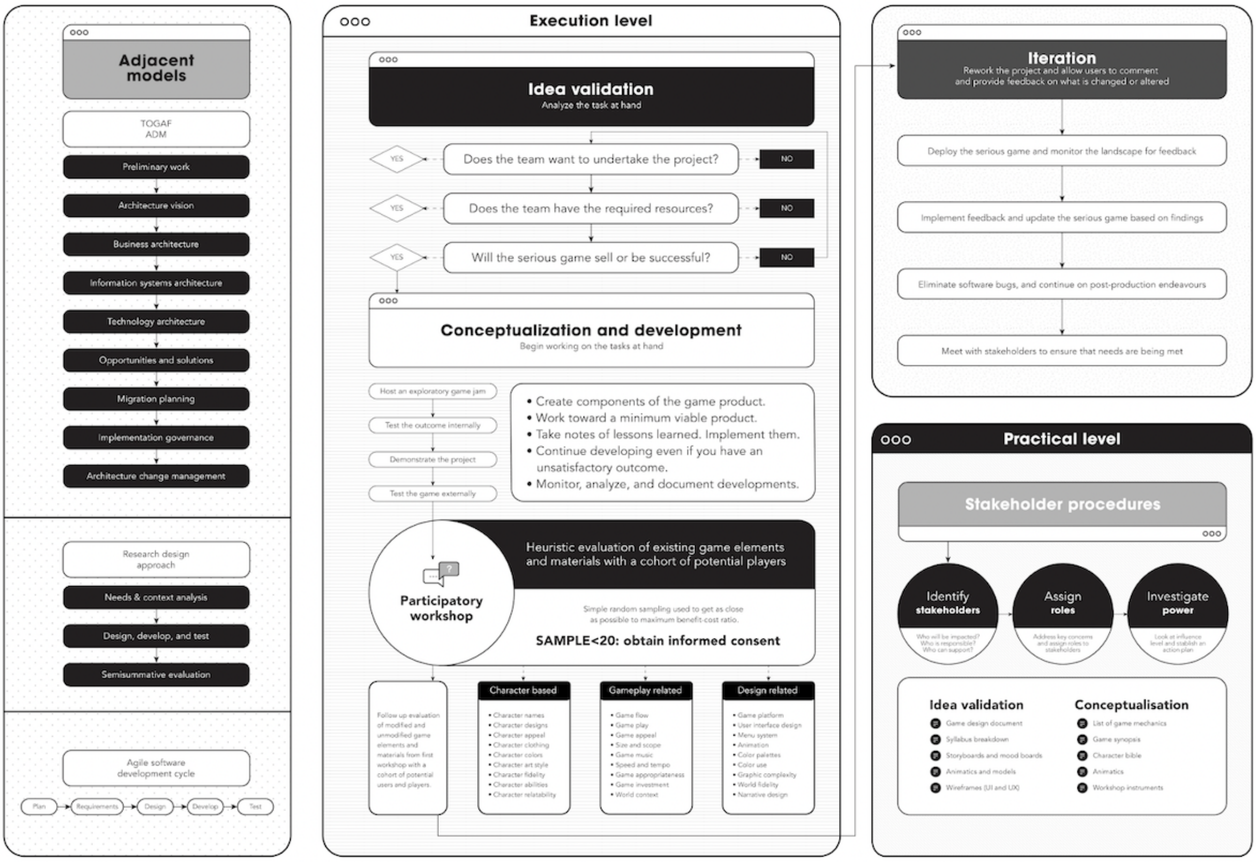
[b]UI: user interface.

[c]ESRB: Entertainment Software Rating Board.

[d]PR: public relations.

[e]IP: intellectual property.

Figure 1. Simplified variant 2 of the stakeholder-centered framework. ADM: Architecture Development Method; TOGAF: The Open Group Architecture Framework; UI: user interface; UX: user experience. For a higher-resolution version of this figure, see Multimedia Appendix 1.



Variant 3: Refinement

Variant 3 of the framework emphasizes human-centeredness and separates idea validation and evaluation (Table 2). The 3 levels are *EA*, *execution*, and *practical*. Each level combines serious game and stakeholder theory literature, practices, and methods, but only the EA level fully represents 1 of the 3 TOGAF ADM research pillars. The levels help practitioners avoid not seeing the forest for the trees and understand the framework's many components, mechanisms, and prescriptions. The composite nature of serious game development makes the framework stratiform, and the levels isolate and aggregate all interaction-based components, connectors, and relations for every aspect of the system's functionality into a single structural model.

Table 2. The third framework variant.

EA[a] level	Execution level	Practical level
This level establishes the strategic framework for serious game design, aligning game objectives with organizational goals and stakeholder needs through a comprehensive stakeholder analysis.	It transitions the process from strategic planning to the tangible design and development phases, detailing the game's mechanics, story, and technical requirements to ensure alignment with the defined objectives.	• This final level focuses on the deployment, testing, and evaluation of the game in real-world scenarios, emphasizing the adjustment of the game design based on user feedback and the effectiveness of achieving intended outcomes.
Core functions		

This level focuses on the strategic aspects of serious game design, aligning game objectives with broader organizational or project goals. It incorporates stakeholder analysis to ensure that the game's objectives meet the needs and expectations of all relevant parties.	At this level, the framework transitions from strategic planning to operational design and development. It involves the detailed design of the game, including gameplay mechanics, narrative elements, and technical specifications. This level ensures that the game's design is feasible and aligns with the strategic objectives outlined at the EA level.	• The practical level is where the game is deployed and assessed in real-world settings. This involves testing, gathering feedback from end users and stakeholders, and iterating on the design based on this feedback. The focus here is on practical application and the effectiveness of the game in achieving its intended outcomes. The level offers options for game developers:
		• Prediscovery stage
		  • Basic: stakeholder team selection, assembled team, and game design document
		  • Standard: basic outputs, selection of game mechanics, and storyboards
		  • Advanced: standard outputs and detailed curriculum itemization
		• Production
		  • Basic: stakeholder prioritization, game synopsis, and character bible
		  • Standard: basic outputs and mood boards
		  • Advanced: standard outputs, wireframes, and animatics
		• Periphery
		  • Basic: Ongoing stakeholder prioritization, game art development, and level design
		  • Standard: basic outputs and prototype development
		  • Advanced: standard outputs, deeper design practice, and quality assurance

[a]EA: enterprise architecture.

Ethical Considerations

This study was approved by the Institutional Review Board of North-West University, ensuring adherence to ethical standards in research involving human participants (approval number: NWU-01775-20-A9). Informed consent was obtained from all participants prior to their inclusion in the study (in the expert review questionnaire). Participants were informed of their right to opt out at any time without any consequences. Data collected during this study were anonymized to protect participant confidentiality. Identifiable information was removed, and data were stored securely in a password-protected database. Participants were not compensated for their time and effort in participating in the study. They were, however, promised a copy of the academic work once published.

Results

Expert Review Analysis

Overview

The expert review questionnaire regarding the stakeholder-centered framework was distributed to 220 serious game practitioners and experts internationally, of whom 29 (13.2%) completed it. On average, questionnaire completion took 57.2 (range 14.5-252) minutes. Considering the in-depth nature of the research, a completion time of approximately 24 minutes (excluding the outlier) is acceptable, despite the recommended 15-minute length for questionnaires. This study's niche focus on serious games results in a smaller expert pool; thus, the response rate and data volume are considered satisfactory. The questionnaire, designed for comprehensive data collection on the stakeholder-centered framework, uses both qualitative and inferential statistical analyses.

The research accounts for web-based survey challenges by ensuring content validity and question clarity, balancing open-ended and closed-ended questions, and maintaining reliability. Despite initial plans, level-specific explainer videos were excluded to prevent extending the questionnaire's length. An introductory explainer video was provided [44], and participants had full access to the framework for a thorough review. To ensure depth and accuracy, participants were granted access to all aspects of the framework to ensure that they could perform a multifaceted expert review.

Section A: General Information

The questionnaire respondents predominantly skewed younger, with 45% (13/29) aged 26 to 35 years and 38% (11/29) aged 36 to 45 years. Those aged 46 to 55 years constituted 10% (3/29) of the sample, while those aged 18 to 25 years and ≥66 years each represented 3% (1/29). White individuals made up 69% (20/29) of the respondents, followed by 14% (4/29) of individuals of other ethnic backgrounds including Hispanic individuals, Latinx individuals, people of color, and others. Asian respondents accounted for 7% (2/29) of the sample; and African, Indian, and undisclosed categories each accounted for 3% (1/29). Gender distribution among the respondents was fairly even, with 56% (16/29) identifying as man and 41% (12/29) as woman; of the 29 respondents, 1 (3%) preferred not to disclose their gender. In terms of geography, 45% (14/29) of the participants were from South Africa, reflecting the study's origin and local interest. Thailand and Australia each contributed 7% (2/29) of the respondents, while the remaining countries (11/13, 85%) each contributed 3% (1/29) of the respondents, broadening the international representation.

Section B: Game Development Experience

Overview

The survey section on game design experience collected data on qualifications, occupations, and development experience, including roles and satisfaction in game development. The respondents had high qualifications, with 55% (16/29) holding doctoral degrees, 24% (7/29) master's degrees, and 14% (4/29) honors degrees. The occupational profile was academic-centric, with 24% (7/29) being lecturers and 17% (5/29) senior lecturers. Others (17/29, 59%) included professors, researchers, and various roles in private industry. A significant proportion of the respondents (16/29, 56%) had >5 years of game development experience, showcasing their expertise in the field. Most (22/29, 76%) had also been involved in serious game development, although a few (3/29, 10%) had not, and some (2/29, 7%) were unsure or had projects in development. In terms of team experience, the majority (22/29, 76%) affirmed involvement, with a small percentage (3/29, 10%) either working independently or not at all in serious game development. Satisfaction across 11 development factors (DFs) was measured, with the highest scores (out of 4) being for collaboration (3.54), skills (3.56), vision (3.56), and educational aspects (3.7) and the lowest for management (2.85). The DFs and their resulting scores were as follows:

- DF1: collaboration, average score=3.54
- DF2: communication, average score=3.22
- DF3: resources, average score=3.19
- DF4: team composition, average score=3.3
- DF5: skills, average score=3.56
- DF6: management, average score=2.85 (this is the lowest average score among the 11 DFs studied)
- DF7: vision, average score=3.56
- DF8: procedures and processes, average score=2.96
- DF9: outcomes, average score=3.12
- DF10: conflict, average score=3.31
- DF11: educational and edifying aspects, average score=3.7 (this is the highest average score among the 11 DFs investigated)

Respondents expressed their views on various aspects of serious game development in this section:

- Collaboration (DF1): respondents were largely satisfied with their collaborative efforts in developing games.
- Communication (DF2): although rated slightly lower than collaboration, communication during serious game design was still positively regarded.
- Resources (DF3): the resources available for serious game development, including educational materials, software tools, and marketing aids, were deemed satisfactory.
- Team composition (DF4): the composition of serious game teams was viewed favorably, with the right mix of skills and expertise viewed as to the team's goals and performance.
- Skills (DF5): team members' skills were rated as fitting for serious game development tasks.
- Management (DF6): satisfaction with management was moderate, indicating that some areas may require improvement.
- Vision (DF7): respondents were content with the guiding visions for serious game projects, which help in goal setting and decision-making.
- Procedures and processes (DF8): there was some dissatisfaction with the processes involved in transforming ideas into final products.
- Outcomes (DF9): the outcomes of serious game projects were generally met with approval, suggesting satisfaction with the services or interventions provided.
- Conflict (DF10): opinions on conflict were mixed but leaned toward satisfaction with handling disagreements during serious game projects.
- Educational and edifying aspects (DF11): given the respondents' backgrounds in education and research, they highly rated the educational value of the games produced.

The section B responses indicated that the experts were well-versed in game development, with a specific focus on serious game development. Their moderate satisfaction across key production factors attested to their practical experience, reinforcing the study's credibility and reliability. Predominantly researchers, these individuals engage deeply with the field, often acting as SMEs in serious game projects. The most frequently reported challenges were resource-related: time, budget, and skills. Acknowledging these common hurdles faced by serious game professionals helps refine the framework to address and mitigate such issues more effectively.

Serious Game Development Roles

Researcher emerged as the most common role among serious game professionals, accounting for 14% (4/29) of the respondents, highlighting their involvement in data collection, analysis, and contribution to scholarly literature. The role of *educational theorist* followed at 10% (3/29), underscoring expertise in teaching methods. *Content expert*, *designer*, and *tester* each constituted 9% (3/29) of the respondents. Additional roles such as *project manager*, *CEO* (chief executive officer), and *UX* (user experience)/*UI* (user interface) designer were specified under *Other*. With education-related roles being predominant, this reflects the survey's findings on respondent occupations. A total of 176 roles were reported, averaging 6 roles per person, indicating the multifaceted nature of serious game stakeholder involvement. The diversity of roles suggests that stakeholders often wear multiple hats in their projects. Notably, *lawyer* and *licensor* were the only roles not represented among the respondents.

Serious Game Development Activities

Respondents reported a broad spectrum of activities within serious game development, categorized into *preactivity stage*, *development*, *postactivity stage*, *continuous*, and *unknown*:

- *Preactivities* are preparatory steps such as topic research, fundraising, context analysis, problem definition, game scope determination, learning content creation, and initial consultations.
- *Development* activities encompass the actual creation process, including game design, iteration, implementation, programming, artwork, and character design.
- *Postactivities* might consist of usability testing and game evaluations, depending on the project's goals.
- *Continuous* activities are ongoing tasks such as management, research, education, administration, and marketing that span the project's life cycle.
- *Unknown* captures any unclear or undefined responses.

The bulk of the feedback pertained to the hands-on development tasks—programming, art, writing, and design—aligning with the framework's emphasis on development processes. Game research and evaluation were equally represented, each with 9 mentions, while learning content development received 7 mentions, reflecting the educational aspect of serious game projects.

Serious Game Development Issues

Respondents were asked about common issues encountered during game development, with the question focused on *resources* and *game-specific* challenges.

Resource-related issues highlighted included the following:

- Time management, with 7 (24%) of the 29 respondents noting the extensive duration needed for serious game projects, often described as time consuming and unrealistic
- Budget constraints, also mentioned by 7 (24%) of the 29 respondents, indicating that limited funding, especially within educational environments, affects the scope of development
- Skills shortage, with responses pointing to a lack of necessary expertise and experience among serious game stakeholders
- Team-related factors, with, for example, size and composition, tools for development, intellectual property concerns, and marketing resources highlighted as challenges

Game-specific issues centered on the following aspects:

- The balance between educational content and entertainment value, with respondents expressing difficulty in finding the right mix
- Validation of serious game effectiveness, including measuring the impact of serious games on players, which was mentioned as a key concern

End-user considerations include player demographics, abilities, and gaming background, along with their engagement levels and ability to reach states of flow during gameplay.

Sections C, D, and E: Framework-Level Impressions

The 3 levels of the framework are *EA*, *execution* (process oriented), and *practical* (outcomes). The following aspects of the conceptual framework levels were examined in sections C, D, and E of the expert review questionnaire:

- Comprehensibility: the degree to which the framework, including its overall structure and key components, can be understood and comprehended by its intended audience
- Fluency: the ease with which the framework can be applied or implemented by its users, considering the clarity of instructions and the usability of any associated tools and resources
- Length: the appropriate duration or scope of the framework to ensure that it is neither too long nor too short and provides adequate guidance to achieve the desired results
- Accessibility: the extent to which the framework is accessible to all potential users, including those with physical or cognitive limitations, and the availability of the resources required to implement the framework
- Applicability: the relevance and utility of the framework in addressing the challenges or opportunities it is intended to address
- Utility: the effectiveness of the framework in achieving its intended outcomes, including its capacity to produce measurable and quantifiable outcomes
- Contextuality: the extent to which the framework is tailored to the context or situation in which it will be applied, including cultural and social considerations
- Outputs: the tangible and measurable results or outcomes produced by the application of the framework, such as changes in behavior and performance enhancements, as well as other demonstrable effects

The results from sections C, D, and E are presented in Table 3.

Table 3. Questionnaire results for sections C, D, and E (n=29).

Framework aspect	5-point scale ratings					Overall comments
	Strongly agree, n (%)	Agree, n (%)	Neutral, n (%)	Disagree, n (%)	Strongly disagree, n (%)	
Comprehensibility (clarity of framework structure and components)						
EA[a] level	—[b]	9 (33)	11 (41)	—	7 (26)	Needs more clarity
Execution level	—	21 (75)	6 (21)	—	1 (4)	Clear to most respondents
Practical level	23 (81)	—	—	—	—	Rated highest for clarity
Fluency (ease of applying or implementing the framework)						
EA level	19 (68)	—	8 (29)	—	1 (4)	Logical progression noted
Execution level	22 (79)	—	4 (14)	—	2 (7)	Highly logical flow
Practical level	23 (81)	—	—	—	—	Streamlined progression
Length (adequacy of framework duration and scope)						
EA level	—	7 (27)	13 (46)	7 (27)	—	Divided opinions
Execution level	13 (46)	—	11 (39)	4 (14)	—	Some found it lengthy
Practical level	17 (62)	—	—	—	—	Most agreeable length
Accessibility (ease of access for all users, including those with limitations)						
EA level	—	5 (20)	12 (44)	10 (36)	—	Complex for laypersons
Execution level	—	13 (48)	11 (41)	3 (11)	—	Accessible to general users
Practical level	13 (48)	—	—	—	—	Most accessible level
Applicability (relevance and adaptability of the framework to different scenarios)						
EA level	—	11 (39)	13 (48)	3 (11)	—	Requires more relevance
Execution level	19 (68)	—	7 (25)	2 (7)	—	Pertinent to game design
Practical level	21 (74)	—	—	—	—	Highly relevant to practice
Utility (effectiveness in producing intended outcomes)						
EA level	—	10 (36)	15 (54)	3 (11)	—	Utility is acknowledged
Execution level	—	10 (36)	15 (54)	3 (11)	—	Comparable to EA level
Practical level	13 (46)	—	13 (46)	—	—	Divided on effectiveness
Contextuality (suitability of the framework for various cultural and social settings)						
EA level	—	10 (36)	15 (52)	3 (11)	—	Needs more adaptability
Execution level	15 (52)	—	7 (26)	3 (11)	—	Flexible across settings
Practical level	13 (48)	—	—	—	—	Well-tailored to contexts
Outputs (tangible results or benefits from using the framework)						
EA level	—	10 (37)	13 (48)	4 (15)	—	Essential outputs produced
Execution level	16 (57)	—	9 (32)	3 (11)	—	Effective in generating outcomes
Practical level	19 (67)	—	—	—	—	Highest positive review

[a]EA: enterprise architecture.

[b]Not applicable.

Section F: Overall Impressions

Expert feedback on the stakeholder-centered framework revealed several key themes. Most of the participants agreed that the framework is useful for facilitating serious game development, highlighting its organized approach and detailed guidance. However, worries about its intricacy indicate that it could be overwhelming for smaller teams or individuals inexperienced in serious game development. Some of the respondents proposed that the framework should be used primarily as a diagnostic tool rather than a prescriptive one, hinting at a possible adjustment in its application to better suit serious game developers' varying levels of expertise.

Feedback on the framework's features suggested the necessity for additional refinement to improve its structure and comprehensibility. Respondents requested a clearer definition of serious game design elements and a greater emphasis on the gameplay experience. The relationship between the different levels of the framework and how well they work together with other frameworks were recognized as areas that require focus. There was a clear desire for participatory processes, emphasizing a preference for a stakeholder-centered approach that maximizes production and team engagement.

The framework's implementation elicited varied responses, with a significant portion finding it easy to use, while a noteworthy percentage encountered challenges. These observations emphasize the significance of customized training and emphasize the intricate nature of the framework. Providing stakeholders with necessary tools and ensuring that the framework is easily accessible can help alleviate these challenges.

Opinions on the provision of necessary development instruments were mostly positive, although some of the respondents noted that the framework does not fully address all aspects of information systems development or early serious game design requirements. This indicates potential for growth and a more detailed incorporation of serious game design mechanisms. Many of the respondents viewed the motivation to excel while using the framework positively because it offers clarity on roles and progression through the serious game development stages. However, some of the respondents doubted its impact on motivation, citing the possibility of heightened demands because of the framework's procedural intricacy. Respondents had a positive outlook on how the framework would affect stakeholder efficiency and management, expecting enhancements in planning and stakeholder engagement. However, some of them believed that it might lead to increased resource demands and project delays, highlighting the importance of finding a balance between specific instructions and managing work efficiently.

Summary

Overall, the stakeholder-centered framework was acknowledged as a valuable tool for serious game development, but it requires simplification and more user-friendly adjustments. The feedback is crucial for future improvements, guaranteeing that the framework stays pertinent and efficient for various serious game development scenarios.

Discussion

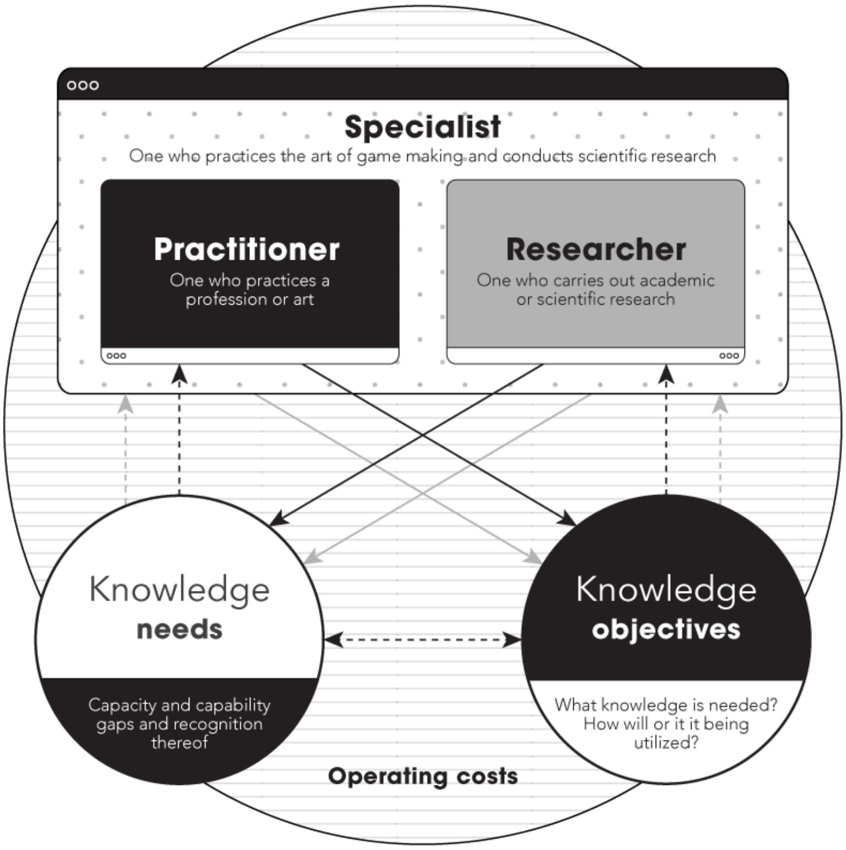
Principal Findings

The study highlights that serious game practitioners, researchers, and specialists have varying knowledge needs and objectives; for instance, a serious game practitioner in private industry may seek financial information related to serious games for profitability, while a researcher may focus on evaluating the effectiveness of serious game media. Serious game specialists may require a combination of knowledge needs to fulfil their role. As indicated in Figure 2, it is crucial for managerial staff to be aware of these differences and understand their team members' knowledge needs and objectives to effectively manage operating costs and stakeholder needs in a serious game project.

The neglect of elements such as threat assessment in serious game practice can lead to increased risk, which can impact revenue and project success. It is important for administrative and managerial staff to consider different types of risks, such as integrated, behavioral, strategic, financial, compliance, legal, and operational risks before, during, and after serious game production. Risk assessment has significant implications for stakeholder management, uncertainty management, hazard evaluation, control measures, and workplace safety and should be considered in any framework aimed at supporting stakeholders in creating effective serious game media.

The stakeholder-centered framework is mostly prescriptive and lacks personalization, and stakeholder input is necessary for improvement. The framework also lacks emphasis on game design principles and evaluation. Future research can explore ways to facilitate stakeholder participation and integrate *serious* considerations such as learning analytics, knowledge management systems, evaluation frameworks, and more.

Figure 2. Overcoming variance in knowledge needs and objectives for serious game practitioners, researchers, and specialists.



Limitations

One limitation is the challenge of incorporating 3 different theoretical pillars, which increases the complexity and can make it difficult to achieve brevity in practical research. In addition, the qualitative nature of the investigation means that the focus is on a specific sample group with distinct demographic, psychological, social, and cultural traits, making it difficult to generalize the findings to all comparable groups or circumstances. As a result, transferability is more relevant for this qualitative research.

Time constraints are another limitation imposed on the study because it is cross-sectional in nature, giving us a limited time frame to deliver our work for examination. However, the DSR approach allows the framework to undergo imminent development and iteration.

The modest sample size of the study (n=29) could also be considered a limitation because serious games are a niche field that often require expertise in education, health, or public policy, which may limit their developers. However, we contacted 220 people to take part in the study after extensive market research, and additional data would have reduced random variation and increased statistical power, making the research more accurate and reliable.

Another limitation of the research is that the framework could only be evaluated on a particular level of response assessment. Future studies should be conducted with teams to see how the framework functions in practice, according to all 4 levels of artifact assessment: response (participant feelings), learning (knowledge transfer), behavior (work performance), and outcomes (effect over time).

Finally, the reliability of questionnaire data analysis is highly dependent on several factors, such as the quality and depth of the responses, the structure of the questionnaire, and the lack of observations regarding alterations in the respondents' states of mind, feelings, and behaviors. Therefore, these factors should be taken into consideration when interpreting the results of the study.

Recommendations

We offer the following recommendations for future work:

- Forthcoming work on this topic should isolate each theoretical domain, examine them discretely, and combine, compare, and synthesize the results.
- A positivistic study that gathers quantitative data would intensify the generalizability of the findings relating to the stakeholder-centered framework. Quantitative research, such as experimental studies, offers a good basis for developing wide generalizability, given that generalizability requires data from large populations.
- Longitudinal research over an extended period of time could better assess the affects and effects of the framework. The analysis could also be richer if the inquiry extends beyond a single moment in time. DSR is typically carried out in iterative cycles of design, implementation, and evaluation, which enables researchers to refine and improve their solutions over time, allowing for strong longitudinal studies. This iterative approach also allows for data collection at multiple points in time, which can provide insights into the

effectiveness and long-term viability of the solutions being developed. The framework becomes a living artifact in this way.

- A larger sample population can feature in impending studies. The greater the sample size, the more precise the calculated mean values will be. Error margins are also reduced if a bigger sample is used.
- More participants enable the facts to speak for themselves, rather than depending on assumptions and the researcher's subjective relationships with the data. Additional data also lead to more accurate and precise units of analysis.
- The stakeholder-centered framework can be assessed according to all 4 levels of artifact assessment proposed by Petri and von Wangenheim [45]. A longitudinal study of this nature would be equipped to establish the effectiveness of the framework regarding its learning potential, behavioral impacts, and outcomes.
- The methods used to appraise the framework could be expanded in future work. This would improve the reliability of the data analysis carried out; for example, structured interviews, semistructured interviews, in-depth interviews, focus groups, field research, ethnography, and observation could be used to strengthen analysis efforts.

Features for the Framework Going Forward

Now that that main recommendations for future research have been presented, we need to consider the requisite features for the framework going forward (Table 4).

Variant 4 of the stakeholder-centered framework reflects the academic and investigative nature of serious games and their development (Figure 3). It includes instructions, demonstrations, descriptions, and definitions that facilitate game design and development and focuses on procedural information rather than technology, expertise, or resources. The length of the tool has been reduced, and the framework is less prescriptive, providing flexibility in project assumptions, goals, and processes. The progressive web application version of the framework enables users to take part in conversations with one another, categorizes procedural information into subdivisions, and includes built-in support mechanisms. The application affords the researcher added control over the transmission, presentation, structure, and extent of the intelligent system and can adapt to any changing needs or patterns of its user base.

Variant 4 also integrates the 3 theoretical domains in a more subtle manner than previous versions. It presents a terser technical diagram for serious game design that omits some information to improve accessibility and usability. The procedures still begin with stakeholder analysis, categorizing stakeholders by their impact and influence on value creation in the development endeavors. The resulting stakeholder categories are development, publishing, context-related, and supplementary teams, which consist of stakeholder roles with their own activities and specializations.

Table 4. How desired framework traits correlate to improvement areas, as well as evidence for the intersection thereof in the progressive web artifact.

Desired framework trait	Improvement areas (from expert review)										Artifact execution (within the progressive web application)
	Abbreviation	Concentration	Configuration	Guidance	Idealism	Milestones	Prescription	Semantics	Simplification	Transmission	
Concerned with serious aspects		✓		✓			✓	✓			Serious game conventions built into the artifact: principles, designs, and evaluations
Concise	✓		✓					✓	✓	✓	Artifact uses chunking to boost content processing
Diagnostic		✓		✓		✓				✓	Artifact facilitates the achievement of development objectives through measurement
Flexible	✓		✓	✓			✓		✓	✓	Artifact is open to changes in assumptions, goals, and process
Informative		✓		✓	✓	✓		✓			Artifact includes instructions, demonstrations, descriptions, and definitions on serious game design
Invested in work, not technology		✓	✓	✓				✓		✓	Artifact makes provision for technology but focuses on procedural information
Participatory		✓	✓				✓			✓	Discussion is facilitated in the artifact by way of private and community chat functions
Procedural			✓	✓	✓	✓	✓			✓	Various activities are divided into practical sections and directed at various stakeholders

Desired framework trait	Improvement areas (from expert review)										Artifact execution (within the progressive web application)
	Abbreviation	Concentration	Configuration	Guidance	Idealism	Milestones	Prescription	Semantics	Simplification	Transmission	
Relevant		✓		✓				✓			Extraneous information is removed using filters, and streams of material are categorized
Repeatable	✓			✓		✓			✓	✓	Sets of actions provided in the artifact are reusable and easily duplicated
Stakeholder centered		✓			✓		✓			✓	Sections of the artifact are targeted toward specific stakeholders
Supportive			✓	✓		✓	✓		✓		Frequently asked questions, data protection, and self or continual support
Sustainable	✓			✓		✓				✓	Scalable design is incorporated into the artifact
Usable	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	User control, consistency standards, minimalist design, and platform compatibility
Vehicle for good design		✓	✓			✓	✓			✓	Artifact encourages good design practice by encouraging users to assess their own practice

Conclusions

The proliferation of serious games and game-assisted learning in education and beyond requires keen awareness, careful contemplation, and steady advancement [46-48]. As serious games become more common in contexts aiming to edify in innovative ways, scholars should not only consider methods to improve the efficacy thereof but also think about how to realistically and efficiently fabricate them as well. Serious game project stakeholders need practical ways to align their interests with those of the enterprise. Stakeholder roles, activities, specializations, potential, competence, and capabilities all impact these experts' productive capacity and labor prospects. However, serious game initiatives vary significantly. To help future game makers, this research inspects serious game design stakeholders and techniques to produce a system capable of supporting these individuals in a range of environments. A stakeholder-centered framework, in this view, may help serious game developers manage their teams and drive practice in beneficial and sustainable ways. In the future, we hope that this investigation will aid in a decrease in serious game project failure, communication breakdown, and apathy regarding the genre of games intending to do more than purely entertain. However, additional research and innovation is needed in fields adjacent to, and embedded in, serious games to support the growing need for novel approaches to demonstrate, educate, simulate, and inform.

Acknowledgments

This work was undertaken as part of a doctoral study at the North-West University, Vanderbijlpark, South Africa. The authors are grateful to Professor Roelien Goede, Professor Japie Greeff, and Professor Estelle Taylor for their contribution and support. The financial support of the Unit for Data Science and Computing at North-West University is gratefully acknowledged. We used the generative AI tools QuillBot [49] to help refine text into manageable portions for the manuscript and ChatGPT [50] to condense the results presented in Table 3 into a more suitable format.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

The study was conceptualized by LB along with JG and ET. All authors were involved in the interpretation of results, manuscript write-up, and revisions. LB was involved in the design of the framework, data collection, data analysis, and the writing of methods and results. Moreover, LB was involved in data collection and logistics. LB conducted statistical analysis under the supervision of JG and ET. JG and ET supervised LB on all tasks pertaining to this project.

