The severity of IGD symptoms was assessed using the Internet Gaming Disorder Scale-Short Form (IGDS9-SF) [56,57]. The IGDS9-SF is a 9-item scale developed from the core symptoms of IGD proposed by the DSM-5 and assesses gaming activities and their adverse effects in the past 12 months. All items are rated on a 5-point Likert scale (1=never to 5=very often). The scores range from 9 to 45. Higher scores represent more severe IGD symptoms. With adequate reliability (Cronbach α≥.9), the Chinese version of the IGDS9-SF was used in our research [58,59]. The Cronbach α was .90 in this study.

Gaming Motives

We assessed gaming motives using the Motives for Online Gaming Questionnaire (MOGQ) [60]. It includes 27 items comprising the following 7 motivational dimensions (all rated on a 4-point Likert scale): escape, skill development, recreation, competition, coping, fantasy, and social. The Chinese version of the MOGQ has excellent reliability (Cronbach α≥.83) and validity [61]. Higher scores reflect stronger motives for online gaming. In this study, the Cronbach α was .95 for the total scale and ranged from 0.84 to 0.89 for each subscale.

Depression and Anxiety

The Patient Health Questionnaire-9 (PHQ-9) [62] was used to measure depressive symptoms. It is a diagnostic screening tool that monitors the severity of depression over the last 2 weeks. All items are scored on a 4-point Likert scale (0=Not at all to 3=Nearly every day). The scores range from 0 to 27. Higher scores denote worse depressive symptoms. The Chinese version of the PHQ-9 [63] has suitable reliability (Cronbach α=.85). The Cronbach α was .89 for this study.

The Generalized Anxiety Disorder-7 (GAD-7) [64] was used to measure anxiety symptoms. It is a self-rated scale that assesses the severity of anxiety symptoms over the last 2 weeks. All items are scored on a 4-point Likert scale (0=Not at all to 3=Nearly every day). The scores range from 0 to 21. Higher scores represent worse anxiety symptoms. The Chinese version of the GAD-7 [65] was used, with appropriate internal consistency (Cronbach α=.90) and validity. The Cronbach α was .92 for this study.

Procedures

The MOGS was translated into Chinese by 2 professional translators using a standard translation and back-translation method [66]. For some controversial items (eg, "Online gaming makes me lose control," "Online gaming makes my worries more bearable"), we consulted the author of the original scale. Considering the original scale, 2 bilingual psychologists revised the translated version and checked its face validity. A pilot study was conducted with 5 adults and 5 adolescents to test the understandability. Based on their feedback, some descriptions of items were modified, and the final Chinese version of the MOGS (C-MOGS) was created.

We conducted this survey online using Questionnaire Star, a professional online survey platform. By reading recruitment advertisements posted on social networking sites (eg, WeChat, Weibo, and other webcast platforms), individuals could open the questionnaire link. On the first page, participants could read the objectives and content of this research and confirm their participation (minors, those younger than 18 years, had to obtain the consent of their guardian). Each IP address can only be used once to avoid repeated participation. After the questionnaire was submitted, all the data were sent to the researcher's account, and only the researcher could view the data.

Data Analyses

Data analyses were conducted using SPSS version 25.0 (IBM Corp) and AMOS version 24.0 (IBM Corp). First, basic statistical analyses (eg, descriptive analysis, independent samples *t* tests, chi-square tests) were performed on sociodemographic variables and Internet gaming characteristics. To analyze the construct of the C-MOGS, the total sample was randomly split into 2 subsamples. Sample-1 (n1=390; 229/390, 58.7% male; age: mean 22.25, SD 9.05 years) was used for EFA, and sample-2 (n2=382; 229/382, 59.9% male; age: mean 21.14, SD 8.52 years) was used for CFA. Except for EFA and CFA, all analyses were conducted on data from the entire sample. Independent samples *t* tests and chi-square tests showed that there were no significant differences between the 2 subsamples regarding age (t_{770}=–1.754, *P*=.08), gender (χ^2_1=0.121, *P*=.73), average weekly gaming time (t_{770}=0.775, *P*=.44), gaming devices (χ^2_1<1.012, *P*=.31), long-term gaming partner (χ^2_3=4.046, *P*=.26), and other demographic variables (*P*=.33-.88). An EFA with principal component analysis (PCA) and varimax-rotation method was conducted on the C-MOGS items. To validate the models derived from the EFA, a CFA was completed with AMOS 24.0 using the maximum likelihood method. The model fit was appraised using multiple fit indexes, including chi-squared:degree of freedom ratio (χ^2/df<5), goodness-of-fit index (GFI>0.90), Tucker-Lewis Index (TLI>0.90), comparative fit index (CFI>0.90), standardized root of the mean square residual (SRMR<0.08), root mean square error of approximation (<0.05=close fit; <0.08=acceptable fit; <0.1=mediocre fit) [67]. The reliability of the C-MOGS was examined by assessing the internal consistency of the scale and subscale. Acceptable values for the Cronbach α and Guttman split-half coefficients are >0.70, while values >0.80 are considered good [68]. Finally, to test the concurrent and incremental validity, correlation analyses and hierarchical multiple regression analyses were conducted between the C-MOGS and Internet gaming characteristics (gaming time, IGD, gaming motives) as well as anxiety and depression.

Results

Sample Characteristics

In this study, analysis was conducted on data from 772 participants (458 men, 59.3%) aged between 13 years and 57 years (age: mean 21.70, SD 8.81 years; participants aged 13-17 years: 281/772, 36.4%). The majority of them were students (555/772, 71.9%). Smartphones were the most popular device for gaming (705/772, 91.3%). Of the sample, 69.4% (536/772) had one or more long-term gaming partners. Participants spent an average of 13.43 (SD 10.88) hours every week playing games. More details on the sample characteristics are shown in Table 1.

Table 1. Sociodemographic and Internet gaming characteristics of the sample (n=772).

Characteristic	Participants' results
Gender, n (%)	
Male	458 (59.3)
Female	314 (40.7)
Age (years), mean (SD)	21.70 (8.81)
Employment , n (%)	
Student	555 (71.9)
Full-time employee	186 (24.1)
Part-time employee	13 (1.7)
Unemployed	18 (2.3)
Length of education (years), n (%)	
≤12	339 (43.9)
>12	433 (56.1)
Single child, n (%)	
Yes	289 (37.4)
No	483 (62.6)
Gaming devices, n (%)	
Smartphone	705 (91.3)
Computer	278 (36.1)
Tablet	125 (16.2)
Game console	51 (6.6)
Long-term gaming partners, n (%)	
None	236 (30.6)
≥1 and <3	198 (25.6)
≥3 and <6	159 (20.6)
≥6	179 (23.2)
Self-evaluation of gaming addiction, n (%)	
Yes	129 (16.7)
No idea	203 (26.3)
No	440 (57.0)
Weekly gaming time (hours), mean (SD)	13.43 (10.88)

Factorial Structure of the C-MOGS

EFA

To identify the potential factorial structure of the C-MOGS, an EFA was performed on data from sample-1 (n=390). First, we used the Kaiser-Meyer-Olkin (KMO) and Bartlett tests of sphericity to ensure that the sample was suitable for EFA. The KMO value was 0.894, and the Bartlett test of sphericity was significant (χ^2_{66}=3159.742, *P*<.001), confirming the data were sufficient.

The initial analysis extracted 2 factors using the criteria of an eigenvalue>1 and factor loading>0.40. The 2-factor solution (eigenvalues of 5.573 and 2.597) accounted for 68.08% of the total variance, and the loading of all the items was >0.4 (0.646-0.918; Table 2). Factor 1 included items 1 through 6, referred to as the N-MOG; factor 2 included items 7 through 12, which described the P-MOG.

Additionally, according to the dimension of the original scale [13], we also conducted a PCA by setting 3 factors to be extracted. The 3-factor solution (eigenvalues of 5.573, 2.597, and 0.797) explained 74.73% of the total variance (37.44%, 19.31%, and 17.98%, respectively). Item-factor loadings are presented in Table 2. The factors were as follows: factor 1 (items 1, 2, and 3) referred to the N-MOGU; factor 2 (items 4, 5, and 6) was related to the N-MOGD; and factor 3 (items 7, 8, 9, 10, 11, and 12) was related to the P-MOG [54].

Table 2. Item-factor loadings of the Chinese version of the Metacognitions about Online Gaming Scale (C-MOGS) based on exploratory factor analyses (sample-1, n=390).

Items	2-factor model			3-factor model			
	F1[a,b]	F2[b,c]	Communality	F1[b,d]	F2[b,e]	F3[b,c]	Communality
(1) I continue to play despite I think it would be better to stop	0.646	0.215	0.463	0.809	0.110	0.178	0.698
(2) I have no control over how much time I play	0.830	0.177	0.721	0.808	0.370	0.151	0.813
(3) Once I start online gaming, I cannot stop	0.808	0.178	0.684	0.743	0.403	0.157	0.739
(4) Online gaming makes me lose control	0.746	0.108	0.569	0.213	0.840	0.134	0.768
(5) Thoughts about online gaming interfere with my functioning	0.743	0.007	0.552	0.222	0.825	0.032	0.731
(6) Thoughts about online gaming are becoming an obsession	0.776	0.165	0.630	0.474	0.624	0.169	0.643

[e]Negative Metacognitions about the Dangers of Online Gaming (N-MOGD).

Confirmatory Factor Analysis

To further evaluate the structural validity of the C-MOGS, we conducted a CFA on sample-2 (n=382) using AMOS 25.0. We compared the goodness of model fit between the 2 aforementioned models. We first tested the 2-factor model, which had a substandard fit in some indexes: χ^2/df=3.962 and root mean squared error of approximation (RMSEA)=0.880. In comparison, the 3-factor model showed an adequate model fit: χ^2/df=3.477, GFI=0.929, CFI=0.958, TLI=0.945, SRMR=0.065, RMSEA=0.081 (Table 3). The correlations between P-MOG, N-MOGU, and N-MOGD were moderate (r=0.389 and 0.377, respectively) and were relatively strong between N-MOGU and N-MOGD (r=0.905).

Due to the high correlation between the 2 negative metacognitive factors, we also created a bifactor model (Figure 1), in which N-MOGU and N-MOGD loaded on a second-order factor (N-MOG) and P-MOG was a first-order factor. In this model, the goodness of model fit was the same as that of the 3-factor model (Table 3), and the correlation between N-MOG and P-MOG was moderate (r=0.396).

Table 3. Model fit indices of the confirmatory factor analyses for the Chinese version of the Metacognitions about Online Gaming Scale (C-MOGS; Sample 2, n=382).

Model	χ^2 (df)	χ^2/df	GFI[a]	CFI[b]	TLI[c]	SRMR[d]	RMSEA[e]
2-factor model	205.517 (52)	3.962	0.917	0.948	0.935	0.067	0.880
3-factor model	173.867 (50)	3.477	0.929	0.958	0.945	0.065	0.810
Bifactor model	173.867 (50)	3.477	0.929	0.958	0.945	0.065	0.810

[a]GFI: goodness-of-fit index.

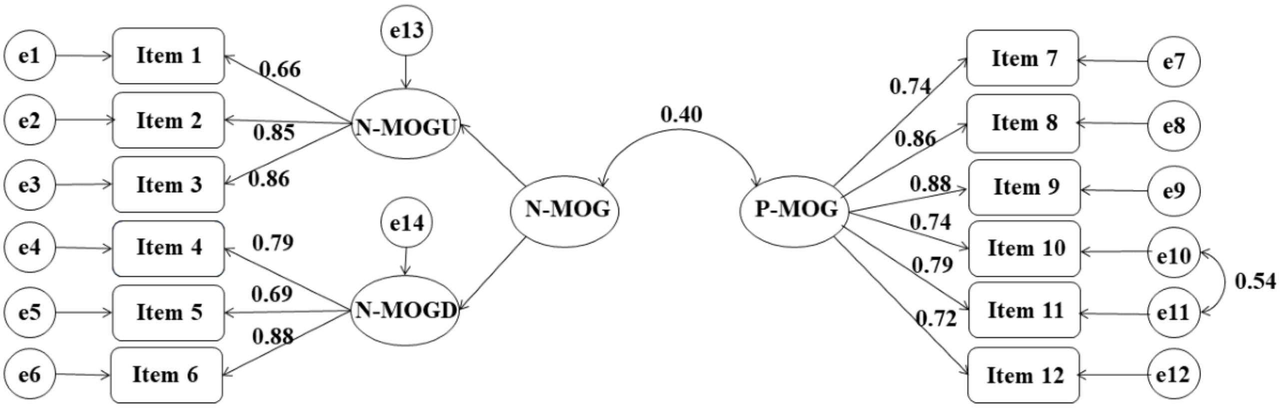
[b]CFI: comparative fit index.

[c]TLI: Tucker-Lewis Index.

[d]SRMR: standardized root of the mean square residual.

[e]RMSEA: root mean square error of approximation.

Figure 1. The bifactor model of the Chinese version of the Metacognitions about Online Gaming Scale (C-MOGS), showing the latent factors as ovals, the 12 items in the C-MOGS as rectangles, the error terms (e1-e14) as circles, and the standardized factor loading above the arrows. N-MOG: Negative Metacognitions about Online Gaming; N-MOGD: Negative Metacognitions about the Dangers of Online Gaming; N-MOGU: Negative Metacognitions about the Uncontrollability of Online Gaming; P-MOG: Positive Metacognitions about Online Gaming.



Reliability

The Cronbach α coefficient and split-half reliability were calculated for the scale and its subscales in the total sample (n=772). The α coefficient for the total scale was .894, and it was .823 for the N-MOGU, .799 for the N-MOGD, and .925 for the P-MOG. No item deletion improved the internal consistency. The Guttman split-half coefficient of the overall scale was 0.942, and for each dimension, the coefficients were 0.776, 0.754, and 0.841. These findings confirmed that the C-MOGS and its subscales exhibit adequate internal consistency.

Moreover, we calculated the correlation coefficient between each item and its relative factor scores. The results showed that the item-total correlations for all items were high (r≥0.551).

Concurrent Validity

We further analyzed the correlation between the 3 factors of the C-MOGS and IGD, gaming motives, anxiety, and depression to test the concurrent validity. Based on the Shapiro-Wilk test, these variables did not follow a normal distribution (all *Ps*<.05). Therefore, Spearman correlation analysis was chosen to explore the relationships between the variables. Table 4 shows the descriptive statistics (median and IQR), and Table 5 shows the correlations between the variables. Each factor of the C-MOGS showed positive correlations with the IGDS9-SF, weekly gaming hours, every dimension of the MOGQ, the PHQ-9, and the GAD-7 (r=0.153 to 0.759, all *Ps*<.01). Moreover, the correlation matrix showed positive correlations between the IGDS9-SF and the other variables (r=0.352 to 0.700, all *Ps*<.01).