Conflicts of Interest

LB is supported by the Unit for Data Science and Computing, North-West University. All other authors declare no other conflicts of interest.

Abstract

Background: Neck pain is a common condition that leads to neck motor dysfunction and subsequent disability, with a significant global health care burden. As a newly emerging tool, virtual reality (VR) technology has been employed to address pain and reduce disability among patients with neck pain. However, there is still a lack of high-quality studies evaluating the efficacy of VR therapy combined with conventional rehabilitation for patients with chronic neck pain, particularly in terms of kinematic function.

Objective: This study aims to investigate the effect of VR therapy combined with conventional rehabilitation on pain, kinematic function, and disability in patients with chronic neck pain.

Methods: We conducted an assessor-blinded, allocation-concealed randomized controlled trial. Sixty-four participants experiencing chronic neck pain were randomly allocated into the experimental group that underwent VR rehabilitation plus conventional rehabilitation or the control group receiving the same amount of conventional rehabilitation alone for 10 sessions over 4 weeks. Pain intensity, disability, kinematic function (cervical range of motion, proprioception, and mean and peak velocity), degree of satisfaction, and relief of symptoms were evaluated at 3 timepoints (baseline, postintervention, and at 3 months follow-up). A 2*3 mixed repeated measures analysis of variance was utilized for analyzing the difference across indicators, with a significant difference level of .05.

Results: Both groups demonstrated significant improvements in pain, disability, and kinematic functions (*P*<.05) at postintervention and at 3-month follow-up. The experimental group showed superior therapeutic outcomes compared to the control group in pain reduction (mean difference from the baseline: 5.50 vs 1.81 at posttreatment; 5.21 vs 1.91 at the 3-month follow-up, respectively; *P*<.001), disability improvement (mean difference from baseline: 3.04 vs 0.50 at posttreatment; 3.20 vs 0.85 at the 3-month follow-up, respectively; *P*<.001), and enhanced kinematic functions (*P*<.05). Moreover, participants in the experimental group reported better satisfaction and relief of symptoms than the control group (*P*<.05), with better initiative for exercising during the follow-up period. However, there was no between-group difference of improvement in proprioception. No adverse events were reported or observed in our research.

Conclusions: The findings of our study support the efficacy of combining VR therapy with conventional rehabilitation in alleviating pain, enhancing kinematic function, and reducing disability of patients with chronic neck pain. Future research should focus on refining the therapeutic protocols and dosages for VR therapy as well as on optimizing its application in clinical settings for improved convenience and effectiveness.

KEYWORDS

virtual reality; neck pain; disability; kinematic function; rehabilitation; physiotherapy; neck; pain; chronic; therapy; kinematic; efficacy; patient; effect

Introduction

Chronic neck pain is a prevalent global health issue, with reported prevalence rates ranging from 10% to 24% [1,2]. This condition is closely associated with motor dysfunction in the cervical region, characterized by deficits in various kinematic functions of the neck [3-5]. Cervical kinematic functions can be operationally defined as the capacity of the neck muscles to generate and regulate movement of the head and neck, including range of motion (ROM), which is the degree of movement that can be achieved in various directions of the cervical spine, velocity, coordination, strength, and endurance. These parameters can be quantified through specific evaluations and measurements such as ROM assessments, manual muscle testing, and functional movement tests. Prior studies have proven that motor dysfunction occurs commonly in patients with neck pain [6-8], and these dysfunctions are highly correlated with the level of pain and disability. That is because weakness in neck muscle strength and coordination will provide more unstable support of the neck segments and additional stress on the neck structure, which restricts the patient's neck movement and results in pain [9]. These diminished motor dysfunctions as well as worse pain and disability undoubtedly impair a patient's work performance and quality of life, leading to large economic losses [10]. Given the abovementioned pivotal role of cervical kinematics in neck pain, interventions aimed at improving motor function hold promise in managing this condition.

To date, active exercise is recommended to be a valid therapy for patients with chronic neck pain based on the current clinical guidelines [11,12]. Virtual reality (VR) is a unique form of exercise established by Morton Heiling in 1962 and has been evolving over the past 60 years [13,14]. VR technology commonly generates virtual environments resembling the real world through devices such as computers or head-mounted displays and interacts with patients to enable them to accomplish the targeted therapeutic goals [15,16]. Regarding the economics of VR treatment, studies [17,18] have reported low costs in VR-based treatments. The hardware devices involved in VR therapy are readily available and inexpensive. Additionally, the one-time cost of patient-specific VR software allows for repeated use, making VR applications relatively less expensive in medical settings. VR serves as a valuable assessment and intervention tool in rehabilitation due to its clinical benefits supported by ongoing research [19], and orthopedic and neurological rehabilitation are the common areas where VR therapy is utilized in clinical practice [20,21]. The potential therapeutic mechanisms of VR include task-oriented repetition, positive feedback, and embodied simulation [22].

As a noninvasive method of pain reduction, VR therapy, both independently and in combination with other interventions, has been investigated in numerous studies. Prior research [23-25] has demonstrated the potential of VR therapy to alleviate pain and disability in patients with orthopedic conditions such as rheumatoid arthritis, shoulder impingement syndrome, and low back pain. However, to date, there is still less research exploring the effects of VR therapy or combined treatment on individuals with chronic neck pain, particularly in terms of improving the cervical motor function [26,27]. Mukherjee et al [28] investigated the efficacy of VR therapy in the treatment of cervical spondylosis. Their findings revealed that patients who underwent VR therapy along with conventional physiotherapy demonstrated notable improvements in pain intensity and active cervical ROM (CROM) compared to those who underwent conventional therapy alone in the short-term period ($P<.05$). However, another study [29] reported that after receiving 4 weeks of VR training, patients with neck pain exhibited significant improvement in mean and maximal velocity, with no observed improvement in CROM indicators compared with the control group. A recent meta-analysis [30] consisting of 2 randomized controlled trials (RCTs) suggested that VR therapy combined with kinematic training could enhance the global perceived effect, patient satisfaction, and general health of patients with neck pain compared to treatment with kinematic training alone. However, evidence supporting the efficacy of VR therapy in strengthening cervical kinematic function remains inconclusive. Given the current gaps in research and the conflicting findings, further high-quality studies are warranted to ascertain the therapeutic effectiveness of VR therapy or combined treatments for individuals with chronic neck pain. Therefore, this RCT aims to evaluate the effects of VR therapy combined with conventional rehabilitation on pain, kinematic functions, and disability in patients with chronic neck pain.

Methods

Study Design and Ethics Approval

This study was designed as an assessor-blinded, allocation-concealed RCT (Multimedia Appendix 1). Ethics approval for this study was obtained from the West China Hospital Clinical Trials and Biomedical Ethics Committee of Sichuan University (approval: HX-IRB-AF-18-2021-1102).

This trial was registered in the Chinese Clinical Trial Registry (ChiCTR2000040132) on November 22, 2020. This study conformed to the Declaration of Helsinki, and all patients provided written consent after recruitment.

Participants

This study was conducted at the Department of Rehabilitation Medicine in West China Hospital. Patients were recruited through various channels such as social networks, posters, and brochures from October to December 2021. Inclusion criteria included age of 18 years and older, a diagnosis of chronic neck pain (>3 months) by a physician, reported pain intensity ≥3 on the numeric rating scale (NRS), and disability ≥6 on the neck disability index. Exclusion criteria included existing vestibular pathology, cervical fracture/dislocation, whiplash injuries, neurological/cardiovascular/respiratory disorders affecting patients' physical performance, inability to provide informed consent, and pregnancy.

Randomization

Randomization was performed using a computer-generated sequence from Randomization.com, with a researcher not involved in treatment overseeing the process. Patients were allocated to either the experimental group or control group based on the odd or even nature of the assigned number within sealed opaque envelopes to ensure blind allocation. Although a blinded researcher assessed the patients during the trial, blinding was not feasible for participants or therapists due to the layout of the VR therapy.

Intervention

VR Treatment

The VR equipment that we used included several hardware and software (Chengdu Feiming Technology Co, Ltd). Hardware included a Pico G2 4k head-mounted VR glass, monitor screen, and optical motion capture camera. Patients wearing VR glasses sat at a distance of 100 cm from the front of the monitor screen. The monitor will display the real-time virtual images that patients see during the experimental process. Therapists can assess the patient's real-time treatment stage by looking at the monitor screen and provide corresponding assistance. During treatment, the optical motion capture camera and customized software collected and analyzed the cervical movement trajectories. Meanwhile, considering the requirement of fully immersive VR therapy, a specific shoulder strap was designed for patient safety during treatment.

In VR therapy, 3 modules (ROM, proprioception, and velocity modules) were designed to enhance the specific kinematic functions of individuals experiencing chronic neck pain. These modules involved patients engaging in targeted cervical movements to attain therapeutic objectives through visual cues. Prior to the beginning of the treatment, each patient underwent a practice trial to mitigate any potential learning biases. Throughout the VR session, patients were fully immersed in a virtual setting resembling a living room, where they could manipulate virtual objects to interact with designated targets. The VR equipment incorporated visual and auditory feedback to augment the interactive and engaging nature of the therapy. The detailed descriptions of the 3 modules are provided below.

In the ROM module, a virtual flying bird is manipulated by the patients' cervical movement. Patients could move birds by neck flexion, extension, lateral flexion, and rotation movement to catch gold or avoid the fire rings appearing in the scene. The placement of the gold items and fire rings was based on baseline kinematic data, with the game's difficulty adjusted continuously to facilitate gradual improvements in CROM across all movement directions (Figure 1).

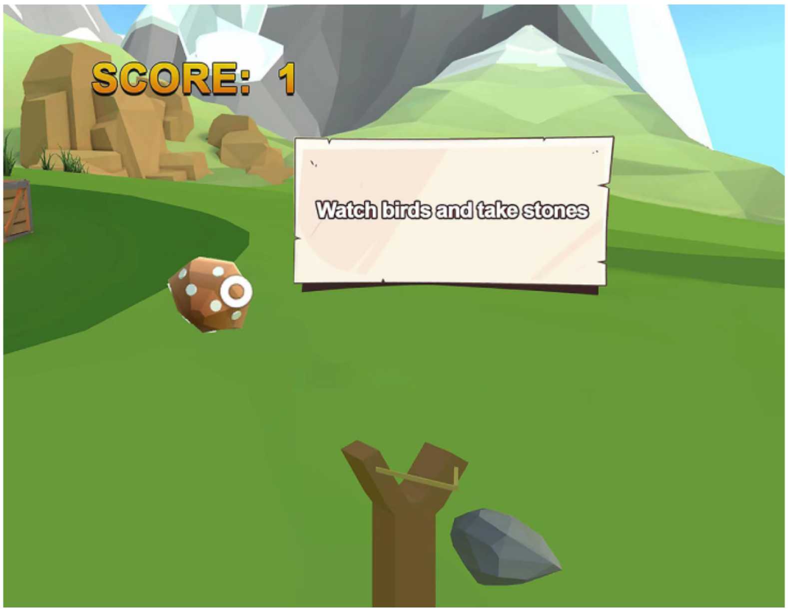
Figure 1. Range of motion module. The bird in the picture is manipulated by the patient's cervical movement (flexion, extension, lateral flexion, and rotation) to catch the gold and avoid obstacles appearing in all directions.

In the proprioception module, patients engage in tasks requiring them to control a virtual bow and arrow by using cervical movements to aim and shoot at a bull's-eye target with closed eyes. Initially, patients face the screen to align the arrow with the bull's-eye, memorizing this starting position. Subsequently, patients close their eyes and follow instructions from the VR system to move their necks to a specific position. They then have to return their neck to the initial position (representing the bull's-eye location) and shoot the arrow. The relocation error, indicating the angular deviation between the shot point and the bull's-eye, serves as a measure of patients' proprioceptive abilities (Figure 2).

Figure 2. Proprioception module. The patient was asked to remember the initial bull's-eye position and then close the eyes. Thereafter, the computer would guide the neck of the patient with the eyes closed to a specific position. The patient needs to move the neck back to the original position based on memory and manipulate the bow and arrow to shoot the bull's-eye.

In the velocity module, participants were tasked with hitting randomly appearing mushrooms within the virtual scene by manipulating virtual stones with cervical movements. Upon mushroom appearance, patients adjusted the slingshot position by moving their neck and launched a stone to hit the mushroom before it disappeared after 5 seconds. Subsequent mushrooms would appear sequentially, prompting patients to swiftly target and strike them. Patient performance was scored based on the success rate of hitting the mushrooms, thereby fostering patient engagement and compliance with the virtual therapy protocol (Figure 3).

Figure 3. Velocity module. Patients were asked to manipulate stones at maximum neck movement speed to hit randomly appearing virtual mushrooms and obtain the corresponding scores.



Conventional Rehabilitation

Patients in the experimental group received a 10-minute conventional rehabilitation session consisting of 5 minutes of active exercise (eg, muscle stretching exercise, strengthening exercise, sling exercise therapy), supported by established guidelines [11,31]. Additionally, patients underwent a 5-minute transcutaneous electrical nerve stimulation for analgesia, which was validated for efficacy in prior studies [2]. Patients in the control group were treated with 30 minutes of conventional rehabilitation, including 15 minutes of active exercise modalities same as the experimental group and an additional 15 minutes of transcutaneous electrical nerve stimulation therapy. The prescription of conventional rehabilitation was tailored based on each patient's motor dysfunction and the clinical expertise of the rehabilitation therapists.

Procedure

Sixty-four patients were randomly allocated into the experimental group or control group, and they underwent 10 treatment sessions over 4 weeks. In the experimental group, interventions included 20 minutes of VR therapy and 10 minutes of conventional rehabilitation per session, while the control group received 30 minutes of only conventional rehabilitation per session. Throughout the treatment, patient safety was closely monitored, and sessions were halted if any adverse events (eg, motion sickness, headache, falls) occurred. Patients were allowed to resume training once the symptoms subsided; otherwise, they were advised to discontinue participation in the study. Following the intervention, both groups were encouraged to continue neck exercises at home for 3 months after treatment. On completion of the follow-up period, each patient was asked to rate their frequency of neck exercise within the 3-month interval to represent their adherence to continued neck exercise. The rating scale ranged from 0 to 4 (0 = no training; 1 = 0-1 hours of training per week; 2 = 1-2 hours of training per week; 3 = 2-3 hours of training per week, ≥4 = >3 hours of training per week). A comparison of the data sets from both groups was conducted to observe the patients' initiative in training at unsupervised situations.

Outcome Measures

All outcome measures were evaluated at 3 timepoints: preintervention, immediately postintervention, and 3-month follow-up. The primary outcomes focused on pain and disability (key concerns for individuals seeking medical help for neck pain). These outcomes were evaluated using offline scales. Secondary outcomes included kinematic indicators (eg, CROM, proprioception, mean and peak velocity), patient satisfaction, and relief of symptoms, which are all crucial aspects in the rehabilitation process for chronic neck pain. These secondary outcomes were assessed using a combination of web-based VR equipment and offline scales.

Primary Outcomes

NRS

The NRS was used to measure the current neck pain intensity. NRS graded the pain intensity from 0 (no pain) to 10 (worst pain imaginable), with higher scores indicating worse pain. Pain levels were categorized as mild (1-3), moderate (4-6), and severe (≥7) based on the score range [32-34]. The NRS has shown validity and reliability, with a minimum clinically important difference (MCID) of 2.7 established in previous studies [35,36].

Neck Disability Index

The neck disability index was employed as a self-reported questionnaire to measure neck pain–related disability. It consisted of 10 items about activities of daily living, with each item scored from 0 (absence of disability) to 5 (complete disability). The neck disability index is recognized for its validity and reliability, with an MCID of 3.5 points considered significant [37,38].

Secondary Outcomes

CROM

CROM was measured using a VR device in 6 directions: flexion, extension, left and right rotation, and left and right lateral flexion. The results were calculated by taking the average of 3 measuring values. This VR equipment evaluation approach demonstrates high repeatability and sensitivity on these cervical kinematics parameters (ie, CROM, proprioception, mean and peak velocity). The reliability and validity of VR devices to measure CROM have been validated. The minimal detectable change (MDC) of CROM in different directions has been previously reported, while the value changed across the 6 movements ranging from 3.6° to 6.5° [39,40].

Proprioception

Proprioception was defined as the perception of change in direction, position, or speed produced by motor organs (eg, muscles, tendons, joints) in 6 directions. It was calculated as the mean of the relocation difference in 3 tests. Prior studies have reported the psychometric properties of VR equipment evaluating proprioception [4,41] but not provided the MCID.

Mean and Peak Velocity

Mean and peak velocity are crucial indicators reflecting cervical kinematic functions. The mean and peak velocity in 4 directions (flexion, extension, left and right rotation) were obtained by calculating the average values of 3 assessed data on angular velocity during the trial. VR devices have shown good repeatability in measuring cervical motion velocity. Although the MDC for average speed is 14.31°/s, that for maximum speed is 34.95°/s [4,42].

Global Perceived Effect

Global perceived effect is a self-administered questionnaire applied to evaluate patient satisfaction and the relief of symptoms in this study [43]. The satisfaction level ranges from –5 (totally dissatisfied) to 5 (totally satisfied). Similarly, patients could report their relief of symptoms by using the Global Perceived Effect scale, with lower scores representing worse therapeutic effects. These 2 indicators were only measured immediately postintervention and at 3 months after intervention.

Sample Size Calculation

The NRS was chosen as the primary outcome measure in this study. With reference to a previous study [44], the effect size estimate for the NRS was medium (SE 0.25). The correlation between repeated measures was assumed to be 0.5. Three measurements were presumed to be performed (baseline, postintervention, and 3-month follow-up) with a sphericity correction of 0.5. Based on the statistical power of 0.85 and an α level of .05, a total sample size of 50 patients was initially estimated. To account for potential dropout rates that have been observed to exceed 15% in similar studies [27,29,45], a conservative dropout rate of 25% was chosen to ensure sufficient patients for statistical analysis, resulting in a final inclusion of

64 patients. The sample size calculation was conducted using the G*Power software (version 3.1.7; University of Düsseldorf).

Statistical Analysis

Statistical analysis was conducted using the SPSS statistical software (version 25.0; IBM Corp) by a blinded researcher. Data analysis followed the intention-to-treat principle, while the Shapiro-Wilk test was applied to check the normality of various data. Descriptive statistics were used to reflect the different types of results such as mean and standard deviation for the parametric variables and median and quartiles for the nonparametric variables. Group equivalence was assessed via the 2-sided independent-sample *t* test or Pearson chi-squared test by comparing the baseline data between the groups. For most variables (all outcomes except the relief of symptoms), which showed normal distribution, a 2*3 mixed repeated measures analysis of variance (ANOVA) with 1 between-subject factor (treatment) and 1 within-subject factor (time) was performed to compare all variables. Post hoc comparisons were conducted using the Bonferroni test, with *P* values for multiple comparisons adjusted using SPSS software. To address violations of the sphericity assumption, the Greenhouse-Geisser correction was applied. With regard to the analysis of the relief of symptoms, nonparametric statistics were used due to the skewed distribution of data. To account for the dropouts, multiple imputations were used to fill the missing data. To show the effect sizes of observed between- or within-group change, partial eta squared and rank correlation were calculated for the parametric and nonparametric variables, respectively. Based on the previous study [46], effect sizes were classified into small (0.2-0.5), medium (0.5-0.8), and large effect sizes (≥0.8). *P* values less than .05 were indicated to be statistically significant.

Results

Baseline Measures

A total of 120 patients underwent the initial screening for eligibility, of which 56 participants were excluded. Following screening, 64 participants were randomly allocated to either the experimental group or the control group. In the 3-month follow-up period, 3 (5%) participants dropped out of the study due to time conflicts or personal reasons. The flow diagram of participant recruitment and research is shown in Figure 4. The baseline characteristics of the participants in both groups are detailed in Table 1. As shown, there was no between-group difference in age, gender, etiology, disability, pain, and other kinematic indicators. No adverse events were reported during treatment, except some discomfort (eg, complaints of heavy helmets, slightly aggravated pain). No differences existed between the 2 groups over the compliance of the patients continuing neck exercise during the 3-month follow-up period (experimental group 2.31, SD 1.25 vs control group 1.96, SD 1.19; *P*=.22). However, a higher proportion of experimental group participants (16 out of 31) engaged in neck exercises for an average of at least 2 hours per week during the follow-up period compared to control group participants, where only 30% (9/30) achieved this level of compliance, indicating the actual differences between the 2 groups.

Figure 4. Flow diagram showing participants' flow and follow-up evaluation.

Primary Variables Measure

Neck Disability

As presented in Table 2 and Figure 5, a repeated measures ANOVA showed a main effect of group ($F_{1,3}$=12.738; *P*=.001; η_p^2=0.291), time ($F_{2,62}$=124.140; *P*<.001; η_p^2=0.800), and the group*time interaction ($F_{2,62}$=31.620; *P*<.001; η_p^2=0.505) on neck disability. Compared with those in the control group, participants in the experimental group showed a significant alleviation in neck disability at postintervention (*P*<.001; η_p^2=0.517) and 3-month follow-up (*P*<.001; η_p^2=0.438). Furthermore, therapies in both groups were shown to improve disability in patients with chronic neck pain after intervention or 3-month follow-up in comparison with the baseline (*P*<.01). Further, the extent of disability alleviation in the experimental group exceeded the MCID at both measurement timepoints (5.50 at posttreatment; 5.21 at the 3-month follow-up), while the controls showed a reduction in the disability score by 1.81 and 1.91 points compared to baseline. A higher percentage of experimental group participants experienced disability score reductions exceeding the MCID compared to the control group at both timepoints (experimental group: 29/32, 91% vs control group: 9/32, 28% at posttreatment; experimental group: 25/31, 81% vs control group 6/30, 20% at the 3-month follow-up).

Figure 5. Rehabilitation effect of virtual reality therapy on disability and pain intensity. NDI: neck disability index; NRS: numeric rating scale; *: a statistically significant difference (*P*<0.05) between the two groups at that timepoint (postintervention or 3-month follow-up).

[a]Cohen d was calculated for the differences between postintervention or 3-month follow-up and preintervention in the experimental group compared to the control group.

[b]Indicates P<.02 (0.05/3) for within-group comparisons by Bonferroni correction compared to the baseline.

[c]P<.05 statistically significant differences were found compared to the control group at the same measuring timepoint.

[d]P<0.01 significant main effects were revealed on the group*time interaction.

[e]P<.05 significant main effects were revealed on the group*time interaction.

[f]N/A: not applicable.

Neck Pain Intensity

For pain, ANOVA results revealed significant differences over time ($F_{1.744,54.077}$=87.369; P<.001; η_p^2=0.738), group ($F_{1,31}$=28.138; P<.001; η_p^2=0.476), and the group*time interaction ($F_{2,62}$=27.277; P<.001; η_p^2=0.468). The post hoc analysis indicated a significant between-group difference at postintervention (P<.001; η_p^2=0.582) and 3 months postintervention (P<.001; η_p^2=0.587), with the experimental group representing better enhancement. Compared with baseline, patients in the experimental group experienced pain relief immediately postintervention and at 3-month follow-up, while control group participants did not exhibit significant pain reduction throughout the study. Besides, pain intensity scores decreased in both groups compared to baseline (experimental group 3.04 vs control group 0.50 at posttreatment; experimental group 3.20 vs control group 0.85 at the 3-month follow-up), with patients in the experimental group exceeding the MCID at 2 timepoints. The percentage of data exceeding the MCID significantly differed between the 2 groups (experimental group: 21/32, 66% vs control group: 3/32, 9% at posttreatment; experimental group: 20/31, 65% vs control group 4/30, 13% at the 3-month follow-up).

Secondary Variables Measure

CROM

The results of ANOVA on CROM revealed a significant effect of the group, time, and group*time interaction (P<.05). Participants in the experimental group obtained greater ROM improvement in 6 directions at postintervention and at 3-month follow-up (P<.05) compared to the control group participants. Notably, significant changes were observed after intervention and follow-up in the experimental group from those at baseline (P<.05), while no differences were observed in the control group. The experimental group participants achieved ROM improvements exceeding the MDC in all directions at both timepoints, except for extension ROM at the 3-month follow-up, highlighting the clinical effectiveness of the intervention in the experimental group compared to the control group. Specific data on this indicator can be found in Multimedia Appendix 2.

Proprioception

Regarding proprioception, the ANOVA results revealed no significant difference in the group*time interaction for 6 directions, except for left rotation. For the proprioception of left rotation, significant effects occurred in the group*time interaction. The post hoc analysis showed that patients receiving VR intervention attained lesser improvement after the 3-month follow-up than the control group. However, no within-group differences were reported. Upon further analysis of other directions, proprioception in flexion, extension, and right rotation directions was found to achieve improvement in both groups after treatment and follow-up versus the baseline, and proprioception of left flexion showed a noticeable improvement after the follow-up in comparison with the baseline. However, the between-group analysis showed no marked difference in all directions. The detailed data regarding this parameter are presented in Multimedia Appendix 2.

Mean and Peak Velocity

There were significant main effects for the interaction between time and group (P<.05) for the mean velocity of extension and left rotation. The post hoc analysis revealed significant gains after the 3-month follow-up in the experimental group compared to that in the control group or baseline for these 2 directions. No significant effects for the interaction between time and group were found in the mean velocity of flexion and right rotation. For intergroup comparisons, patients receiving VR training showed better improvement in the mean velocity of flexion than the control group, which was not found in the right rotation direction. As for the within-group comparison, both groups showed superiority over baseline in the mean velocity of flexion at posttreatment and the 3-month follow-up, and the mean velocity of right rotation remained negative. However, the magnitude of improvement in the mean velocity in both the groups did not surpass the corresponding MDC in any direction.

A repeated measures ANOVA showed a main effect for the group*time interaction for the peak velocity in all 4 directions. Compared with the baseline, the experimental group participants gained significant enhancement (*P*<.05) at the 3-month follow-up. Furthermore, the between-group comparisons supported better therapeutic effects with VR devices than the control after intervention and 3-month follow-up period (Table 2). Increased maximal velocity of flexion and left rotation directions was significantly higher in the experimental group over MDC after the follow-up, which did not occur in the other directions or the control group. For specific data on the mean and peak velocity, please refer to Multimedia Appendix 2.

Global Perceived Effect

Considering patient satisfaction, the results revealed a significant between-group difference at postintervention and 3-month follow-up (experimental group 3.03, SD 1.33 vs control group 1.66, SD 1.82) with an advantage to the experimental group. The within-group analysis showed no significant effects among different timepoints for the 2 groups. In the Mann-Whitney *U* test, obvious between-group differences were found in the relief of symptoms at postintervention (experimental group 3.00, SD 2.00 vs control group 2.00, SD 3.00) and 3-month follow-up (experimental group 4.00, SD 1.00 vs control group 2.00, SD 2.00). Furthermore, significant improvements were observed in the experimental group after the 3-month follow-up compared to those at postintervention, while no differences were observed in the control group (Table 2). The specific data related to these indicators can be obtained in Multimedia Appendix 2.

Discussion

Overview

This RCT was intended to compare the benefits of combining VR therapy and conventional rehabilitation with those of conventional rehabilitation alone for treating chronic neck pain. Overall, our results show that patients in both groups reported reduced pain and disability and demonstrated improved kinematic functions. Direct comparisons between the 2 groups revealed that VR treatment in addition to conventional rehabilitation was superior to conventional rehabilitation alone for improvement in the pain, disability, and kinematic indicators, and the effects of combined therapy could be maintained over the 3-month follow-up period. Additionally, participants in the VR therapy group reported higher satisfaction levels, better symptom improvement, and greater willingness to engage in exercises during the follow-up period.

Effects of VR Therapy Combined With Conventional Rehabilitation on Pain and Disability

Although reduced pain and disability were found in both treatment groups at 2 timepoints, these indicators were decreased nearly 3 times more in the experimental group than in the control group. Furthermore, the improvement of pain and disability observed at 2 measuring timepoints in the experimental group was higher than the MCID, which has been previously reported as 2.7 and 3.5 points, respectively [37,38]. This finding indicates the significant and clinical effectiveness of VR therapy in addition to conventional rehabilitation in alleviating pain and disability. The corresponding size effects were medium, highlighting the notable differences between the 2 groups.

Multiple studies have shown that patients with neck pain experienced significant improvements in pain intensity with VR treatment compared to baseline [45,47] and markedly superior to control groups receiving laser training [27] or conventional rehabilitation [28]. Further, a recent meta-analysis [48] incorporating 8 RCTs revealed that better analgesic effects were found in the multimodal intervention (VR technique in combination with other therapies) than in the other interventions and in the patients treated in the clinic or research unit than the controls. This also provides a new perspective on VR analgesia research. However, some studies have reported conflicting results. For instance, a study [44] investigating the efficacy of a 120-minute VR therapy session for patients with chronic neck pain indicated remarkable improvement in pain intensity at rest or during motion compared to baseline as well as alleviation in the disability level. However, no significant between-group differences were observed in these metrics in the VR intervention group as compared to the 2 control groups undergoing conventional rehabilitation alone or general sensorimotor training plus conventional rehabilitation. This discrepancy may be attributed to the smaller sample size in that study (17 individuals per group) [44], which lowered the statistical power representation of between-group differences. Similarly, the VR gaming scenario utilized in that study [44] lacked sufficient visual and auditory feedback compared to the VR design in our research, and this might have limited the analgesic effect of VR treatment.

The potential efficacy of VR therapy in reducing neck pain and disability may be attributed to its ability to enhance coordination between the deep and superficial cervical muscles [49]. Poor sensorimotor control by cervical muscles in patients with neck pain has been indicated in previous research [5,9] and is considered to trigger associated disability and kinematic disorders. Although muscle activation was not evaluated in this study, VR therapy appears to promote the function and coordination of cervical muscles, thereby reducing the stress on cervical segments and alleviating neck pain and disability. Another possible reason could be the deep engagement required by the virtual environment, blocking the transmission of sensory information related to pain and achieving analgesic effects.

Effects of VR Therapy Combined With Conventional Rehabilitation on Cervical Kinematic Function

The secondary outcomes yielded interesting findings that VR therapy could increase the ROM, mean velocity, and peak velocity at 2 timepoints compared to those in the baseline or control group. This conclusion was consistent with that reported in previous research [28,44,50]. Tejera et al [50] in 2021 reported the positive results of VR therapy on increasing CROM in patients with chronic neck pain, which can be attributed to the sufficient feedback provided by VR devices. The visualization of images was widely perceived as useful in activating the corticospinal system and enhancing the intensity of muscle recruitment, thereby improving the overall neck kinematic functions. Fowler et al [51] showed that VR might encourage patients to turn their heads farther and faster by its effect on reducing fear of movement, which has been reported in other studies [52-54]. Besides these, continuous progressive VR treatment dosage based on real-time assessment data on motor function assisted patients in restoring their motor function.

As can be observed from the mean and maximum velocity data in various directions, the experimental group always showed no between-group differences after training but showed between-group differences after the 3 months follow-up compared to the control group, suggesting that this may be attributed to the insufficient training time during the intervention. Upon analyzing the training length after the intervention, we could see that the training frequency of patients in the experimental group was higher than that of the control group during the follow-up period, reaching an average of 1-2 hours of training per week, and more training time outside of the experiment would probably promote further improvement of motor function. These findings indicate that researchers as well as clinical specialists should pay more attention to the supervision and education of home-based active exercise in the future.

Regarding proprioception, both groups showed significant improvement in several directions after treatment or 3-month follow-up; however, no between-group differences were found. Prior studies [49,55] have confirmed that multiple exercise programs, including head relocation practice, gaze stability, eye-follow, and eye/head coordination, are effective in improving proprioception. In this study, however, only head relocation practice was used (the participant was instructed to memorize the head-neck position and try to find the initial position with eyes closed after moving), and satisfactory results were obtained. Moreover, other studies [27,44] have utilized alternative proprioceptive training with similarly favorable outcomes. Some investigators noticed that eye-follow and eye/head coordination training greatly enhanced patients' accuracy, which was likely attributed to improved motor control and coordination of the neck [47]. This suggests that more consideration should be given to focus on all forms of proprioceptive training in the clinical management of patients with chronic neck pain.

Effects of VR Therapy Combined With Conventional Rehabilitation on Satisfaction and Relief of Symptoms

Besides the indicators mentioned above, the marked between-group difference was observed in patient satisfaction and relief of symptoms at both timepoints, with some advantages in the combined treatment. These 2 self-rating indicators are considered important for recovering from chronic neck pain. The enjoyment derived from VR equipment, multiple visual and auditory feedback, personalized tasks, and adjustable difficulty levels likely contributed to the higher satisfaction levels and greater therapeutic efficacy in the experimental group. Notably, no adverse events such as motion sickness were reported during the research period.