Table 4. Descriptive statistics for the variables (n=772).

Incremental Validity

We conducted a hierarchical multiple linear regression analysis to identify the incremental effect of metacognitions about online gaming on IGD. The IGDS9-SF was the outcome variable, and the 3 factors of the C-MOGS were predictor variables, along with other variables related to the IGDS9-SF (gender, weekly gaming hours, the 7 factors of the MOGQ, and the total PHQ-9 and GAD-7 scores). Each variable was input in the following order: step 1: age and gender (0=female, 1=male); step 2: weekly gaming hours; step 3: the 7 factors of the MOGQ; step 4: GAD-7, PHQ-9; step 5: the 3 dimensions of the C-MOGS.

The Durbin-Watson statistic showed that the observed values were independent of each other (D-W=2.077). All tolerance values were above 0.1 (0.180-0.878), indicating no multicollinearity. The results are presented in Table 6. The 3 factors of the C-MOGS accounted for 13.0% of the variance in the IGDS9-SF (*P*<.001). In step 5, the final model indicated that gender, weekly gaming hours, the PHQ-9 score, the MOGQ-Escape score, the MOGQ-Competition score, and the factors of the C-MOGS were significant positive predictors of the IGDS9-SF (R^2=0.729, *P*<.001, adjusted R^2=0.724), and the most important predictor was the N-MOGU (β=0.326, *P*<.001).

Table 6. Hierarchical multiple regression analyses with the Internet Gaming Disorder Scale-Short Form (IGDS9-SF) as the outcome variable and the Chinese version of the Metacognitions about Online Gaming Scale (C-MOGS) factors as predictor variables, together with gender, weekly gaming hours, motives related to online gaming, depression, and anxiety (n=772).

Discussion

Principal Findings

To investigate the psychometric properties of the Chinese MOGS and its association with IGD, this study translated and tested it in China for the first time. In general, the results suggested that the C-MOGS could potentially serve as a valid and reliable tool to assess specific metacognitions about online gaming and it may have the capacity to predict IGD independently.

First, factor analyses were used to explore the structural validity of the scale. The EFA suggested a 2-factor solution (N-MOG and P-MOG), which was consistent with the first assumption of the original scale [13]. By setting 3 factors to be extracted, the EFA also obtained the same 3-factor solution as the final version of the original scale (N-MOGU, N-MOGD, and P-MOG) [13,54]. Through CFA, the 3-factor model was later proved to have the best data fit. Moreover, we attempted to build a bifactor model that included a first-order factor (P-MOG) and a second-order factor (N-MOG: N-MOGU and N-MOGD). This model had the same goodness of model fit as the 3-factor structure. To maintain consistency with the original scale, the 3-factor structure is recommended for measuring specific online gaming metacognitions in the Chinese population. For studies that compare N-MOG and P-MOG, the bifactor model can be considered.

The 3-factor structure of the C-MOGS demonstrated adequate internal consistency, with Cronbach α coefficients ranging from .799 to .925 for each factor and the full scale, along with Guttman split-half coefficients ranging from 0.754 to 0.942. The current findings also provide evidence for the concurrent and incremental validity of the C-MOGS. Each subscale was significantly positively correlated with IGD, weekly gaming hours, gaming motives, depression, and anxiety. Moreover, the C-MOGS accounted for 13.0% of the variance in IGD while controlling for other variables. These findings highlight the utility of the C-MOGS as a reliable and valid tool to assess metacognitions about online gaming among the Chinese population.

Furthermore, this study explored the effects of metacognitions about online gaming, gaming motives, anxiety, and depression on IGD using hierarchical multiple linear regression analysis. After adding metacognitions about online gaming to the regression equations, the final model accounted for 72.9% of the variance in IGD. In addition to metacognitions, gender, weekly gaming hours, escapism motives, competition motives, and depression significantly predicted IGD, suggesting that these factors collectively contribute to the development and maintenance of IGD [69-71]. Importantly, the inclusion of metacognitions led to a reduction in the standardized regression coefficients of these variables, and the predictive effect of anxiety on IGD became nonsignificant. This indicates that metacognition may partially mediate or explain the impact of these factors on IGD. This finding is consistent with previous research, suggesting that metacognitions about online gaming may mediate the influence of other psychological factors, such as psychological dependence, anxiety, and depression, on IGD [55,72-75]. These results indicate that specific metacognitions about online gaming are important predictors of IGD, which is consistent with previous studies [13,54,55]. However, the mechanisms underlying the role of metacognitions in IGD seem to be interrelated with other psychological factors, which remains inconclusive.

In a hypothesized model, metacognitions about online gaming may promote problematic gaming engagement by increasing gaming time and disrupting normal emotion and cognition [76]. Consistent with this view, our study found that people with more metacognitions about online gaming would spend more time playing games and feel more anxious and depressed. P-MOG increases gaming time by promoting online gaming as a self-regulation method for emotion and cognition [13,21]. N-MOGU will maintain problematic gaming engagement by destroying one's confidence in self-control, while N-MOGD can induce negative reinforcement and compulsive gaming engagement by triggering negative emotions such as anxiety and depression [21,76]. Furthermore, gaming motives may be an intermediate factor, as our study found: Gaming motives were simultaneously significantly correlated with MOGS and IGD. Dysfunctional metacognition activates maladaptive coping strategies and motivation, which causes negative emotions to persist and eventually leads to IGD [77]. Moreover, other studies have different views. For example, metacognitions have a mediating effect on the association between emotional dysregulation and problematic Internet use [78], and online gaming thought suppression and impulsiveness mediate the relationship between metacognition and IGD [79]. Therefore, the association between metacognition and IGD cannot be summarized by simple causality. Other psychological variables, such as motives, coping style, impulsiveness, and emotional regulation, should be considered in future research.

Since maladaptive metacognitions are an important predictor of IGD, interventions specifically addressing maladaptive metacognitions, such as metacognition therapy (MCT), may be beneficial for the prevention and treatment of IGD. MCT, an intervention aimed at modifying dysfunctional metacognition, is effective for treating psychiatric and psychological diseases such as anxiety, depression, and schizophrenia [80-84]. Although MCT is not widely used in the treatment of addictive behaviors, researchers are attempting to prove its efficacy [11]. In some pilot studies, MCT was used to effectively treat alcohol abuse and gambling disorder [85,86]. However, the specific efficacy of MCT for treating IGD needs to be further verified in clinical research. This study provides evidence for the potential value of MCT in the clinical treatment of IGD and offers an effective tool for conducting MCT for IGD specifically in the Chinese population.

Limitations

Although this study has the advantages of a large sample size with people of different ages, it has several limitations that should be considered. First, this study adopted convenience sampling instead of random sampling, and only gamers were included. Therefore, it does not sufficiently represent all Chinese people. Second, collecting data using an online self-report questionnaire may increase the probability of participants giving false answers. However, this procedure is reported to be as reliable as pencil-and-paper surveys [87], which is likely to reduce social desirability and increase levels of honesty [88]. Third, this study lacked test-retest reliability of the C-MOGS; further research is required to test its stability. Finally, as a cross-sectional study, we could not infer the causality of the studied variables. Thus, longitudinal research is needed to further explore the relationship between metacognition and IGD.

Conclusion

In summary, this study offers some evidence that supports the satisfactory psychometric properties of the C-MOGS and highlights the possibility of metacognition as an independent risk factor in gaming behavior. It may be a useful and prospective tool for exploring psychological mechanisms of IGD and helping health professionals identify risky gamers (eg, individuals with more metacognitions about online gaming, specifically negative metacognitions about the uncontrollability of online gaming). Additionally, MCT may be beneficial for the prevention and treatment of IGD. This study may support more attention for metacognitive beliefs in addictive behaviors.

Abstract

Background: The video game industry has introduced a new form of monetization through microtransactions. A controversial example has been the so-called "loot boxes" (LBs) as virtual objects, which are randomized and bought with legal money. In recent years, LBs have come to connect 2 distinct problem behaviors, namely internet gaming disorder (IGD) and online gambling disorder (OGD). Many association studies have been conducted on the 3 constructs, but few have delved into the relationship of problematic use of LBs (PU-LB) with IGD and OGD.

Objective: This study aims to explore the mediating role of the PU-LB between IGD and OGD.

Methods: This cross-sectional and analytical study used incidental sampling in 24 Spanish schools. The final sample consisted of 542 participants (male: n=523, 96.5%; age: range 11 - 30 y) who played video games, bought LBs, and had gambled online in the last 12 months. Participants then completed the Spanish versions of the Internet Gaming Disorder Scale–Short Form, Online Gambling Disorder Questionnaire, and PU-LB scale.

Results: IGD scores were found to be significantly associated with both PU-LB (*r*=0.473, *P*<.001) and OGD (*r*=0.209, *P*<.001). Moreover, PU-LB was significantly associated with OGD (*r*=0.351, *P*<.001). The structural equation model results indicated that IGD had no significant direct effect on OGD (*P*=.903). However, the indirect effect of IGD on OGD through PU-LB was significant (*P*<.001). Therefore, PU-LB fully mediated the relationship between IGD and OGD. Furthermore, these results were found in the subsamples of both minors (<18 y) and young adults (≥18 y).

Conclusions: It is suggested that there is a mediation effect of problematic LB use between internet gambling and online gambling problems in both minors and young adults. This has potential practical implications by providing more evidence on how LBs have become a hinge feature between 2 clinically relevant and independent issues. In this regard, adequate industry self-regulation is needed, and effective legislation for the protection of minors is necessary.

Introduction

Video games are a form of interactive entertainment that has gained enormous popularity around the world. Video games can be seen even as a form of cultural expression because they reflect the creativity, values, beliefs, and experiences of both game developers and gamers alike [1].

According to a report by DFC Intelligence, 40% of the global population plays video games, which represents an estimated 3.1 billion people playing video games as of 2022 [2]. In 2022, the global video game industry reached a market size of approximately US $246 billion [3]. According to the Spanish Video Game Association [4], in 2022, a total of 18.2 million people in Spain were recorded as gamers (there will be more than 48 million inhabitants in 2023), with 53% being male and 47% female. According to the report, Spaniards play video games for 7.42 hours per week (8% less than in the previous report), and turnover has risen to 2012 million euros (an increase of 12% compared with the previous year). Furthermore, the age profile of Spanish video game players is mainly young, with 79% between 6 and 11 years old, 84% between 11 and 14 years old, and 71% between 15 and 24 years old [4]. In addition to the increase in video game sales, one of the factors behind this economic success lies in the incorporation of in-game purchases, which represent an increasingly large revenue stream for the industry [5,6]. In this regard, in 2023, a national study in Spain showed that 17.7% of adolescents between 14 and 18 years of age had gambled online. Of these, more than 50% claim to have gambled in the context of video games [7].

There is an ever-increasing number of video games that offer microtransactions (ie, the payment of a stipulated price for a specific, well-known skin or perk) [8]. Each video game features its own type of microtransactions, some of which are only of an aesthetic nature, while others may influence the dynamics of the game. Within the microtransactions, there is a special modality that in recent years has attracted the attention of researchers for its possible relation to random reward mechanisms: loot boxes (LBs), which are also called crates, cases, or chests. The acquisition of LBs involves the purchase of a virtual object (which can be acquired in various manifestations such as boxes, slot machines, chests, or in the form of animals), which is randomized and paid for with legal tender (this can be obtained from a prepaid card, a credit card payment or by prepurchasing currency from a game or environment to buy LBs) [9]. The fact that this virtual object is the product of a random reward is what has made it similar to gambling, as both share a random reward mechanism [9-11]. Paradigmatic examples of LBs in video games may be the case analyzed by Lemmens [12] on FIFA Ultimate Team and those analyzed by Xiao et al [13], with some of the top downloaded games for Android, such as Game of Thrones: Conquest or Pokemon GO, including LBs.

On the one hand, some primary studies have associated LB purchases with clinical problems with video games (usually assessed with questionnaires that follow the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [*DSM-5*] criteria for internet gaming disorder [IGD]). Supporting evidence for this link has been found by authors in cross-sectional studies [6,14,15], but there is hardly any longitudinal evidence [16]. On the other hand, there is more evidence of a direct relationship between the purchase of LBs and problem gambling [5,10,11,15,17-24]. However, only a few studies have related the purchase of LBs to clinical problems of online gambling (following the *DSM-5* [25] and *International Classification of Diseases, 11th Revision* [*ICD-11*] criteria) [26], and almost all these have been cross-sectional studies. One of them is the research with minors and adults by González-Cabrera et al [27] carried out in Spain with a large sample of more than 6500 participants, where 3 out of every 10 participants purchased LBs in the last 12 months. Although limited, there is also evidence of the association of these problems over time in minors, with over 50% of LB purchasers still buying after 6 months [16]. Studies have also already been conducted as adults linking LBs to gambling over time [28].

Overall, we still need to answer the possible hypotheses raised by Spicer et al [29] about LBs and gambling: either (1) users who gamble in other environments buy more LBs; (2) buyers of LBs are more likely to start gambling, through the "gateway effect"; or (3) there is a complex and dynamic relationship between both behaviors, where gambling is known to interact with other risky behaviors. In line with the latter suggestion, LBs have been related to gaming and gambling problems in minors and mostly adults [19,27,29,30]. Nevertheless, the possible mediating role of LBs between both clinical problems has been much less addressed. LBs have been a novel and relatively massive phenomenon over the past 5 years (approximately). This phenomenon has become the hinge that can bridge 2 clinical and nosological entities that appear separately in the diagnostic manuals [25] and that have not been modified in the current revision of the *DSM-5-TR* [31]. As such, a pioneering study was conducted with adults in which the mediation of microtransaction engagement between gaming and gambling was analyzed [32]. This mediating construct was assessed using the Risky Loot-Box Index (RLI) [17], which captures cognitive concern about LB use, impulsive use, and chasing losses, but it has limitations in terms of validity and reliability. In addition, this study did not use a clinical assessment tool for online gambling (and did not consider research with minors).Despite these limitations, the results were interesting as they did not achieve a complete mediation (ie, the direct relationship between video game problems and betting was also significant). Overall, the results indicate that participants with IGD were more likely to purchase microtransactions and to report more gambling-related problems. It is also possible that there have been significant changes in the consumption of LBs since the 2020 release (King et al [32]), as this business model has become increasingly common and has grown in recent years [13].

This study, based on the study by King et al [32], included 2 clinical measures of online gaming and gambling problems and an instrument with adequate validity indicators of problematic LB use. In addition, a large sample of adults and minors (often less addressed in the literature) was included, with the latter requiring special safeguards regarding the LB phenomenon as covert gambling [9]. The authors posit the hypothesis that there is no direct relationship between clinical problems with video games and online gambling, unless there is a problematic use of LBs (PU-LB) that mediates this relationship and therefore generates a significant indirect effect between the 2 clinical variables in the model. Thus, the aim was to perform a mediation of the PU-LB scale between IGD and online gambling disorder (OGD) in a sample of minors and young adults.

Methods

Design and Recruitment

This study used a cross-sectional design. The sampling was incidental and was carried out in 24 nonuniversity educational centers in 8 Spanish regions (ie, Asturias, Cantabria, Castilla la Mancha, Castilla y Leon, Comunidad de Madrid, Comunidad

Foral de Navarra, Comunidad Valenciana, and País Vasco). The educational stages covered ranged from compulsory secondary education (approximately between 11 and 16 y of age) to baccalaureate education (approximately between 16 and 18 y of age), with the addition of vocational training (where the ages range between 15 and 30 y old). This sample is part of a larger study on internet risks in adolescence. The final sample consisted of participants (both younger and older than 18 years) who had answered “yes” to the following 3 questions: have you played video games in the last 12 months, have you bought any video game LBs with money in the last 12 months, and have you gambled online in any type of game in the last 12 months?

Assessment Instruments

Participants were initially asked sociodemographic questions (gender, age, study center, and province).

IGD was assessed with the Spanish version of the Internet Gaming Disorder Scale–Short Form (IGD9-SF) [33-35]. This scale consists of 9 items based on the *DSM-5* criteria for IGD (eg, “Have you deceived any of your family, therapists, or friends about the time you spend gaming?”) [25]. The scale response options range from 0 (never) to 4 (very often). The total score ranges between 0 and 36, with greater scores suggesting higher symptom-severity of disordered gaming. In terms of internal reliability, the Cronbach α coefficient and ω coefficient in the present sample were 0.85 and 0.86, respectively.

As for OGD, this construct was evaluated with the Online Gambling Disorder Questionnaire (OGD-Q) [36]. This scale consists of 11 items that assess OGD in adolescence (eg, “Do you feel nervous, irritated, or angry when trying to reduce or stop gambling online?”). The scale response options range from 0 (never) to 4 (every day), with greater scores suggesting higher symptom-severity of disordered gambling. The total score ranges between 0 and 45. The scale Cronbach α coefficient and ω coefficient were 0.92 and 0.92, respectively.

The PU-LB scale [27], consists of 18 items assessing the potentially problematic nature of engaging in LB purchasing behavior (eg, “Loot boxes have caused problems in my life (either social, economic, family, school, or work. etc” or “I usually buy loot boxes to feel better or happier”). The scale response options range from 0 (strongly disagree) to 5 (strongly agree), with total scores ranging from 0 to 90, where higher scores suggest a more PU-LB. In relation to its internal reliability, the Cronbach α coefficient and ω coefficient in the present sample were 0.92 and 0.87, respectively.

Procedure

The survey was conducted online through the Survey Monkey platform on either a mobile device or computer. The participants were given access to and supervised by their teachers. The evaluation was carried out in educational centers (during the school timetable). The researchers previously trained the teachers in data collection. In addition, participant detection mechanisms were enabled, such as those suggested by Niessen et al [37], which included maximum response time “longstring” and “person-fit statistics.” The time needed to complete the questionnaires ranged between 5 and 15 minutes, depending on students’ age and reading comprehension.

Ethical Considerations

The study was conducted with the authorization of all the participants in the investigation and with the consent of the school directors, students, and families. Students and families’ collaboration was voluntary, anonymous, and disinterested. The project was approved by the Research Ethics Committee of International University of La Rioja (Spain) (PI007-2020 y PI001/2021), and the Juvenile Prosecutor’s Office was informed. The study received consent from all participants and school principals. Consent forms were sent to parents or guardians of participants younger than 18 years, and the purpose of the study was explained. About 0.8% of the participants did not want to respond to the questionnaire, while less than 1% of parents or guardians refused participation. Participants older than 18 years provided informed consent when completing the survey. Although there were no formal exclusion criteria, except for refusal to participate by parents or guardians for the overall sample, to be included in this study, participants had to answer affirmatively to a dichotomous question (yes or no) on whether they had played video games in the last 12 months, whether they had gambled online in the last 12 months, and whether they had bought LBs in the last 12 months. Only those who answered “yes” to each of these questions were assessed and included in the study.

Statistical Analysis

The SPSS (version 26; IBM Corp) program was used to (1) explore and screen all data through descriptive statistics; (2) test for reliability by Cronbach α, ω coefficient, and normality through skewness and kurtosis; and (3) explore the relationships between variables through bivariate correlations. The absolute values of skewness and kurtosis are normal when they are below ±3 for skewness and ±10 for kurtosis [38].

MPLUS (version 8.0; Muthen & Muthen) [39] was used to test (1) the factor structure of the PU-LB through confirmatory factor analysis (CFA) and (2) the relationships between IGD, PU-LB, and OGD through structural equation modeling analysis. The Maximum Likelihood Robust Estimator was used, and the fit of the model was estimated with the most reliable fit indices [40]: the Satorra-Bentler chi-square (S-Bχ^2), the root mean square error of approximation (RMSEA), the comparative fit index (CFI), the Tucker-Lewis index (TLI), and the standardized root mean square residual (SRMR). A model was considered to adequately fit the data at values ≥.90 for the CFI and TLI, with values above .95 preferred, and values ≤.08 for the RMSEA and SRMR [38]. The significance of mediational paths was tested by means of bias-corrected bootstrapping with 5000 samples.

Results

Participants, Descriptive Statistics, Normality, and Reliability

The sample was composed of 542 participants (male: n=523, 96.5%) who played video games, purchased LBs, and gambled online in the last 12 months. The average age of the sample was 17.78 (SD 2.78) years (age: range 11 - 30 y), out of which 47.2% (n=256) were minors ($mean_{age}$ 15.3, SD 1.71 y) and the remaining 56.3% (n=306) were young adults older than 18 years ($mean_{age}$ 19.6, SD 1.88 y). There were also 107 (19.7%) students in compulsory secondary education, 36 (6.6%) in baccalaureate education, and 399 (73.7%) in vocational training.

Descriptives, segregated by age groups (minors and adults), for all variables, including the means, SDs, and Pearson bivariate correlations between the variables of the study, are presented in Table 1. Moreover, for the total sample (minors and adults), the descriptive statistics were as follows: for IGD, mean 8.216 (SD 0.301), skewness=1.023, and kurtosis=0.858; for PU-LB, mean 12.583 (SD 14.890), skewness=1.590, and kurtosis=2.794; and for OGD, mean 4.053 (SD 7.104), skewness=2.585, and kurtosis=7.385.

IGD scores were found to be significantly associated with both PU-LB (*r*=0.473, *P*<.001) and OGD (*r*=0.209, *P*<.001). Additionally, PU-LB was significantly associated with OGD (*r*=0.351, *P*<.001).

Table . Correlation matrix, descriptive statistics for internet gaming disorder (IGD), problematic use of loot boxes (PU-LB), and online gambling disorder (OGD). The results for the minors (n=236) are shown below the diagonal. The results for adults (n=306) are shown above the diagonal.

	Variables			Minors (n=256)			Young adults (n=306)		
	IGD	PU-LB	OGD	Questionnaire Score, mean (SD)	Skew[a]	Kurt[b]	Questionnaire Score, mean (SD)	Skew	Kurt
IGD	—[c]	0.477[d]	0.229[d]	8.22 (7.07)	1.02	1.23	8.2 (7.48)	1.025	0.64
PU-LB	0.484[d]	—	0.354[d]	15.33 (14.83)	0.96	0.12	10.46 (14.6)	2.203	6.02
OGD	0.179[d]	0.410[d]	—	3.3 (6.09)	3.19	12.18	4.62 (7.75)	2.282	5.33

[a]Skew: skewness.
[b]Kurt: kurtosis.
[c]Not applicable.
[d]All correlations were significant at *P*<.001.

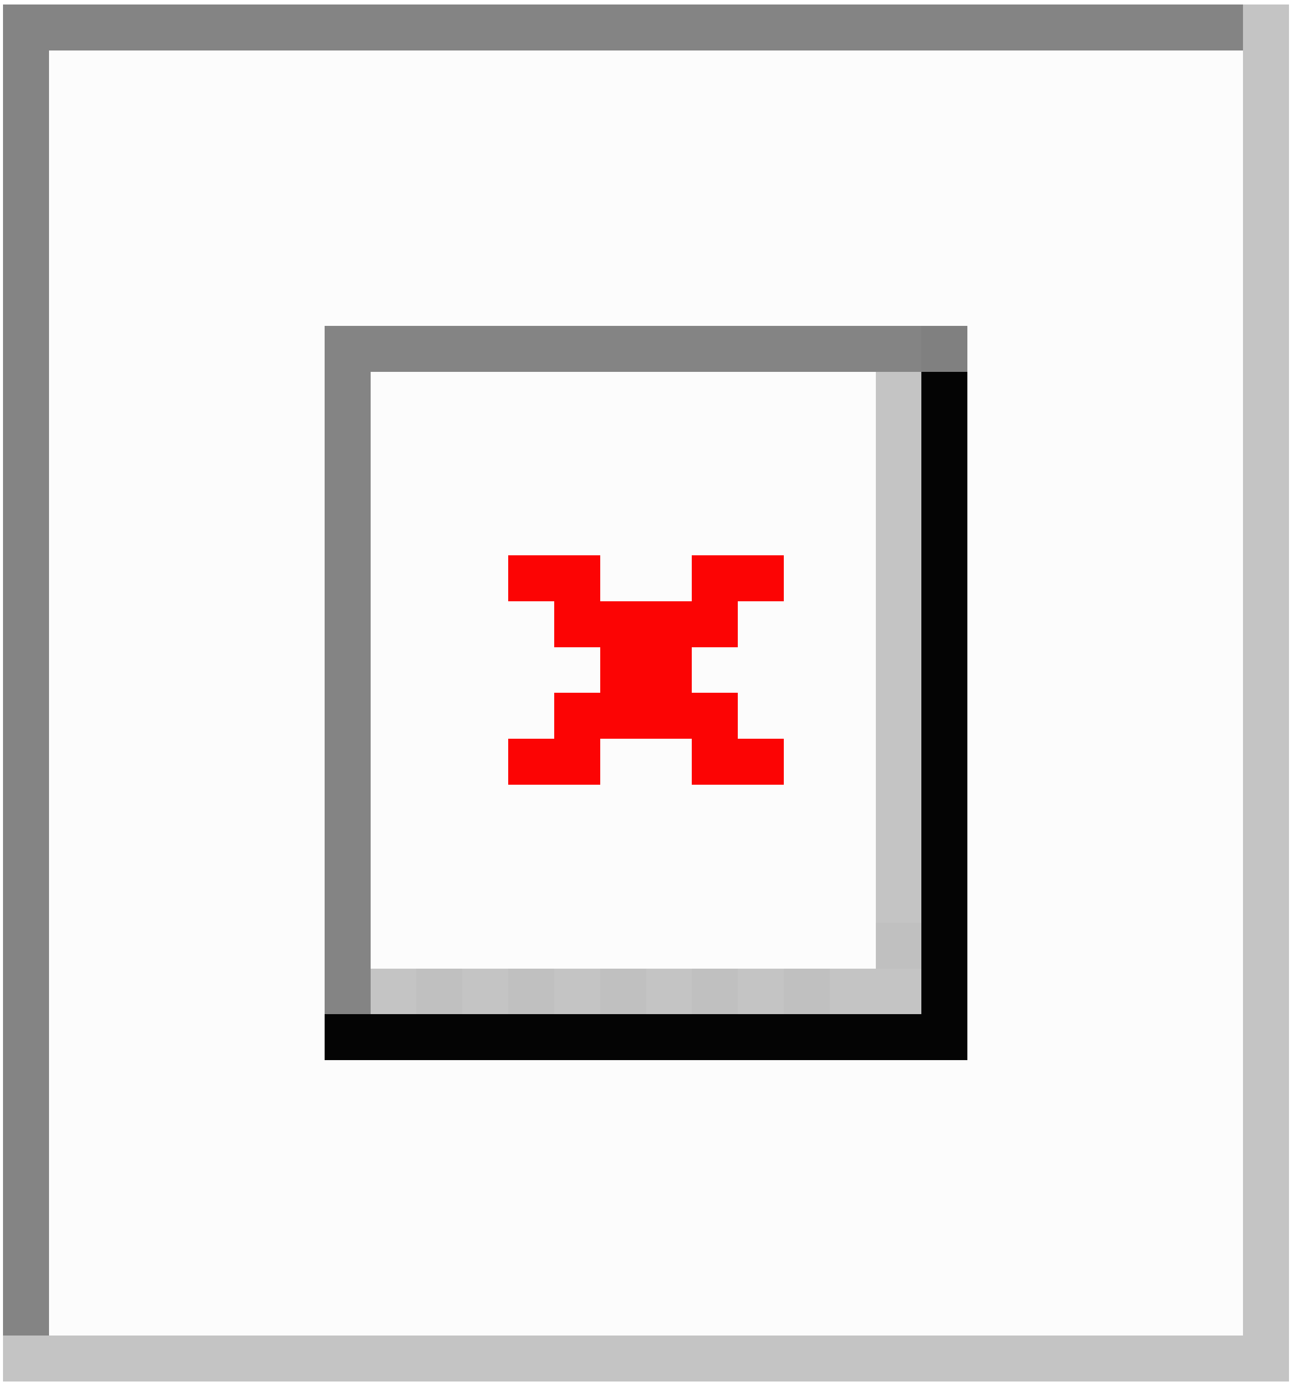
Structural Mediation Model

Before testing the structural mediation model, the CFA model of PU-LB (which had been validated through exploratory factor analysis but not through CFA) yielded some evidence for satisfactory fit (S-Bχ^2_{125}=300.207; RMSEA=.051, 90% CI .044-.058; CFI=.929; TLI=.913; SRMR=.054). The IGDS9-SF and OGD-Q had been previously validated and had shown good structural properties in previous studies [33,36].