Limitations

Several limitations of this study warrant consideration. The absence of a placebo group receiving sham VR therapy raises concerns about the potential overestimation of VR therapy's therapeutic effects. However, the substantial improvements in pain, disability, and CROM surpassing the MCID suggest that the effect may be due to the treatment itself other than the placebo effect. Moreover, the impact of varying durations of conventional rehabilitation (30 minutes vs 10 minutes) on therapeutic outcomes remains uncertain, potentially influencing the perceived efficacy of VR treatment. Additionally, the inability to blind patients due to the experimental nature of this study introduces a risk of bias. The lack of long-term follow-up data further limits the generalizability of the findings. Lastly, the absence of assessment indicators for mental function and quality of life hinders the comprehensive evaluation of VR therapy's overall therapeutic efficacy.

Implications

This study provides support for the effectiveness of a combined approach involving VR therapy and conventional rehabilitation in managing chronic neck pain. However, uncertainties persist regarding the optimal dosage, underlying mechanisms of VR therapy, and the comparative effectiveness of different VR equipment types (eg, semi-immersive, nonimmersive). Future investigations should design specific trials to address these knowledge gaps. Furthermore, exploring the synergistic benefits of integrating VR training with other evidence-based interventions such as manipulation and sensorimotor training is warranted.

Conclusions

In conclusion, the integration of VR intervention with conventional rehabilitation demonstrates significant improvements in pain, disability, and kinematic function among patients with chronic neck pain at both postintervention and 3-month follow-up assessments. Although patients can benefit from conventional rehabilitation alone, the combination of VR therapy and conventional rehabilitation is more effective for improvement in the abovementioned indicators. Considering the higher satisfaction as well as greater training initiative in the experimental group and the absence of adverse events, this feasible and effective intervention could be integrated into the standard rehabilitation treatment plan for patients with chronic neck pain. Future research endeavors should focus on refining therapeutic regimens, determining optimal dosages for VR therapy, and streamlining the implementation of this intervention in clinical settings to enhance convenience and efficacy.

Acknowledgments

The authors would like to thank all of the patients who took part in this study. This work was supported by the Key Research Project of the Science and Technology Department of Sichuan Province (2021YFS0069).

Authors' Contributions

Q Guo, LZ, LLH, CG, and Q Gao contributed to the conception and design, acquisition of data, drafting of the paper, and critical revision of important intellectual content. GC, CL, and WW were responsible for the analysis and interpretation of the data. All authors discussed the results, commented on the manuscript, and approved the final manuscript.

Abstract

Background: Many people want to build good habits to become healthier, live longer, or become happier but struggle to change their behavior. Gamification can make behavior change easier by awarding points for the desired behavior and deducting points for its omission.

Objective: In this study, we introduced a principled mathematical method for determining how many points should be awarded or deducted for the enactment or omission of the desired behavior, depending on when and how often the person has succeeded versus failed to enact it in the past. We called this approach *optimized gamification of behavior change*.

Methods: As a proof of concept, we designed a chatbot that applies our optimized gamification method to help people build healthy water-drinking habits. We evaluated the effectiveness of this gamified intervention in a 40-day field experiment with 1 experimental group (n=43) that used the chatbot with optimized gamification and 2 active control groups for which the chatbot's optimized gamification feature was disabled. For the first control group (n=48), all other features were available, including verbal feedback. The second control group (n=51) received no feedback or reminders. We measured the strength of all participants' water-drinking habits before, during, and after the intervention using the Self-Report Habit Index and by asking participants on how many days of the previous week they enacted the desired habit. In addition, all participants provided daily reports on whether they enacted their water-drinking intention that day.

Results: A Poisson regression analysis revealed that, during the intervention, users who received feedback based on optimized gamification enacted the desired behavior more often (mean 14.71, SD 6.57 times) than the active (mean 11.64, SD 6.38 times; $P<.001$; incidence rate ratio=0.80, 95% CI 0.71-0.91) or passive (mean 11.64, SD 5.43 times; $P=.001$; incidence rate ratio=0.78, 95% CI 0.69-0.89) control groups. The Self-Report Habit Index score significantly increased in all conditions ($P<.001$ in all cases) but did not differ between the experimental and control conditions ($P>.11$ in all cases). After the intervention, the experimental group performed the desired behavior as often as the 2 control groups ($P\geq.17$ in all cases).

Conclusions: Our findings suggest that optimized gamification can be used to make digital behavior change interventions more effective.

Introduction

Background

Overview

People often struggle to change their behavior in ways that would benefit them in the long run. For instance, many people could improve their health and life expectancy by building healthy habits such as exercising [1], healthy eating [2], or drinking a glass of water before every meal [3,4]. People who want to adopt healthy habits because they know about their benefits nevertheless struggle to change their behavior accordingly.

Building a good habit is especially difficult when the benefits of the desired behavior cannot be felt immediately. One approach to alleviate this challenge is to create apps that encourage the desired behavior using incentives or immediate positive feedback [5-7] or discourage unwanted behavior using immediate negative feedback [8]. Doing so in a gameful way can be a promising approach to improving people's health behaviors [5-7,9-12]. Using game elements to improve people's behavior in the real world is known as gamification [13]. One of the most commonly used gamification methods is awarding people points for specific behaviors [14,15]. The awarded points are often used to provide feedback to the user, define levels, award badges, or create leaderboards.

Despite the widespread use of points, levels, badges, and leaderboards, there is currently no principled way to choose precisely how many points a person should be awarded and when. This is a problem as making those decisions based on intuition can lead to point systems that inadvertently incentivize counterproductive behaviors or undermine the users' motivation [16-18]. For instance, a recent study found that the point system of the popular gamified habit formation app Habitica is actively harmful [17].

To help practitioners master the challenge of designing effective point systems that reliably foster positive behavior change, we introduced a mathematical principle for computing the number of points a person should receive for engaging in the desired behavior depending on their history of either engaging or not engaging in this behavior and how many points they should lose when they fail to do so. We called this principle *optimized gamification of behavior change*. As a proof of concept, we applied optimized gamification to design a chatbot that helps people develop the healthy habit of drinking water before every meal [3,4]. Our chatbot awards points for the desired behavior and deducts points for its omission. Critically, the number of points that the user gains or loses is computed using optimized gamification. Our chatbot combines optimized gamification with three established principles of behavior change: it (1) guides the user to set an implementation intention, (2) reminds them of their good intentions, and (3) supports self-monitoring.

We evaluated our chatbot in a longitudinal field experiment and found that optimized gamification can make digital behavior change interventions more effective. Our findings provide a proof of concept for a very general and principled approach to improving human behavior in the real world. In addition to this theoretical contribution, we introduced a chatbot for helping people develop a specific healthy habit (water drinking): the Good Habit Bot. This chatbot can easily be adapted to other health behaviors, including more critical health behaviors such as exercising, healthy eating, and other good habits that people want to establish.

The plan for this paper is as follows. We first introduce relevant background information about behavior change and gamification. We then present our theory of optimized gamification for behavior change. Next, we present the chatbot we designed as a proof of principle. After that, we present the methods and results of our field experiment and discuss its findings and implications.

Behavior Change Goals Versus Automatic Behavior

Human behavior is controlled by a combination of goal-directed decision-making (eg, *I will buy a gym membership because I want to lose weight*) and more automatic reactions to certain stimuli (eg, always stopping by the gym on the way home from work) [19]. Goal-directed decision-making derives choices from the outcomes that people value (eg, health or money) or want to avoid (eg, pain) according to their mental models of how those outcomes can be obtained. In contrast, automatic reactions do not consider the behavior's likely consequences in the current situation.

Obstacles to Behavior Change: Automaticity and Temporal Discounting

Most of our behavior is not primarily controlled by goal-directed decision-making but determined by people's automatic reactions. Therefore, automatic behavioral responses can interfere with people's ability to act in accordance with their behavior change goals. This is the proverbial conflict between bad habits and good intentions. People can inhibit and override their automatic behavioral responses (*bad habits*), but their capacity to do so is limited [20]. Therefore, the automaticity of human behavior is a crucial obstacle to intentional behavior change.

A second obstacle to successful behavior change is that the mechanisms of goal-directed decision-making are demonstrably biased in favor of immediate outcomes [21]. People give too much weight to their decision's immediate consequences and too little weight to its long-term consequences. This phenomenon is known as present bias [22]. It has been proposed that present bias occurs because the brain discounts delayed benefits as if they become less valuable the later they occur [23]. This phenomenon, which is known as temporal discounting, is well established in research on economic decisions and animal behavior.

Moreover, according to temporal motivation theory [24], temporal discounting is one of the main reasons why people fail to enact good intentions. Such failures of self-regulation are a critical obstacle to health behavior change [25,26]. Consistent with this explanation, people who discount delayed outcomes more strongly are likelier to engage in unhealthy behaviors and experience poor health [26].

Reinforcement Learning as a Mechanism of Behavior Change

As automatic responses are powerful drivers of human behavior, successful behavior change typically involves translating behavior change goals into automatic behavioral responses [27].

Automatic behavioral responses, including exercise habits, can be acquired through learning from experience. Model-free reinforcement learning is a well-established mechanism of learning automatic behavioral responses from experience [19]. This mechanism increases or decreases a person's propensity to engage in a specific behavior in a particular situation (eg, going to the gym after work) according to whether they experience the behavior's overall consequences as positive or negative. The vast literature on operant conditioning in animals and humans underscores that learning from reward and punishment is a powerful mechanism of behavior change [28,29]. Another complementary learning mechanism involves strengthening habits through mere repetition [30].

Supporting Behavior Change Through Incentives and Reinforcement

The literature surveyed previously demonstrates that goal-directed decision-making and automatic behavioral responses are responsive to rewards and punishments. Goal-directed decision-making is sensitive to anticipated future rewards, and automatic behavioral responses are shaped by the rewards or punishments that those behaviors have generated in the past. These effects can be leveraged to support behavior change. To foster behavior change via goal-directed decision-making, behavior change interventions can create and announce incentives for engaging in the desired behavior. To foster behavior change via reinforcement learning, behavior change interventions can reinforce the desired behavior with rewards or positive feedback.

A highly effective behavior change intervention that leverages both effects is contingency management [31]. Contingency management incentivizes a desired behavior change and rewards people when they enact it. Voucher-based reinforcement therapy for treating addiction is a highly successful example of contingency management [32]. This behavior change intervention awards the patient a voucher every time they submit a negative drug test. More recently, it has also been applied to foster other types of behavior change, including physical exercise [7,33] and treatment attendance [34]. Contingency management appears to be more effective when the desired behavior is reinforced more promptly, more frequently, and with rewards that are larger or increase throughout the intervention [35-37].

Digital Behavior Change Interventions

Developing digital behavior change interventions is a young and booming field [38]. Mobile apps have shown potential for fostering positive behavior change in domains such as physical exercise and healthy eating [38,39]. However, the average effect size of such interventions is still relatively small [40,41]. Most behavior change interventions are not derived from any theory, model, or framework [38]. Therefore, we suspect that there is still room for improvement and that at least some of this potential can be realized by adopting a more theory-driven approach.

Goal setting and self-monitoring are the most commonly used behavior change techniques [38]. A meta-analysis of studies on digital interventions for promoting physical exercise found that these 2 techniques are also the most effective ingredients of current digital behavior change interventions [41]. Goal setting entails guiding people to articulate their intent to perform certain behaviors in certain situations (eg, drinking a glass of water before every meal). Supporting self-monitoring often takes the form of helping people check or record whether they have enacted those intentions or track related outcomes (eg, their weight). Goal setting is especially effective when people formulate simple plans that specify the intended behavior and the situation in which they want to perform it as concretely as possible [42,43]. This approach is known as *implementation intentions*. Moreover, reminding people of their intentions via SMS text messages [44] and presenting them with positive reinforcement when they enact their intentions [5,7,33] have been found to be highly effective in promoting physical exercise.

Gamification

A recent meta-analysis found that approximately 1 in 5 digital behavior change interventions are designed within the gamification framework [38]. Gamification entails applying principles from game design and game elements, such as storytelling and rules for earning points and winning the game, to address real-world problems [13]. The basic idea is to motivate people to do things that benefit them or others, such as exercising and studying, in a gameful way. Previous research has found that gamification can improve people's behavior, achieve desired outcomes, and improve people's subjective experiences [45].

Gamification is already widely used in designing digital behavior change interventions [5], and previous studies have suggested that it can improve people's health behaviors [7,9-12,33]. One gamification strategy that is effective in digital behavior change interventions is awarding the user points as positive feedback for the desired behavior [5,7,33]. Such extrinsic incentives can increase the frequency of the targeted behaviors without affecting people's intrinsic motivation [46,47].

However, when gamification is not correctly designed, it can backfire and have adverse effects [16,17,48]. This has also been observed in the behavior change literature [12,49] and in gamified habit formation apps [17]. Getting the incentives exactly right can be crucial as points, levels, badges, and leaderboards do not foster the user's intrinsic motivation [46,47] and might sometimes even undermine it when they are not embedded in a compelling narrative [18]. Motivated by these problems, many authors have called for a more theory-driven approach to gamification in general [50] and gamifying digital behavior change interventions in particular [12].

Optimized Gamification

Previous work has investigated how many points should be awarded for which behavior to maximally benefit the user in the context of to-do list apps that help the user achieve their own goals [51,52]. Building on temporal motivation theory [24], this work assumed that people's motivation is insufficiently sensitive to long-term benefits such as good health in old age and overly sensitive to immediate costs (eg, the effort of exercising) and short-term pleasure (eg, from receiving immediate positive feedback). To help people overcome the resulting motivational problems (eg, procrastination) [53], Lieder et al [51] developed a mathematical theory for designing point systems that provide immediate positive feedback for activities that are beneficial in the long run and immediate negative feedback for activities that are not. The basic idea is to align each action's immediate and long-term consequences. The action that is best in the long run should be made most appealing in the short run, and actions with undesirable long-term consequences should be made unappealing in the short run.

Therefore, optimized gamification strives to incentivize each of the available actions through a number of points proportional to how much that action increases or decreases the sum total of future happiness. This idea is implemented by modeling the activities to be incentivized as steps that lead toward a valuable goal or away from it. Actions that lead toward the goal increase the time the person will spend in the more valuable state in which the goal has been achieved. In contrast, actions that lead away from the goal decrease the time the person will spend in the more valuable state in which the goal has been achieved and increase the effort required to achieve it afterward. On the basis of this mathematical model, dynamic programming and reinforcement learning methods can estimate how much a given action improves or worsens the person's situation. These estimates are then translated into incentives that encourage good choices and discourage bad ones. The resulting point values are optimal in that they would enable even a purely myopic decision maker who only cares about immediate outcomes to choose the actions that are best for them in the long run [51].

Although optimized gamification construes points as incentives and uses mathematical and computational methods from the field of reinforcement learning, using it does not constitute a commitment to behaviorism and is fully compatible with cognitive theories of motivation [54].

Optimized gamification has been used to encourage users to tackle the tasks on their to-do lists [32] and encourage students to select the most valuable learning activities [55,56]. Optimized gamification has also been applied to give people feedback on how they think about what to do [57] and on whether they succeeded in staying focused on a chosen task or got distracted [58]. However, to date, this approach has never been applied to support habit formation.

Objectives

The first goal of this study was to introduce a principled method for computing feedback on the enactment or omission of the desired behavior and experimentally test whether it can be used to enhance digital behavior change interventions. The second goal of this study was to introduce a chatbot that uses this method to help people develop healthy water-drinking habits and evaluate it in a longitudinal field experiment.

Methods

Optimized Gamification of Behavior Change

Overview

We conceptualized behavior change as a special case of repeatedly choosing and learning when to do what. As reviewed in the *Background* section, optimized gamification can encourage desired behaviors and accelerate learning [57]. To apply this method to promote the desired behavior and accelerate the formation of healthy habits, we first have to model habit formation as a Markov decision process (MDP) [59].

Modeling Habit Formation

An MDP is a scenario in which an agent faces a series of choices. Each choice (*a*) has 2 effects. First, it yields an immediate reward (*r*) that may be positive, negative, or zero. Second, it may change the state (*s*) the agent finds itself in. In an MDP, the agent's goal is to maximize the sum of the rewards it accumulates from its first decision to its last one.

We model behavior change problems as a straightforward MDP, in which a person repeatedly chooses between 2 possible actions when they find themselves in a particular situation: enacting the desired behavior (a=1) or not enacting it (a=0). Our model assumes that a given behavior change intervention aims to turn the desired behavior into a habit. Therefore, we define the state as the strength of the person's healthy habit, measured using a single number, s_{habit}, which can range from 0 to 1. Following standard habit formation models [30], we assume that enacting the habit increases its strength from

$$s_{habit} \text{ to } s_{habit} + \alpha \times (1 - s_{habit}),$$

where α is a free parameter that describes how quickly habits form. Conversely, our model assumes that failure to enact the desired behavior decreases the strength of the habit to $s_{habit} \times (1 - \alpha)$. We assume that the habit has been cultivated when its strength exceeds some threshold θ (eg, θ=0.9) and model the health benefits conferred by achieving this goal as a reward (r_{goal}) that is attained when the habit strength crosses this threshold. Enacting the desired behavior is assumed to incur a cost that decreases with the strength of the habit ($r[s_{habit}, 1]=–[1 – s_{habit}]$), whereas not performing the behavior is assumed to be effortless ($r[s_{habit}, 0]=0$).

Computing Optimal Feedback

The basic idea of optimized gamification is to reward each action using a number of points that are proportional to its long-term benefits. These long-term benefits are measured via the decrease in future costs and the increase in future rewards brought about by transitioning to a state in which the habit is stronger. In situations in which the benefits of developing the good habit outweigh its costs, the value of having a habit of strength s_{habit} and then following through with the process of building the habit is as follows:

where the number $n(s_{habit}; \theta)$ specifies how often the behavior must be enacted until the habit strength reaches its target value θ. Therefore, for someone who will follow through with building the habit, the long-term benefits of enacting the habit one more time when its current strength is s_{habit} are

$$f(s_{habit}, 1) = V^*(s_{habit} + \alpha \times [1 - s_{habit}]) - V^*(s_{habit}) = 1 - s_{habit}.$$

Conversely, the long-term costs of failing to enact the desired behavior in the situation in which it is supposed to become a habit are

$$f(s_{habit}, 0) = V^*(s_{habit} \times [1 - \alpha]) - V^*(s_{habit}).$$

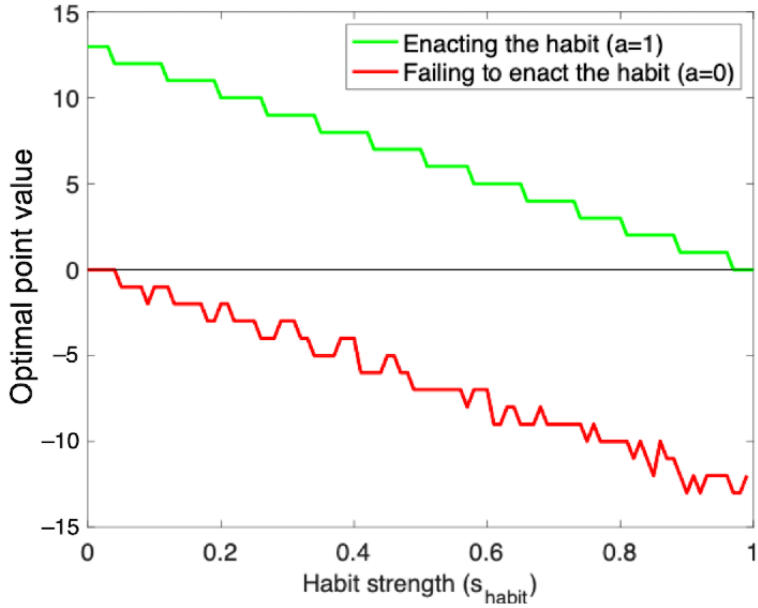
Please note that, even though we are talking about a situation in which it is rational for people to build the habit, this does not mean that we assume people to be rational. For our method, it does not matter why people follow through with building the habit. In fact, we assume that some people will follow through with building the habit only because they are (irrationally strongly) motivated by the immediate rewards conferred by feedback.

The lowest possible negative value of f is $f(\theta, 0)$, and the largest possible positive value is $f(0, 1)$. Although the exact values depend on the model parameters, they are typically approximately –1 and 1, respectively. Therefore, to transform those values into points, it is desirable to scale them by the desired maximum point value (M) that the application should award to the user and then round the scaled values to the nearest integer. This yields the following equation for the number of points that the application should award when a user reports that they have enacted their intention (a=1) or have not enacted their intention (a=0):

$$\text{points}(s_{habit}, a) = \text{round}(M \times f(s_{habit}, a)) \text{ (Equation 1).}$$

Figure 1 illustrates the point values as a function of the user's habit strength in an example application with a learning rate of α=0.1, a target habit strength of θ=0.9, and a maximal point value of M=13. Multimedia Appendix 1 provides more details on our mathematical model and the resulting optimal point system.

Figure 1. Point values for enacting versus failing to enact the habit at different habit strengths for a learning rate of α=0.1 and a threshold of θ=0.9.



As illustrated in Figure 1, the number of points for enacting the desired behavior is largest when the habit is weakest and gradually decreases toward 0 as the habit strengthens. This is intuitive as performing the desired behavior becomes easier the more often one has already performed it. Conversely, the number of points that should be deducted when the user fails to enact the habit is smallest when the strength of the habit is 0 and then increases as the habit becomes stronger. This is an intuitive consequence of our model's assumption that failing to enact the desired behavior in the specified situation weakens the habit strength by approximately 10%. The stronger the habit, the more is lost when its strength is reduced by 10%. The number of points awarded for enacting the desired behavior is a monotonically decreasing function of the habit strength. In contrast, the point value for failing to enact the desired behavior changes more erratically. This is because the number of steps required to reach the desired habit strength changes abruptly with the current habit strength. For instance, failing to enact the behavior at a habit strength of 0.09 increases the number of times the behavior needs to be enacted to achieve the desired habit strength from 21 to 22 times. However, if the habit strength is 0.08 or 0.10, the number of times the desired behavior has to be enacted remains 22 and 21 times, respectively. Individual users rarely experience such irregular changes as the change in their habit strength typically skips across those small areas in which the point value changes nonmonotonically. Moreover, our simulations suggest that the penalty for failing to enact the desired behavior can be approximated using a linear function with the same slope as the number of points for performing the desired behavior.

Application to Supporting Positive Behavior Change

The optimized gamification method described previously can be applied to help people form good habits. The equations for computing the number of points are easy to implement within digital behavior change interventions such as chatbots and habit trackers. All that is needed is to ask the user which habit they want to develop and estimate its initial strength, set the learning rate parameter and the habit's target strength to reasonable values (eg, α=0.1 and θ=0.9), and record when the user did versus did not act in accordance with the desired habit. To define the desired habit, the user has to specify the desired behavior and the situation in which they want to perform it. The user's initial habit strength can be estimated through the desired behavior's relative frequency in that situation in the previous weeks (eg, at 2 of the previous 7 lunches). The habit strength can then be initialized using that proportion. Alternatively, when it makes sense to assume that the user wants to build an entirely new habit, the strength can be initialized as 0. Then, whenever the user reports having or not having enacted their intention, the optimized gamification equation can be applied to compute how many points the user should gain or lose. Whenever the user reports having performed the desired behavior, the estimate of the habit strength should be increased to

$$s_{habit} + \alpha \times (1 - s_{habit}),$$

and whenever the user reports having missed an opportunity to enact their intention, the estimate of their habit strength decreases to $s_{habit} \times (1 - \alpha)$. Then, the same procedure repeats when the user reports on their next opportunity to enact the behavior.

This approach can be used to support many different types of positive behavior change. It can help people build good habits in areas such as exercise, sleep, taking medication, nutrition, work, chores, and leisure activities. It can be used in interventions focusing on specific habits and, in general, in habit formation tools that let users choose any habit they want to develop. Another possible application is helping people overcome bad habits (eg, smoking cessation) [60]. It can support applications that run on practically any device, from smartwatches and wristbands to mobile phones, desktop applications, web applications, and smart glasses.

Proof of Concept: A Chatbot for Building a Healthy Water-Drinking Habit

As a proof of concept for the application of optimized gamification to support behavior change, we implemented this idea as a Telegram (Telegram FZ LLC) chatbot called the *Good Habit Bot*. This chatbot helps the user develop a healthy water-drinking habit by combining 4 behavior change techniques: goal setting, reminders, support for self-monitoring, and feedback. Concretely, the Good Habit Bot guides the user to formulate an implementation intention that links a specific desired behavior to a concrete daily event, reminds the user of their intention on a daily basis, checks in with them on whether they followed through on their intention every day, and then gives them positive or negative feedback depending on whether they did or did not follow through on their intention.

When the user starts their first conversation with the Good Habit Bot, the chatbot introduces itself and says that its purpose is to help the user form a healthy water-drinking habit. The Good Habit Bot then asks the user to choose which of 8 concrete, recurring moments in their day they want to use as the trigger for their water-drinking habit (eg, *when my wake-up alarm rings* or *when I have the first bite of my lunch*; for the complete list, see Multimedia Appendix 2). Next, the Good Habit Bot asks the user how much water they want to drink in that situation (eg, 1 glass or 0.5 glasses) and how often they did so in the previous 7 days. The chatbot then uses the number of days *n* of the previous week in which the user acted in accordance with the habit (eg, n=2) to initialize their habit strength by n/7 (eg, s_{habit} = 2/7). Then, in the evening of the first day (ie, at 9 PM), the chatbot reminds the user of their intention to drink a specific amount of water at a particular moment of the following day (eg, *Remember your intention*: *When I have the first bite of my lunch, I will drink 1.5 glasses of water*). Then, sometime after the moment in which the user wanted to enact their intention, the chatbot asks them whether they did so (ie, *Did you accomplish your goal today to drink 1.5 glasses of water*). If the user affirms that they followed through on their intention, the chatbot gives them positive feedback (Figure 2). This feedback comprises a congratulatory message (eg, *That's wonderful!)* whose text alternates among 5 possible phrases (Multimedia Appendix 2) and a second message that awards the user the number of points computed by our optimized gamification method (eg, *I am glad to grant you 5 points for keeping a good habit! Your total score is 49 points*). In contrast, if the user responds that they missed their chance to enact their water-drinking intention, the Good Habit Bot tells them *Okay. Keep going tomorrow!* and informs them how many points they lost and how many they have left (Multimedia Appendix 2). Afterward, the chatbot updates the user's habit strength. Later that day, the Good Habit Bot reminds the user of their intention for the next day, and then the cycle repeats.

Critically, the chatbot computes how many points to award or take away from the user according to the optimized gamification method described previously (equation 1). One can read the number of points the chatbot we used in our experiment awarded in different situations in Figure 1 as it used the same set of parameters (ie, α=0.1; θ=0.9; *M*=13). For instance, if a user who reported having performed the desired behavior twice in the previous week enacted their intention on the first day, they earned 9 points, and their habit strength increased from

Conversely, if they failed to enact their intention, they would lose 4 points, and their habit strength would decrease to

The Good Habit Bot is freely available on the Telegram messenger app, where it can be found by searching for its alias, @learn_good_habits_bot.

Figure 2. Screenshot of the feedback method with point values computed by our optimized gamification method.

Study Design

To evaluate the effectiveness of our intervention and assess the relative contributions of reminders versus optimized gamification, we ran a longitudinal between-subject experiment with 1 experimental condition with optimized gamification (*optimized gamification condition*), 1 *baseline condition*, and 1 *control condition with reminders and feedback* (Table 1). In the *optimized gamification condition*, the chatbot delivered all 4 techniques described previously, including feedback messages based on optimized gamification (Figure 1). Participants in the other 2 conditions could not gain or lose any points (no optimized gamification). They differed in whether they received feedback messages for enacting versus failing to enact the intended behavior. In the *control condition with reminders and feedback*, participants received a positive feedback message when they reported having enacted their intention (eg, *That's wonderful!)* and a more neutral message when they reported not having done so (eg, *Okay. Keep going tomorrow!).* To create the *baseline condition*, we replaced the first control group's positive and negative feedback message with a neutral message (*OK*) and removed the daily reminders. Participants completed the self-report measures of habit strength described in the following sections before the intervention (pretest time point), immediately after the intervention (posttest time point), and approximately 3 weeks later (follow-up). Moreover, participants reported how often they engaged in the desired behavior the week before the intervention (pretest time point) and the week after the intervention (posttest time point). Finally, participants also completed daily reports of whether they enacted their intention on each day of the intervention.

Table 1. Experimental conditions.

Experimental condition	Implementation intentions	Support for self-monitoring	Reminders	Feedback
Optimized gamification condition	Yes	Yes	Yes	Optimized gamification and positive vs negative text
Control condition with reminders and feedback	Yes	Yes	Yes	Positive vs negative text
Baseline condition	Yes	Yes	No	None

Ethical Consideration

This experiment was conducted according to study protocol 401/2020BO2 approved by the Independent Ethics Commission at the Faculty of Medicine of the University of Tübingen. All data was collected and handled according to the General Data Protection Regulation of the European Union. All data has been de-identified.

Recruitment and Reimbursement

We recruited 132 participants (n=41, 31.1% for the baseline condition; n=43, 32.6% for the optimized gamification condition; n=48, 36.4% for the control condition; n=93, 70.5% female) on the web-based research platform Prolific. Based on considerations about the cost of the study, the sample size was determined a priori so that we would retain 3x40=120 participants after an anticipated 10% of participants dropped out of the study. The requirements for participation were being a native English speaker, not having interacted with our chatbot before, and having previously completed at least 10 prolific assignments with an approval rate of at least 95%. Moreover, participants had to be aged ≥18 years. The average age of the participants was 31.5 (SD 9.9; range 19-79) years.

The study description informed participants about the study's duration, activities, time commitment, and pay. Participants were paid £1.95 (US $2.45) for completing the onboarding survey. We informed them that the base pay for completing the remainder of the 40-day study would be £7.80 (US $9.81) and that they could earn an additional bonus of £8 (US $10.06). The description strongly recommended that only people who were already using Telegram on their smartphones should participate. Moreover, the study description informed potential participants about the potential health benefits of regular water drinking. Participants were then shown the consent form. Upon providing informed consent, participants who already had the Telegram app clicked on a link that started a conversation with the Telegram chatbot for their corresponding experimental condition. Participants who had not installed the Telegram app yet were directed to download it first.

At the end of the 40-day study, the chatbot directed participants to a second Prolific HIT where they received the announced payments contingent on their sustained active participation. All participants who completed the pretest, posttest, and follow-up measures and continued to report their daily intention enactment after the 10th day received a second payment of £15.80 (US $19.86). Participants who did not meet these criteria did not receive the second payment.

Outcome Measures and Procedure

Outcome Measures

We measured the outcome variables described in the following sections.

Dropout

We measured whether a participant dropped out of our study using a binary variable indicating whether the participant stopped responding to all daily reports at least 3 days before the end of the study.

Engagement

We measured each participant's *engagement* with our digital intervention based on the number of days on which they interacted with the Good Habit Bot.

Self-Report Habit Index

The Self-Report Habit Index (SRHI) [61] is a 12-item self-report measure of habit strength on a 7-point Likert scale. It comprises 3 subscales measuring the behavior's *history of repetition*, its *automaticity*, and the extent to which it is part of the person's *identity*. In this study, we administered the first 2 subscales. The SRHI has been found to be a 1D construct. Therefore, we averaged the scores of all items. The SRHI has been found to have high validity and very high reliability (Cronbach α of approximately 0.90; test-retest reliability: r=0.91).

Daily Intention Enactment

To measure how often each participant enacted their water-drinking intention during the intervention, we asked them the following question—*Did you accomplish your goal to drink 1 glass of water?*—on each day of the intervention. The question was asked between 30 minutes and 2.5 hours after the time at which the participant intended to drink water. Participants responded by selecting between the responses *Yes, I did!* and *No, I didn't.* After the study, we calculated each participant's *daily intention enactment* score by counting on how many of the 21 days of the intervention period they enacted their intention. Therefore, the daily intention enactment score could range from 0 to 21.