Figure 1 displays standardized path coefficients for the structural equation modeling with the total sample and subsamples of minors and young adults. The model for the overall sample had an adequate fit (S-Bχ^2_{647}=1156.821; RMSEA=.038, 90% CI .035-.042; CFI=.924; TLI=.918; SRMR=.055). All items loading onto latent variable were significant (*P*<.001) and ranged from .45 to .86. Moreover, model for the subsample of young adults (*n*=306) (S-Bχ^2_{647}=1057.634; RMSEA=.046, 90% CI .041-.050; CFI=.910; TLI=.908; SRMR=.064), and minors (n=236) (S-Bχ^2_{647}=980.688; RMSEA=.047, 90% CI .041-.052; CFI=.892; TLI=.882; SRMR=.065), showed inconsistent indexes for CFI and TLI, and while the RMSEA and SRMR values remain acceptable, the values for the CFI fail to meet the cut-off (≥.90). However, Raykov [41] defended that CFI is a measure based on noncentrality and therefore, could be biased.

The results in the total sample indicated that IGD did not have a significant direct effect on OGD (β=.004, *P*=.903). However, the indirect effect of IGD on OGD by PU-LB was significant: (β=.223, 95% CI .131-.338, *P*<.001). Therefore, PU-LB fully mediated the relationship between IGD and OGD. In addition, these results were also found in the subsamples of minors (β=.327, 95% CI .177-.561, *P*<.001) and young adults (β=.187, 95% CI .072-.324, *P*<.001).

Figure 1. Structural equation model for IGD, PU-LB, and OGD with standardized factorial loadings. ***P*<.001; the values provided are in the format "total sample, (young adults), [minors]." IGD: internet gaming disorder; PU-LB: problematic use of loot boxes; OGD: online gambling disorder.



Discussion

The business model of many video game companies has been linked to LBs; this is worrying for many sectors of society, and this has generated wide interest in the academic and research context. Moreover, LBs appear to be a hinge that links 2 problem behaviors (IGD and OGD). In this regard, at an early stage in the study of LBs, King et al [32] conducted a mediation of microtransaction engagement between gaming and gambling in adults. There is evidence of an increase in the number of video games with LBs in recent years [13] and the difficulty for laws restricting the use of LBs to be effective [42]. The aim was of this study to perform a model that would allow us to analyze whether there would be a direct relationship between IGD and OGD in video game users who are LBs buyers and online gamblers in the last year or if, on the contrary, there would be an indirect effect thanks to the mediation of the PU-LB. The results suggest that because of the significant indirect effect (and the absence of direct effect), there is a total mediation effect. This reinforces the idea that the PU-LB may be a problem connecting 2 different problem behaviors (IGD and OGD) and that LBs, as a random reward mechanism, can be associated with gambling as a gateway or as a further gambling mechanism [29]. Thus, LBs seem to have spurred and connected 2 very pernicious issues to each other, adding a layer of complexity to the problem. Furthermore, this phenomenon is especially worrisome because minors are involved in these mechanisms (the model adjusts for the total sample and for minors and adults). From these data, important theoretical implications are derived. On the one hand, problems with gaming do not have a direct effect on gambling, and on the other hand, PU-LB generates a full mediation, justifying that hinge role. It should be noted that the entire study sample consisted of buyers of LBs, so it is not only necessary to buy them but also to present a problem with them. This is also related to the emphasis of the *ICD-11* [23] on the consequences that behavioral disorders should have. With the above, it is clear that industry mechanisms do not seem to be sufficient to regulate this process [43], nor are the governmental measures taken in some countries to curb the problem [44].

The study by King et al [32], as well as other studies, used the RLI to assess the risk of LB use [10,28,32]. In general, the RLI shows deficiencies in its psychometric validation process, as well as drawbacks for not covering other key aspects related to the problems that may arise due to the behavior of purchasing LBs (eg, impulsivity to buy more LBs, personal consequences, salience of play time or guilt, among others). For this reason, we used the PU-LB [16], which presents adequate validity and reliability indicators; its content includes validity indicators of general problems about LBs and specific indicators regarding the association among LBs, gaming, and gambling (mood regulation through the purchase or opening of LBs, postponing activities to get LBs, feeling the urge to buy them, thinking about the purchase activity or feeling bad about the time or money invested, etc). Furthermore, contributing to the pioneering work of King et al [32] is the use of clinical questionnaires (IGDS9-SF and OGD-Q) based on the diagnostic criteria of the *DSM-5* [25] and *ICD-11* [45] (including minors and adults). In this sense, there are no data to compare with, as this study has a singular focus.

This study has some relevant limitations. First, only self-report measures were used, which may generate response bias and social desirability bias. Second, there may be a retrospective recall bias, as participants were asked to think back to what they did in the last 12 months. Third, although the sample of participants was large and geographically dispersed, the sampling was not random, so it is not representative of the Spanish context. Fourth, there is an overrepresentation of male participants in the study, which is a common issue in many studies, since consumers of video games, gambling and LBs are mostly male. However, these data also indicate that boys require special attention regarding the LB problem (at least in the Spanish context). Fifth, the OGD-Q questionnaire is validated in Spanish adolescents (up to the age of 19 years) and not in adults. Although the reliability indicators are adequate, this may be a limitation of the study. Sixth, all parameters, apart from the OGD variable in the group of minors, exhibited skewness and kurtosis values indicative of a normal distribution. However, it is emphasized that the lack of normality does not pose a methodological obstacle, as a robust approach was used to effectively address the presence of nonnormal distributions in the statistical analysis. Finally, the fit indices of the model for minors are slightly below the thresholds considered good (particularly the CFI and TLI). However, this may be due to the nature of the constructs and the fact that online gambling is an illegal activity for minors; therefore, the data related to the OGD may have affected the model in general.

Given these potential limitations, future research should include longitudinal designs that take into account the variables used in this study and answer the questions posed by Spicer et al [29] on the "gateway effect" of LBs or the relationship between who opens and who purchases LBs, as opening is likely to focus more on gaming problems and purchasing is likely to focus more on gambling. As such, exploring the independent and additive effect of both roles may be an area for future research. However, this study has been able to address questions also raised by these authors in relation to the relationship between gaming and gambling problems. This study has potential practical implications by providing more evidence on how LBs have become a hinge feature between 2 clinically relevant and independent issues. While there has been very strict legislation on LBs in countries such as Belgium [42], it has not been effective because it has not been properly enforced. Despite this situation, there is still a need for politicians to properly regulate the LB framework and prevent minors from purchasing LBs. The key aspect is to enforce the law and provide resources to do so. In the Spanish context, there has been a draft bill in place since 2022 to regulate random reward mechanisms associated with interactive software products [46]. This draft bill has basic limitations such as a remarkably restrictive definition of a LB (article 3, point C), which, if approved, will be clearly insufficient. This is why, in the Spanish case, it is necessary to improve legislative efforts and add other actions. In this sense, it could help to make it a requirement for the video game industry to include information on LBs (within the framework of the Pan-European Gaming Information [PEGI] system), but this must be clear, specific, and comprehensible [43]. Finally, and perhaps most importantly, there is also a need for psychoeducational actions aimed primarily at preventing the purchase of LBs by minors. These actions should be evidence-based. Education of minors and their families is key and is the future course of action.

In conclusion, this study suggests that there is a mediation effect of problematic LB use between IGD and OGD in both minors and young adults.

Acknowledgments

This study was funded by Universidad Internacional de La Rioja (UNIR Research Plan [2022-2024]), Ministerio de Consumo (Dirección General de Ordenación del Juego-SUBV23/00022), and ITEI-UNIR (B23-006 & B24-001).

Abstract

Background: Adolescent internet gaming disorder (IGD) was associated with severe harm, including suicidal ideation. While suicidal ideation was predictive of completed suicides, further research is required to clarify the association between IGD and suicidal ideation among adolescents, as well as the mechanisms involved.

Objective: This study aimed to investigate the understudied association between IGD and suicidal ideation, as well as novel mechanisms associated with it, among Chinese adolescent internet gamers through psychosocial coping resources and psychosocial problems.

Methods: An anonymous, self-administered, cross-sectional survey was conducted among secondary school students who had played internet games in the past year in Guangzhou and Chengdu, China (from October 2019 to January 2020). In total, 1693 adolescent internet gamers were included in this study; the mean age was 13.48 (SD 0.80) years, and 60% (n=1016) were males. IGD was assessed by the 9-item Internet Gaming Disorder Checklist of the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]), while a single item assessed suicidal ideation: “Have you ever considered committing suicide in the past 12 months?” Univariate and multivariate logistic regression associations were conducted to test the significance and directions of the potential factors for suicidal ideation. The mediation mechanism was examined by structural equation modeling.

Results: Among all participants, the prevalence of IGD and suicidal ideation was 16.95% (287/1693) and 43.06% (729/1693), respectively. IGD cases were 2.42 times more likely than non-IGD cases to report suicidal ideation (adjusted odds ratio [OR] 2.42, 95% CI 1.73-3.37). Other significant factors of suicidal ideation included psychosocial coping resources (resilience and social support, both adjusted OR 0.97, 95% CI 0.96-0.98) and psychosocial problems (social anxiety: adjusted OR 1.07, 95% CI

1.05-1.09; loneliness, adjusted OR 1.13, 95% CI 1.10-1.16). The association between IGD and suicidal ideation was partially mediated by 3 indirect paths, including (1) the 2-step path that IGD reduced psychosocial coping resources, which in turn increased suicidal ideation; (2) the 2-step path that IGD increased psychosocial problems, which in turn increased suicidal ideation; and (3) the 3-step path that IGD reduced psychosocial coping resources which then increased psychosocial problems, which in turn increased suicidal ideation, with effect sizes of 10.7% (indirect effect/total effect: 0.016/0.15), 30.0% (0.05/0.15), and 13.3% (0.02/0.15), respectively. The direct path remained statistically significant.

Conclusions: IGD and suicidal ideation were alarmingly prevalent. Evidently and importantly, IGD was a significant risk factor for suicidal ideation. The association was partially explained by psychosocial coping resources of resilience and social support and psychosocial problems of social anxiety and loneliness. Longitudinal studies are needed to confirm the findings. Pilot randomized controlled trials are recommended to evaluate the effectiveness of interventions in reducing suicidal ideation by reducing IGD, improving psychosocial coping resources, and reducing psychosocial problems investigated in this study.

KEYWORDS

internet gaming disorder; suicidal ideation; adolescents; mediation; structural equation modelling; resilience; loneliness; social support; social anxiety

Introduction

Adolescent suicide is the fourth leading cause of death among adolescents aged 15-19 years [1]. A review including studies conducted in 15 countries reported age-standardized suicide rates among male and female youths aged 15-29 years ranging from 2.4 to 51 per 100,000 and from 1.1 to 16.4 per 100,000, respectively [2]. A national report showed the prevalence of suicide ranging from 8 to 11.8 per 100,000 among adolescents aged 15-20 years in China [3,4]. The spectrum of suicide includes conditions ranging from suicidal ideation (having thoughts of ending one's own life), suicidal intent (having the specific intention of ending one's own life, often including planning or preparation), suicidal attempt (having attempted to end one's own life but not resulting in death), to death [5]. Suicidal ideation increases the risk of suicidal behaviors [6]. A better understanding of the risk factors of adolescent suicidal ideation and related mechanisms is warranted.

Addictive behaviors (eg, substance use and internet addiction) are well-documented risk factors for suicidal ideation [7,8]. Internet gaming disorder (IGD), which is a subtype of gaming disorder, has been included as a mental disorder in the *ICD-11* (*International Classification of Diseases* [*11th Revision*]) published by the World Health Organization in 2018 [9]. It was associated with harmful behavioral and psychological consequences, including suicidal ideation [10]. A review of 12 cross-sectional studies found moderate-to-strong positive associations between problematic gaming and suicidal ideation [11]. However, only 1 study targeted Chinese adolescents [12]. In addition, only 1 longitudinal study conducted among Swedish adults looked at such a relationship and found that behavioral addiction (including IGD) at age 25 years significantly predicted suicidal ideation at age 28 years [13]. Understanding the mechanisms between IGD and suicidal ideation would guide the development of effective interventions. To our knowledge, however, only 1 study conducted in China had investigated 1 such potential mechanism (ie, IGD was associated with increased insomnia symptoms that led to a higher risk of depression, which in turn elevated the risk of suicidal ideation) among adolescents [12]. Research is greatly warranted to fill this knowledge gap.

The psychosocial problems of social anxiety and loneliness are potential mediators between IGD and suicidal ideation. Loneliness refers to distressing feelings that arise when there is a lack of intimate or satisfactory social connections [14]. In contrast, social anxiety refers to the perceived fear of being watched and judged by others in social situations [15]. Loneliness increases the risk of social anxiety and vice versa [16]. Furthermore, they often come together and are positively associated with mental problems, including thoughts of self-harm and suicide [17-19]. In addition, there is further support for the above-proposed mediation. First, pathological internet use (including IGD) has been postulated to cause deficient face-to-face social interactions that would lead to social isolation [20,21]. Longitudinal studies have also reported that adolescent IGD predicted social anxiety and loneliness [22,23]. Second, according to the Interpersonal-Psychological Theory of Suicide, suicidal thoughts are determined by perceived burdensomeness to others or society and thwarted belongingness [24], which is potentially associated with social anxiety and loneliness [24,25].

It is plausible that psychosocial coping resources (eg, resilience and social support) will further mediate the association between IGD and psychosocial problems (eg, social anxiety and loneliness). In that case, a serial mediation between IGD and suicidal ideation, first by psychosocial coping resources and then by social anxiety and loneliness, would occur. Regarding psychosocial coping resources, resilience is a personal resource referring to the ability to withstand and bounce back from difficult life events [26]. Social support is an interpersonal resource referring to receiving assistance or comfort from interpersonal relationships within an individual's social network [27,28]. A couple of theories support the proposed mediation between IGD and psychosocial problems through psychosocial coping resources. First, potential functional impairments of IGD (eg, problems in personal life, social relationships, and academic performance) can be seen as strong stressors [29]. According to the Resource Deterioration Model, the presence of such stressors (functional impairments of IGD in this case) would diminish coping resources (resilience and social support in this case) [30,31]. Second, the Conversation of Resource theory postulates that losses in personal and interpersonal resources (those resulting from IGD in this case) would cause psychosocial problems (social anxiety and loneliness in this case) and suicidal ideation [32-35]. Thus, this study contended that IGD would reduce both personal coping resources (resilience) and interpersonal coping resources (social support), which would then increase social anxiety and loneliness, which would, in turn, increase suicidal ideation.

The proposed mechanisms of this study have further empirical support. First, a study conducted in Taiwan reported that the IGD group showed a higher level of stress and a lower level of resilience than the non-IGD group [36], while a longitudinal study found that IGD predicted a lower level of social support among Chinese university students [37]. Second, resilience and social support were negatively associated with social anxiety [38,39], loneliness [40,41], and suicidal ideation [42,43]. Third, social anxiety and loneliness were significantly associated with suicidal ideation [17,44]. Furthermore, extant literature has reported significant mediations between psychosocial resources and mental disorders through psychosocial problems. For instance, loneliness significantly mediated the association between perceived social support and depression among Chinese rural-to-urban migrants [45].

Given the background, this study investigated the prevalence of IGD and suicidal ideation among adolescent internet gamers in 2 Chinese cities. Factors of suicidal ideation were investigated, including (1) IGD, (2) a total of 2 types of psychosocial coping resources (resilience and social support), and (3) a total of 2 types of psychosocial problems (social anxiety and loneliness). The tested mediation model contains 3 mediation paths (indirect effects) between IGD and suicidal ideation that are (1) a 2-step path, in which IGD would reduce psychosocial resources (resilience and social support), which would, in turn, increase suicidal ideation; (2) a 2-step path, where IGD would increase psychosocial problems (social anxiety and loneliness), which would, in turn, increase suicidal ideation; and (3) a 3-step serial mediation path postulating that IGD would reduce psychosocial resources (resilience and social support), which would then increase psychosocial problems (social anxiety and loneliness), which would, in turn, increase suicidal ideation. In addition, the direct path from IGD to suicidal ideation was tested.

Methods

Participants and Data Collection

A cross-sectional survey was conducted among junior middle school students in 2 metropolises (Guangzhou and Chengdu) in China from October 2019 to January 2020. Guangzhou and Chengdu had population sizes of 15.3 and 16.3 million in 2019, respectively. All eighth-grade students from 4 Guangzhou schools and all seventh to ninth grade students from 3 Chengdu schools were conveniently selected and invited to participate in this survey. Notably, the Guangzhou sample has been used in 2 previous publications whose topics were completely different from this study; one investigated the impacts of the medicalization of IGD [46], and the other validated an assessment tool for potential resource losses related to gaming time reduction [47]. The data collection procedure was, hence, the same as those in these published studies and was briefly introduced here.

In the absence of teachers, students self-administered an anonymous, structured questionnaire using paper and pencil in the classroom. Well-trained fieldworkers briefed the students about the anonymous and voluntary nature and logistics of the study, that there would be no consequences of refusing or quitting this survey at any time if wished, and that the return of the completed questionnaires would imply informed consent. The questionnaire took 30 to 40 minutes to complete. The fieldworkers also assisted with inquiries from the students if needed and did the quality check when the students submitted the questionnaire.

There were 3039 completed questionnaires (a response rate of 99.09%, 3039/3067), among which 74 participants (2.44%) were removed from data analysis due to missing data in ≥20% of the questionnaire items (n=60, 1.97%) or any missing data in the key variables (eg, IGD and suicidal ideation; n=14, 0.46%). Out of the 2965 valid responses, 1272 (42.90%) participants had not played internet games in the past 12 months (nongamers) and were excluded from data analysis. The effective sample size of this study was hence 1693 (Guangzhou: 55.46%, n=939; Chengdu: 44.54%, n=754).

Ethical Considerations

This study involved informed consent from 3 parties. First, school consent was obtained from school principals before the investigation. Second, parents were informed about the survey, and the opt-out procedure was exercised. Third, students were briefed by the fieldworkers about the anonymous and voluntary nature of this study and that the submission of a completed questionnaire would indicate informed consent, such information was also printed on the cover page of the questionnaire; no written informed consent was obtained to avoid disclosure of personal identity. No incentive was provided to school coordinators, school staff, parents, and students. This project and the above-informed consent procedures were approved by the Survey and Behavioral Research Ethics Committee of the Chinese University of Hong Kong in 2019 (SBRE-18-430).

Measurements

Sociodemographics

Information was collected about age (years), sex, whether living with both parents or a single-parent family, and self-rated household financial situations relative to the participant's classmates (5 points: very poor, poor, moderate, good, or very good). Notably, the relative financial situation had much greater predictive validity for self-reported health and well-being than the absolute financial situation [48].

Suicidal Ideation

Furthermore, 1 item assessed, "Have you ever considered committing suicide in the past 12 months?" (yes or no were the response options). The single-item assessment of suicidal ideation has shown predictive validity for passive and active suicidal ideation as well as depression [49]. In addition, previous studies have used the same or similar single items to assess suicidal ideation [12,50,51].

IGD

It was assessed by the 9-item IGD Checklist of the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]). IGD was defined as the endorsement of at least 5 of the 9 types of *DSM-5* symptoms (preoccupation, withdrawal, tolerance, inability to control internet gaming, prioritization over other activities, continuation of internet gaming despite adverse consequences, deception of internet gaming time, avoidance, and significant loss due to internet gaming) in the past 12 months (yes or no response options) [52]. The Chinese version of the checklist has been validated among Chinese adolescents and yielded satisfactory psychometric properties [53]. The Cronbach α of the scale was 0.79 in this study.

Resilience

It was assessed by the 10-item Connor-Davidson Resilience Scale [26]; its Chinese version has been validated among adolescents and showed satisfactory psychometric properties [54]. A sample item is “I can adapt to change.” The items were rated on a 5-point Likert scale (0=never to 4=always). The Cronbach α of the scale was 0.93 in this study.

Social Support

It was assessed by 2 subscales of the Multidimensional Scale of Perceived Social Support, which assessed perceived social support from family members and friends [27]. Its Chinese version has been validated among adolescents in China and showed acceptable psychometric properties [55]. A sample item is “My family members/friends really try to help me.” The items were rated on a 7-point Likert scale (1=extremely disagree to 7=extremely agree). The Cronbach α of the scale was 0.93 in this study.

Social Anxiety

It was assessed by using the 9-item social anxiety subscale of the Multidimensional Anxiety Scale for Children [56]; the Chinese version has been validated among adolescents in China and showed good psychometric properties [57]. A sample item is “I’m afraid other people will think I’m stupid.” The items were rated on a 4-point Likert scale (0=disagree to 3=always agree). The Cronbach α of the scale was 0.92 in this study.

Loneliness

It was assessed by using the 8-item short-form of the UCLA (University of California, Los Angeles) Loneliness Scale; the Chinese version has been validated among adolescents in China, which showed acceptable psychometric properties [58]. A sample item is “I feel isolation from others.” The items were rated on a 4-point Likert scale (0=never to 3=always); higher scores indicated higher levels of loneliness. The Cronbach α of the scale was 0.78 in this study.

Probable Moderate or Above Depression

It was assessed by the 9-item Patient Health Questionnaire (PHQ-9), which is a multipurpose instrument for screening, diagnosing, and monitoring the severity of depression. Its Chinese version has been validated in adolescents and showed good psychometric properties [59,60]. A sample item is “Little interest or pleasure in doing things.” The items were rated on a 4-point Likert scale on the frequency of having potential symptoms of depression in the past 2 weeks (0=not at all to 3=nearly every day). Probable moderate or above depression was defined as a PHQ-9 score ≥10 in this study; it has been used in several previous studies [61,62]. The Cronbach α of the scale was 0.93 in this study.

Statistical Analysis

IGD status and probable moderate or above depression were used in binary forms. Mean (SD, range) and frequency (proportion) were used to statistically describe continuous and categorical variables, respectively. The Chi-square (χ^2) test and independent-sample *t* test were performed to examine between-group differences regarding categorical and continuous variables, respectively. Pearson correlation coefficients (*r*) were generated to assess correlations between variables. Univariate and multivariate logistic regression analyses (adjusted for sociodemographics and probable moderate or above depression) were conducted to test the significant factors (IGD and psychosocial factors) for suicidal ideation. Unadjusted odds ratios (ORs) and adjusted ORs and their respective 95% CIs were presented.

Structural equation modeling (SEM) was fit to test the underlying mechanisms between IGD and suicidal ideation through the 4 psychosocial variables. The estimator of weighted least square mean and variance was used in SEM. A total of 2 latent variables were created: (1) the latent variable of psychosocial resources was generated from the scale scores of both resilience and social support, and (2) the latent variable of psychosocial problems was generated from the scale scores of both social anxiety and loneliness. The goodness-of-fit of the SEM model was evaluated by comparative fit index (CFI) ≥0.90 and root-mean-square error of approximation (RMSEA) ≤0.08 [63,64]. Standardized path coefficients (β) were reported.

SPSS Statistics (version 23.0; IBM Corp) and Mplus (version 7.0; Muthen & Muthen) were used for statistical analyses; *P*<.05 was considered statistically significant.

Results

Descriptive Statistics: Sociodemographics

Among all participants, the mean age was 13.48 (SD 0.80; range 10-19) years. Over half of them were male (60%, 1016/1693); about one-fifth did not live with both parents (20.08%, 340/1693) or lived in a single-parent family (15.95%, 270/1693); 12.52% (212/1693) considered their household financial situation poorer or much poorer relative to their classmates (Table 1).

Table 1. Descriptive statistics.

[a]IGD: internet gaming disorder; IGD was defined as the endorsement of 5 or more out of the 9-item IGD checklist of the DSM-5 (Diagnostic and Statistical Manual of Mental Disorders [Fifth Edition]).

[b]Probable moderate or above depression was defined as the scale score of the Patient Health Questionnaire-9 score of ≥10.

Prevalence of IGD, Probable Moderate or Above Depression, and Suicidal Ideation

The results are shown in Table 1. Over two-fifths (43.06%, 729/1693) reported suicidal ideation in the past year, and 16.95% (287/1693) were classified as IGD cases. Compared with their non-IGD counterparts (mean 13.46, SD 0.79), those with IGD (mean 13.60, SD 0.81) were more likely to be older (*P*=.01), belonging to the Chengdu sample (185/287, 64.46% vs 569/1406, 40.47%), and male (203/287, 70.73% vs 813/1406, 57.82%), and self-reported poor or very poor relative household financial situation (57/287, 19.86% vs 155/1406, 11.02%). The prevalence of probable moderate or above depression (PHQ-9 score≥10) was 30.77% (521/1693); the mean score of PHQ-9 was 7.29 (SD 6.82, range 0-27). IGD was significantly and positively associated with both probable moderate or above depression (172/287, 59.93% vs 349/1406, 24.82%; *P*<.001) and suicidal ideation (197/287, 68.64% vs 532/1406, 37.84%; *P*<.001).

Levels of Psychosocial Resources and Psychosocial Problems

The mean scores of the resilience, social support, social anxiety, and loneliness scales were 23.07 (SD 8.73, range 0-40), 38.30 (SD 11.73, range 8-56), 12.70 (SD 7.14, range 0-27), and 15.78 (SD 5.04, range 8-32), respectively. The IGD group had significantly lower levels of psychosocial resources of resilience and social support and higher levels of psychosocial problems of social anxiety and loneliness than their counterparts (moderate to strong effect sizes; Cohen *d*=0.49-0.79; Table 2).

Table 2. Between-group differences in psychosocial resources and problems by IGD status (N=1693).

	Range	Overall, mean (SD)	IGD[a], mean (SD)	Non-IGD, mean (SD)	*P* value	Cohen *d*
Psychosocial resources						
Resilience	0-40	23.07 (8.74)	19.68 (7.84)	23.76 (8.75)	<.001	0.49
Social support	8-56	38.30 (11.73)	33.18 (11.63)	39.34 (11.48)	<.001	0.53
Psychosocial problems						
Social anxiety	0-27	12.70 (7.14)	15.80 (6.35)	12.08 (7.13)	<.001	0.55

[a]IGD: internet gaming disorder.

Correlations

[Table 3](#) shows the significant positive correlations between resilience and social support (psychosocial coping resources; *r*=0.50) and between loneliness and social anxiety (psychosocial problems; *r*=0.48). The 2 psychosocial resource variables were negatively correlated with the 2 psychosocial problems (*r*=–0.40 to –0.13).

Table 3. Correlation analysis (n=1693).

Factors of Suicidal Ideation

Similar to the results of the univariate logistic regression analysis, multivariate logistic regression adjusting for the sociodemographics and probable moderate or above depression reported that increases in psychosocial coping resources of resilience (adjusted OR 0.97, 95% CI 0.96-0.98) and social support (adjusted OR 0.97, 95% CI 0.96-0.98) were associated with a lower risk of suicidal ideation while increases in IGD (adjusted OR 2.42, 95% CI 1.73-3.37) and psychosocial problems of social anxiety (adjusted OR 1.07, 95% CI 1.05-1.09) and loneliness (adjusted OR 1.13, 95% CI 1.10-1.16) were associated with a higher risk of suicidal ideation (Table 4).

Table 4. Univariate and multivariate logistic regression analysis on the individual associations between independent variables and suicidal ideation (n=1693). There are 10 individual models in total, 5 for univariate logistic regression and the other 5 for multivariate logistic regression.

	Unadjusted OR (95% CI)	*P* value	Adjusted OR[a] (95% CI)	*P* value
Psychosocial resources

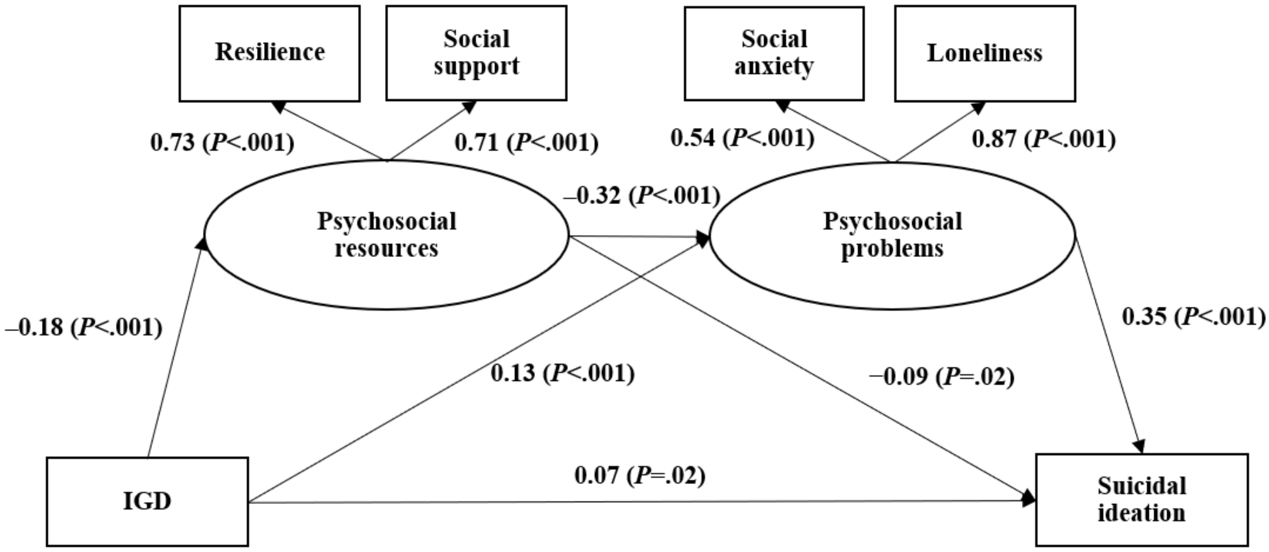
Structural Equation Modeling

Figure 1 presents the results of SEM testing the proposed mediation effects of psychosocial coping resources and psychosocial problems between IGD and suicidal ideation. The model showed satisfactory goodness-of-fit (χ^2_{21}=176.21, *P*<.001; CFI=0.92; RMSEA=0.07), with factor loadings of the 2 latent variables ranging from 0.54 to 0.87 (all *P*<.001). The results showed that IGD had a significant direct effect on suicidal ideation (β=.07, *P*=.02). In addition, IGD was linked to suicidal ideation through 3 indirect paths: (1) a 2-step mediation path involving a negative association between IGD and the latent variable of psychosocial coping resources (β=–.18, *P*<.001), which was negatively associated with suicidal ideation (β=–.09, *P*=.02); (2) a 2-step mediation path involving a positive association between IGD and the latent variable of psychosocial problems (β=.13, *P*<.001), which was positively associated with suicidal ideation (β=.35, *P*<.001); and (3) a 3-step serial path involving a negative association between IGD and the latent variable of psychosocial coping resources (β=–.18, *P*<.001) and then a negative association between psychosocial coping resources and psychosocial problems (β=–.32, *P*<.001), which was in turn positively associated with suicidal ideation (β=.35, *P*<.001). Partial mediations were found as the direct path from IGD to suicidal ideation was of statistical significance. The corresponding mediation effect size of the above 3 indirect paths were 10.7% (indirect effect/total effect: 0.016/0.15), 30.0% (0.05/0.15), and 13.3% (β=.02/0.15, *P*<.001), respectively.