Retrospective Intention Enactment

To measure how regularly participants engaged in the intended behavior (eg, drinking a glass of water before lunch) in the weeks before and after the intervention, we asked them to answer the following question—*On how many days of the previous week did you keep the habit of drinking water?*—by selecting one of the answer choices (0, 1, 2, 3, 4, 5, or 6 days). We referred to the resulting number of days as the *retroactive intention enactment* score.

Procedure

We created 3 separate Prolific HITs for each of the 3 conditions of the experiment (Table 1), and each person was allowed to participate in at most one of these HITs. The experiment ran from November 11, 2021 to December 19, 2021. As illustrated in Table 2, the experiment was divided into 3 phases: the preintervention period (day 0), intervention period (days 1-21), and postintervention period (days 22-40). In the preintervention period, participants provided informed consent, completed the onboarding process, and completed the pretest. We blinded participants to the experimental manipulation by giving all participants the same information about the chatbot they were interacting with and the anticipated benefits of interacting with it. During onboarding, participants were directed to start the first conversation with the Good Habit Bot in the Telegram app on their mobile phones. In this initial conversation, the chatbot asked the participants to select a concrete daily situation in which they wanted to drink water and how much water they wanted to drink, as described previously. The pretest comprised 2 self-report measures: the *SRHI* and the *retrospective intention enactment* measure for the week before the study.

During the intervention period, each participant interacted with 1 of the 3 versions of our chatbot according to the condition they were in (Table 1). On each day of the intervention period, all 3 groups reported whether they successfully enacted their intention to drink water in the specific situation they had selected (*daily intention enactment*). At the end of the intervention period, all 3 groups completed the *SRHI* for the second time (posttest time point).

The postintervention period started with a 1-week break during which the chatbot did not communicate with the participants. Then, on day 28 (follow-up 1) and day 35 (follow-up 2), the chatbot asked participants from all 3 groups to report on how many days of the previous week (ie, the first and second week of the postintervention period, respectively) they had acted in accordance with the desired habit (*retroactive intention enactment*). Finally, on day 40, the chatbot asked all participants to complete the *SRHI* questionnaire for the third time (follow-up). Participants received 3 email reminders to resume interacting with the chatbot on the day of the first follow-up survey (day 28), the day of the second follow-up survey (day 35), and the day of the final follow-up survey (day 40).

Table 2. Experimental procedure.

Experimental phase and day	Optimized gamification condition	Control condition with reminders and feedback	Baseline condition
Before the intervention			
Day 0	• Onboarding • Retrospective intention enactment • SRHI[a]	• Onboarding • Retrospective intention enactment • SRHI	• Onboarding • Retrospective intention enactment • SRHI
Intervention			
Days 1-21	• Reminder, report, and feedback (optimal points+text) • Daily intention enactment	• Reminder, report, and feedback (text only) • Daily intention enactment	• Daily intention enactment
Day 21	• SRHI	• SRHI	• SRHI
After the intervention			
Days 22-27	• No reports	• No reports	• No reports
Day 28	• Retrospective intention enactment	• Retrospective intention enactment	• Retrospective intention enactment

[a]SRHI: Self-Report Habit Index.

Data Analysis

The hypotheses and statistical analysis plan were preregistered on the internet [62]. Participants who completed 0 daily water consumption reports were excluded from all analyses apart from the dropout analysis. Other than that, all analyses were conducted on all available data from all participants who completed at least one daily water consumption report. We retained 37/41 participants from the baseline condition, 39/43 participants from the control condition with reminders and feedback, and 42/48 participants from the optimized gamification condition. All comparisons between conditions were based on the originally assigned groups. We used Poisson regression analyses for binary outcome variables. For continuous outcome variables, we used linear multilevel modeling.

Results

There was no indication of failure of random assignment for initial habit strength, automaticity, or history of repetition (pairwise *P*>.14 in all cases).

Dropout

As an initial step, we examined whether there was a differential dropout among the 3 conditions using a chi-square test of independence. There was no effect of condition on dropout (χ^2_2=0.7; Cramer *V*=0.07; *P*=.72).

Engagement

The *engagement* variable was entered into a Poisson regression model with 2 dummy variables for the effects of optimized gamification and feedback and reminders. The *automaticity* and *history of repetition* scores from the SRHI before the intervention and the preintervention *retrospective intention enactment* score were entered as control variables. As shown in Table 3, optimized gamification did not increase engagement compared with the *baseline condition*. However, it appears that being in the control condition with reminders and feedback without optimal points reduced *engagement* compared with the *optimized gamification* condition (Table 3) and the *baseline* condition (incidence rate ratio=0.84, 95% CI 0.75-0.94; *P*=.002).

Table 3. Predicting the number of days on which participants engaged with the app (engagement) from their condition and time-1 habit-related control variables (N=126)[a].

Predictor	Incidence rate ratio (95% CI)	*P* value
Intercept	18.88 (16.61-21.43)	<.001
Baseline vs optimized gamification	1.02 (0.91-1.14)	.72
Reminders and feedback vs optimized gamification	0.86 (0.76-0.96)	.008
Preintervention habit strength	1.03 (1.00-1.07)	.07
History of repetition	0.85 (0.79-0.92)	<.001
Automaticity	1.08 (1.01-1.16)	.03

[a]Nagelkerke R^2=0.33. The treatment group with optimal points is the reference group.

Daily Intention Enactment

The outcome variable measuring participants' daily enactment of the desired behavior (ie, water drinking) was subjected to a Poisson regression model with the same set of predictors as for *engagement*. Critically, we found that participants in the optimized gamification condition enacted the daily intention to drink water more often (mean 14.71, SD 6.57 times) than either the participants in the baseline condition (mean 11.64, SD 5.43 times) or the participants in the control condition with reminders and feedback (mean 11.64, SD 6.38 times; Table 4). Furthermore, reminders and feedback without points did not result in more water drinking than the *baseline condition* (incidence rate ratio=1.03, 95% CI 0.90-1.17; *P*=.70).

Table 4. Predicting the number of days on which participants drank water (daily intention enactment) from their condition and preintervention measurements of habit-related control variables (n=118)[a].

Predictor	Incidence rate ratio (95% CI)	*P* value
Intercept	16.02 (13.93-18.41)	<.001
Baseline vs optimized gamification	0.78 (0.69-0.89)	.001
Reminders and feedback vs optimized gamification	0.80 (0.71-0.91)	<.001
Preintervention retrospective intention enactment	1.01 (0.97-1.05)	.64
History of repetition	0.91 (0.84-0.99)	.02
Automaticity	1.07 (0.99-1.15)	.10

[a]Nagelkerke R^2=0.21. The treatment group with optimal points is the reference group.

Self-Reported Habit Strength

To test whether optimized gamification promoted habit formation, we compared the change in the SRHI self-report measures of *automaticity* and *history of repetition* from pretest to posttest to follow-up time points among the 3 experimental conditions (Figure S1 in Multimedia Appendix 3) using a multilevel model with fixed-effects predictors for time point, 2 dummy codes for the experimental condition with the *optimized gamification condition* as the reference, and all pairwise *time*×*condition* interactions (Tables S1 and S2 in Multimedia Appendix 3). We found that, compared with the pretest time point, both measures of habit strength were significantly higher immediately after the intervention (*P*<.001 in all cases) and at follow-up (*P*<.001 in all cases). However, these effects were no larger in the *optimized gamification condition* than in the baseline condition (*P*≥.20 in all cases) or the control condition with reminders and feedback (*P*≥.12 in all cases).

Behavior After the Intervention

As a further test of whether the behavior change we observed during the intervention was maintained, we analyzed the number of times participants reported having enacted their intention in the week before the intervention versus the first week after the intervention and the second week after the intervention (*retrospective intention enactment*; Figure S2 in Multimedia Appendix 3) using a multilevel model with fixed-effects predictors for time point, 2 dummy codes for the experimental condition with *the optimized gamification condition* as the reference, and all pairwise *time*×*condition* interactions (Table S3 in Multimedia Appendix 3). We found that, compared with the week before the intervention (mean 1.8, SD 2.1 times), participants enacted the desired behavior significantly more often after the intervention (1-week follow-up: mean 5.2, SD 1.9 times, t_{299}=15.21, and *P*<.001; 2-week follow-up: mean 5.1, SD 2.1 times, t_{299}=14.86, and *P*<.001). However, these effects were no larger in the optimized gamification condition than they were in the baseline condition (*P*≥.18 in all cases) or the control condition with reminders and feedback (*P*≥.32 in all cases).

Discussion

Principal Findings

In this study, we derived a mathematical principle for designing the point systems of gamified behavior change interventions. Our proof-of-concept study suggests that this principled approach to gamifying behavior change can be beneficial. We found that our gamified behavior change chatbot fostered positive behavior change during the intervention. This is consistent with previous findings that goal setting, reinforcement, reminders, and self-monitoring are effective techniques for promoting behavior change [7,33,39,41,44].

Moreover, we found that the behavior change that occurred during the intervention was maintained in all 3 conditions. The elements that the behavior change interventions in all 3 groups shared were goal setting and self-monitoring. Therefore, goal setting and self-monitoring may be sufficient for sustained behavior change. Adding reinforcement to goal setting and self-monitoring was beneficial during the intervention, but the additional benefits of reinforcement ceased to be statistically significant ($P \geq .17$ in all cases) in the week following the intervention. However, as our study had a small sample size, this apparent discrepancy could be an artifact of us having used different methods to measure behavior change during versus after the intervention. During the intervention, we measured behavior change through daily self-reports. After the intervention, we asked participants to retrospectively report on their behavior in the previous week, which is less accurate because of participants' fallible memory, and complete self-report questionnaires about their perceived habit strength, which are less objective than reports on behavior. Consistent with the interpretation that our study had insufficient statistical power for detecting retention effects, the measures we used to assess the maintenance of behavior change consistently showed a nonsignificant trend in favor of optimized gamification (Figures S1 and S2 in Multimedia Appendix 3). Moreover, previous studies have found that gamification-induced behavior change can persist over extended periods [63].

Limitations

From a theoretical perspective, the main limitation of our study is that it did not compare the effectiveness of the points computed by our optimized gamification method with alternative point schemes. Previous work has found optimized gamification to be more effective than several heuristic methods for designing point systems in contexts in which people choose among several activities [51]. However, the decisions that people face in behavior change applications appear to be simpler. Therefore, it remains unclear how much of the beneficial effects of optimized gamification on behavior change are specific to optimized gamification. Relatedly, it remains unclear which property of the points generated through optimized gamification is responsible for their effects on behavior change. Future work could address these questions by comparing optimized gamification of behavior change with simpler, alternative feedback mechanisms such as always awarding the same number of points or a streak-based point system.

However, we did evaluate optimized gamification against rewarding each enactment of the desired behavior using the same positive feedback message and punishing each failure to enact the desired behavior using the same negative feedback message (control condition with reminders and feedback). From a reinforcement learning perspective, this condition is equivalent to always awarding the same number of points when the behavior is enacted and always deducting the same number of points when the user fails to enact the behavior. We found that optimized gamification is more effective than this alternative feedback mechanism. This suggests that optimized gamification might be more effective than awarding the same number of points for each instance of the desired behavior. However, whether this interpretation is correct remains to be tested.

We illustrated the application of the general framework of optimized gamification to behavior change using a simple model of habit formation, which assumes that the user will indefinitely maintain the good habit once it has been established. This assumption is highly simplistic. In reality, maintenance is far from automatic. On the contrary, people may experience backsliding, and the strength of the habit may continue to wax and wane [64]. This could be captured by letting the process of deciding whether to perform the behavior continue indefinitely until the user dies. In this way, lapses could occur at any time and weaken the habit no matter how strong it is. In such a model, the health benefits of the behavior could be modeled explicitly in terms of its effects on a state variable that models the user's health status. Refining our method's model in this way would reduce the reinforcement for engaging in the behavior when the habit is weak and increase it when the habit is strong. This may make our method even more effective.

From an empirical perspective, the main limitation of the work presented in this paper is the relatively small sample size of our field experiment. Given that we collected <30 complete data sets per condition, the power of some of the statistical tests is relatively low. Therefore, the absence of significant differences in self-reported habit strength and retroactive intention enactment after the intervention does not provide strong evidence against the maintenance of the benefits of optimized gamification. Moreover, given that habit formation can take a very long time, our intervention may have been too short to fully capture the effects of the 3 different interventions on habit formation.

One flaw in our experiment was that some of the chatbot's messages were not worded in perfect, idiomatic English (Multimedia Appendix 2). We think that it is unlikely that our participants misunderstood any of the messages. However, it is possible that participants would have taken the messages more seriously if all of them had been written in perfect, idiomatic English. Another minor limitation of our chatbot is that its users started with a score of 0. Thus, if they failed to enact the desired behavior, their score fell to negative values, which might be demotivating. Therefore, future versions of our chatbot will award users a number of points (eg, 20) for setting the intention to build a good habit.

Finally, another weakness of our study design is that our intervention sought to strengthen water drinking in healthy people. Therefore, we cannot draw conclusions about the potential utility of our chatbot for clinical populations for which developing a healthy water-drinking habit might be crucial [3,4]. Moreover, it remains unclear whether our findings can be generalized to other habits that are more vital to people's health. In addition, our study was not specifically about water drinking as a weight loss strategy as only some participants tied water drinking to their meals. However, we introduced a general method that can be used to improve digital interventions for many critical behavior change applications.

Comparison With Prior Work

This study builds on previous work on optimized gamification [51]. Optimized gamification has been previously applied to help people decide what to work on [51] and which goals to set [52,55,56,65]. Moreover, optimized gamification has also been applied to help people stay focused on their work [58]. However, the work presented in this paper is the first application of optimized gamification to support habit formation. Moreover, it is one of the first real-world applications of optimized gamification as most previous work was confined to controlled laboratory experiments.

As our chatbot combined 4 established behavior change techniques (ie, goal setting, reminders, support for self-monitoring, and reinforcement), its design and effectiveness are therefore consistent with several extant theories of behavior change [66]. In particular, our optimized gamification method is consistent with behavior change methods that acknowledge the importance of providing positive feedback on improvements in behavior [28,66-69].

The most similar gamified digital intervention for behavior change that we are aware of is the SMS text messaging–based WalkIT intervention for promoting physical exercise [7,33,70]. Participants of the WalkIT trial received SMS text messages with daily physical exercise goals. Physical exercise (walking) was measured using the accelerometers of their smartphones and reported to a server. Participants received feedback on whether they met the exercise goal via an SMS text message that included points that were converted into money. Depending on the stage of the experiment, the number of points for achieving a goal was either constant or determined at random. The number of points awarded for failing to achieve a goal was 0. In contrast, our optimized gamification method provides a principled way to choose the exact number of points that a person should be awarded for meeting their daily goal or lose for failing to meet that goal. Therefore, our method could be used to enhance the WalkIT intervention with a more principled way of choosing the number of points depending on the user's history of successful and unsuccessful goal achievement. Conversely, WalkIT has many sophisticated features that go beyond the chatbot we introduced here. This includes an algorithm for adaptive goal setting, automatically delivered financial incentives, and an evidence-based sequence of different reward schedules that differ in the probability that goal achievement will be rewarded and whether the magnitude of the reward will be fixed or random. Consistent with our finding that the more performance-contingent feedback of the optimized gamification condition was more effective than less informative feedback or no feedback, the WalkIT studies found that immediate, behavior-contingent reinforcement was more effective in promoting behavior change than delayed, behavior-independent reinforcement.

Another gamified digital intervention for supporting behavior change is Habitica. Habitica embeds working through one's to-do list into a role-playing game in which the user's character can earn points by completing their daily to-dos. The points serve as an in-game currency that the player can use to buy weapons and armor for their avatar. Conversely, when the user does not complete a daily to-do, they lose points. As far as we can tell, the developers of Habitica chose the number of points the user gains for completing a to-do and the number of points they lose for failing to complete a daily to-do somewhat arbitrarily based on their intuitions. A recent study found that only 49% of Habitica's users rate its rewards as (rather) appropriate and that most experience counterproductive effects of Habitica's approach to gamification [17]. Given that optimized gamification was effective in our study and in previous studies, it is possible that redesigning Habitica's point system according to optimized gamification could alleviate some of the counterproductive effects of their users' experience.

The method introduced in this study mitigates the adverse effects of temporal discounting on people's health behavior [26]. Its approach is to add immediate rewards that are aligned with the behavior's long-term consequences for the user's health; that is, optimized gamification redesigns the decision environment so that people's shortsighted biases lead to decisions that are good for them in the long run [51]. Recent work on this topic introduced a computational model of intertemporal choice and applied it to compute personalized incentives for helping people more patiently work toward obtaining a larger reward later instead of abandoning the project in favor of a smaller immediate reward [71,72]. Similar to optimized gamification, their approach uses an MDP framework. However, their problem formulation and solution are different. The main difference lies in the application area. Sukumar et al [71] focused on canonical delay-of-gratification tasks, whereas we modeled habit formation. They tested their approach in online experiments in which participants played a *queue waiting game* and found that personalized incentives can increase people's patience while waiting in a simulated queue. In contrast, we conducted a field experiment on behavior change in which the incentives motivated people to act more farsightedly in the real world. Despite this critical difference, investigating whether modeling and measuring individual differences can be used to make optimized gamification more effective is an exciting direction for future work. Moreover, a computational model such as the one proposed by Sukumar et al [71] could be used to simulate the effects of alternative incentive schemes.

Previous work has found that drinking water before meals is an effective weight loss strategy for adults with obesity [3,4]. In the randomized controlled trial by Parretti et al [4], participants were instructed to use the water-drinking strategy in a face-to-face weight loss consultation. They did not receive any additional support in implementing this strategy. The chatbot we developed could be used to augment those weight loss consultations with a digital tool that helps people follow through on their resolutions. Alternatively, an appropriately adapted version of our chatbot could be used as a highly scalable, low-cost alternative to face-to-face weight loss consultations.

Conclusions

In conclusion, optimized gamification is a practically helpful theoretical principle for designing the point systems of (digital) behavior change tools and interventions. It can be implemented in just a few lines of code, and the point values can be computed instantaneously. It can be applied to improve or augment many existing (digital) behavior change interventions and can also be used to create new ones. Thus, optimized gamification can help tackle many challenging behavior change problems using scalable digital interventions. Testing whether, when, and how optimized gamification can make a positive difference in critical practical applications is an exciting direction for future research. A crucial next step will be to test our point system against simpler heuristic point systems for supporting behavior change. Moreover, our chatbot can be extended to support various health behaviors and other forms of positive behavior change.

Acknowledgments

This work was supported by grant 1757269 from the National Science Foundation.

Data Availability

The data generated in this study, the R scripts used to analyze the data, and the MATLAB (MathWorks) implementation of the optimized gamification method are available on the project's Open Science Framework repository [73].

Authors' Contributions

FL conceived and designed the study, developed the optimized gamification method, and wrote the manuscript. PZC designed and implemented the Good Habit Bot and co-designed and conducted the field experiment. MP conducted the data analysis. VA supported PZC in designing and conducting the field experiment and in the design of the Good Habit Bot. MT contributed to the implementation of the Good Habit Bot.

Abstract

Physical activity is important for everyone to maintain and improve health, especially for people with chronic diseases. Mobile exergaming has the potential to increase physical activity and to specifically reach people with poor activity levels. However, commercial mobile exergames are not specially designed for older people with chronic illnesses such as heart failure. The primary aim of this viewpoint is to describe the underlying reasoning guiding the design choices made in developing a mobile exergame, Heart Farming, tailored specifically for sedentary older people diagnosed with heart failure. The goal of the exergame is to increase physical activity levels by increasing the daily walking duration of patients with heart failure by at least 10 minutes. The rationale guiding the design decisions of the mobile exergame is grounded in the thoughtful integration of gamification strategies tailored for application in cardiovascular care. This integration is achieved through applying gamification components, gamification elements, and gamification principles. The Heart Farming mobile exergame is about helping a farmer take care of and expand a virtual farm, with these activities taking place while the patient walks in the real world. The exergame can be adapted to individual preferences and physical condition regarding where, how, when, and how much to play and walk. The exergame is developed using augmented reality so it can be played both indoors and outdoors. Augmented reality technology is used to track the patients' movement in the real world and to interpret that movement into events in the exergame rather than to augment the mobile user interface.

Introduction

Background

Physical activity is important for everyone, especially for people with chronic disease [1]. Low levels of physical activity are commonly reported by patients with cardiac disease, which raises the risk of both illness progression and death [2-4]. Patients with heart failure benefit from physical exercise, but the activity must be tailored to the patient's baseline condition and the intensity of their symptoms [5]. A promising, innovative way to motivate people to become more physically active is the use of exergames. Exergames are games that combine gameplay with physical activity, requiring people to move in the real world [6]. They lead to an increase in physical activity [7] and have the potential to reach people with poor activity levels [8]. Nintendo Wii and the X-Box Kinect are well-known commercial exergames that have been tested for effectiveness in older people and for patients in cardiac rehabilitation programs [9-11]. Although some exergame studies show benefits for physical activity, a meta-analysis showed that exergaming, when compared to conventional cardiac rehabilitation programs, showed equal effects in terms of improving exercise capacity, quality of life, and mental health [11]. Nevertheless, commercially available exergames, using a "one size fits all" approach, fail to cater adequately to the specific requirements of the older adult population in general [12,13], and more specifically, to individuals dealing with heart failure [14]. A randomized controlled trial using a commercially available, off-the-shelf product demonstrated ineffectiveness in enhancing submaximal exercise capacity among patients with heart failure [15]. Based on interview studies regarding mostly commercial exergames, adult players perceived barriers to exergaming that might be related to the fact that the exergames were initially designed for children or young adults [14,16,17]. Barriers that could hinder older peoples' abilities to exergame were poor vision, physical function limitations, and other health conditions [14,17].

For this reason, the design of exergames for older people should focus on suitability, usability, and accessibility, as this will increase acceptance. An important aspect to consider in designing exergames for older people is that the location of play should be flexible, for example, offering the potential to be played both indoors and outdoors. This can be realized by developing the exergame for a smartphone, instead of a stationary computer. Another benefit is that smartphones are accessible to the target group. Even though older people might be interested in using mobile phones [18] and mobile health applications can help older people in self-care of illnesses and lifestyle improvement [19], there are no specific mobile exergames designed for older people with heart failure.

The aim of this paper is to describe the principles and technology used in Heart Farming, a mobile exergame designed with the objective of increasing physical activity for inactive older people with heart failure by increasing their walking time by at least 10 minutes each day, as this has been shown to reduce the risk of death or hospitalization by 4% [20]. The Heart Farming exergame was designed and developed using an adapted version of the player-centered, iterative, interdisciplinary, and integrated framework for serious games [21].

Mobile Exergames for Older People

A previous study shows that outdoor mobile exergames increase older peoples' engagement, satisfaction, and interest in physical activity [22]. Furthermore, previous research shows that the quality of life for patients with heart conditions can be improved by using mobile phones as health interventions to stimulate physical activities, medication management, dermatology, fall detection, and exercise monitoring [23]. Smartphones are recommended for non–face-to-face physical activity interventions for older people [24]. Smartphones contain built-in technologies, for example, accelerometers, cameras, and sensors, that measure users' movement and can provide the users with real-time monitoring and feedback on their physical activity without the use of a separate device [25-28]. Furthermore, smartphones provide connectivity, enabling users to get social support that can impact individual motivation positively and consequently improve goal attainment [26,29,30]. Flowie is one of the first mobile exergames to promote increased physical activity among older people and is designed to motivate them to enhance levels of physical activity using a virtual coach [31]. During an 11-day exploratory intervention, participants expressed positive feedback regarding the virtual coach, highlighting increased motivation to engage in exercise. However, quantitative data did not demonstrate a timely increase in physical activity, possibly due to the prototype's limited activity-sensing capabilities and varying weather conditions during the study. Another mobile exergame is Solitaire Fitness, an asynchronous exergame designed to enhance cognitive and physical ability for older people [32]. The exergame is built on a well-established card game, solitaire, since familiarity can impact the experience positively. The exergame gathers gameplay data so researchers and health professionals can assess project success by measuring user exercise levels and the frequency of features used in the exergame. The authors argue that the general attractiveness and engagement of the game might be improved, while offering health advantages, if new mechanisms are included while keeping it accessible and familiar.

To provide older people with an exergame experience that is perceived as meaningful play, it is important to understand their needs and why they would want to play the exergame [33]. Exergames need to be both attractive to the players as well as effective as an exercise [34]. There are several guidelines for game design [35], exergame design [14,36], and fitness applications [37], as well as motivational factors for mobile games for older adult users [38], all of which need to be considered when designing exergames for older people with heart failure. For example, the benefits gained from playing the exergame need to be clear since they will impact older adults' use of the exergame [38]. Furthermore, the exergame topic should be adjusted to the interests of older people [36,39,40], and the players' physical condition should be considered with a suitable difficulty setting [36,39]. Furthermore, the user interface should be adapted to older people [36,39] by, for example, having an easy-to-use user interface and avoiding small objects by, for example, using bigger game characters [36]. Feedback should be both auditory and visual [36], and no feedback should be provided about unachieved goals or unperformed activities, since only positive reinforcement should be used to improve behaviors in exergames for older people [40].

Gamification Features in Exergames

Overview

Gamification can be used to enhance user motivation and engagement with systems [41] by using game design to create gamified experiences [42]. Therefore, gamification features can be integrated in exergames [43]. Matallaoui et al [43] consider exergames to consist of 3 gamification components [41,42] that can be applied for people with heart failure together with gamification principles and gamification elements [44].

Gamification Components

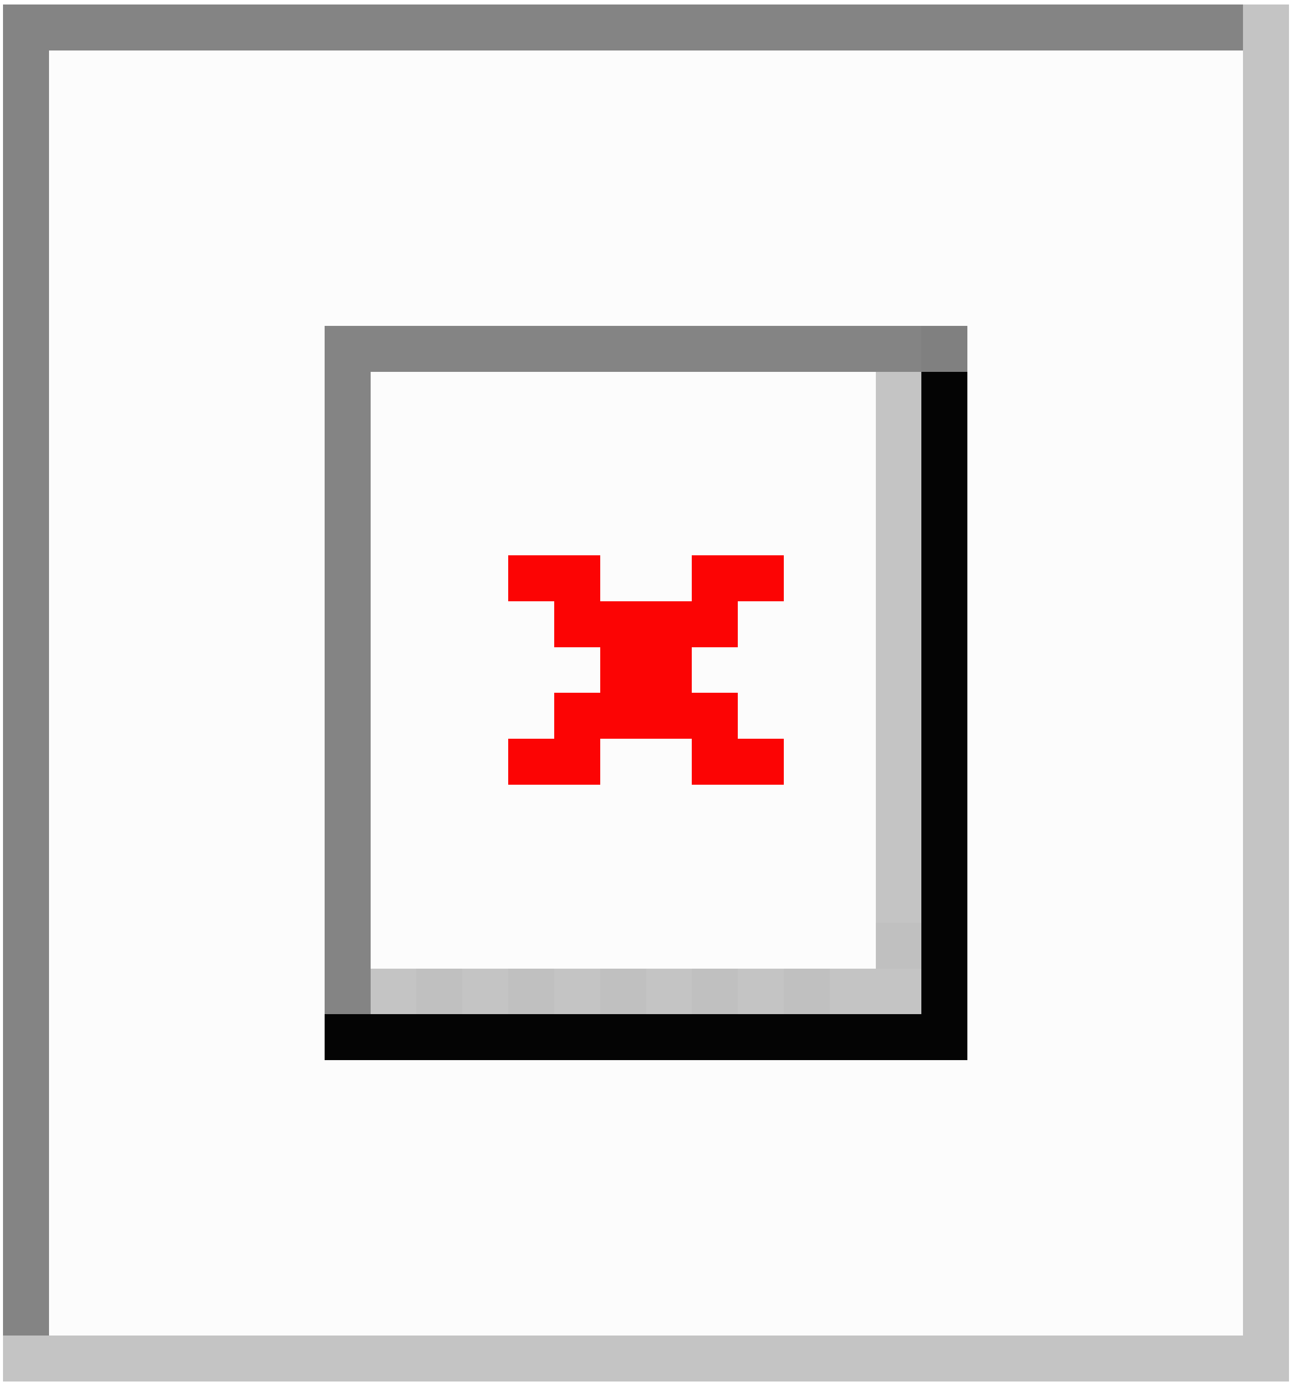
Gamification can be presented as a process with 3 main components, and these components are the fundamental building blocks that make up a gamified experience [41,44] (Figure 1):

1. *Implemented motivational affordance*: Objects in the user interface of the exergame have properties that allow the players to experience the satisfaction of their psychological, internal, motivational needs. These are used to motivate users to engage with a gamified experience and provide users with a sense of challenge, accomplishment, and reward.
2. *Psychological outcomes*: These are the psychological experiences promoted by the exergame to motivate the user to perform activities. These are the emotional or cognitive effects that gamification can have on users. Examples of psychological outcomes include increased engagement and a sense of accomplishment.
3. *Behavioral outcomes*: These are the behaviors that the exergame will change and that will affect the player's health. These are the specific actions and behaviors that users take as a result of engaging with a gamified experience. Examples of behavioral outcomes include

increased participation, the completion of tasks, and adherence to a desired behavior.

The gamification process starts with motivational affordances that facilitate the psychological experiences that will, together with the implemented affordances, in turn influence the behavioral outcomes (ie, the physical activity for exergames).

Figure 1. Gamification components adapted from Berglund et al [44], which is published under Creative Commons Attribution 4.0 International License [45].



Gamification Principles

Gamification principles are the underlying concepts and strategies that guide the design and implementation of gamification. These principles are the fundamental rules that govern how a game is played and are used to create and extend the player experience [46] and increase overall enjoyment. There are 5 principles that impact the gamification process [47]:

1. *Meaningful purpose*: The goal of the game should align with the users' motivations [47].
2. *Meaningful choice*: Players have agency over how they achieve their goals and make progress in the game [47] to satisfy their motivational needs [48].
3. *Supporting player archetypes*: The game's mechanics allow for individual play styles and characteristics [47].
4. *Feedback*: Feedback on how actions performed in the game affect the player's progress is clearly communicated to the

player [47]. Instant feedback makes the game responsive and helps maintain the game's appeal [49]. Accumulated feedback provides information about the progress of players, which makes it suitable for comparison [49] and can be a source of motivation when players evaluate how close their current behavior is in relation to the goal, thus facilitating self-monitoring [50].

5. *Visibility*: The player can see the status of their current progress, including how much remains to meet their goals or finish a task [47].

Gamification Elements

Gamification elements are the specific parts that make up the game. The main difference between gamification principles and gamification elements is that gamification principles define how a game works, are used to create an engaging and fun gameplay experience for players, and refer to the overarching design concepts that guide the creation of a game, whereas gamification elements are the specific implementations used to achieve the principles. The 6 most common gamification elements used in health care are as follows [51]:

1. *Leaderboards*: Leaderboards (or high score lists) present the rank of players based on their experience points [51]. Leaderboards enable players to compare themselves with others and evaluate their performance [52].
2. *Levels of achievement or rank*: These are sums of points or credits associated with levels. Levels could evoke a feeling of progression [51].
3. *Digital rewards*: Rewards for achievements in the game can have a positive impact on interest and enjoyment [53] and influence the player's behavior in different ways [54]. There are 8 forms of rewards [49]:
   - 3.1. *Score systems*: Numbers are used to mark player performance.
   - 3.2. *Experience points reward systems*: Experience points are earned during gameplay and lead to "leveling up" when specified goals are achieved.
   - 3.3. *Item-granting system rewards*: These are virtual items that can be used by players.
   - 3.4. *Resources*: Virtual resources can be collected and used in the game in a manner that affects gameplay.
   - 3.5. *Achievement systems*: Players can collect achievements by fulfilling clearly stated conditions.
   - 3.6. *Feedback messages for immediate rewards*: Some examples include text, sound effects, and animations.
   - 3.7. *Plot animations and pictures*: These are provided after important events in the game such as clearing a new level.
   - 3.8. *Unlocking mechanisms*: Players are rewarded by getting access to game content, for example, new levels achieved when the required experience points are gained.
4. *Real-world prizes*: Players can exchange credits or points earned in the exergame for real-world prizes such as vouchers, goods, or services.
5. *Competitions*: Competitions can be invoked through comparisons with oneself or with peers [50]. Competition appeals to the player's social needs, which impacts their intrinsic motivation [48].
6. *Social or peer pressure*: Cooperation appeals primarily to the player's psychological need for relatedness [48] and can complement competition [50].

Exergames and Augmented Reality

Augmented reality (AR) is a technology that involves the use of sensors and cameras to collect and interpret data from the surrounding environment. AR combines virtual information with the real world and can be used for intelligent displays, 3D registration technology, or intelligent interaction technology [55]. AR technology is usually used to present information (eg, graphics, video, or sound) in a dynamic and interactive manner by overlaying digital content onto the real-world environment [56], and it is highly recommended for health applications that bridge the virtual and real worlds [57]. Furthermore, AR has been used for indoor navigation [28,58,59] by using the technology to determine the user's position in the physical environment. AR can support localization, but for the technology to work properly, users need to hold the smartphone device in a specific orientation and position [59].

The application of AR in fitness is a novel approach for patient intervention in clinical environments, promotes physical activity, and protects the public from noncommunicable illnesses [60]. Furthermore, AR has the potential to play a role in encouraging and sustaining an active lifestyle, fostering overall well-being among the older adult population [61]. Since AR mobile exergames have the potential to enhance cardiovascular health and physical exercise, they are appropriate for person-centered care interventions [62]. AR technologies have the potential to complement physical interventions in altering human behaviors and influencing physical activity [63]. However, there are several challenges to successfully implement AR techniques in exergames for older people, and usability is one of the challenges. According to a study by Stamm et al [60], older people found it challenging to use complex gestures and navigate menus in AR exergames. Another challenge is safety, and the danger of falling has been identified as a safety challenge that impacts patients' use of AR exergames [60]. The acceptance of technology is another challenge that needs to be considered in AR exergames [60,64].

To create exergames that are fun to play, the physical environment needs to be considered, since it influences physical activity [65] and the appropriate technology that needs to be used. AR has been used for both outdoor [66] and indoor [67] exergaming. GPS, a satellite-based radio navigation system, is another technology used in many mobile location-based exergames intended for outdoor use [8,68,69]. The error margin of most mobile GPS trackers is in the 5- to 10-m range, which means registering shorter distances when walking back and forth (as people playing in smaller areas might have to do) is not possible. However, GPS has a reduced signal strength or lack of signals in indoors environments due to the fact that physical obstructions such as buildings may weaken and even block GPS signals [70,71]. Therefore, GPS is more suitable for outdoors positioning while AR can be used both indoors [72,73] and outdoors [74]. Using the camera for movement tracking results in spatial movement detection nearly 10 times more precise than that achieved by a GPS sensor [58]. AR and GPS can be combined in exergaming. One of the most well-known mobile exergames using both GPS and AR is Pokémon GO, which was shown to increase physical activity [8,68]. Pokémon GO increased user steps by an average of 1473 steps per day over a period of 30 days [8]. However, Pokémon GO has been criticized for the potential harm it could cause via traffic accidents due to players' distraction or through players placing themselves in dangerous situations or environments while playing [75,76].

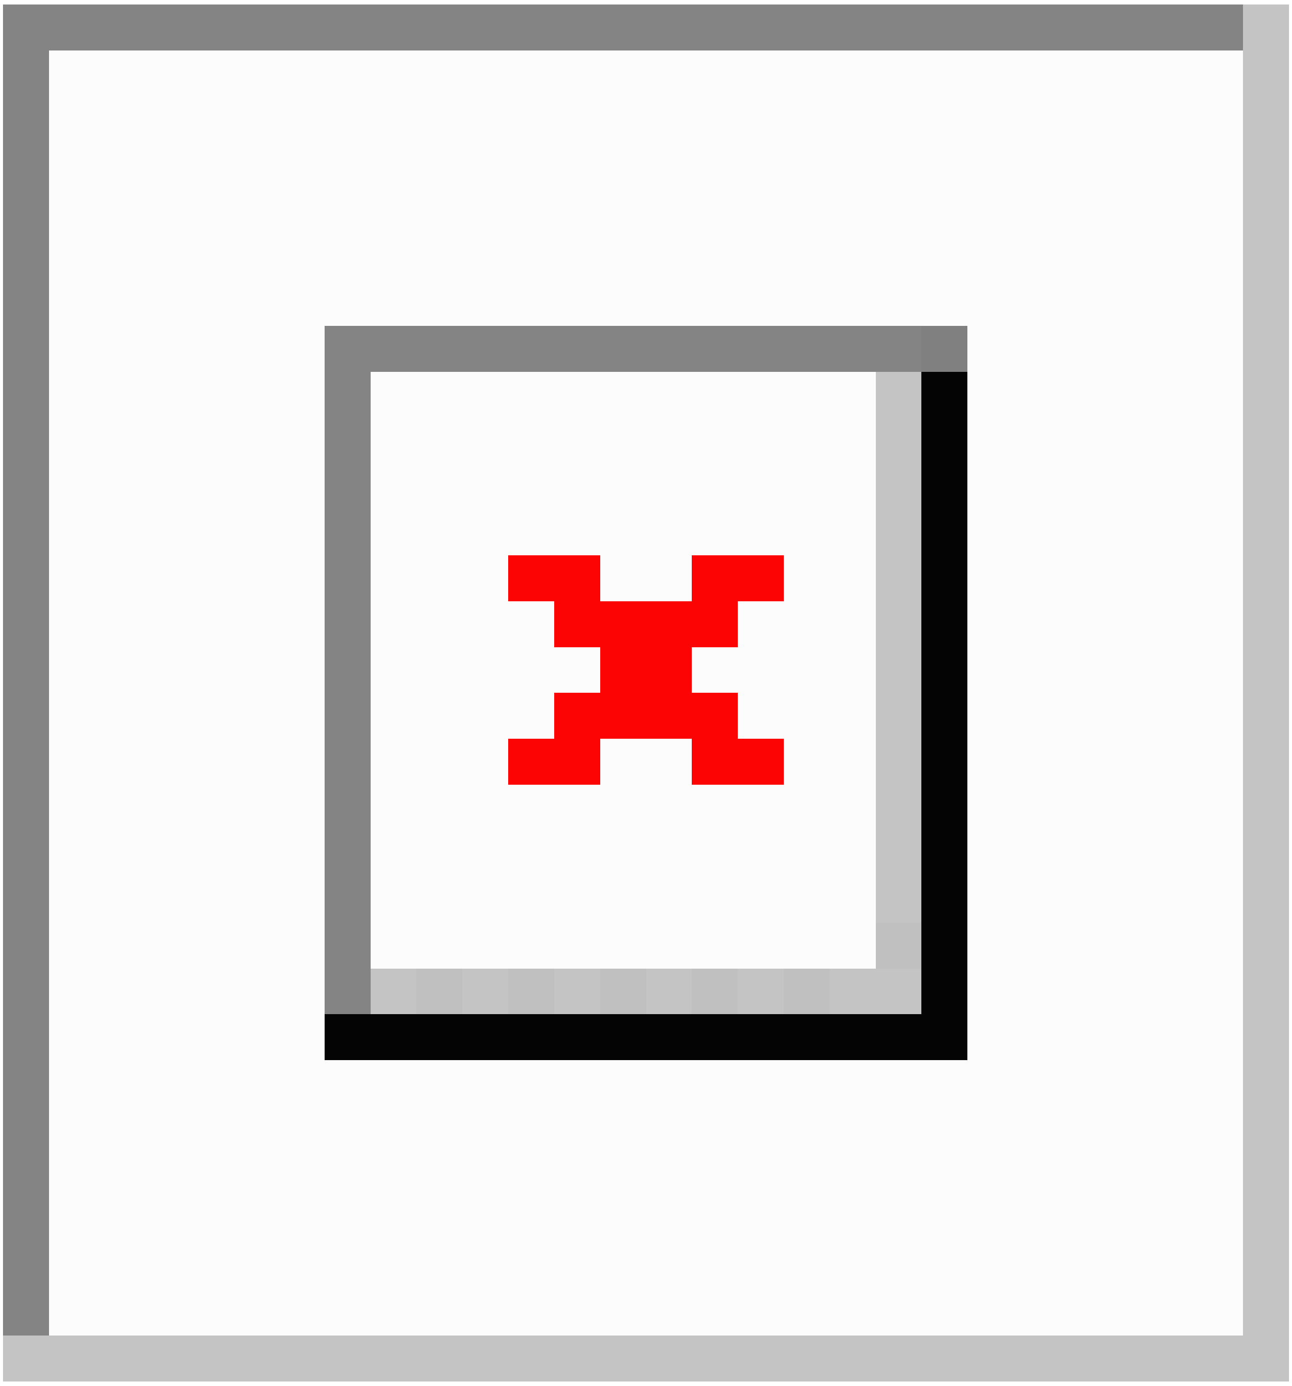
In summary, older people with heart failure often lead sedentary lifestyles. AR mobile exergames have the potential to encourage increased physical activity, yet the current lack of mobile exergames designed for both indoor and outdoor use, incorporating gamification features to influence patient behavior, presents a notable gap in the available solutions. In this viewpoint, we describe the rationale behind the design decisions in Heart Farming, a mobile exergame tailored for older people with heart failure.

Heart Farming: A Mobile Exergame

Overview

The Heart Farming exergame uses a farming theme, which involves helping a farmer take care of and expand a farm (Figure 2A and B). The players can plan activities in the exergame and then walk in the physical world, indoors or outdoors, to perform the activities they have planned without the need to look at the screen while walking (Figure 2B and C). Available activities are planting and collecting crops of various kinds (eg, sowing carrots, watering strawberries, and harvesting oranges), buying new fields, foraging in the forest, fishing, and selling crops to neighbors on the farm (see Figure 2A-C). Fields and neighbors are visible on a map (Figure 2A and B), and the player must walk in the real world, both to perform the planned activities and to move between locations. As players take care of the farm, they gain experience points, which, over time, unlock new types of crops to farm as well as new neighbors to sell to.

Figure 2. Images from the Heart Farming exergame: (A) main view of the exergame showing the farm before any planning of activities, (B) farm scene as the player plans activities, (C) planned activities are shown in a list view with a progress bar as the player walks, and (D) player statistics and progress in the exergame.



Gamification Features in Heart Farming

The gamification components applied in Heart Farming are as follows:

1. *Implemented motivational affordance*: The desired behavior of being physically active is paired with rewards, for example, numeric rewards such as walked distance and experience points. Walked distance builds up to complete the daily goal and is only earned while performing activities in the Heart Farming exergame that require walking. Sums of experience points are associated with levels, which evoke a feeling of progression (Figure 2D). The player gets experience points by performing activities in the exergame, which are based on how many meters of movement the AR system has registered, balanced to match the player's own physical activity levels. Experience points can be earned from all activities, including sit-to-stand activities, and can be given as a reward, for example, for reaching the daily goal.
2. *Psychological outcomes*: The purpose is to increase players' motivation and self-efficacy for physical activity, since these factors are important for patients with heart failure [77]. It is common for patients with low exercise capacity to be motivated but lack the confidence to become more physically active [77]. Achieving daily goals in the Heart

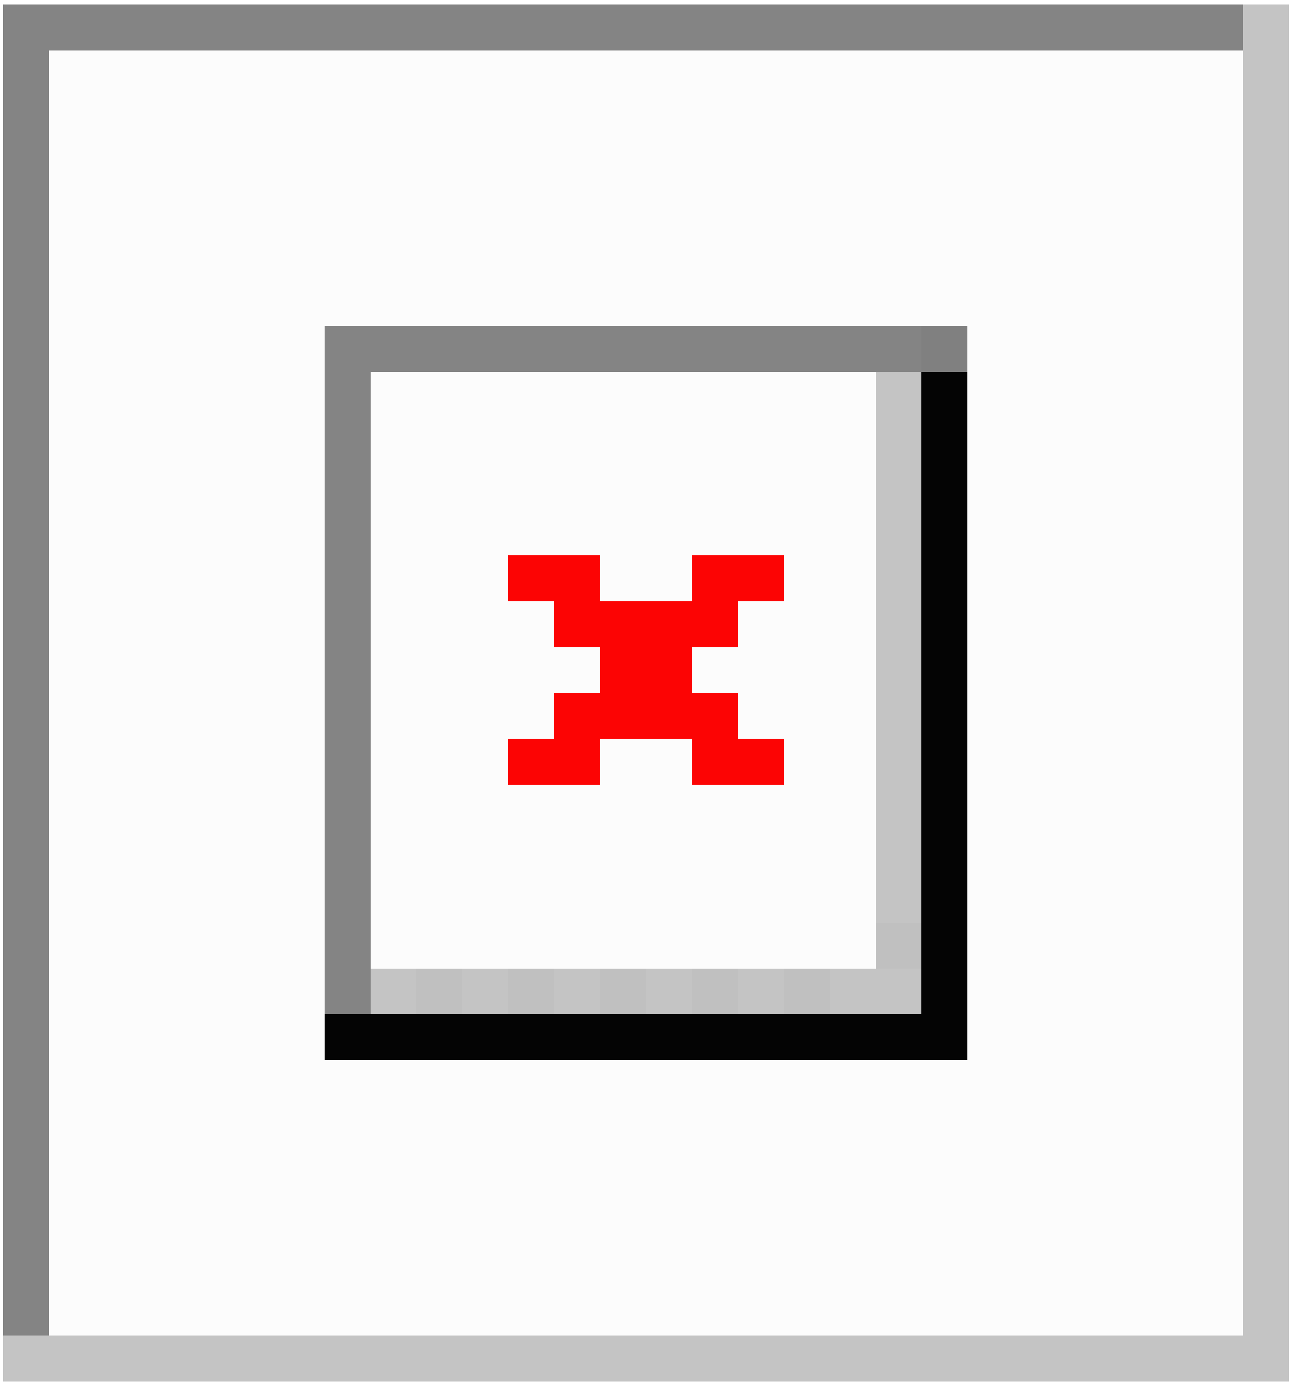
Farming exergame means that patients are following the physical health recommendation, which might increase their confidence in walking.

3. *Behavioral outcomes*: The goal is to increase physical activity by walking for 10 minutes every day with the Heart Farming exergame. To create a trigger for the player to help create the habit of playing every day, the exergame logs whether players have played or not and sends a reminder at 12 PM if they have not yet played that day. A mission book is also included to give players regular missions; the missions trigger them to do specific activities in the exergame and encourage curiosity about later content (see Figure 3D).

The gamification principles applied in Heart Farming are as follows:

1. *Meaningful purpose*: Real-life physical activity is used to progress in Heart Farming. Players can do 2 types of physical activities: walking in real life and doing sit-to-stand activities. Both activities are performed using the smartphone, which registers the movements and converts them into virtual exergame progress and rewards. Walking is required to meet the player's daily goal.
2. *Meaningful choice*: Players can choose freely how, when, and where to play. Players who are not interested in optimizing the rewards can choose the automatic mode, which only requires the press of a button before the patient can begin to walk. Players who want more challenges and to perform well in the exergame can instead use the strategic gameplay mode to plan farming activities, which are chosen freely with little or no real analysis of the exergame rules and progress. How players choose to plan their tasks affects the number of rewards they get. Players can also choose to play to complete missions in a mission book. Completing the missions is not obligatory to progress in the exergame, and many tasks in the missions can be completed in more than 1 way to give players choices in how to play the exergame, while others are more specific to encourage players to try new things or extend their farm further. An optional sit-to-stand activity that gives the players experience points or crops is also included to facilitate players with varying degrees of mobility.
3. *Supporting player archetypes*: The goal distance to walk each day is adapted to the players' exercise capacity. Players are represented in Heart Farming by an avatar in the form of a hat seen from above. As players progress in the exergame, new hats are unlocked, so players can choose a hat that they can identify themselves with. The avatar reflects in-game activities conducted by the player, such as moving on the map when the player walks. Heart Farming is also designed to be adaptable to the players' exercise capacity. The goal of 10 minutes of walking per day can be based on the number of meters walked during a 6-minute walk test [78]. When players walk their daily goal in the exergame, they receive a trophy. When they have walked twice or 3 times their daily goal, they are rewarded with a smaller experience point boost and a flag animation. After the player has walked 3 times their daily goal, the walking distance is registered and displayed to the player, but in a toned-down fashion without motivational components such as rewards and with the progress bar completely filled.
4. *Feedback*: The players receive multiple types of immediate feedback for performing actions in Heart Farming that communicates clearly how their actions affect progress in the exergame. Instant feedback is provided as visual and auditory information about the behavior that is currently being performed. For example, while walking with a plan in motion, the player can see a progress bar fill up on the current task and hear sounds corresponding to the action being performed (eg, watering sounds while watering a field; see Figure 2C).
5. *Visibility*: All progress in the form of number of meters walked is displayed visually so players can see their overall progress in the Heart Farming exergame as well as their current progress on their daily goal at any time (see Figure 2B-D).

Figure 3. Digital rewards in Heart Farming: (A) score system, (B) experience points, (C) daily gifts, (D) achievement systems, and (E) crops that can be sold to a neighbor.



The gamification elements applied in Heart Farming are as follows (Figures 3 and 4):

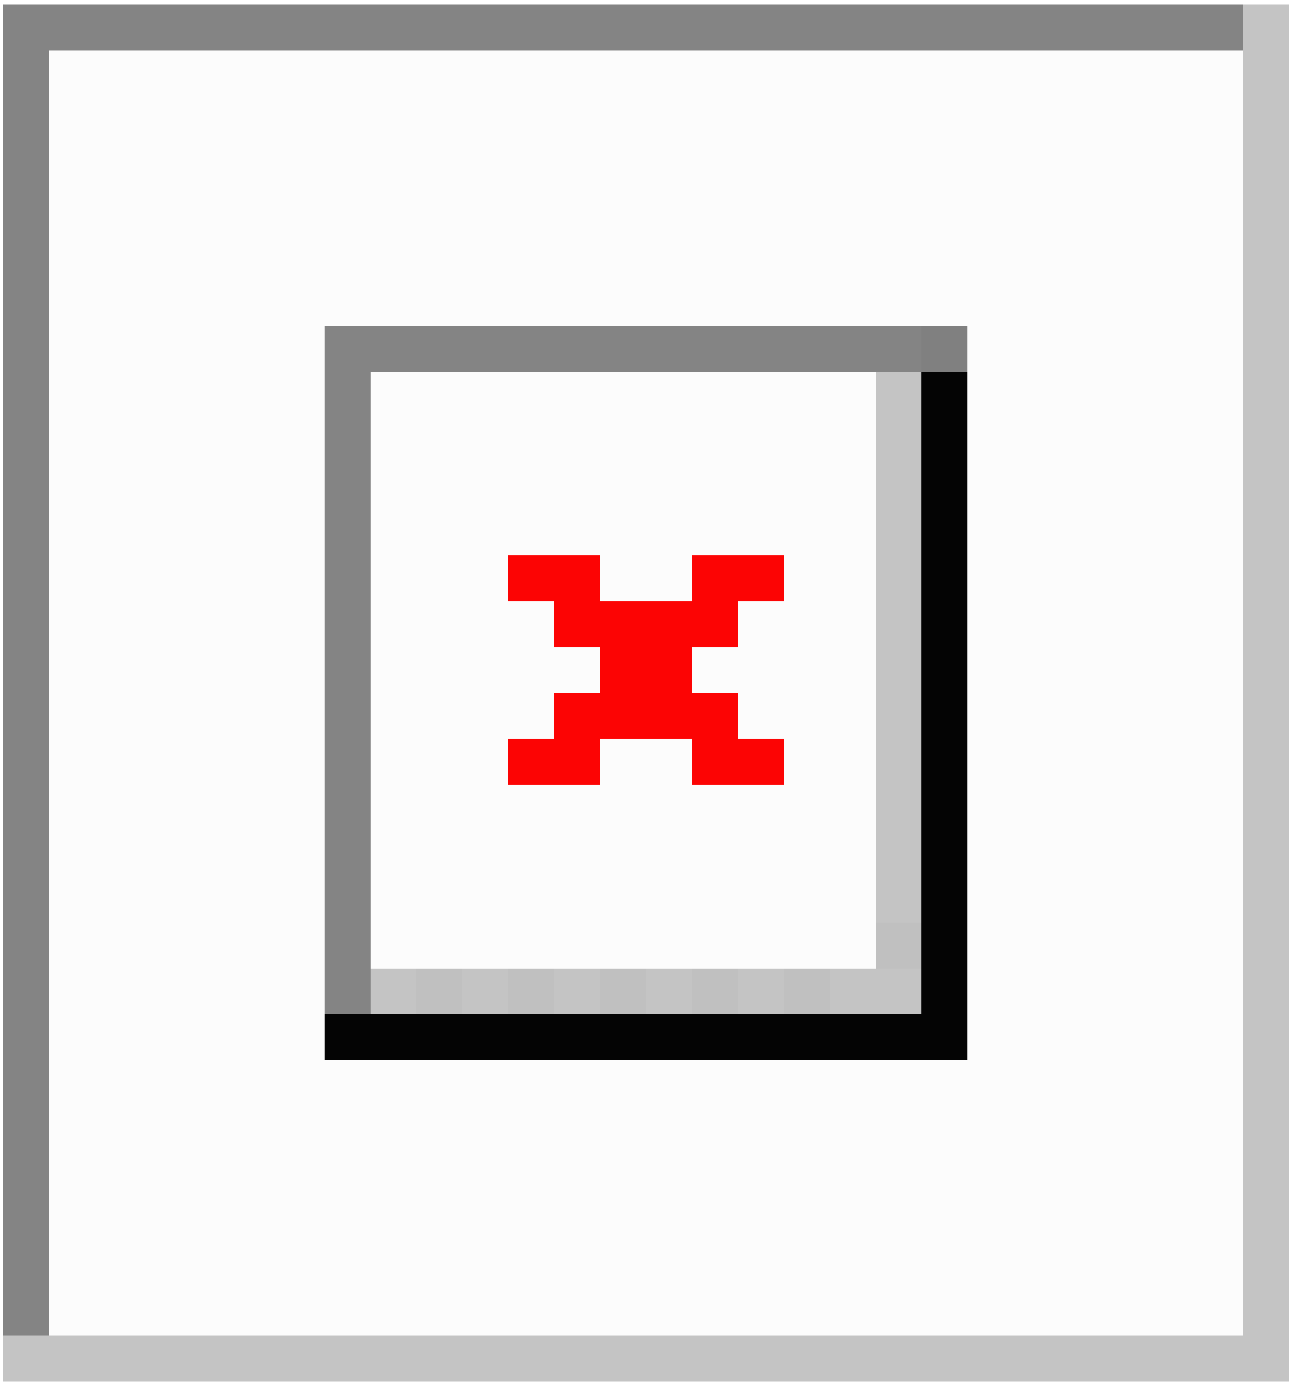
1. *Leaderboards*: A leaderboard displays the in-game postal codes of the players that gained the most experience points the previous day (Figure 4A). Since low-performing players can be demotivated by a leaderboard when they fall behind and feel that they cannot catch up with others [79], our leaderboard is designed so that players have the same opportunity to be included in it every day, regardless of their performance in the days prior to the current one.
2. *Levels of achievement or rank*: Sums of experience points are associated with levels that evoke a feeling of progression . Each level also unlocks a new type of crop to farm or forage, a new tool that makes farming easier , a new neighbor to whom the player can sell crops (), or a new decorative hat for the farmer to use (Figure 4B). The actual level is always displayed in the upper left corner (Figure 3).
3. *Digital rewards*: The following digital rewards are included in Heart Farming exergame (Figure 3):
   - 3.1. *Score systems*: The total distance walked adds up to reach the daily goal. It is displayed as a progress bar in the lower part of the screen (Figure 3A).
   - 3.2. *Experience points reward systems*: Each activity in the exergame is translated to experience points, which are required for the player to level up over time.

A star symbol is used for experience points (Figure 3B).

- 3.3. *Item-granting system rewards*: Every day, players get a gift of free crops to encourage them to come back to the farm each day (Figure 3C). This incentive fosters a daily habit of playing, which in turn promotes walking every day.
- 3.4. *Resources*: Coins are needed to buy new fields and are earned from selling crops (Figure 3A).
- 3.5. *Achievement systems*: Completing specific tasks unlocks unique animals. Each neighbor has hearts that are filled by selling them specific crops, and if all hearts are filled before the end of the week, the player gets a special decoration (Figure 3D).
- 3.6. *Feedback messages for immediate rewards*: Both animations and sound effects are used to provide feedback when the players perform actions. When players complete the daily goal, they get a reward in the form of an animated trophy and a boost of extra experience points.
- 3.7. *Plot animations and pictures*: These were not used.
- 3.8. *Unlocking mechanisms*: The players unlock new tools and crops at higher levels (Figure 4B).

4. *Real-world prizes*: The exergame does not include any real-world prizes.
5. *Competitions*: The exergame does not include any competition.
6. *Social or peer pressure*: Each player has their own in-game postal code that can be used to communicate with other players by sending emojis (eg, smile messages) with positive reinforcement and packages with crops to help each other progress in the exergame (Figure 4C).

Figure 4. Gamification elements in Heart Farming: (A) leaderboards, (B) levels, and (C) social or peer pressure.