Figure 1. Structural equation modeling testing the mediation effect of psychosocial coping resources and psychosocial problems between internet gaming disorder (IGD) and suicidal ideation (standard coefficients were reported).



Discussion

Principal Findings

This survey was conducted among Chinese adolescents and found that IGD increased the risk of suicidal ideation. Both protective factors of psychosocial resources (resilience and social support) and risk factors of psychosocial problems (social anxiety and loneliness) for suicidal ideation were also identified. Furthermore, this study was novel to reveal the serial mediation mechanisms through psychosocial resources and psychosocial problems between IGD and suicidal ideation, which provide empirical evidence for future interventions targeting suicidal ideation as a negative consequence of IGD.

Comparison With Previous Work

This study observed the alarmingly high prevalence of suicidal ideation of 43.06% (729/1693) among junior middle school students in 2 Chinese cities, which was higher than that of studies previously conducted in adolescents of other Chinese cities (18.2%-27.2%) [12,65], Poland (24.7%) [51], and Japan (25.7%) [66] based on the same measurement of suicidal ideation. Notably, this study was conducted before the COVID-19 pandemic period. A study conducted on Canadian adolescents reported that the prevalence of suicidal ideation has tripled to 44% since the beginning of the COVID-19 pandemic [67]. The prevalence of adolescent suicidal ideation during the pandemic period in China might have also increased due to the suspension of classes and interruptions of social interactions and activities. As suicidal ideation predicts suicidal behavior, early detection, together with timely and evidence-based secondary interventions, are greatly warranted [68,69].

Corroborating previous cross-sectional and longitudinal findings [11,13], this study found a strong association between adolescent IGD and suicidal ideation. In addition, the high prevalence of IGD of 16.95% (287/1693) was reported among adolescent gamers in this study. Previous studies found a similarly high prevalence among adolescents in China [12,70], which was higher than the global prevalence estimate of 3.1% [71]. It was suggested by some researchers that Asian adolescents tend to have higher IGD prevalence than those in Western countries [72]. Such findings highlight the importance of preventing and treating adolescent IGD, which was associated with various negative consequences, including depression, sleep problems, and physical violence [10,23]. A review summarized several efficacious intervention strategies for the purpose, including psychotherapies such as mindfulness, gaming-specific cognitive behavioral therapy, basic counseling and support groups, family therapy, gaming abstinence, self-discovery camp, and residential camp and parent management [73].

A novel finding of this study is about the mediation mechanisms between IGD and suicidal ideation through psychosocial coping resources (resilience and social support) and psychosocial problems (social anxiety and loneliness). As the direct effect of IGD on suicidal ideation remained statistically significant, the association between IGD and suicidal ideation was partially mediated by 3 indirect paths. These findings add empirical evidence to support the theoretical postulations of the Interpersonal-Psychological Theory of Suicide [24], the Resource Deterioration Model [30,31], and the Conservation of Resource Theory [32-35] aforementioned in the Introduction section. In comparison, the 2-step indirect path that IGD increased psychosocial problems, which then increased suicidal ideation, explained a larger proportion of the association between IGD and suicidal ideation than the other 2-step path and the 3-step path. Psychosocial problems might thus have explained more harmful effects of IGD on suicidal ideation than losses in psychosocial resources. Notably, as these 3 indirect paths only showed an overall partial mediation effect, other unstudied plausible mediators may exist. Examples include health problems (eg, sleep quality), psychological well-being (eg, life satisfaction and quality of life), and stress, which were associated with both IGD and determinants of suicidal ideation [74,75].

Notably, the multivariate logistic regression analyses and SEM in this study were adjusted for depression in addition to sociodemographics. As this study aimed to understand the relationship between IGD and suicidal ideation, given the known associations between depression and IGD [10], suicidal ideation [43], and the 4 psychosocial mediators [45,76], the adjustment for depression could ensure that the relationship of interest would not have been confounded by depression. A similar approach has been used in the extant literature investigating the independent associations between both risk and protective factors and suicidal ideation [43,77].

This study has added empirical evidence to the knowledge that psychosocial coping resources of resilience and social support are protective factors, while psychosocial problems are risk factors for adolescent suicidal ideation. There are thus reasons to believe that modification of these 4 psychosocial variables would reduce suicidal ideation directly and indirectly by reducing the harmful impact of IGD on suicidal ideation. Enhancement of psychosocial resources would also reduce psychosocial problems and the impact of IGD on psychosocial problems. Furthermore, according to a meta-analysis, interventions focusing on psychoeducation and social cognitions were efficacious in reducing loneliness and social isolation. Related interventions included guided social group participation, psychological therapy sessions, self-management, and training enhancing social and emotional skills, social interaction, and social support [78]. Another meta-analysis reported that resilience-improving interventions based on a combination of cognitive behavioral therapy and mindfulness techniques were able to improve resilience and overall well-being (eg, lower levels of anxiety) [79]. Future interventions may consider these approaches.

Strengths and Limitations

This study was novel to investigate the harmful effect of IGD on suicidal ideation among Chinese adolescents and reveal the serial mediation mechanism potentially explaining this association through psychosocial resources and psychosocial problems. The results are implicative for future interventions. However, this study has other limitations. First, although using a single item to assess suicidal ideation has been widely used in the literature [67,68], such an assessment may be subject to misclassification (ie, false negative cases are those having suicidal ideation who were not screened out by the single-item question) in comparison with the multi-item assessment [68]. It may lead to an underestimation of the prevalence of suicidal ideation in this study and implies an alarmingly higher prevalence of suicidal ideation in Chinese adolescents. Second, social desirability bias may exist as the questions regarding IGD symptoms and suicidal ideation are sensitive and socially undesirable. Third, the cross-sectional study design precluded inference of temporal or causal relationships; future longitudinal and intervention studies are needed to confirm the findings. Fourth, the study population was conveniently selected from 7 schools in 2 Chinese cities; generalization of the results to other regions and populations in China and other countries should be made cautiously. Fifth, the relationships among IGD, psychosocial coping resources, and psychosocial problems may be bidirectional, as the literature also reported that resilience, social support, social anxiety, and loneliness were predictors of IGD [22,80-83]. Finally, some potential mediators between IGD and suicidal ideation (eg, sleep quality, psychological well-being, and stress) had not been investigated in this study.

Conclusions

In conclusion, this study observed alarmingly high levels of both IGD and suicidal ideation among adolescents in 2 Chinese metropolises. Very importantly and corroborating previous studies, a strong and positive association between IGD and suicidal ideation was found in this study, indicating that IGD may potentially lead to adolescent suicide. Adolescents and stakeholders (parents, teachers, and health workers) need to be made aware of the potential risk of IGD in elevating suicidal ideation. Future studies should also investigate factors moderating such a relationship. Furthermore, it is important and novel that this study revealed the mechanism of such an association, which included 3 indirect paths through psychosocial resources (resilience and social support) and psychosocial problems (social anxiety and loneliness) between IGD and suicidal ideation. Longitudinal and intervention studies are warranted to confirm these findings and explore other mechanisms. Tailor-made modifications of these psychosocial variables (especially psychosocial problems) may directly and indirectly reduce the harmful impacts of IGD on suicidal ideation.

Acknowledgments

This research was funded by the Shanghai Pujiang Programme (23PJC018) and the Young Scientists Fund of the National Natural Science Foundation of China (82304258). We would like to thank the participants for their contribution to this study.

In “Effects of Virtual Reality Therapy for Patients With Breast Cancer During Chemotherapy: Randomized Controlled Trial” (JMIR Serious Games 2024;12: e53825) the authors noted two errors.

Affiliation 2 was previously listed as:

> *National Cancer Center, National Clinical Research Center for Cancer, Cancer Hospital & Shenzhen Hospital*

This has been changed to the following:

> *National Cancer Center, National Clinical Research Center for Cancer, Cancer Hospital & Shenzhen Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College*

As this affiliation was also included in the corresponding author’s address, the address has been modified in that location as well.

Additionally, the authorship’s degrees were previously listed as:

> *Mengdan Li, MD; Zhifu Yu, MD; Hui Li, MD; Li Cao, BM; Huihui Yu, MD; Ning Deng, PhD; Yunyong Liu, MD*

These have been replaced as follows:

> *Mengdan Li, MPH; Zhifu Yu, MPH; Hui Li, MSN; Li Cao, BSN; Huihui Yu, MPH; Ning Deng, MD; Yunyong Liu, MM*

The correction will appear in the online version of the paper on the JMIR Publications website on November 6, 2024, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Submitted 19.10.24; this is a non–peer-reviewed article;accepted 22.10.24; published 06.11.24.

Abstract

(JMIR Serious Games 2024;12:e63113) doi:10.2196/63113

In "Efficacy of a Virtual 3D Simulation–Based Digital Training Module for Building Dental Technology Students' Long-Term Competency in Removable Partial Denture Design: Prospective Cohort Study" (JMIR Serious Games 2024;12:e46789) the authors made one addition.

The "Acknowledgments" section has been amended within the manuscript to read as follows:

> *KXL and YQX are co-first authors of this work, and XHZ and MWP are co-corresponding authors (XHZ can be reached at haoxiaohan_buaa@163.com for correspondence).*
>
> *The engineers' group from Beijing Unidraw Virtual Reality Technology Research Institute Co. Ltd., led by XZ, helped develop the Objective Manipulative Skill Examination of Dental Technicians system, including the digital removable partial denture module. The Zhaozhi student team assisted in the early design and pre-experimental data collection for the digital removable partial denture module. This research was funded by the CQMU Program for Youth Innovation in Future Medicine (W0002 for LJ), and the Chongqing Municipal Teaching Reformation Fund (193070 for XF).*

The correction will appear in the online version of the paper on the JMIR Publications website on August 19, 2024, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

(JMIR Serious Games 2024;12:e57714) doi:10.2196/57714

KEYWORDS

digital mental health interventions; mental health; psychiatry; gaming; serious games; casual video games; commercial games; exergames; adolescent; anxiety; teenage; video game; youth

In their exploratory study, Pine et al [1] unveil promising results indicating the potential therapeutic benefits of using casual video games. While caution is necessary, particularly concerning the interpretation of student feedback, self-assessment effectiveness, recruitment, pandemic effects, and the absence of mental distress screening, the study demonstrates that video games integrating brief mental health messages provide a promising approach to merging digital intervention with the accessibility of commercial gaming. Although a randomized controlled trial is also required for precise clinical impact assessment, these preliminary findings bolster the notion that "gaming" (primarily commercial video games, serious games, and exergames) within mental health services is validated as a viable alternative or complement to conventional methods of prevention, assessment, and treatment.

Gaming, in a broad sense, is one of the most popular leisure activities globally, estimated to involve millions of gamers worldwide [2], making it ubiquitous and omnipresent, regardless of whether one has a mental illness or not. Considering the growing disparity between demand and supply for mental health assistance, combined with factors such as high disease burden, treatment costs, and long waiting lists, new alternative solutions must be explored. Coupled with accelerating technology-based game development and popularity, it may just be a matter of time before gaming truly disrupts several aspects of psychiatric work.

At present, gaming research has been conducted in the context of different psychiatric disorders such as anxiety, depression, eating disorders, attention-deficit/hyperactivity disorder (ADHD), stress symptoms, posttraumatic stress disorder (PTSD), autism, phobias, and schizophrenia, as well as in forensic psychiatry. The results vary, but reduced symptomatology, improved social, executive, and cognitive functions, as well as improved attention processes and problem-solving, have been reported. Gaming has also proven effective in offering temporary distraction from serious events, and it fosters social communities [3].

However, there are several challenges to research and practical application of gaming in mental health services. Moreover, there are critical concerns regarding the limited number of high-quality studies; weak research designs; methodological issues; and questions about generalizability, causality, mechanisms of action, control groups, effect sizes, definitions, terminology, comparability, theoretical strength, harmful effects, and transferability [2,3]. In addition, critics highlight concerns, such as gaming disorders as outlined in the *ICD-11 (International Classification of Diseases 11th Revision)*, prolonged sedentary screen time, exposure to violence, and instances of excessive or problematic gaming behavior [2,4]. Furthermore, critics argue that gaming encourages avoidance tactics, hindering physical interactions within communities. This challenge is compounded by distant communication, escapism, isolation, loneliness, emotional detachment, addiction, sleep disturbances, and physical inactivity, all posing risks of worsening the individual's condition. Critics argue gaming is not a treatment strategy but rather a tool for enhancing communication and presence among individuals.

Research and applications of gaming in psychiatry are expanding and proving beneficial for specific patient demographics, yet there is a pressing need for a more robust knowledge base to fully grasp both the potentials and challenges involved [5]. Capitalizing on these opportunities for clinical use will demand innovative thinking within multidisciplinary research environments [2]. In conclusion, it is evident that gaming, which is deeply embedded in our culture, possesses promising yet unexplored avenues to emerge as a vital component in forthcoming treatments for mental disorders.