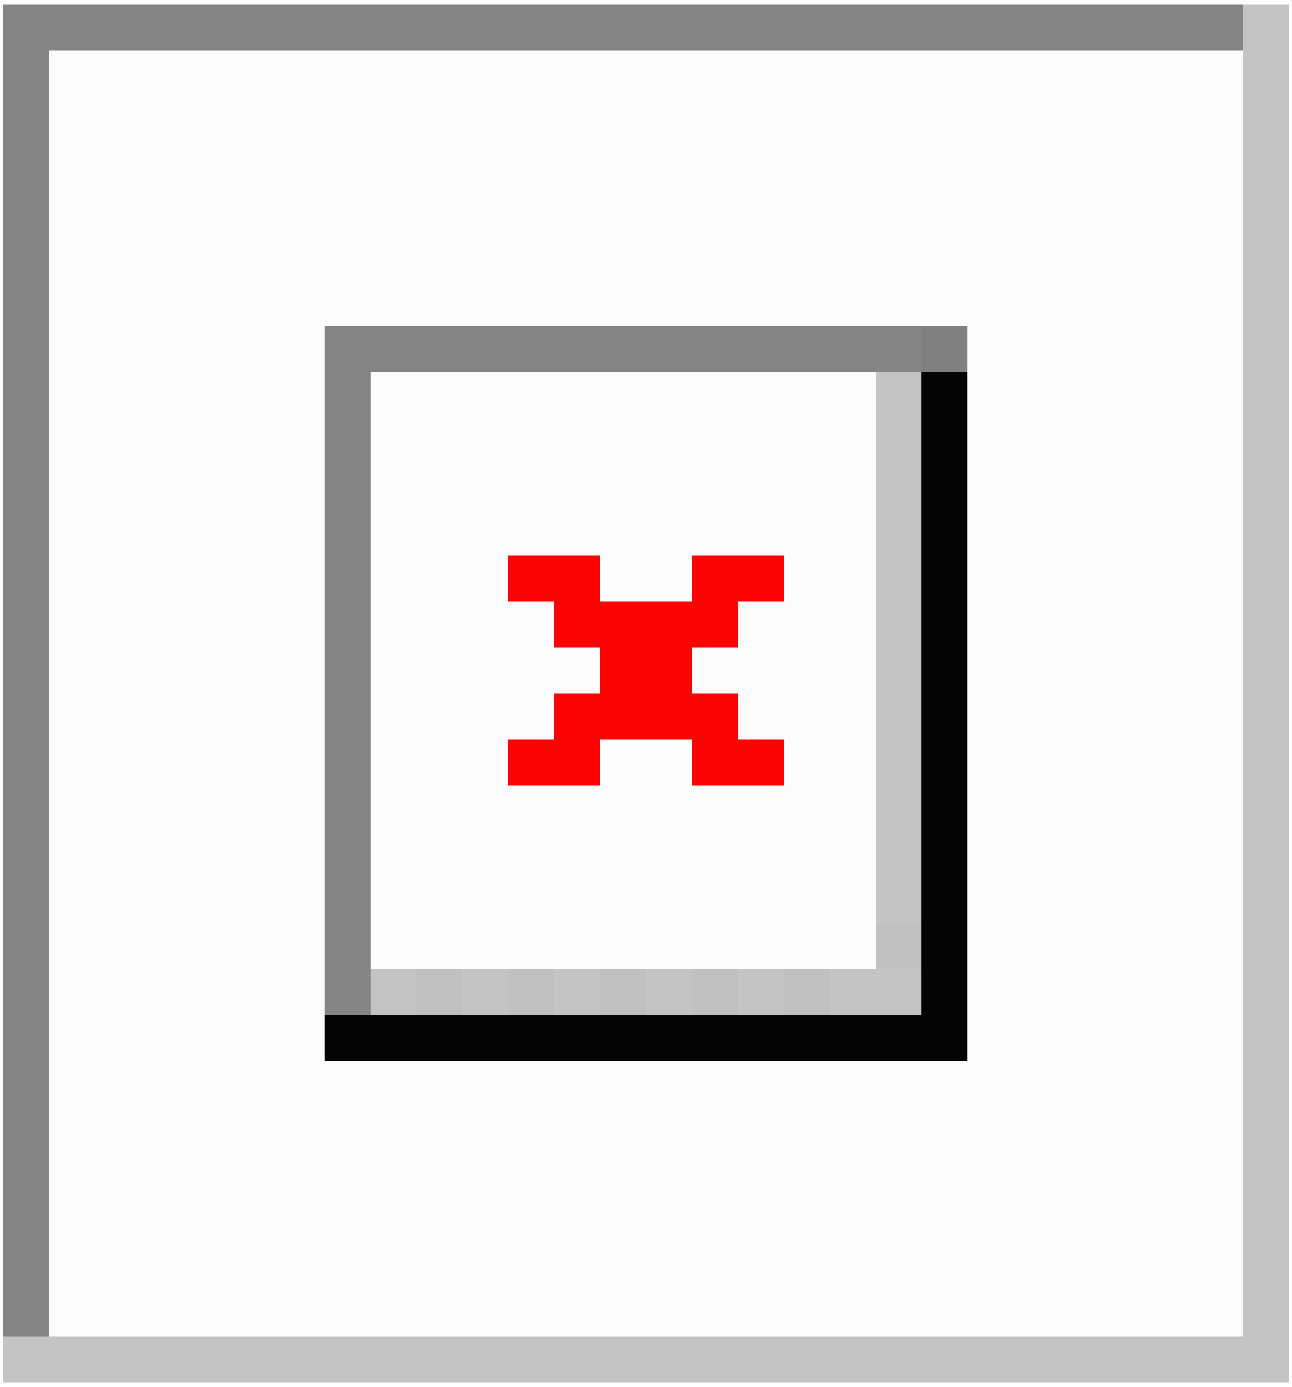


The Exergame Development

The game development engine Unity was used for the exergame development. The player data are stored in an SQLite database that is connected to a Flask server. The exergame was developed for both the Android and the iOS smartphone operating systems that support AR. The AR is only used to track the players' movements when walking in the real world. AR enables acceleration-independent tracking by analyzing visual discrepancies among identified landmarks by calculating the change through the AR program's SLAM solution [80,81]. The status of the AR program is displayed for the player using a stop traffic light with 2 colors: a green light means that the AR can track and register the player's movement so the player can walk, whereas a red light means that the AR is not working. A red light may either indicate that the AR program is loading or that it is unable to analyze the current camera feed for some reason, for example, it is too dark, the player is moving too fast, or the camera feed is covered. A warning pop-up is displayed for the player and proposes a solution based on the problem. If the camera feed is too dark, the player is prompted to relocate to a brighter place, and if the movement speed is too high (biking or driving speed), the player is prompted with 1 of the 3 different messages: "bad camera image (dark/covered)," "too fast motions for camera," and "initializing/restarting tracking" (Figure 5).

To mitigate the risk of falling, the player does not need to look at the screen while walking. The player creates a plan with activities and can then walk to perform all activities in the plan without the need to look at the screen. Each activity has a sound to provide feedback for the player about what is happening on the farm.

Figure 5. (A) Green traffic light and (B-D) red traffic light with warning messages.



Discussion

Principal Findings

Research indicates that older people with heart failure can potentially reduce the risk of death or hospitalization by 4% simply by adding a daily 10-minute walk to their routine [20]. In response to this, we developed a mobile exergame, Heart Farming, specifically designed to increase their physical activity levels. The rationale that directed the design decisions of the mobile exergame described in this work is based on well-established game design methods to support behavioral changes for inactive patients with heart failure in an enjoyable way. Gamification components, gamification principles, and gamification elements have been applied for designing the exergame. Heart Farming is based on a farming theme, and to play the game, players need to walk in the real world.

Exergames can persuade people to exercise more when they are designed for exercising [82], but defining appropriate goals is difficult, and therefore, official institutional guideline values can be used appropriately as a starting reference point [64]. Since regular physical activity can help preserve health and enhance the quality of life for the patient group, the exergame is designed so that the patient comes back to the exergame and plays every day, for example, using daily gifts with different crops and daily reminders when the patient has not walked.

The gamification components in Heart Farming are provided to increase the patients' physical activity, which requires behavioral changes. Since motivation drives humans to perform and can arise from physiological or psychological needs, thoughts, or emotions [83], the design and technical implementation is applied to balance the patients' physical needs with an elusive fun factor. To perform a behavior, a person must be motivated, have sufficient ability, and have a trigger to prompt the behavior [84]. Thus, the design of Heart Farming aims to increase the motivation to engage in physical activity and keep it at a level where the patients' abilities are sufficient to perform the activity. For the trigger, the exergame sends a reminder at 12 PM if the player has not yet played that day. By setting the reminder around lunch time, the patient can associate playing the exergame with an existing habit of eating lunch, making it easier to create a new habit either before or after eating. According to Stawarz et al [85], reminders can, however, hinder habit formation if the user gets reliant on the reminders, which causes the habit to die out if the user stops using the app. By only sending reminders to players who have not played yet, only those who need the reminder get them, and as they start connecting a trigger event in their lives to the new habit, the reminders might phase out naturally over time. A potential problem with having a set time for the reminders is that the time might not work for some patients, as they might be busy or might not have any trigger events such as having lunch around that time. Allowing patients to set their own reminder time might make it easier for them to form a habit.

The only way for players to customize their avatar is to change the hat that is visible from above. Furthermore, the players only unlock new hats after reaching higher levels and thus have very limited choices in the beginning. This could make it harder to relate to and identify with the avatar, which has been shown to be important for games that aim to change behavior [82]. However, changing to a more human avatar could raise issues regarding how much personalization is needed to ensure that nobody feels alienated by the available choices. It may therefore be better to stick to an avatar where the patient must imagine what the farmer looks like on their own.

To avoid endangering the patients' health and to avoid physical overexertion, as demonstrated with Pokémon GO [86], players will not be encouraged to walk after reaching 3 times their daily goal, but they are not prohibited from continuing to walk if they wish to exercise further, and the data will still be collected and stored by the game. This allows for individual play styles and characteristics, which has been identified as an important principle [44]. Players can also decide which play style they want to use when playing the exergame (automatic plan or strategic plan).

Players that wish to compare themselves to others as a way of challenging themselves to do better can use the leaderboard to see the scores from other players from the previous day and work toward reaching the top of the board. By resetting scores daily and collecting scores 1 day at a time, new players or those who have not played the exergame in a while still have an opportunity to top the leaderboard. Players can compare their results by looking at the leaderboard or by talking to other players about their scores and progress. Players can also interact with other players in the exergame by sending messages. The possibility to play with others has been identified as a desired feature in exergaming for patients with heart failure [14,17]. The question of whether sending messages is an optimal format for interaction should be further explored.

To not endanger the patients' health, the AR technique is used to track the players' movements when walking rather than to enhance the real world. The AR technology is used to detect the players' motion in the real world so players can choose to be physically active indoors, outdoors, or both. Using AR technology may have some practical constraints. When using the AR as a tool for motion detection, it is important that the players understand why and how the camera in the smartphone is used, so they feel confident when they play and can interact with the exergame as required. For Heart Farming, the players can play the exergame by either holding the smartphone in front of them or hanging the smartphone in a bag around the neck. In both cases, the front-facing camera must have a clear view of the surroundings. However, the player does not need to look at the screen while walking, which mitigates the risk of falling. The players get audio feedback informing them about the performed activities. AR is not the only technique available for tracking the players' movement. GPS and step counting are 2 possible alternatives, both of which could be used even if the smartphone is kept inside a pocket. Step counting is an offline data stream that is reported occasionally, so it is not directly accessible by the system for instant feedback. Step counting also does not provide good data for users that move slowly or generate little vibration from their steps and is therefore unsuitable for the target patient group. Since GPS lacks precision or fails entirely indoors, it is not suitable for indoor use. However, GPS could be incorporated for outdoor use only, with AR still used for indoor movement, although making the choice between the technologies in an easy way could be challenging.

The effects of playing the Heart Farming exergame will be investigated in a randomized control trial with patients with heart failure, and the data are currently being collected. In the study, the patients' experiences from playing the exergame will also be investigated.

Conclusion

Heart Farming is a mobile exergame tailored to increase physical activity in inactive older people with heart failure by encouraging them to walk for at least 10 minutes each day. The Heart Farming exergame is about helping a farmer take care of and expand a virtual farm. The advantages of the proposed exergame can be summarized as follows:

- The Heart Farming exergame detects patients' physical activities by using AR technology to detect patients' movements in the real world, both indoors and outdoors.
- The AR technology in the Heart Farming exergame continuously registers patients' movements in the real world and interprets them into events in the exergame, which then generates both visual and auditory feedback.

- The Heart Farming exergame can support patients' own individual preferences and conditions regarding where (indoors or outdoors), how (automatic or strategic gameplay), how much (patients are rewarded for once, twice, or 3 times their daily goal, and after that, progress is registered and displayed without rewards), and when (patients are remined at 12 PM if they have not played that day) to play.

Acknowledgments

The authors would like to thank the the Swedish National Science Council (2020-01109); The Swedish Heart and Lung Foundation (20200190); the Kamprad Foundation (20210074) and the Research Council in South East Sweden (FORSS-940933 and FORSS-995300) for their support of this work.

Authors' Contributions

TJ, AB, EB, LK, and AS acquired the funding for the study. The conception of the study was carried out by AB, AS, EB, LK, and TJ. The design was collaboratively developed by AB, AS, EB, HO, JF, LK, and TJ. AS and EB were responsible for the software development and analysis, while the interpretation of data was conducted by AB, AS, EB, HO, LK, and TJ. The initial draft of the work was written by AS and EB. Substantive revisions were made by AS, EB, HO, JF, LK, and TJ. Finally, the submitted version was reviewed and approved by AB, TJ, HO, JF, AS, and EB.

Abstract

At the Worldwide Developers Conference in June 2023, Apple introduced the Vision Pro. The Apple Vision Pro (AVP) is a mixed reality headset; more specifically, it is a virtual reality device with an additional video see-through capability. The video see-through capability turns the AVP into an augmented reality (AR) device. The AR feature is enabled by streaming the real world via cameras on the (virtual reality) screens in front of the user's eyes. This is, of course, not unique and is similar to other devices, such as the Varjo XR-3 (Varjo Technologies Oy). Nevertheless, the AVP has some interesting features, such as an inside-out screen that can show the headset wearer's eyes to "outsiders," and a button on the top, called the "digital crown," that allows a seamless blend of digital content with the user's physical space by turning it. In addition, it is untethered, except for the cable to the battery, which makes the headset more agile, compared to the Varjo XR-3. This could actually come closer to "The Ultimate Display," which Ivan Sutherland had already sketched in 1965. After a great response from the media and social networks to the release, we were able to test and review the new AVP ourselves in March 2024. Including an expert survey with 13 of our colleagues after testing the AVP in our institute, this Viewpoint explores whether the AVP can overcome clinical challenges that AR especially still faces in the medical domain; we also go beyond this and discuss whether the AVP could support clinicians in essential tasks to allow them to spend more time with their patients.

(JMIR Serious Games 2024;12:e52785) doi:10.2196/52785

KEYWORDS

Apple Vision Pro; mixed reality; augmented reality; virtual reality; health care; mobile phone

Introduction

In his highly influential paper "The Ultimate Display" [1], Ivan Sutherland, the pioneer of computer graphics and creator of the first augmented reality (AR) head-mounted display (HMD) in the early 1960s, predating the advent of PCs, described aspects that Apple's Vision Pro aims to implement. The Apple Vision Pro (AVP) can span the wide range of the reality-virtuality continuum, as explained by Milgram et al [2], starting from unaltered *reality*, achieved by streaming the real world without additional information to the user; progressing through *mixed reality* (MR) [3], involving the integration of digital information into the real world (referred to as AR) and vice versa (augmented virtuality); and extending to complete immersion, also known as virtual reality (VR), where the user experiences only computer-generated virtual content.

In the realm of VR, there is currently a broader selection of headsets at various price points, including offerings from Meta, Vive, Varjo, PlayStation, and Google (with the most economical probably being the now-discontinued Google Cardboard or a similar variant from another vendor), compared to AR. AR faces a distinct challenge because of the need to analyze *reality* to augment it at the *right* position with digital content for the user. An exception is AR used for a *pure* simulation, where the AR hologram is indeed shown in the real world but has no meaningful relation to or interactions with real-world objects. An example of such a scenario is a surgical simulation [4]. The AR hologram is shown in front of the user to allow them to inspect and interact with it. Still, the underlying hardware and software need to capture and model the real world to *anchor* the hologram within it so that the hologram does not *drift* away from the user's view.

In a medical scenario, AR can enable equips a physician with x-ray vision into a patient [5]. This capability is a valuable advancement from the current practice of viewing patient information, such as preoperative imaging, on PC monitors, contributing to the "switching focus problem," where a physician must divide their attention between the patient and the digital information. Hansen et al [6] outlined that such a division leads to an increased mental workload, disorientation, and deteriorated hand-eye coordination. Instead, AR can display patient information directly in the physician's view of the patient, additionally offering spatial perception even before any incisions are made. A recent systematic review of the AR headset HoloLens (Microsoft Corp) in medicine [7] showed its broad applications and the massive research efforts during the recent years in all these areas (medicine and health care with applications for patients, physicians or surgeons and students, which should ultimately lead to the development of an intelligent health care metaverse [8,9]). Hence, we highlight the user groups and applications targeted by AR in the next sections and discuss how common challenges in AR can be overcome with the AVP's capabilities. Furthermore, we share our findings about the new AVP gathered through a structured survey among ourselves and colleagues who had the opportunity to try out the AVP.

Target Groups

Physicians and Health Care Professionals

Physicians and health care professionals comprise, by far, the largest target group for AR applications [7]. The adoption and use cases of AR within nursing departments are growing, focusing on wound care, information retrieval, injections, and education [10]. In this context, the accuracy of the visualization is not of utmost importance, but having a wearable "sensing" computer can increase time at the bedside through automatic information retrieval and documentation. However, especially for AR-supported image guidance and navigation, such as in surgery, very high accuracy and reliability are needed [11]. Applications for which submillimeter precision is not necessary are, for example, ablations, ventriculostomies [12-16], and certain orthopedic interventions [17]. Here, the HoloLens is, with its inside-out tracking, already a promising tool, but for applications that need, for example, submillimeter precision, it cannot be used reliably yet. An example is the deep brain stimulation procedure used for treating essential tremors and Parkinson disease, where millimeter-to-submillimeter accuracy in deep brain stimulation targeting (an electrode placement inside the brain) can be important [18]. Another study exploring the clinical accuracy of the HoloLens for neuronavigation concluded that it is currently not within clinically acceptable levels [19]. The same holds true for some application scenarios in orthopedic surgery [20], such as screw placement, where there is still room for improvement [21]. This improvement can be achieved through external tracking hardware [22,23], but it may come at the cost of mobility and increased expenses. The AVP is promising due to its superior sensing technology, as discussed in the Accuracy and Reliability subsection. More importantly, the powerful Apple M1 and R1 chipsets can handle the sensor data appropriately to exploit them completely. This technology comes at a high price, but the often-criticized end-user price of US $3499 (without tax) for the AVP does not seem to be an issue for health professionals who want to use it in health care. The price is similar to that of the HoloLens and much cheaper than (a fraction of) those of existing and clinically used conventional medical navigation systems, for example, those from Brainlab (Stefan Vilsmeier) or Medtronic (Earl Bakken and Palmer Hermundslie). In this context, it is important to mention that the use of AR HMDs with direct patient reference, outside of research in the context of feasibility studies, must obtain appropriate regulatory approval, and the AT HMDs must be certified and classified as medical devices. The Magic Leap 2 (Rony Abovitz), for example, received certification for use in an operating room last year (2023). The requirements to be met are still up to debate, for example, when it comes to active or passive cooling. In contrast to the HoloLens 2, both AVP and Magic Leap have active cooling, potentially compromising the sterile airflow. Furthermore, sterilization is a problem because Apple recommends not using isopropyl alcohol or other solvents for cleaning. This should not be an absolute impediment, given the approval of the Magic Leap 2 for use in the operating theater and the use of regular glasses in the operating theater. We do, however, think that the time is coming when clinicians, technicians, and manufacturers should come together to meet binding guidelines.

Another challenge for clinical adoption is the integration of the device within the digital infrastructure of the hospital, for example, to retrieve data from and transfer data to the electronic health records. Moreover, and especially in a medical context, the display may also require an image focus at surgical table distance [24]. In combination with the outward sensors, this would be ideal for medical scenarios.

Students

Students are the second most common intended target group [7] for AR applications, for example, in educational training, such as the HoloPointer, a virtual AR pointer for laparoscopic surgery training [25]. Another example is the use of AR to teach medical students catheter placement [26] and the use of AR for training on central venous access [27]. Notably, the aforementioned partially outward-oriented sensors, unlike those in other headsets, allow for the accurate tracking of all "normal" (hand) movements for interaction, regardless of (head) position. This is also valuable for health care professionals when practicing or working at the patient's bedside. When combined with speech commands and eye-controlled interactions, physicians can expectantly implement the AVP easily and in a sterile manner.

However, we found that the effects of HoloLens-based learning compared to those of conventional learning, for example, using cadavers or other computerized methods, seem to be rather small [7]. A reason for this is that the learning tools usually used are relatively simple, conventional 3D models, and more innovative visualizations, including interactive, dynamic content, which cannot be easily delivered through regular computerized methods, have not been explored in depth yet [7]. Here, we believe that the AVP can raise the bar because of its high-resolution visualization (consisting of 2 micro-OLED displays with 23 megapixels) that uses eye-tracking to make the headset also usable as a desktop screen with its fine textual details. In addition, the 3D user interface, using precise and intuitive finger tracking in combination with eye interactions, can be a game changer. Despite these advances, it remains to be seen whether an AR headset has a major advantage over a conventional screen. The cost of the AVP is also a concern, especially for students with a limited financial budget, but the "pro" might indicate that a "regular" version will also be released. For medical simulation training, however, an examination of costs [28] suggests that using the AVP is a financially viable option. The AVP is, however, highly personalized to the individual user to optimize the experience and accuracy. Luckily for the student group, the AVP can be shared, and the interpupillary distance setting (IDP) is adaptable, compromising the experience minimally, but sharing greatly reduces cost for simulation purposes.

Patients

Patients are currently the least frequented target group for extended reality (XR) devices [7]. An example is the use of MemHolo, which provides MR experiences for patients with Alzheimer disease [29]. Other examples in this area include the use of the HoloLens as an assistance and monitoring tool for medication adherence [30] and the use of a HoloLens-based system for functional mobility assessment [31]. We expect the advanced eye-tracking to enhance the user experience because visual cues will not merely exist within the user's field of view but can also be precisely situated in the user's focal point. However, many interesting assistance and monitoring applications are limited by the restricted possible use time of untethered AR headsets, primarily due to battery life, and this problem seems to exist in the AVP, which has a similar battery life to that of the HoloLens, approximately 2 hours. The only consolation is the "external" battery pack of the AVP, which can be swapped. Finally, the Apple M2 chip and the new R1 chip of the AVP could potentially boost the relatively small number of applications that have been explored so far, for example, by increasing the frames per second, minimizing display latency, and thus reducing motion sickness, especially useful for older patients, who are more susceptible to MR sickness than younger users [32,33].

Differences Between Target Groups

An example of different use cases per user group is shown in Textbox 1. The main target group is health care professionals, which can be divided into several subgroups, such as surgeons, physicians, and nurses. Unlike the other groups, price is not a major issue for this group, but the use cases are different from those of the other groups. For nurses, data retrieval, documentation, and guidance without the need for high accuracy are the estimated use cases, freeing up time at the bedside. The AVP's high data transfer rate and processing power are more important. For a surgeon, however, accuracy is critical for surgical navigation [34]. For the general practitioner, seamless integration and unparalleled view during transport may be the greatest values of the AVP. For other groups, price is an important consideration, with the caveat that it could reduce overall costs for medical simulation training. The average patient is not expected to be able to afford this device on their own. For now, it could be used for therapies in the clinic, where it can be shared among several patients. However, this makes cleaning the device more important than if there is a single user. We expect to see silicon-replaceable parts for the device, which would ultimately benefit all groups. The AVP has similar challenges to other headsets in terms of battery life and motion sickness, which affects all groups, especially nurses during long, hectic shifts with movement and sometimes no breaks. The integration of an external battery makes battery life easy to address in future hardware updates. Regarding motion sickness, we expect Apple to offer a lower resolution for a higher refresh rate in combination with its foveated rendering to combat this. In summary, the biggest differences between target groups are in the need for high accuracy and the willingness to accept the high price.

Textbox 1. Possible health care scenarios with the Apple Vision Pro.

Health care professionals

- Patient record retrieval
- Automated documentation
- Guidance in medical procedures and equipment
- Surgical preoperative planning
- Surgical navigation
- Peerless public medical record viewer

Students

- Complex anatomy education
- Complex pathophysiology education
- Training simulators
- Automated skill evaluation

Patients

- Patient treatment preparation
- Patient education
- (Automated) diagnostics
- Rehabilitation
- Improved patient well-being

Challenges

Despite significant research efforts in medical AR, clinical translation remains limited so far [35]. Several technical challenges require ongoing multidisciplinary efforts among software developers, hardware manufacturers, regulatory entities, and clinical personnel to create safe, effective, and seamlessly integrated AR solutions in health care. Some of these challenges could be addressed by the AVP's hardware and user interface.

Accuracy and Reliability

The most significant challenge in medical AR systems is their accuracy and reliability in registration and calibration, which are critical for aligning virtual objects with real-world elements. Failures in tracking or registration components can misguide physicians, potentially leading to serious medical accidents. Although recent developments in tracking technology are encouraging [36,37], clinical settings pose additional challenges with limited space, unconventional lighting, and dynamic environments. A solution is to combine an AR device with external tracking systems to increase precision [22]. On the downside, such combinations require complicated setups and the calibration of bulky (external) devices, diminishing the simplicity and lightweight nature of purely head-worn systems. The latest sensor technology, combined with state-of-the-art tracking and registration algorithms, could eliminate the need for external systems to meet clinical requirements. We expect the AVP to move the needle in terms of accuracy because of its strong inside-out tracking through 12 built-in cameras and light detection and ranging sensing method, which is the key aspect for increasing the accuracy of AR. We expect that enhanced eye-tracking capabilities and the incorporation of multiple outward-facing sensors will substantially enhance the reliability and stability of user interactions. The increase in both the quantity and range of sensors, coupled with a more potent chipset, is bound to increase spatial resolution and visualization accuracy significantly in comparison to untethered alternatives. Future research should focus on exploiting this improved hardware setup.

Usability and Human Factors

In complex clinical environments, a seamless integration of AR systems into existing clinical processes is crucial. Existing AR solutions often add undue complexity and disrupt established workflows, requiring intricate hardware, many manual steps, and elevated technical knowledge and understanding. Health care professionals, who possess varying degrees of technical background, or patients, who represent diverse demographics, cannot be reasonably expected to meet these demands. Hence, AR systems need to be intuitive and user-friendly. Apple products are known for their user-centric design and seamless integration of hardware and software. We expect that the AVP's user experience, in terms of interface, interaction, and feedback, will be more intuitive for a diverse audience than existing HMDs and VR glasses.

As a demonstration of this ease of use, the AVP connects automatically to nearby Apple MacBooks, commonly used by physicians, to display the screen and access files in real time without any effort. An obvious use case is secure, peerless access to patient files while using public transportation. This is valuable for working with all medical records. Apple products work seamlessly with each other, but in a clinical setting, not all products may come from Apple or its partners. A combined challenge and focus should be to enable cross-manufacturer integration.

In addition, as mentioned earlier, more natural and user-guided interactions are possible with the outward and eye-tracking sensors. This will allow developers to create more intuitive applications. The improved hardware should not be underestimated. For example, Gsaxner et al [38] developed stand-alone marker-less image registration, which has potential in many medical applications, but the setup of an additional laptop is cumbersome and another potential risk for data breach. With the AVP, this type of setup is most likely not needed.

Visualization and Perception

Current AR devices face limitations in terms of view, resolution, and brightness, impacting visual fidelity [39]. In addition to these hardware constraints, challenges include depth perception and occlusion between virtual and real content [40]. Current optical see-through (OST) displays, such as that of the popular HoloLens, struggle to address these issues adequately, as they cannot modify the reality presented. By contrast, the AVP's video see-through (VST) system provides significantly more possibilities for seamlessly and adaptively integrating virtual elements with the real environment. Visual accuracy is difficult to achieve and user dependent, but eye-tracking and automatic eye calibration, combined with the high-resolution displays inside the headset, make us believe that the AVP could set new standards in terms of the quality and perception of visualization.

In summary, hardware limitations are the main bottleneck in developing AR applications suitable for the clinical translation of AR that cannot be addressed by software developers. Another bottleneck is the regulation and list of requirements for 3D smart glasses in surgery. Combining hardware technology and software from different companies, especially for data transfer, is the final major issue, however, but it is not limited to 3D smart glasses and has been a persistent obstacle in health care [41].

We believe that the AVP can provide significant advancements as the new state-of-the-art device, with much-needed improvements in precision, reliability, usability, workflow, and perception. The combination of AR and VR in an XR device has the potential to transform health care by aiding in diagnostics, improving surgical procedures, facilitating remote patient care, and enhancing medical training. Many other novel applications may emerge because of the advancements in AVP hardware and software platform. Returning to our main question, the AVP has the potential to enhance medical education and therapy, medical record evaluation, data retrieval, and documentation automation while improving patient outcomes and freeing up clinicians to spend more time at the patient's bedside. Of course, this will require a collaborative effort among engineers, researchers, and clinicians to develop or enhance these applications and to prove cost-effectiveness to ensure clinical adoption.

The New AVP

Highlighted Features

Apple announced some interesting (and still unique) features of the AVP. In the upcoming sections, we introduce and discuss these features in the context of medical MR with a focus on AR.

Digital Crown

The digital crown is a turning button that allows the user to blend digital content easily and seamlessly with the physical environment surrounding them. The button is named the same as that in the Apple Watch, but it serves a different function in the AVP by providing an easy option to quickly *escape* VR without the need to remove the headset. Depending on the capabilities and accessibility of developers to exploit the digital crown, it could also enable diminished reality (DR) [3,42]. This feature would allow users, such as physicians, students, and patients, to remove distracting real-world objects or environments, thereby reducing visual overstimulation. Notably, DR may even extend to diminishing or removing the headsets of other users. To elaborate, the AVP can create realistic avatars of its users. When using the FaceTime application, the movement and direction of the eyes, tongue, and facial muscles are correctly tracked and visualized for other users of the AVP inside the same FaceTime application. This could be used to give the wearer of the headset the ability to perform DR, that is, to diminish the headset and in paint the face when communicating with other AVP users in the real world but via the pass-through mode. The idea of DR is not new, but its implementation, especially in medicine, is a relatively novel [43]. The AVP may be the first untethered device capable of providing DR in a medically relevant and accurate context without the need for external hardware.

Notably, DR needs, in general, a VST capability and cannot be realized by OST displays, such as that in the HoloLens. The medical HMD from VOSTARS has addressed this by combining an OST display, that is, the view through a semitransparent glass, with a VST function [44]. VOSTARS has realized this with a semitransparent glass that can transition into a nontransparent mode. The AVP, by contrast, does not conform to the OST versus VST dichotomy but rather operates on the VST versus VR HMD spectrum, aligning with the reality-virtuality continuum, postulated by Milgram and Kishino in 1994 [45].

Virtual Eyes

Spooky at first sight, the outward display reveals a user's eyes while wearing the AVP. According to Apple, this feature is meant to let others know when the AVP wearer is using apps or is completely immersed in a virtual world. This feature is not needed in OST AR devices, such as the HoloLens, because the headset wearer's eyes can be seen through the transparent display. This feature is particularly crucial when considering patients who are dealing with serious illnesses. The transparency ensures that medical professionals, while using the device, do not create an additional layer of detachment by being obscured behind a screen, potentially alleviating concerns about the impact on patient-physician interactions.

3D Camera

The AVP features a 3D camera, which allows a user to capture spatial photos and spatial videos in 3D. This could hold significant potential for the professional health care sector. The ability to capture spatial photos and videos in 3D could prove immensely valuable for documenting medical interventions. This is certainly also of interest for medical training, allowing residents to review and reenact treatments in 3D from different viewpoints. It could also serve as a tool to uncover malpractice. The 3D capabilities can also provide an alternative or an addition to the 3D documentation of crime and crash scenes, which is common practice during forensic and medicolegal investigations [46].

Interaction

According to Apple, a user can interact with virtual content by simply looking at an element, tapping the fingers together to select it, and using the virtual keyboard or dictation to type. There also seems to be a “visual search” function, which may be similar to the “visual look up” feature found on iPhones and iPads. “Visual search” will allow users to interact with items and text for opening webpages and translating into other languages in real time. Interestingly, this was already described by Sutherland [1] as “the language of glances” to interact with a computer, with an example where looking at a corner of a triangle makes it become rounded. Looking something up is definitely of interest, for example, to surgeons who have their hands full with (surgical) instruments or nonverbal users.

Optic ID

The AVP is supposed to support the optical identification of a user for authentication, such the iPhone’s face identification. The biometric method is enabled by scanning the iris of the user wearing the headset. This is not unique to the AVP because the HoloLens 2 already supported an iris authentication. However, this is also an important feature for the AVP in health care, where you have sensitive patient data, and unlocking the device and accessing the data should be permitted only for authorized users. Furthermore, it enables hands-free log-in in a potentially sterile environment.

ZEISS Optical Inserts

Carl Zeiss AG is working together with Apple to provide precision optics for users who require vision correction. This will improve the visual experience and provide greater comfort, as users do not need to wear their prescription glasses and frames inside the limited space within the AVP. In addition, it may help avoid side effects such as “overheating,” headaches, and light bleeding. The additional lenses can be attached magnetically to the main lens, which makes insertion and replacement easy.