Abstract

Background: Artificial intelligence (AI) and game-based methods such as serious games or gamification are both emerging technologies and methodologies in health care. The merging of the two could provide greater advantages, particularly in the field of therapeutic interventions in medicine.

Objective: This scoping review sought to generate an overview of the currently existing literature on the connection of AI and game-based approaches in health care. The primary objectives were to cluster studies by disease and health topic addressed, level of care, and AI or games technology.

Methods: For this scoping review, the databases PubMed, Scopus, IEEE Xplore, Cochrane Library, and PubPsych were comprehensively searched on February 2, 2022. Two independent authors conducted the screening process using Rayyan software (Rayyan Systems Inc). Only original studies published in English since 1992 were eligible for inclusion. The studies had to involve aspects of therapy or education in medicine and the use of AI in combination with game-based approaches. Each publication was coded for basic characteristics, including the population, intervention, comparison, and outcomes (PICO) criteria; the level of evidence; the disease and health issue; the level of care; the game variant; the AI technology; and the function type. Inductive coding was used to identify the patterns, themes, and categories in the data. Individual codings were analyzed and summarized narratively.

Results: A total of 16 papers met all inclusion criteria. Most of the studies (10/16, 63%) were conducted in disease rehabilitation, tackling motion impairment (eg, after stroke or trauma). Another cluster of studies (3/16, 19%) was found in the detection and rehabilitation of cognitive impairment. Machine learning was the main AI technology applied and serious games the main game-based approach used. However, direct interaction between the technologies occurred only in 3 (19%) of the 16 studies. The included studies all show very limited quality evidence. From the patients' and healthy individuals' perspective, generally high usability, motivation, and satisfaction were found.

Conclusions: The review shows limited quality of evidence for the combination of AI and games in health care. Most of the included studies were nonrandomized pilot studies with few participants (14/16, 88%). This leads to a high risk for a range of biases and limits overall conclusions. However, the first results present a broad scope of possible applications, especially in motion and cognitive impairment, as well as positive perceptions by patients. In future, the development of adaptive game designs with direct interaction between AI and games seems promising and should be a topic for future reviews.

Introduction

Background

Artificial intelligence (AI) and serious games are both relevant topics in the health sector, and the body of studies and literature is continuously growing. Interestingly, in terms of the research landscape, the 2 topics are not connected; rather, existing research views them independently.

The use of games for educational and serious purposes is nearly as old as the history of humankind and is an integral part of our culture [1]. In 1970, Abt [2] used the term "serious games" for the first time in his book with the same name. Sawyer and Smith [3] take a broad definition and consider serious games as "any computerized game whose chief mission is not entertainment and all entertainment games which can be reapplied to a different mission other than entertainment." What serious games have in common is that they pursue a concrete (pedagogical) intention and aim to provide information on a specific topic (eg, health) that is accessible in an entertaining and interactive way to deepen competencies or to achieve a change in behavior [4].

Serious games for health can be used in the fields of medical diagnostics, therapy, and prevention, as well as health promotion and medical or patient education [5]. From a didactic and learning psychology perspective, the effect of serious games is based on the integration of the motivating and multimedia aspects of computer and video games. Serious games can increase engagement, motivation, enthusiasm, and interest [6,7]. There are several existing use cases in health contexts [8-11]. One example is the game EndeavorRx. In 2020, the US Food and Drug Administration permitted its marketing as the first game-based digital therapeutic device to improve attention function in children with attention-deficit/hyperactivity disorder (ADHD) [12]. The game Re-Mission was developed for children with cancer and showed good results regarding compliance and the understanding of disease-related issues in the target group [13]. EMERGE is a simulation game that recreates an emergency department in real time to improve the clinical reasoning skills of physicians [14].

Next to serious games, gamification has emerged as a major trend in the health sector, which is reflected in a growing number of publications, including several meta-analyses [15-17]. The most used definition of this concept is "the use of game design elements in non-game contexts" [18]. The motivational effect of the game elements can be explained in different ways. Sailer et al [19] established the link between various gamification elements (eg, points, leaderboards, and badges) and the self-determination theory proposed by Ryan and Deci [20]. As a theory of motivation, this defines three universal psychological basic needs that determine human action: (1) competence, (2) autonomy, and (3) social inclusion. If ≥1 of these needs are addressed (eg, through gamification elements), this has positive effects on behavior and its determinants [19]. In the health sector, there are numerous studies that have demonstrated the effects of using gamification on motivation, performance, engagement, health, and well-being status [5,21,22].

According to Westera et al [23], computer games have been linked with AI since the first computer was programmed to play chess [24]. New AI methods have been used in computer games, for instance, to generate levels, scenarios, and storylines; to balance complexity; or to add intelligent behaviors to nonplayer characters (NPCs) [25]. However, over the years, various authors have pointed at the marginal penetration of academic game AI methods in industrial game production [26]. AI techniques will become indispensable to coordinate the ever-growing complexity and dynamics of games [23]. AI-driven adaptation and assessment systems are used to offer learner-centered environments [27]. As an example, NPCs controlled by AI can adapt to the behavior of the gamer and can enrich immersive and challenging experiences within the game play.

When transferring these principles to health care, the interaction between AI and games could provide a benefit, especially in the management of chronic diseases, which most game designs already target. The possibility to quickly adapt to new game-generated data or performance and provide live feedback could lead to more individual and thus more patient-centered game design in both illness detection and treatment. This could increase motivation and engagement for patients, leading to higher therapy adherence through more personal involvement. The vast body of evidence in the field of serious games and gamification, along with the growing body of evidence in the use of AI, may thus form a new field of research.

Scope

Therefore, this scoping review sought to generate an overview of the currently existing literature on the interaction of AI and game-based approaches in health care. At this point, to the best of our knowledge, this is the only review that targets this interaction.

The primary objective was to analyze the current body of evidence based on (1) the disease or health issue being evaluated, (2) the process of care in which these projects are located, and (3) the kind of AI and type of game-based approach used and the interaction of both techniques.

A secondary objective was to obtain an overview of publications on the interaction of AI and game-based approaches such as serious games, gamification, commercial games, and game periphery. Another secondary objective was to analyze the quality of the existing studies in this field regarding their grade of evidence and the conducted study types.

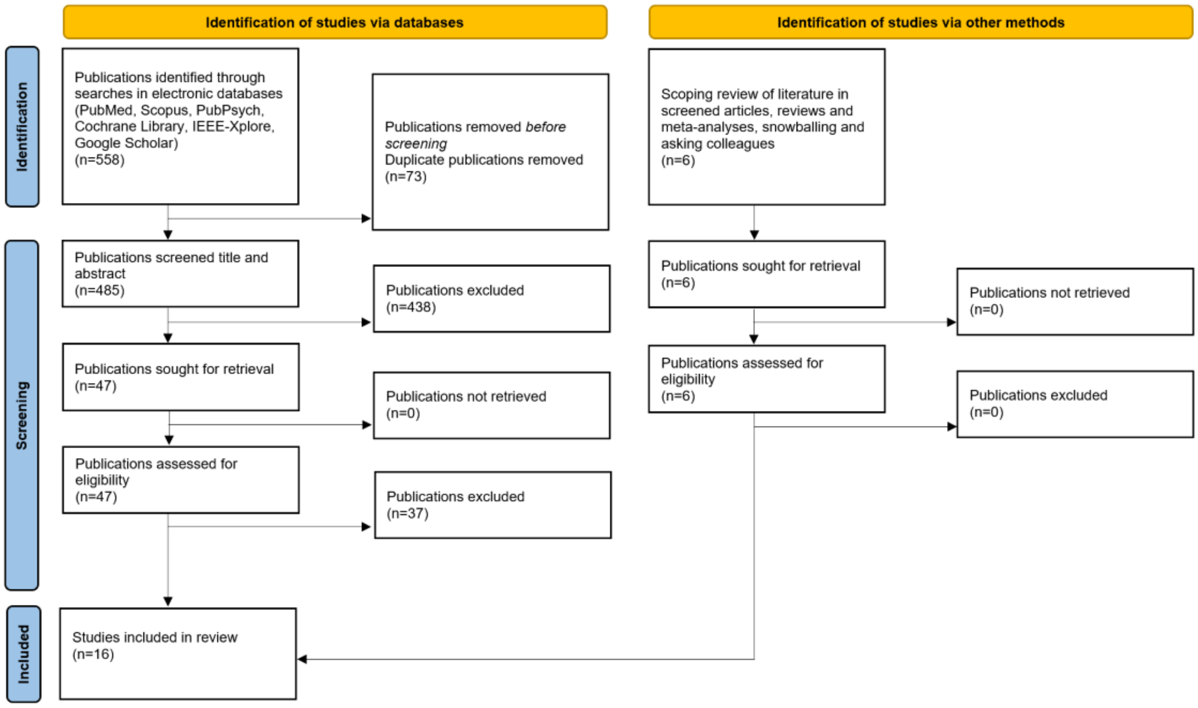
Methods

Overview

For this scoping review, we applied the PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols; Figure 1) guidelines [28]. Furthermore, we used the recommendations of the Cochrane Consortium for conducting systematic reviews and the RefHunter website as guidance [29].

Before starting the review process, we defined the inclusion and exclusion criteria (Textbox 1).

Figure 1. PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols) flow diagram.



Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Article type: original study, journal article, or conference paper
- Article scope: articles report the use of artificial intelligence (AI), machine learning, and deep learning in combination with game-based approaches (serious games, gamification, and game-based-learning)
- Health profession: medicine
- Area of application: articles that conducted research in the field of education, therapy, and health
- Language: English
- Publication period: last 20 years

Exclusion criteria

- Article type: opinion, commentary, or letter to the editor
- Article scope: not related to AI and game-based approaches
- Health profession: other than medicine
- Area of application: not related to health and medicine
- Language: not in English
- Publication period: published >20 years ago

For this review, we conducted the following steps:

1. Literature search
2. Title and abstract screening
3. Content screening
4. Further in-depth screening (snowballing method and asking colleagues)

Step 1: Literature Search

We applied the search terms primarily in the database PubMed on February 2, 2022. We tested and honed different search terms and Boolean operators (Multimedia Appendix 1) until sufficiently fitting results seemed to have been obtained (n=305). The final search term was defined as follows:

[“game” OR “gamification”] AND “artificial intelligence”

The search was extended to more open databases to assess studies that target AI and serious games in medicine-related research areas or interprofessional approaches that may include medical professions and in more technically oriented databases such as IEEE Xplore [30] to include papers from informatics and engineering with a focus on technical issues.

The same search term ([“game” OR “gamification”] AND “artificial intelligence”) AND “artificial intelligence”) was used for IEEE Xplore (n=98), Cochrane Library [31] (n=25), and PubPsych [32] (n=89). In Scopus, the search term used in the other databases showed fewer results and were modified to extend the range of hits (“serious” AND “game” AND “artificial intelligence”; n=41).

In addition, we conducted a search in Google Scholar [33]. However, the results from Google Scholar were not precise enough for inclusion in a review, which is consistent with the results of several studies [34-36].

After deduplication using Rayyan software (Rayyan Systems Inc), the combined search in these databases identified 545 (97.7%) publications out of the initial 558 identified. We then performed a manual deduplication, which resulted in 60 (11%) of the 545 publications being excluded; thus 485 (89%) publications remained (Multimedia Appendices 1 and 2; Multimedia Appendix 3 [37-51]).

Step 2: Title and Abstract Screening

For the second step of the scoping review (title and abstract screening), we used Rayyan software. The results from the literature search were transferred to the citation software Zotero (version 5.0.85; Rayyan) and to Rayyan software [52]. This software automatically identified duplicates. After iterative deduplication, the publications were subjected to manual screening. The first screening step was conducted using Rayyan and permitted publication inclusion based on their titles and abstracts. Given the volume of the publications to be screened, the title and abstract screening was distributed among 2 authors of this paper (JS and DT). To ensure the uniformity of the screening, the authors conducted several training sessions in Rayyan with the coreviewers. In addition, the authors randomly double-checked some of the excluded publications (25/485, 5.2%) to warrant the consistency of the screening by the other reviewer. This step was conducted independently by both researchers and was followed by a discussion of the results between the 2. As all analysis steps were conducted independently by the 2 researchers, a discussion of differently categorized literature (marked as “Conflict” in Rayyan) and subsequent adaptation were necessary in this step. Overall, only a few adjustments were necessary, and a good agreement between the 2 researchers could be reached. Possible conflicts and all included articles were discussed with a third team member (SK). The data generated by Rayyan can be found in Multimedia Appendix 2.

Step 3: Content Screening

After the primary screening, full-text publications were screened by the 2 lead authors. Toward this end, a table was prepared to compile relevant information (Textbox 2).

Textbox 2. Information compiled for full-text screening.

Relevant details obtained

- Authors, year, title, journal, and digital object identifier (DOI)
- Study type (according to Röhrig et al [53])
- Population, intervention, comparison, and outcomes (PICO) criteria
- Subject (topic of the study)
- Level of evidence (according to the Oxford Centre for Evidence-Based Medicine: Levels of Evidence [54])
- Disease or health issue
- Level of care (prevention, diagnostics, therapy, rehabilitation, nursing, organization or monitoring, and other [55])
- Game variants (serious games, gamification, games, and game controller or periphery)
- Artificial intelligence (AI) technology (machine learning, deep learning, and AI [not further specified])
- Function type (promoting health literacy, analysis and cognition, indirect intervention, direct intervention, documentation of health and medical history, organization and administration, and purchasing and supply) [56]

Some of the studies (4/16, 25%) showed an overlap among different categories (eg, in level of care). In these cases, double classifications were performed. All eligible studies were categorized and coded in detail (Multimedia Appendix 3 [37-51]).

Step 4: Further In-Depth Screening (Snowballing Method and Asking Colleagues)

After conducting the scoping review, we additionally used the “snowballing” approach described by Greenhalgh and Peacock [57], who have stated that in reviews of complex and heterogeneous evidence, formal protocol-driven search strategies may fail to identify important evidence. Informal approaches such as browsing and asking colleagues can substantially increase the efficiency of search efforts. Snowballing methods such as pursuing references of references and electronic citation tracking are very useful for identifying high-quality sources in obscure locations. Therefore, to validate the results of the review, the 2 reviewers searched the literature references used in meta-analyses, reviews, and papers that were closely related to the topic of the search. In addition to using the snowballing method, the method of asking colleagues, as recommended by Greenhalgh and Peacock [57], was applied as a last step.