Head Strap

The head strap of the AVP seems to be easily exchangeable, and there are already several alternatives (in terms of materials, colors, etc) available on the web. This will ultimately enable more comfort in comparison to the HoloLens and the Varjo XR-3, which are adjustable but still consist of quite stiff (plastic) frames around the head. It will definitely be more comfortable than the Sword of Damocles, developed by Ivan Sutherland and his student Bob Sproull [47], where the user had to be strapped into the AR or VR HMD device, which was suspended from the ceiling because it was so heavy. The head strap also contains the AVP’s speaker, which is placed directly over the user’s ears and is supposed to virtualize surround sound. However, the strap means that all main components are integrated with the visor. The HoloLens 2, for example, distributes the weight more evenly by integrating components in a plastic case located at the rear, including the battery and system on a chip board. This was done by Microsoft based on its experiences with the HoloLens 1 to make the HoloLens 2 more comfortable. On the contrary, the AVP seems to be worn more like a VR device that fits tightly onto the face instead of partly hovering in front of the user’s eyes, such as other AR devices that are more similar to prescription glasses. The AVP has a similar weight range (600-650 g) to other popular AR and VR headsets, even though the battery is not integrated into the device and is separate. In part, this could be attributed to the material, for example, the aluminum alloy frame. Furthermore, in a medical context, it is usually necessary to be able to easily disinfect the equipment used. A special version with a disinfectable head strap could meet this requirement.

3D Persona Avatars

During the setup of the AVP, the user’s face is scanned by the headset to create a photorealistic avatar, which is then used by the device’s operating system, called VisionOS. For better fitting purposes, the user’s face can also be scanned with the TrueDepth camera of an iPhone, as seen at a public demo at the Worldwide Developers Conference in June 2023. Furthermore, the user’s ears can be scanned to optimize the speakers that are inside of the head strap because, aside from the shape and size of the head, the ear sizes, positions, and distances can vary a lot between users. All these user-specific options will make the headset more comfortable to wear, and this will finally increase the acceptability of the new device, not only in the health care sector but also in other sectors.

Unity

The Unity engine already supports pretty much all common headset devices, whether it be AR, VR, or MR, such as the Oculus (Palmer Luckey), HoloLens, or Google VR (Google LLC). Unity also supports the OpenVR application programming interface that has already been used in medicine [48]. Therefore, the support of the Unity engine of the AVP makes the development and porting of apps much easier. This also makes a comparison between and an evaluation of devices with the “same” app easier. Notably, Unity currently already allows the development of apps for iPhone, iPad, and Mac while deployment occurs via the Apple app store or Xcode, suggesting future development for the AVP. Overall, Unity support will enable faster development of apps, hopefully fast enough to reach a critical mass before end users may turn their backs, which is needed for the long-term success of the new Apple device.

Medical Device

Talking about the health care sector, we need to mention that the AVP is not certified as a medical device yet. We are not aware of whether Apple has plans in this direction, at least not publicly. Apple, however, promoted Complete HeartX as an education app for medical students by providing hyperrealistic 3D models and animations of the heart and medical issues. In comparison, Microsoft advertised the HoloLens 2 specifically for medical scenarios, for example, with a plenary presentation by Bernard Kress (who was at that time Principal Optical Architect, HoloLens team, Microsoft Corp) at the International Society for Optics and Photonics Medical Imaging in February 2020. Nevertheless, we are sure that the AVP will be used by researchers and companies for medical applications, similar to other devices, if Apple does not explicitly prohibit this somehow, for example, by monitoring their devices and locking them. The integration of the AVP with other software and hardware commonly used in clinical settings, for example, integration with electronic health records, will be interesting [49,50].

First Experience

In March 2024, we had the opportunity to try out the AVP ourselves for the first time (Figure 1). We, therefore, conducted a standardized expert survey among colleagues (and ourselves) at our institute (the Institute for Artificial Intelligence in Medicine). The inclusion criterion was an experience of at least 10 minutes with the AVP. After obtaining written consent, we conducted a structured survey on the AVP. We collected baseline data from the respondents including experience with HMDs (Table 1), as well as asked Likert questions on how far the AVP corresponds to an “Ultimate Display” (Table 2). We also administered the User Experience Questionnaire (UEQ; Figure 2) as well as asked open-ended questions about what is missing from an “Ultimate Display” (Textbox 2).

Figure 1. The illustration of a possible Apple Vision Pro scenario with one of the authors.

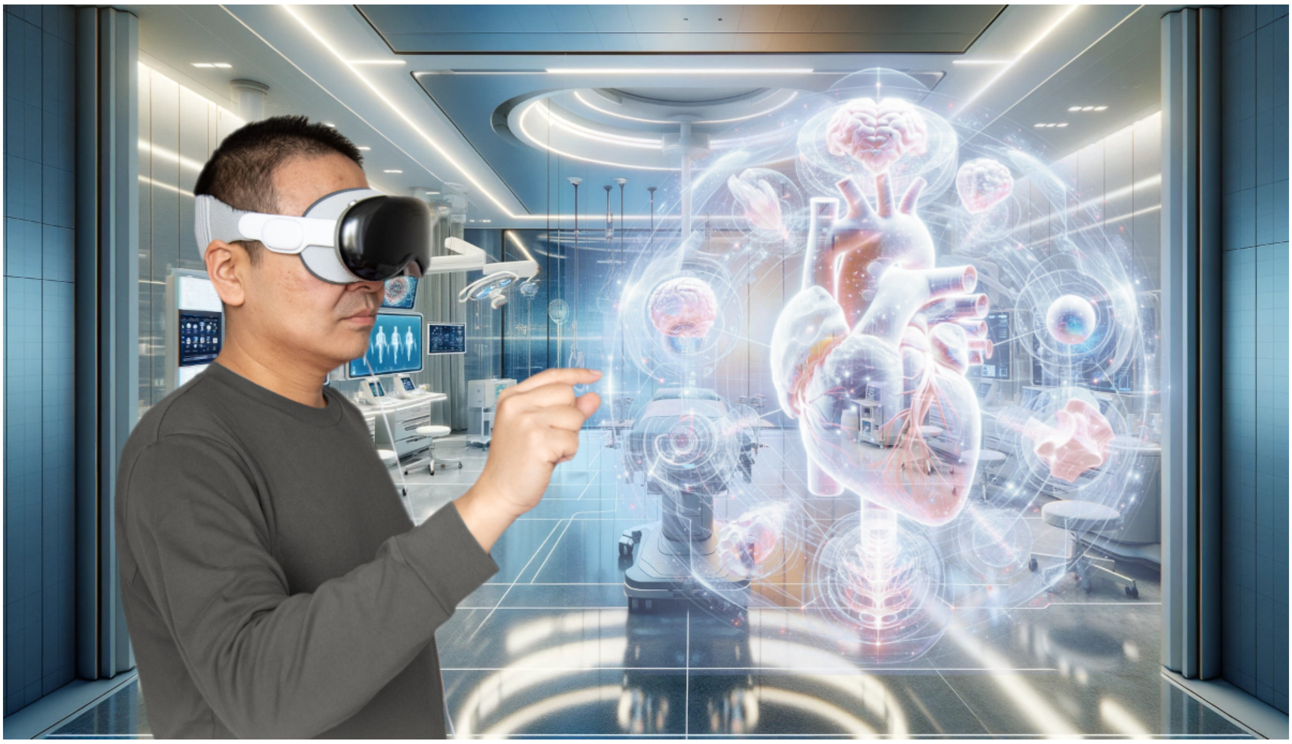

Table 1. Characteristics of the experts interviewed (N=13).

Parameter	Value
Sex	
Female	3 (23)
Male	10 (77)
Age (y), mean (SD; range)	30.9 (6.5; 23-48)
Work experience (y), mean (SD; range)	4.3 (5.6; 0-20)
Previous experience with HMDs[a]	
Yes	9 (69)
No	4 (31)
Previous experience with HMDs (hours)	
Mean (SD)	213.3 (400.8)
Median (range)	1.0 (0-1000)

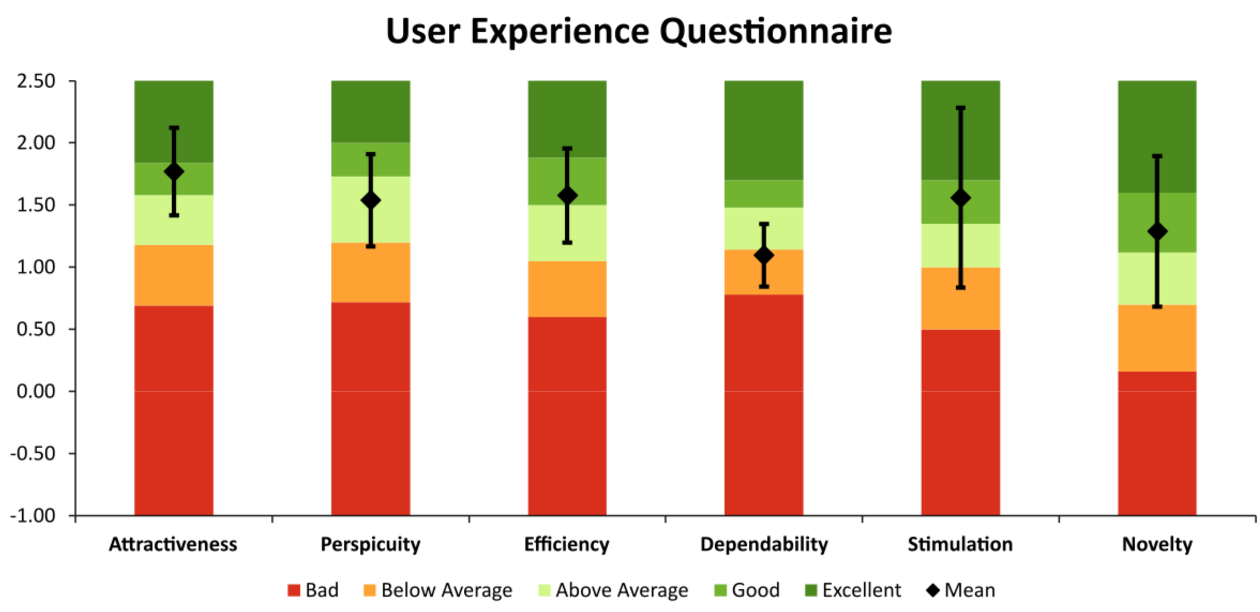
[a]HMD: head-mounted display.

Table 2. Likert questionnaire (N=13).

	Likert item (1=disagree; 7=agree)	Value, mean (SD)
1.	The Apple Vision Pro comes very close to an “Ultimate Display” in terms of realism.	5.5 (1.3)
2.	The Apple Vision Pro comes very close to an “Ultimate Display” in terms of interactivity.	5.0 (1.1)
3.	The Apple Vision Pro is more comfortable than other HMDs[a].	4.9 (1.5)
4.	The Apple Vision Pro is more user-friendly than other HMDs.	5.1 (1.9)
5.	The Apple Vision Pro surpasses other HMDs in immersion and sense of presence.	5.4 (1.6)
6.	The Apple Vision Pro represents a significant technological advance.	5.7 (1.4)

[a]HMD: head-mounted display.

Figure 2. The results (means and SDs) of the User Experience Questionnaire (UEQ) regarding the attractiveness, perspicuity, efficiency, dependability, stimulation, and novelty of the Apple Vision Pro compared to those of a benchmark (bar plot in the background).



Textbox 2. Open questionnaire summary.

Negatives

- Suboptimal weight distribution
- Comparatively heavy among head-mounted display (HMDs)
- Detachable light seal cushion poses potential damage risks and necessitates screen touching before and after use
- Requirement for specialized prescription glasses
- Short battery life (2 hours under normal use)
- Forced interaction method with eyes and pinch
- Inconsistent functionality of eye navigation near the borders of the field of view
- The absence of intelligent automatic transition between real and virtual worlds via the crown button
- Limited field of view compared to other HMDs
- Blurry resolution of real-world pass-through, hindering text legibility
- Clear differentiation between virtual and real environmental components by users

Positives

- Lightweight compared to the currently used hardware and materials
- Natural interaction via outward sensors
- Effective eye-tracking for seamless user interaction
- Rapid and simple adjustment of glasses for user interpupillary distance
- Innovative crown button design with wheel and push functionalities
- Smooth transition between real and virtual worlds facilitated by the crown button
- High-resolution internal display for realistic virtual objects
- High-quality spatial sound experience
- Seamless visualization of the real world
- Minimal app start-up and file loading times
- Autofocus and person blending and unblending for safety precautions
- Simple and fast to learn

Responses to the Likert questions on whether the AVP comes close to an "Ultimate Display" comprised values between 4.9 and 5.7 on a scale of 1 (disagree) to 7 (agree). The UEQ showed good mean results for attractiveness (1.77, SD 0.65), efficiency (1.58, SD 0.70), stimulation (1.56, SD 1.33), and novelty (1.29, SD 1.11) but above average mean result for perspicuity (1.54, SD 0.68) and below average mean result for dependability (1.10, SD 0.46) compared to a benchmark. This fits in with the general perception (Textbox 2) that the AVP is a significant improvement over other HMDs but still behind the "Ultimate Display."

Discussion

To summarize, we see Apple entering the MR headset market with its own device very positively. Another company's contribution can benefit the technical progress in this area, not only from a hardware perspective but also from a software perspective, by enabling new user input concepts and apps. With the current hardware specifications and Apple's history of delivering cutting-edge devices and beyond, there is a very good chance of another AR "evolution" or even "revolution" (Table 3). This is a very important aspect because (1) AR devices are sparse in comparison to VR devices, and (2) the product life cycle to a possible successor is in the range of years, which feels like ages when compared to the current pace of technological developments, especially in (medical) computer science [51]. For example, the first version of the HoloLens was introduced by Microsoft in 2016, and it took Microsoft >3 years to introduce its successor, the HoloLens 2 (released in limited numbers on November 7, 2019).

Table 3. Side-by-side comparison of the specifications of several existing mixed reality headsets with those of the upcoming Apple Vision Pro [52].

Parameter	Apple Vision Pro	Pico 4	Meta Quest 3	HTC Vive XR Elite	Varjo XR-3	HoloLens 2	Magic Leap 2

Steve Jobs released the iPhone in 2007, creating a new category of smartphones. What made it special was that Apple combined existing technologies and software in a manner that made previously unexpected things possible, which Apple repeated with the iPad in 2010 and then with the Apple Watch in 2015. Hence, the AVP could lead to the breakthrough of not only AR, VR, or MR but also DR (because it is a pass-through technique) due to its enormous technological progress. Moreover, technological progress can not only enable more precise, patient-specific treatments but also make these treatments more efficient, for example, through hands-free, instant authentications; documentation; and the visualization of search queries and their results directly within the field of vision of the HMD user. Further, well-engineered AR can help overcome communication barriers in a face-to-face manner. Thus, it supports clinicians in a range of essential tasks and reduces the administrative burden on clinicians to allow them to spend more time with their patients, which is a key challenge for upcoming artificial intelligence (AI)-based foundation models [53].

Moreover, the recent rise of large language models [54], such as ChatGPT, cannot be ignored in the context of the upcoming AVP because it changed how we communicate with computers, and the AVP can certainly be enhanced with the integration of a ChatGPT-like bot. Even though ChatGPT is still in its infancy, when it comes to hard facts, especially in health care [55,56], it already enables a fluent, partly fact-based, conversation. This will, in the short or long run, also completely enter the headset market, where someone can discuss upcoming treatment steps on a humanlike level based on a trained large language model. However, we do not think that this will be specific to the AVP, and with ChatGPT, Microsoft seems to currently have the edge.

Another application is the metaverse, which integrates physical reality and VR [8]. The idea is that users and their avatars interact in an environment with access to an unlimited amount of health data. Metaverse applications focus primarily on AI-based medical practice and medical image–guided diagnosis and therapy [8]. The AVP could make an important contribution as a hardware enabler that allows users to move and interact in the metaverse in a more intuitive manner.

Nevertheless, digitization holds promise for making medical care more efficient. But will screens come between doctors and patients [57]? At the same time, for every hour doctors spend with their patients, they spend 2 hours in front of the computer [58]. The AVP's untethered, external battery, and spooky-eye design with improved sensor and computing hardware has the potential to help health care professionals improve efficiency and patient outcomes, allowing more time for patient care. The improved hardware should allow the levels of accuracy and computing needed for the device to truly function as a stand-alone device for surgery or preoperative planning. Integration with patient records combined with AI allows for patient recognition and provides the health care professional with accurate data retrieval and documentation. The provision of guidance for devices and medical procedures can occur naturally through its outward-facing sensors, making reading books a thing of the past. The VST design opens up futuristic possibilities for DR, while the ghostly eyes maintain a sense of patient contact. We recognize that this is an optimistic outlook and will require the combined efforts of experts in the field.

Whether the AVP will blur the line between patient encounters and computer time also depends on patient and physician acceptance. In ophthalmology, the AVP is seen as a breathtaking application [59]. However, this must first be confirmed in clinical trials with rigorous scientific methodology and hard clinical end points. When the AVP is used for patient scenarios, the focus must be on the patient, not the technology, which is always a vehicle for existing problems.

Conclusions

To sum up, the AVP enriches the current headset market and provides another alternative, especially in the limited AR segment. The AVP will likely be at the technological forefront in this sector, which puts pressure on other vendors to compete by drawing level with and surpassing Apple. The price is certainly a burden for entertainment consumers, but for professionals, especially in the health care sector, with the Microsoft HoloLens being in the same price range and the Varjo XR-3 costing twice as much, it is not a deal-breaker. This becomes even more *irrelevant* if seen in relation to the other hardware costs in health care, such as those of navigation systems and imaging equipment (computed tomography and magnetic resonance imaging scanners), which can reach millions. In Sutherland's [1] sense and our experience, it is not yet the Wonderland that Alice or the doctors (added by us) walked into, but perhaps a bit closer.

Acknowledgments

This work was supported by the REACT-EU project KITE (Plattform für KI-Translation Essen; EFRE-0801977), FWF enFaced 2.0 (KLI 1044), National Institutes of Health (NIH) and National Institute of Allergy and Infectious Diseases (NIAID;

R01AI172875), and NIH and NCATS (UL1 TR001427). BP was funded by the Medical Faculty of the RWTH Aachen University in Germany as part of the Clinician Scientist Program. CG was funded by the Advanced Research Opportunities Program from the RWTH Aachen University. JC was funded by the Federal Ministry of Education and Research (Bundesministerium für Bildung und Forschung [BMBF]) in Germany under the funding reference 161L0272 and supported by the Ministry of Culture and Science of the State of North Rhine-Westphalia (Ministerium für Kultur und Wissenschaft des Landes Nordrhein-Westfalen [MKW NRW]). Furthermore, the authors acknowledge the Center for Virtual and Extended Reality in Medicine (ZvRM) of the University Hospital in Essen, Germany. Finally, the authors want to thank ZhaoDi Deng, Ahmad Idrissi-Yaghir, and Rainer Röhrig. Parts of Figure 1 were created using the generative artificial intelligence tool DALL·E 3 by OpenAI [60].

Conflicts of Interest

Abstract

Background: Health education games make health-related tasks enjoyable and interactive, thereby encouraging user participation. Entrepreneurs and health educators can leverage online crowdfunding platforms, such as Kickstarter, to transform their innovative ideas into funded projects.

Objective: This research focuses on health education game initiatives on Kickstarter. Through an online user survey, it aims to understand user perceptions and evaluate the significance of 8 distinct components that may influence the success of such crowdfunding initiatives.

Methods: A total of 75 participants evaluated games using 8 dimensions: game rules, learning objectives, narrative, content organization, motivation, interactivity, skill building, and assessment and feedback. The survey data were analyzed using descriptive statistical analysis, exploratory factor analysis, the Wilcoxon-Mann-Whitney test, and multivariate analysis.

Results: Exploratory data analysis showed that, among the 8 dimensions, skill building, content organization, and interactivity were the top-ranking dimensions most closely associated with crowdfunding health education game. The 8 dimensions can be grouped into 3 categories from the exploratory factor analysis: game content–, instruction-, and game design–related components. Further statistical analysis confirmed the correlation between these dimensions with the successful crowdfunding of health education games.

Conclusions: This empirical analysis identified critical factors for game proposal design that can increase the likelihood of securing crowdfunding support.

Introduction

Background

Digital strategies, particularly gamification, have introduced a refreshing dynamic to health education [1,2]. Platforms, such as Kickstarter [3], champion these tech-infused health games, providing a unique avenue for their development. By leveraging the power of crowdfunding, Kickstarter and similar platforms facilitate the evolution of health education games. This allows entrepreneurs, educators, game developers, and supporters to access essential resources and connect with audiences eager for meaningful health support and intervention.

Gamification in Health

Gamification in health integrates game-design elements into nongame health scenarios, aiming to boost user engagement and immersion in health solutions. This transforms routine health tasks into enjoyable, competitive activities. This approach leads to positive behavioral changes, improving overall health, fitness, and adherence to medical treatments and programs [1,2,4,5]. Gamification has been applied to a wide range of medical fields, including health education, medical therapy, obesity, and mental health [1,2,4,5].

Health education games are interactive digital tools specifically designed to impart knowledge or skills related to health and wellness [1,2]. These games transform traditional health-related lessons into enjoyable and engaging tasks, aiming to enhance retention and application of health information in daily life [1,2,4]. Serious health games, created primarily for specific health objectives rather than solely for entertainment, use gaming components to create an educational environment [1,2]. They use gaming components to facilitate a teaching environment, enabling users to learn specific health skills or gain valuable health-related information [1,2]. Especially beneficial for long-term health and chronic-related applications, these games foster positive emotional or empathetic connections among users, leading to improved medical treatment plans and behavior changes [1,2,4].

The Role of Crowdfunding in Promoting Health Education Games

Given the modest initial investment required and the scale of crowdfunding, it is advocated that crowdfunding serves as a primary method to promote and support the development of health education games. With the recent success of platforms such as Kickstarter, researchers and health care advocates are turning to these tools to fund their projects [6,7]. Through crowdfunding, health educators, entrepreneurs, and other stakeholders can conduct their work to meet community needs while also achieving financial and community outreach goals. This method attracts a varied group of participants who contribute financially, participate in the development, and offer social support [8-12].

Health education games, similar to other game-based learning tools, motivate users by making health-related tasks more enjoyable [1,13]. Online crowdfunding can assist entrepreneurs and health educators with limited resources to translate their innovative ideas into solid and appealing content and formats [14,15]. Crowdfunding platforms help individuals transform ideas into fundable and actionable projects [16,17].

Crowdfunding for health education games benefits users' self-efficacy, well-being, chronic disease management, and physical activity [9-11]. Rewards, feedback, and socialization elements are frequently used to gamify eHealth in crowdfunding-based health education games. Furthermore, health education games can positively change their health behaviors, benefiting their overall health and wellness [2]. Successful health education crowdfunding projects elicit both intrinsic (altruistic) and extrinsic (rewards and feedback) motivation in order to attract a diverse range of crowdfunding donors, and they work by effortlessly facilitating online digital health engagement [18]. This study aims to explore 8 critical evaluation dimensions from the user's perspective that influence the success of crowdfunding campaigns for health education games. The findings will guide practitioners and entrepreneurs in strategizing and designing impactful crowdfunding campaigns for health education games.

Related Works

To understand the intricacies of successful crowdfunding for health education games, we performed a literature review to acquire insights on the various dimensions related to the subject. The literature review enabled us to systematically explore the dynamics of crowdfunding, the principles of game-based learning, and the factors that influence the success of health education games.

Dynamics and Success Factors of Crowdfunding Initiatives

To develop and promote content for successful crowdfunding campaigns, extensive planning, outreach, and marketing are required. Data suggest that the most popular crowdfunding projects are those that are creative, participatory, or consumable, such as games, technology, film and video, and art and design [19]. In general, crowdfunding projects have small funding sizes and offer various donor incentives, small gifts, or awards, which leads to a higher success rate for the projects [19]. Such success not only mirrors financial objectives but also nurtures the emergence of communities with shared interests [20]. Numerous game developers have used crowdfunding to fund the initial investment in educational applications [21]. This then encourages more entrepreneurs to participate in collaborative crowdfunding platforms and launch their projects.

Unlike a traditional purchase, crowdfunding involves a high level of social capital influence, particularly the status and reach on social network sites [17]. Social capital creates an online environment that combines collective knowledge, appeal, and emotional responses, enabling investors to make well-informed decisions [17]. This investment process shapes perception and investment behavior. The interaction mechanism has a broader and more pervasive contextual impact, and the crowdfunding campaign design and features also influence decisions [21].

Crowdfunding initiatives require both content richness and ownership diversity [22]. Several studies have explored strategies to optimize the success of such crowdfunding efforts [22,23]. Notably, during crowdfunding, potential investors often evaluate founders based on their personal communication skills and presentation, both of which influence investment decisions [24]. In addition, the use of specific language, the length of campaign text, the frequency of updates, and the inclusion of video in campaign texts have all been correlated with the success of crowdfunding campaigns [25,26]. Reducing the cognitive effort needed to understand campaign content has been shown to result in increased funding [15].

Researchers have also linked crowdfunding success to the trustworthiness and reputation of developers, as well as their experiences on social crowdfunding networks [27,28]. However, the quality of the presented information also plays an important role in determining crowdfunding success [9,29,30]. Factors that contribute to successful crowdfunding factors include the content of the campaign, audience participation, and the timing of fundraising development [31].

Health Education Game Development and User Experience

Gamification has been proven to enhance medication and treatment adherence among patients with chronic disease [4,32]. Health serious games, on the other hand, have been praised for their ability to help people with chronic illnesses improve their behavior [2,33]. These games mirror real-life challenges, allowing players to develop coping strategies [17]. They educate players about their condition and the necessary lifestyle alterations, with compelling storylines that ensure better engagement [15,17]. Game interactivity allows players to make decisions, learn from outcomes, and receive feedback on health implications [2,17].

When evaluating the feasibility of a game proposal, it is important to consider both the organization and narrative of the content, as well as the effectiveness of interactive games as a learning tool [34]. A well-organized and clearly written proposal can help the investor understand the purpose, goals, and potential value of the project [31]. Interactive health games can educate users with content and skills [34]. Users can also actively engage with the material, explore and experiment with different concepts and strategies, and receive immediate feedback on their progress [35]. This can help them understand and retain the content and skills being taught.

Game rules and interactivity stand as important components in health game design. Game rules ensure alignment with educational objectives, and the inherent challenge-reward system in these games drives players to continue, thereby continuously learning and adopting healthier behaviors [5,13]. Defining game rules or challenges and delivering feedback can increase users' self-concept, efficacy, knowledge skills, communication, and social support, resulting in better health behaviors for self-care and adherence, lowering health costs, and establishing a stronger health system [18].

Health education game users are drawn to characters that resemble them, experiencing validation when such characters are featured in media [36]. Young role models, especially those in media genres such as cartoons and video games, are particularly valued by these users [37]. For example, the motivation and design of the interactive health game series can focus on using positive role models to inspire and motivate players [37,38]. These role models are described as being successful in their adventures while also managing their health, which could help users, including children with chronic illnesses such as asthma or diabetes, feel more positive about their own abilities to manage their health and self-care [37,38].

Interestingly, health game players without specific medical conditions are often less certain about in-game decisions compared to their peers with those conditions [37]. Health education games allow players to try new things, fail, learn, and eventually win. Such games also motivate users to adopt a healthier lifestyle, adhere to medical advice when unwell, navigate life crises, and foster close social connections for support [39].

Regarding assessments and feedback mechanisms, health learners who receive personalized feedback and engage deeply with medical content tend to experience great benefit. This approach is especially effective in reaching younger individuals who might not typically consult other media or seek expert health advice [40]. Interactive health games not only foster communication and social support but also empower users to discuss their health with friends, family, and health care professionals. They also motivate users to actively seek out advice and support [37]. For instance, in a series of interactive health games, players accessed factual details about the causes, treatments, social contexts, and self-care options related to specific health topics [37].

Game-Based Learning Principles

One of the game-based learning principles that allows users to benefit from the game is the development of problem-solving skills [41], and educational games can assist users in developing these skills [41,42]. The modalities of game content representation should be adjusted to boost motivation and performance [43]. If learners cannot understand the app's content, no matter how rich and useful it is or how beautiful the design is, the app's entire instructional value is lost [44]. Learners can learn problem-solving, strategic and analytical thinking, decision-making, and other 21st century skills in narrative-centered learning environments [45].

Based on the constructivist learning theory, individuals gain deeper insights about the world through direct experiences and interactions [46,47]. Games offer a dynamic and interactive environment that aligns with this theory, enabling learners to actively explore, experiment, and tackle challenges [46,47]. The appeal of a game's narrative indicates its potential to captivate users [48]. The game creators should focus more on the content, storyline, and interaction components of the game to attract individual users when determining whether it will be successful or not [48].

The quality of a learning game is significantly influenced by the effectiveness of user feedback [49,50]. Numerous studies have shown that feedback enhances learning outcomes [51]. It provides learners with clarity on their strengths and areas that need improvement; it also serves as a motivational tool, encouraging continuous learning even within the gaming context [51].

Educational games can customize learning experiences by gauging a student's readiness, providing constructive feedback, and modifying the level of challenge [52]. It is essential for an educational game to have well-defined learning objectives that detail the desired skills and knowledge [53]. Game rules facilitate learning by allowing players to interact with their environment [54]. Achieving these objectives depends on adhering to specific rules, which may involve certain challenges or conditions that the learner must satisfy [43].

A learner's level of motivation can greatly influence their enthusiasm or indifference toward a task [55,56]. Moreover, there is substantial evidence suggesting that motivation enhances cognitive functions, particularly influencing what learners focus on and how they assimilate information [57-59].

Literature suggests that multiple factors influence the success of crowdfunding campaigns, especially those related to health education games [51,54]. These range from the trustworthiness of the developers and the quality of information presented to the design and content of the game itself. Although previous studies have shed light on the general principles of game-based learning and the dynamics of crowdfunding, there remains a gap in understanding how these principles specifically apply to health education games on platforms such as Kickstarter. Moreover, the user's perspective, which is crucial in determining the success of such campaigns, has not been thoroughly explored. We aim to bridge this knowledge gap by focusing on the user's perception and evaluating the critical components that resonate most with potential users, thereby influencing the success of health education game initiatives on crowdfunding platforms.

Objectives

This study aims to provide a comprehensive overview of 17 health education game projects launched on the crowdfunding platform Kickstarter and to understand user perceptions concerning the important factors that determine the success of such health education game crowdfunding initiatives. To achieve this, we conducted a user survey using a health education assessment rubric specifically designed to evaluate the key components contributing to the success of these projects on Kickstarter.

Methods

Data Collection for Health Education Games

A comprehensive keyword search using "Health, Education, Learning, Game" was conducted in August 2019 on Kickstarter, which identified 17 online health education game projects (Table 1). On the Kickstarter site, the system marked a project as "Successful" if it met or exceeded its financial goal within the time set by the creators. Conversely, projects that failed to meet their financial target within the designated period were labeled as "Unsuccessful" (Table 1).

Table . Descriptive data of health education game projects from the crowdfunding site Kickstarter. A project's success on Kickstarter was determined by its ability to achieve its financial goal within the set time frame.

Health education game	Pledge (US $)	Goal (US $)	Backer count, n	Country	Successful[a]
Playout: The Exercise Card Game [60]	11,011	10,000	224	United States	Yes
ACLS MegaCode Simulator for health care professionals [61]	328	1997	8	Canada	No
Blush by Renaissance [62]	5065	3500	80	Canada	Yes
Body Cycle Health Education App [63]	1778	20,000	41	United States	No
CHiLD - a psychological 2D RPG [64]	1199	554	92	Norway	Yes
Destiny's Sword for mental health [65]	30,930	30,000	209	Canada	Yes
Facing Dragons: a mixed-reality game to unlock your purpose [66]	3361	7104	34	Canada	No
Freestyle Jam Camp [67]	1145	500	18	United States	Yes
Mobile games to quantify symptoms of mental health disorders [68]	127	450,000	5	United States	No
PRESCRIPTION Playing Cards [69]	30,420	7500	178	Canada	Yes
Talk to Me visual novel: mental health [70]	4977	4460	146	United States	Yes
TEN: a card game designed to promote brain health [71]	1445	14,000	39	United States	No
The Chakra Collectable Coin [72]	1682	1300	41	United States	Yes
The Woosah Kit: a mental health first aid [73]	41	6236	3	United Kingdom	No
Tournesol Kids Game: activity cards to build resilience [74]	10,435	5000	140	United States	Yes
Youth Run The World 5K [75]	7370	7000	74	United States	Yes
Zombied: gamify health and fitness activities [76]	12	37,217	2	United Kingdom	No

[a]"Yes" refers to "Successful" projects that met or exceeded their financial goal, whereas "No" refers to "Unsuccessful" projects that did not.

Ethical Considerations

Before commencing this study, the researchers obtained approval from the Institutional Review Board of the University of South Florida (001588). The participants provided informed consent, with the option to withdraw at any time without penalty. The Institutional Review Board approval sufficiently covered the secondary use of data. The study guaranteed that all collected data were either anonymized or deidentified to protect personal information, with stringent protective measures in place for any data that could not be fully anonymized. The study was voluntary, without any compensation for participation.

Online Survey Design

We use the Qualtrics online survey platform (Qualtrics) to create an online survey based on health education game assessment rubrics derived from the literature. This survey allowed participants to evaluate and rank crowdfunding health education games on the Kickstarter website. The survey incorporated 8 dimensions—each essential for the evaluation of health education games. These dimensions, along with their definitions and cited literature, are presented in Table 2.

Table . Crowdfunding health education game evaluation dimensions and definitions.

Dimensions	Definition	Related literature
Skill building	The game's ability to progressively impart and reinforce health-related skills to players, ensuring that learning is continuous and effective throughout the game's duration.	[42,77]
Content organization	The clarity, structure, and logical flow of the game's health education content, ensuring that it is presented in a manner that is both comprehensible and engaging for players.	[35,53,78]
Narrative	The clarity and continuity of the game's storyline in relation to health education, ensuring that players experience a coherent sense of progression and purpose as they navigate through the game's content.	[25,48]
Interactivity	The game's ability to facilitate effective interactions, the completion of health-related tasks, and active participation through user-driven inputs and actions.	[35,77,79]
Assessment and feedback	The game's capability to immediately evaluate and communicate a player's progression and provide timely and relevant feedback.	[35,80-82]
Game rules	The game provides clear, concise, and easily comprehensible rules to the players.	[35,52,83,84]
Learning objectives	The game delineates specific, measurable outcomes that players are anticipated to achieve upon its completion.	[35,85-87]
Motivation	The game's elements are intriguing and appealing enough to prompt user participation and action.	[88-90]

Before the main survey was launched, a pilot test of the survey instrument was conducted with 7 undergraduate students majoring in health science. This pilot test aimed to assess the validity and understandability of the survey questions. The participants were asked to read through the survey and provide feedback on its clarity and relevance. Based on their comments, necessary revisions were made to the questions to enhance the overall quality of the survey.

In the final version of the survey, participants rated the dimensions on a 3-point Likert scale. The scoring system for these dimensions ranged from 0 to 2, with the following interpretations: 0="Does not meet expectations" or "Poor," 1="Meets expectations" or "Fair," and 2="Exceeds expectations" or "Good." Participants could also select "Unable to decide" or "Not applicable" if they felt unable to make a judgment on a particular dimension. Additionally, an open-ended question was incorporated: "Do you have any comments or concerns (accuracy of terms, comprehensiveness, clarity of questions, etc) for this question sets?" This allowed participants to provide further feedback on the survey questions.

In November 2019, undergraduate students majoring in health science were invited to participate in the online survey. Those who agreed to participate were provided with a standardized set of questions, accompanied by comprehensive instructions and definitions for the 8 evaluation dimensions, as detailed in Table 2. Each student was then randomly assigned 1 specific crowdfunding health education game from a pool of 17 games, referenced in Table 1. Their task was to evaluate their assigned game based on these 8 dimensions. Ultimately, 75 undergraduate students were recruited as participants.

Data Analysis

We used STATA 15 software (StataCorp) for statistical analyses. We used several data analysis approaches to understand the results.

Descriptive Statistical Analysis

This method provides a summary of the main aspects of the data, offering a simple overview of the data. By calculating the percentage of ranking types and the mean scores of the dimensions, we can gain insights into the general behavior and preferences of the survey participants.

Exploratory Factor Analysis

Exploratory factor analysis is used to reduce the data's dimensionality and identify the underlying relationships between the measured variables [91]. It was used to group the 8 dimensions into meaningful categories, helping to decipher any latent structures within the data set. This ensured that we could identify which sets of dimensions tended to co-occur or were rated similarly by participants.

Wilcoxon-Mann-Whitney Test

The Wilcoxon-Mann-Whitney test [92] is a nonparametric statistical hypothesis test used to compare 2 unrelated samples. This test was used to determine if there were any significant differences in the rankings given by participants to different game dimensions.

Multivariate Analysis

The aim of this study extends beyond merely understanding the dimensions. It also seeks to predict the success of crowdfunding health education games based on these dimensions. We used logistic regression with a binary variable—success of the crowdfunding project—for prediction [91]. This model can determine the odds of a game being successful based on the rankings of its dimensions, offering insights into which dimensions are the most influential predictors of success.

By using these methods, the study ensured a comprehensive analysis of the data—from understanding the basic patterns and deciphering underlying component structures to finally being able to predict the success of crowdfunding health education games based on their dimensions.

Results

A list of health education games launched on Kickstarter is presented in Table 1. This table enumerates 17 distinct health education games originating from various countries, namely the United States, Canada, Norway, and the United Kingdom. Some projects have exceeded their goals by a large margin, whereas others have fallen substantially short. The diversity of the sample provides a comprehensive foundation for our study. This diversity enabled an exploration into users' perceptions regarding educational game assessment rubrics. Such an investigation can discern potential factors that could influence the success trajectory of health education games on crowdfunding platforms such as Kickstarter.

Table 2 focuses on the various dimensions relevant to the design and evaluation of games. These dimensions were based on established literature, highlighting their credibility and validity. When assessing potential predictors of crowdfunding success based on feedback from 75 survey participants, certain dimensions stood out as being more important (Table 3).

Table . Ranking of the 8 assessed dimensions for crowdfunding health education games (n=75).

Dimensions	Score, mean (SD)[a]
Skill building	1.77 (0.54)
Content organization	1.7 (0.52)
Narrative	1.51 (0.69)
Interactivity	1.51 (0.75)
Assessment and feedback	1.49 (0.69)
Game rules	1.47 (0.71)
Learning objectives	1.39 (0.64)
Motivation	1.29 (0.59)

[a]Scoring system: 0=”Poor,” 1=”Fair,” and 2=”Good.”

Skill building was ranked first, followed by content organization and then narrative. Skill building holds the top rank due to its emphasis on continuous learning and engagement, ensuring that players progressively acquire and refine their skills throughout the game (Table 3). The importance of content organization is highlighted by its role in enhancing user experience; a well-organized game offers clear navigation, allowing players to immerse themselves fully (Table 3). Narrative further enhances the gaming experience by introducing an engaging storyline that lends context and purpose, enriching the gameplay. Interactivity is important for keeping players engaged. It gives them a sense of belonging and influence within the game world. Yet, intriguingly, motivation ranks the lowest among these dimensions, even though its presence ensures that games are compelling enough to retain players' interest and drive continuous participation (Table 3). Although skill building and content organization seem to be the areas where these games excel, motivation appears to be a challenging area for many developers.

To identify the assessment structure for campaign initiatives' quality reflected by 75 survey respondents' rankings, the study conducted an exploratory factor analysis using principal-components analysis as the extraction method and varimax with Kaiser normalization as the rotation method (Table 4). The cutoff size for criterion loadings was set to 0.45 [59]. Both the Bartlett (χ^2=68.26, P<.001) and measure of sampling adequacy (0.57) tests for the sample pointed to a significant level of correlation among the dimensions.

Table . Factor components for the 8 dimensions in crowdfunding health education games. Principal-components analysis served as the extraction method, and varimax with Kaiser normalization served as the rotation method.

Dimensions	Component		
	1	2	3
Game rules	−0.050	−0.057	0.843[a]
Learning objectives	0.253	0.727[a]	−0.025
Narrative	0.181	0.629[a]	−0.335
Motivation	0.665[a]	0.102	−0.021
Interactivity	0.489	0.185	0.506[a]
Skill building	−0.136	0.727[a]	0.266
Assessment and feedback	0.883[a]	−0.036	−0.019
Content organization	0.490[a]	0.370	0.033

[a]Values above the cutoff size for criterion loadings (0.45).

The exploratory factor analysis indicated that these 8 dimensions can be grouped into 3 components: game content (content organization, motivation, and assessment and feedback), instruction (learning objectives, narrative, and skill building), and game design (game rules and interactivity; Table 4). The game content–related components suggests that a well-organized game with clear feedback mechanisms can effectively motivate players. The instruction-related components reflect the instructional journey of the player, from understanding the objectives and engaging with narrative to building skills. The game design–related components are fundamental to the gameplay experience, ensuring that players are not just passive observers but active participants.

To review the perception gaps among these dimensions for successful or unsuccessful crowdfunding campaigns, group-based comparison was conducted between these dimensional means. Table 5 showed the gaps between successful and unsuccessful games in dimension ratings. Among them, motivation, interactivity, game rules, and learning objectives demonstrated larger difference gaps in decreasing order, and these were followed by assessment and feedback, skill building, narrative, and content organization.

Table . Wilcoxon-Mann-Whitney test of the 8 assessments based on successful or unsuccessful crowdfunding of health education games.

Dimensions and categories		Answers, n	Score, mean (SD)	*U* statistic	*P* value
Content organization				0.28	.78
	Success	53	1.68 (0.55)		
	Unsuccessful	15	1.67 (0.49)		
Interactivity				2.05	.04[a]
	Success	53	1.57 (0.72)		
	Unsuccessful	15	1.13 (0.83)		
Skill building				0.94	.35
	Success	53	1.79 (0.49)		
	Unsuccessful	15	1.60 (0.74)		
Learning objectives				2.03	.04[a]
	Success	51	1.43 (0.64)		
	Unsuccessful	15	1.07 (0.59)		
Narrative				.09	.37
	Success	53	1.53 (0.70)		
	Unsuccessful	14	1.36 (0.74)		
Motivation				2.91	.004[a]
	Success	53	1.38 (0.56)		
	Unsuccessful	15	0.87 (0.52)		
Game rules				2.14	.03[a]
	Success	53	1.55 (0.70)		
	Unsuccessful	15	1.13 (0.74)		
Assessment and feedback				1	.32
	Success	53	1.49 (0.64)		
	Unsuccessful	14	1.29 (0.73)		

[a]Significant level $P<.05$.

The Wilcoxon-Mann-Whitney test comparing distributions of successful and unsuccessful games showed that motivation (P=.004), game rules (P=.03), learning objectives (P=.04), and interactivity (P=.04) showed statistically significant difference among these 2 groups (Table 5). These dimensions showed clear distinctions between successful and unsuccessful games, suggesting that these dimensions might be crucial for the success of such games. On the other hand, dimensions such as content organization and skill building, while important, did not show a significant difference between the 2 categories of games. This could mean that both successful and unsuccessful games have well implemented these dimensions, but they might not be the distinguishing factors for success. The multivariate analysis showed that learning objectives and motivation were 2 significant dimensions associated with successful health education game crowdfunding campaigns (Table 6). This suggests that these 2 dimensions might be especially important for the success of health-related games.

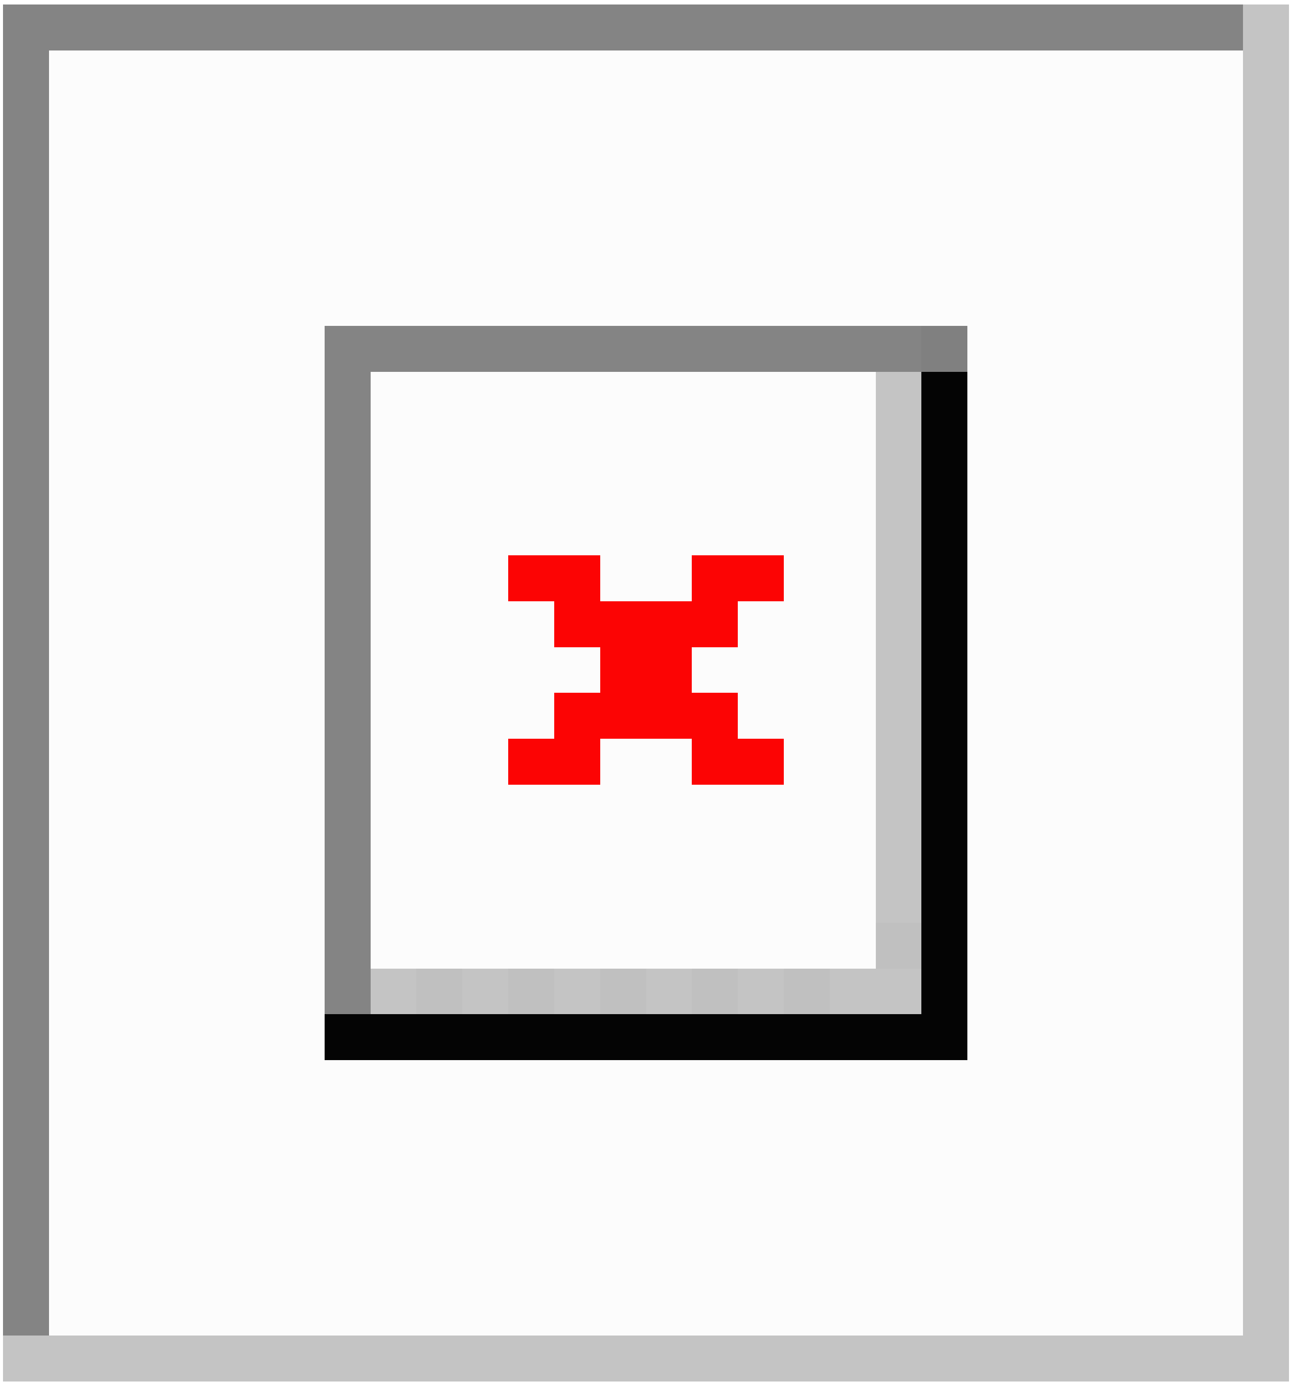
Table . Multivariate logistic regression predicting the success of the health educational games.

Dimensions	Odds ratio (95% CI)	*P* value
Game rules	3.24 (0.68-18.40)	.13
Learning objectives	3.55 (1.42-14.38)	.02[a]
Narrative	1.57 (0.37-6.61)	.54
Content organization	0.07 (0.01-1.55)	.09
Motivation	3.05 (1.46-9.36)	.03[a]
Interactivity	1.70 (0.46-6.22)	.42
Skill building	1.31 (0.21-8.18)	.77
Assessment and feedback	1.38 (0.21-8.88)	.73

[a]Significant level $P<.05$.

Figure 1 presents an empirical framework that outlines the key components underpinning the success of health education game crowdfunding. The model highlights the balance between foundational structural components, such as game rules and content organization, and experiential elements that enhance the player's immersion and engagement, such as motivation and narrative. A successful educational game should seamlessly integrate all these facets. This not only ensures the delivery of educational content but also fosters an environment where players are intrinsically driven to remain engaged and continue their learning journey within the game.

Figure 1. Framework for successful crowdfunding of health education games.



Discussion

Principal Findings

The crowdfunding landscape for health education games is diverse, with success determined by a myriad of factors beyond just a funding goal. Factors such as the clarity of the project's purpose, its presentation, and its marketing likely play a substantial role in attracting users [35,41]. It is also important to have a reasonable and attainable goal, as this might increase the likelihood of a project's success.

Crowdfunding backers, especially on platforms such as Kickstarter, often support projects that offer value beyond just entertainment. Skill building in games implies that players will acquire new abilities or knowledge, making them both fun and beneficial. This dual-purpose might appeal to game players who see an opportunity for a return on investment, not just in potential product rewards but also in personal or societal skill development.

The ranking of these dimensions sheds light on the preferences and priorities of both backers and players. It is possible that backers perceive tangible attributes such as skill building and content organization as immediate indicators of game quality and potential success. These elements can be readily demonstrated in promotional materials, making them more attractive to potential backers. On the other hand, motivation, being more abstract and subjective, might be harder to convey and measure, leading to its lower ranking. It is essential for game developers to recognize these perceptions and strike a balance in their design, ensuring a comprehensive and engaging game experience that appeals to a broad audience.

For skill building, it is essential for players to acquire and build skills as they progress in the game. This ensures continuous learning and engagement. Well-structured game content helps players navigate and understand the game better, thus enhancing their experience. An engaging storyline provides context and purpose, making gameplay more meaningful. Player interactivity is vital for player engagement. Players should feel that they are part of the game world and can influence it. Immediate feedback helps players understand their progression and areas of improvement. Clear rules ensure that players can easily understand how to play the games, leading to smoother game experiences. For health education games, it is important to have clear learning outcomes that guide the game design. The game must be engaging enough to keep players interested and motivated to continue.

The multivariate analysis identified learning objectives and motivation as the 2 significant predictors of a health education game's crowdfunding success, as detailed in Table 6. This indicates the emphasis users place on clear educational outcomes and the motivation to engage with the game. Users prioritize games that offer clear educational outcomes and that effectively motivate players to engage. The significance of learning objectives suggests that backers might prioritize games that have a clear educational goal, ensuring that players gain tangible knowledge or skills. Motivation, on the other hand, ensures that players remain engaged and committed to the game's objectives. When combined, these dimensions can lead to a game that not only educates but does so in a compelling manner, maximizing player retention and learning outcomes.

Limitations and Future Work

The study has some limitations due to the examination of user perception, which is based on a small number of user responses in a small number of crowdfunding campaigns. The study examined subjective opinions across 8 evaluation dimensions, but the reasons for crowdfunding's effectiveness in health education games require further investigation. In addition, we surveyed participants as potential backers. A more comprehensive approach would involve surveying actual backers, those who make real investments, to discern any differences in perceptions. This could provide a richer understanding of the dynamics at play. The impact of quality on the campaign content and media aspects, as well as user indicators of motivation and interactivity, was investigated in this study. Through crowdfunding, health education games improve engagements, learning components, and cultural adaptability for user engagement [8-10].

Conclusion

Crowdfunding for health education games presents a unique opportunity to bridge the gap between game developers and potential users. There has been little research that has provided empirical evidence for evaluating user perspectives on crowdfunding health education games. Further empirical evaluations are clearly beneficial to providing a rigorous validation of gamification's effectiveness in eHealth. This research conducted an exploratory study and identified 3 major components that matter for health game crowdfunding success. These components are related to game design, instruction, and game content. Interestingly, motivation and assessment and feedback were grouped into game content categories, not into game design categories. This indicates that the proposals for health-related crowdfunding education games are comprehensive, encompassing content that is engaging, interesting, and attractive, with solid assessment and feedback components. Among them, given the nature of health subjects, entrepreneurs and educators should pay more attention to game development factors such as motivation, interactivity, and game rules, so that the health or scientific subjects can be easily infused in the gaming process. Making health games look playful and attractive enables users to easily grasp basic health knowledge during the gaming process [93]. Interestingly, there is little difference in content organization between successful and unsuccessful games, which indicates that even if the game content is easy to follow, it is still not enough. Backers and potential funders or users mostly agree with the health content itself, but they care more about the game development components, using these dimensions to assess the crowdfunding game proposal and determine if these game designs are acceptable and make logical sense.

Our findings recognize the importance of aligning game design with user preferences. The success of health education games on crowdfunding platforms relies on a combination of clear educational objectives, effective player engagement mechanism, and well-structured game content. The study highlights the significance of learning objectives and motivation as key determinants of crowdfunding success for health education games. Game developers aiming for success in this domain should prioritize these dimensions, thus ensuring that their games offer a clear educational outcome.

Acknowledgments

We would like to extend our sincere gratitude to the 3 anonymous reviewers for their invaluable and insightful feedback on our manuscript. Their consistent comments significantly improved our manuscript.

Abstract

Background: Metacognitions about online gaming have been shown to be correlated with Internet Gaming Disorder (IGD). Knowledge of metacognitions about online gaming can help to understand IGD. The Metacognitions about Online Gaming Scale (MOGS) is a reliable and valid tool to measure specific metacognitions about online gaming in both adults and adolescents, which is lacking in China.

Objective: This study was conducted to assess the psychometric properties of the Chinese version of the MOGS (C-MOGS) and its relationship with IGD in the Chinese population.

Methods: A total of 772 Chinese individuals (age: mean 21.70, SD 8.81 years; age range: 13-57 years; 458/772, 59.3% male) completed a web-based questionnaire survey, including the C-MOGS and a battery of validated scales measuring IGD, gaming motives, depression, and anxiety.

Results: Through exploratory and confirmatory factor analyses, the 3-factor structure was confirmed to have adequate model fit and internal consistency reliability (Cronbach α≥.799, Guttman split-half coefficients≥0.754). Concurrent validity of the C-MOGS was supported by its correlations with IGD (*P*<.001), gaming motives (*P*<.001), depression (*P*<.001), and anxiety (*P*<.001). Furthermore, the incremental validity analysis showed that the C-MOGS predicted 13% of the variance in IGD while controlling for gender, age, weekly gaming hours, gaming motives, depression, and anxiety.

Conclusions: This study provides evidence that the psychometric properties of the C-MOGS are appropriate and emphasizes its positive association with IGD. The C-MOGS is a reliable and valid instrument for mental health workers to assess metacognitions about online gaming in the Chinese population.

metacognition; metacognitions about online gaming; Internet Gaming Disorder; psychometric properties; Chinese

Introduction

Metacognition refers to the awareness of one's own thoughts and behaviors, as well as the ability to monitor and alter behavior. It encompasses any cognitive process that receives information from and exerts a controlling influence on another cognitive process [1-4]. More specifically, it comprises metacognitive knowledge and metacognitive regulation. Metacognitive knowledge refers to information and beliefs about one's cognitive processes, while metacognitive regulation pertains to skills to regulate thoughts, including planning, supervision, and regulation [5]. Metacognition contributes to effective decision-making across a variety of contexts [4]. For instance, it facilitates the smooth operation of ongoing thought and behavior by helping us recognize our errors [6], regulate the deployment of executive function [7], and detect lapses of attention [8]. Originating from cognitive psychology, metacognition has been linked to psychological disturbances [9,10].

In recent years, studies have highlighted the potential role of metacognitions in the development of addictive behaviors, such as problematic gaming behavior [11,12]. However, due to the lack of suitable research instruments, conducting further investigations in China has been challenging. To address this issue, this study aimed to evaluate the validity of the Metacognitions about Online Gaming Scale (MOGS) [13] among the Chinese population and its association with gaming behavior.

According to the self-regulatory executive function model, metacognitions play a critical role in the occurrence and development of psychological dysfunction [14]. In this model, psychological dysfunction is activated and perpetuated by a fixed thinking pattern called cognitive attentional syndrome (CAS), which comprises several maladaptive coping strategies (eg, rumination, threat-monitoring, and avoidance). The CAS is driven and maintained by maladaptive metacognitions [15]. Maladaptive metacognitions mistakenly regard the CAS as an effective coping style, resulting in a vicious cycle of ineffective self-regulation [16]. Over the last 40 years, metacognitions have been associated with several mental and psychological problems [17], such as obsessive-compulsive disorder, schizophrenia, addiction, anxiety, and depression [18-20].

In the domain of addictive behaviors, metacognitions are divided into 2 subtypes: positive and negative [21]. The former refers to the beliefs that engaging in specific addictive behaviors is a strategy of affective and cognitive self-regulation, such as "Drinking helps me think more clearly" and "Gambling can improve my mood" [22,23]. The latter refers to the concerns about the uncontrollability and danger of thoughts or engagement with addictive behaviors. For example, "Drinking will interfere with my thought" and "Once I start thinking about drinking, I cannot stop" [24]. Previous studies have shown that positive metacognitions can motivate addictive behaviors in the early stage, while negative metacognitions contribute to their perpetuation by activating negative emotional states as a reinforcement [11,21]. In recent years, metacognition has been correlated with many addictive behaviors, such as problematic alcohol use [25-27], nicotine dependence [28,29], gambling disorder [30-32], problematic Internet use [33-35], problematic social media use [36-38], and Internet Gaming Disorder (IGD; problematic online gaming) [39,40].

As an addictive behavior, IGD was first included in the research appendix section of the Fifth Edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) in 2013 [41], then it was officially included in the addiction disease unit of the *Eleventh Revision of the International Classification of Diseases (ICD-11)* in 2018 [42]. Its core characteristics include losing control while gaming, prioritizing gaming over other interests, and causing functional damage in daily life. Excessive online gaming results in various problems, such as sacrificing real-life relationships, sleep, work, and education, leading to brain damage [43-46]. According to a recent review, the global prevalence of IGD was 3.05%, and it was higher among Asians (5.08%) than Europeans (2.72%) [47]. In China, the prevalence ranges from 3.5% to 17%, which is higher than the global average level [48-50].

In order to effectively prevent and treat this disorder, extensive research has been conducted to investigate its etiology. These studies have revealed a significant association between IGD and various psychological factors, including negative affect, gaming motives, and maladaptive cognition [51]. The Interaction of Person-Affect-Cognition-Execution (I-PACE) model proposed by Brand et al [52,53] suggests that the initiation of addictive behaviors arise from the integration of emotional and cognitive responses to internal or external stimuli along with specific motivations. Motives are sets of knowledge that represent the emotional preferences expressed in our thoughts and concepts. Gaming motives could be considered as stimulating factors of gaming behavior, which may play an important role in the development of IGD [51]. Furthermore, Spada et al [21] posited that the development and persistence of addictive behaviors, including IGD, are strongly influenced by particular metacognitions about addictive behaviors.

According to previous studies, metacognitions have been associated with IGD [38,39]. However, these studies mainly focused on generic metacognitions (eg, beliefs about worry, cognitive monitoring, the need for thought suppression). To assess specific metacognitions about online gaming, Spada and Caselli [13] developed a self-rating instrument called the Metacognitions about Online Gaming Scale (MOGS). In the original validation of the MOGS, an exploratory factor analysis (EFA) was performed with 225 adults in Study 1 that suggested a 2-factor solution: Negative Metacognitions about Online Gaming (N-MOG; 6 items) and Positive Metacognitions about Online Gaming (P-MOG; 6 items) [13]. The N-MOG assesses negative metacognitions about the uncontrollability and danger of thoughts on gaming. The P-MOG measures positive metacognitions in which online gaming helps individuals regulate affect and thought. In Study 2, the confirmatory factor analysis (CFA) with another sample of 348 individuals further divided N-MOG into 2 factors and built a 3-factor structure: Negative Metacognitions about the Uncontrollability of Online Gaming (N-MOGU), Negative Metacognitions about the Dangers of Online Gaming (N-MOGD), and P-MOG [13]. All 3 factors reported adequate internal reliability (Cronbach $\alpha \geq .79$).

While exploring predictive validity, the study showed that MOGS was positively related to gaming hours and Internet addiction [13]. Overall, these findings demonstrated the reliability and validity of the MOGS.

To extend the utility of the MOGS to adolescent populations from other countries, Akbari et al [54] translated it into Persian and evaluated its psychometric properties among 769 Iranian adolescents. The results showed that the 3-factor structure had appropriate construct validity and internal consistency (Cronbach α≥.79). Furthermore, metacognitions about online gaming were able to independently predict problematic gaming behavior while controlling for personality traits, gaming motives, gaming-related cognitions, and negative affect [54]. Another study investigating the association between IGD and social anxiety reported that metacognitions about online gaming were significantly correlated with IGD and mediated the latter's relationship with social anxiety [55].

These studies indicated an association between specific metacognitions about online gaming and IGD. Further exploration could be beneficial for the treatment and prevention of IGD, especially in countries with a higher prevalence, such as China. However, it is difficult to conduct relevant research in China because of the lack of instruments used to evaluate specific metacognitions. Therefore, the primary objective of this study was to translate the MOGS into Chinese and validate its psychometric properties among Chinese adolescent and adult gamers using online convenience sampling. Additionally, the study aimed to investigate the unique influence of metacognitions about online gaming on IGD while considering variables such as anxiety, depression, and motivation. The hypothesis was that, within the Chinese population, positive and negative metacognitions about online gaming would serve as independent risk factors for IGD, distinct from other contributing factors.

Methods

Participants

We recruited all individuals online through convenience sampling in June 2021. The inclusion criteria were as follows: (1) age ≥13 years, (2) Chinese speakers who could understand the questionnaires, (3) consent to participate (adolescents with parental consent), and (4) played games at least one hour every week (excluding online gambling) in the last 12 months.

In total, 996 individuals participated in this survey. We excluded 88 individuals whose answer was "No" to the item "Are your answers to this questionnaire true and reliable?", 37 who gave the same answers to more than 50% of the questions and whose time spent on the questionnaire was less than the mean minus 3 SD, and 99 who were younger than 13 years old. The final sample included 772 participants.

Ethical Considerations

Before starting the anonymous online investigation, participants were informed about the purpose and rights of the study and signed an online informed consent form. Those younger than 18 years needed to inform their guardians and obtain consent before filling out the questionnaire. The ethics committee of the Second Xiangya Hospital of Central South University approved this study (protocol code 2020004; dated March 1, 2020).

Measures

Basic Information

Basic information included sociodemographic information and Internet gaming characteristics. The former included gender, age, employment, years of education, and family structure (eg, single-child family). For the latter, participants reported their average time spent gaming (weekly gaming hours), gaming devices (a multiple-choice question), the number of long-term gaming partners, and self-evaluation of gaming addiction.

Metacognitions About Online Gaming

Metacognitions about online gaming were measured using the MOGS [13], which contains 12 items rated on a 4-point Likert scale (1=Do not agree to 4=Agree very much). The MOGS comprises the following 3 factors: (1) N-MOGU (3 items, such as "Once I start online gaming I cannot stop"), (2) N-MOGD (3 items, such as "Online gaming makes me lose control"), and (3) P-MOG (6 items, such as "Online gaming stops me from worrying"). A higher score indicates a higher degree of specific metacognition about online gaming.