Results

Overview

When applying the aforementioned search terms, we initially identified 335 studies on the topic of games and the use of AI in health care in the last 20 years. The subsequently performed step of title and abstract screening reduced the number of the initially identified studies from 335 to 47 (14%). In the next step, assessing the actual full-text literature, of the 47 papers, 3 (6%) were excluded because their full text was not in English, and the aforementioned inclusion and exclusion criteria were applied to the remaining 44 (94%). After the full-text screening, 10 (23%) of the 44 papers met all inclusion criteria. Using the snowballing method, 1 additional paper could be identified. Asking colleagues revealed 5 additional papers, which led to an overall total of 16 eligible papers (Figure 1). Not all criteria showed hits (eg, function type showed hits only in 2 categories, whereas level of care showed no hits in nursing).

Categories

Overview

The eligible papers showed a clear emphasis on certain categories (Table 1). Regarding the targeted diseases, the field of motion impairment was investigated the most (5/16, 31%). Cognitive impairment was targeted in 19% (3/16) of the studies, phantom limb pain or limb absence in 19% (3/16), rheumatoid arthritis in 13% (2/16), cancer in 6% (1/16), and ADHD in 6% (1/16). The primary focus on rehabilitation (10/16, 63%) was the most compelling. Of the 16 studies, 5 (31%) took place in the field of prevention, 4 (25%) in the field of diagnostics, and 1 (6%) in a nonrehabilitation therapeutic context (4 double assignments).

Most of the studies (12/16, 75%) applied machine learning as the AI technology, and 13% (2/16) used deep learning, whereas the remaining studies (2/16, 13%) did not specify the AI technology. Most of the studies (11/16, 69%) used a serious game, whereas 19% (3/16) used a commercial games approach. Despite the highly increased use of gamification in health and education, of the 16 studies, only 1 (6%) specifically used gamification to improve the motivation of patients, and 1 (6%) used game design–like interactions.

We further clustered and outlined the eligible papers according to the targeted disease (Table 2). A more detailed description of every included publication with a more specific outline of the use of AI and game variant can be found in Multimedia Appendix 4 [37-51].

Table 1. Categories.

Category	Studies, n (%)
Disease or health topic (n=16)	
Motion impairment	5 (31)
Phantom limb pain or limb absence	3 (19)
Cognitive impairment	3 (19)
Rheumatoid arthritis	2 (13)
Cancer	1 (6)
Attention-deficit/hyperactivity disorder	1 (6)
Other	1 (6)
Function type (n=16)	
Direct intervention	9 (56)
Analysis and cognition	7 (44)
Level of care (n=20[a])	
Prevention	5 (25)
Diagnostics	4 (20)
Therapy	1 (5)
Rehabilitation	10 (50)
AI[b] technology (n=16)	
Machine learning	12 (75)
Deep learning	2 (13)
AI (not further specified)	2 (13)
Game variant (n=16)	
Serious games	11 (69)
Gamification	1 (6)
Games	3 (19)
Game periphery	1 (6)

[a]A total of 4 studies showed an overlap between prevention and diagnostics and were double classified, resulting in an overall total of 20 studies.
[b]AI: artificial intelligence.

Table 2. Overview of included papers, structured by disease or health topic.

Authors; year	Target group (participants, n)	Subject	Study design	Level of evidence[a]	Level of care	Function type	AI[b] technology	Game variant
Disease or health topic: motion impairment								
Yeh et al [43]; 2014	Patients (48)	Noninvasive balance training	Case control study	3b	Therapy	Direct intervention	Machine learning	Games
Lyu et al [44]; 2019	Healthy individuals (8)	Electromyography-controlled knee exoskeleton	Quantitative, proof of concept	5	Rehabilitation	Analysis and cognition	Deep learning	Games
Nasri et al [45]; 2020	Patients (15)	Real-time hand gesture recognition	Case series	4	Rehabilitation	Direct intervention	Deep learning	Serious games
Burdea et al [42]; 2021	Healthy individuals (2)	Game controller–based telerehabilitation	Proof of concept	5	Rehabilitation	Direct intervention	AI	Game controller or periphery
Zhang et al [46]; 2021	Patients (5)	Gait analysis and waist motion capture	Case series	4	Rehabilitation	Direct intervention	Machine learning	Serious games
Disease or health topic: phantom limb pain or limb absence								
Ortiz-Catalan et al [47]; 2016	Patients (14)	Phantom motor execution	Quantitative clinical trial	4	Rehabilitation	Direct intervention	Machine learning	Games
Lendaro et al [48]; 2019	Patients (4)	Phantom motor execution	Quantitative clinical trial	4	Rehabilitation	Analysis and cognition	Machine learning	Serious games
Kristofferson et al [49]; 2021	Patients (4)	Prosthesis system	Explorative study	4	Rehabilitation	Direct intervention	Machine learning	Serious games
Disease or health topic: cognitive impairment								
Valladares-Rodriguez et al [50]; 2018	Healthy individuals or patients (16)	Early detection of mild cognitive impairment	Proof of concept	5	Prevention or diagnostics	Analysis and cognition	Machine learning	Serious games
Valladares-Rodriguez et al [51]; 2019	Patients (74)	Early detection of mild cognitive impairment	Case series	4	Prevention or diagnostics	Analysis and cognition	Machine learning	Serious games
Jung et al [37]; 2019	Patients (12)	Mini-Mental State Examination	Case series	4	Rehabilitation	Direct intervention	Machine learning	Serious games
Disease or health topic: cancer								
Good et al [39]; 2014	Registered players (1077)	Gene Selection for breast cancer survival prediction	Quantitative study	5	Prevention	Analysis and cognition	Machine learning	Serious games
Disease or health topic: attention-deficit/hyperactivity disorder								
Keshav et al [40]; 2019	Patients (7)	Digital attention-related augmented reality game	Case series	4	Prevention or diagnostics	Analysis and cognition	AI	Serious games
Disease or health topic: rheumatoid arthritis								
Varga et al [38]; 2021	Healthy individuals (7)	Virtual arthritis rehabilitation app	Proof of concept	5	Rehabilitation	Direct intervention	Machine learning	Serious games
Varga et al [58]; 2022	Patients (10)	Virtual arthritis rehabilitation app	Case series	4	Rehabilitation	Direct intervention	Machine learning	Serious games

[b]AI: artificial intelligence.

Motion Impairment

Almost one-third of the studies (5/16, 31%) targeted the objective of motion impairment. Studies included upper- and lower-limb rehabilitation with a broad range of possible medical indications, ranging from poststroke to vestibular dysfunction. Games were used to enhance motivation and provide a user-friendly at-home training experience. Some of the studies (5/16, 31%) achieved this through an integration of virtual reality and artificial reality. AI was integrated in different ways. Some of the studies (4/16, 25%) used games as a training tool and then analyzed and classified the collected data with AI. Other studies (3/16, 19%) first processed sensor data via AI to improve the quality of an associated game. Direct interaction between the AI and the games component was shown in 2 (40%) of the 5 studies, in which AI adapted the game design and difficulty to the ability level of the patient.

Only 1 (20%) of the 5 studies tested the design using a control group analyzing patient improvements in clinical parameters. All other studies demonstrated the functionality and usability of their technical approach in pilot studies.

Phantom Limb Pain or Limb Absence

Of the 16 studies, 3 (19%) targeted the topic of phantom limb pain or limb absence, where a game environment can support at-home therapy and provide enhanced visual feedback. Of the 3 studies, 2 (67%) by the same research group targeted phantom motor execution with similar approaches. Machine learning was used to improve the quality of electromyography sensor data and thus provide better data input for training. Different training methods in the spectrum of virtual reality and augmented reality and serious games were tested. Of the 3 studies, 1 (33%) focused on ethnographic user–type analysis, and 1 (33%) effected a decrease in phantom pain. The third study tested a machine learning–aided prothesis, comparing 2 different training approaches—1 conventional and 1 via a serious game—to collect electromyography data. Testing was only conducted on 4 patients; however, the results were insignificant.

Cognitive Impairment

In cognitive impairment, the included studies used a set of games covering different cognitive functions as diagnostic instruments. Data were then processed by machine learning techniques to further improve outcome quality. Of the 3 studies, 1 (33%) focused on evaluating patients with cognitive impairment after stroke. Scores acquired from a game set were analyzed by AI and compared with the clinically widely used Mini-Mental State Examination (MMSE) [37]. Of the 3 studies, 2 (67%) used a game set for predicting the future development of mild cognitive impairment, using AI to automatically distinguish between healthy individuals and individuals who were possibly affected. In both fields, pilot studies were conducted with patients, showing high motivation to participate and good usability of the game sets.

Rheumatoid Arthritis

In rheumatoid arthritis, a serious game for hand rehabilitation was developed. Neural networks for processing data and machine learning for testing the accuracy of hand movements for individually adapting difficulty were integrated. Two small pilot studies, 1 with healthy individuals and 1 with patients, showed high accuracy of the machine learning algorithm and good usability, whereas clinical benefits have not yet been measured [38].

Cancer

In cancer, a crowdsourcing campaign was set up via an open web-based game that captured inputs from players regarding their estimation of 5 specific genes, which can be used as predictors of breast cancer survival. Gene selections were processed by machine learning to identify the best prediction models. When only including inputs from people with a self-proclaimed Doctor of Medicine degree, a Doctor of Philosophy degree, or expertise in cancer, the resulting models performed similarly to clinically established gene sets [39].

ADHD Severity

A set of smartglasses was developed to assess ADHD severity through playing an attention-related augmented reality game designed as a social-emotional communication aid. AI was used to analyze video and audio as well as affective and behavioral data and provided users with in-game rewards based on their performance. The study showed significant correlation of the game score to validated clinical gold standard assessments for ADHD [40].

Other

To improve the prevention of cognitive and physical decline, an at-home innovative system consisting of remote monitoring and neurocognitive games was developed. Feedback to the user, including badges or benefits for real-life events, is provided via machine learning analysis. Older adult users indicated "great acceptability" of the system [41].

Discussion

Principal Findings

Currently, there are only a limited number of studies involving a combination of game-based methods and AI in health. Almost one-third of the included studies (5/16, 31%) were centered on addressing motion impairment. The primary emphasis of the research was on rehabilitation. In addition, most of the studies (9/16, 56%) focused on prevention and diagnostics. In terms of AI technology, machine learning was the most commonly used approach (12/16, 75%). Furthermore, serious games were used in most of the studies (11/16, 69%).

When analyzing the studies by disease category, most of the studies (5/16, 31%) used a rehabilitation approach for different aspects of motion impairment (eg, in poststroke conditions, phantom limb pain or limb absence, and rheumatoid arthritis). In this field, studies have a focus on providing individual, at-home, and complex training opportunities for improving motoric limb function, in which therapeutic concepts rely on long-term and self-guided exercising. Games take the role of a training tool, enhancing at-home training motivation and providing multidimensional and exercises compared with the current standard of care. In addition, in some of the studies (5/16, 31%), the integration of virtual reality and augmented reality provided an immersive experience. The role of AI in this context is diverse, sometimes to analyze and classify collected data to improve game setup and level, sometimes to analyze data resulting from game play itself.

In a second cluster, studies for neurological diseases, including those handling cognitive impairment in older adults as well as 1 study for ADHD in younger patients, there was a clear focus on diagnostic evaluations. Here, different sets of games were used to assess various cognitive subdomains, with AI processing these different data inputs and calculating scores and predictions. The advantages in this field are the wide range of possible game designs and the feasibility to play these games individually at home. This could reduce health professionals' time in assessing cognitive function during face-to-face visits or supplement them by enabling longitudinally acquired data sets and trajectories. The first results show promising results in comparison with standard clinical scores obtained using, for instance, the MMSE.

The direct interaction between the games approach and AI technology was only described in 3 (19%) of the 16 studies. Most of the time, the 2 entities follow each other, with the AI technology not analyzing live in-game playing data. However, direct interaction holds a promise of benefit through an AI-enabled assessment of the patient's ability during game play and individualized live adjustments of game design and difficulty. Examples using this approach showed good technical functioning and positive user feedback [42]. Even so, the limited number of published studies suggest that the potential of this integrated approach has so far not been fully used yet. This is rather surprising, given the fact that the direct link between AI and games is widely prevalent in the commercial games sector. The reasons for this are purely speculative. The transition of findings from 1 field to another is still pending, perhaps because studies in the commercial games field have a different scope than those in medicine and health. Another reason could be the resource-intensive nature of research. However, the future potential of this interaction seems promising, with the stimulation of user motivation by game design and gamification elements and with AI being used to process large and multimodal data sources and to perform individualized adaptations.

When analyzing further categories, our review shows that the studies so far have produced very limited quality evidence (all studies have an evidence level of 4 or 5, except for 1 study that has an evidence level of 3b), with most of the studies presenting either a rather technical proof of concept (15/16, 94%) or performing usability testing with a small sample size of healthy individuals and patients (14/16, 88%). Higher-quality studies with control groups and end points focusing on specific clinical outcomes are missing.

Of note, the research field is still young. All studies were conducted in the last 8 years, with 13 (81%) of the 16 studies being published in the last 3 years. All research settings however bear the potential of conducting higher-quality studies with bigger sample sizes and specific medical outcomes in the near future.

However, the studies in this review already show promising results, with overall well-functioning technical implementation of the game elements and high accuracy and usefulness of the AI integration. From the patients' and healthy individuals' perspective, generally high usability, motivation, and satisfaction were found, mostly assessed by established usability questionnaires and qualitative interviews. This is an encouraging perspective for the future because individualized patient-driven at-home diagnostic and therapeutic approaches are increasingly relevant in all fields of medicine.

All 16 studies identified in this review have a relatively low level of evidence (3b: n=1, 6%; 4: n=10, 63%; and 5: n=5, 31%). The risks of bias in these studies are multifaceted. Pilot studies, often conducted to assess the feasibility of a full-scale study, typically featured small sample sizes and often lacked rigorous methodology, randomization, and blinding procedures. As a result, they are susceptible to a range of biases, including selection bias, performance bias, and detection bias. Studies were characterized by weaker methodologies, which can lead to biases in data collection, analysis, and reporting. Nonrandomized studies were prone to selection bias, confounding, and other methodological flaws. The high heterogeneity of the identified studies encompassed a wide range of disease or health issues, populations, and interventions. This heterogeneity makes it challenging or impossible to integrate data and limits overall conclusions.

Limitations

First, as described earlier, the field of research is still very interdisciplinary, and the studies carried out are very diverse based on the vast variety of game-based approaches and therapeutic interventions.

This review only covered original studies in English, which were found in the PubMed, Scopus, IEEE Xplore, Cochrane Library, and PubPsych databases and published in the last 20 years. Although these are widely recognized and commonly used databases in the field of health care research, restricting the review to these 5 databases may have resulted in the exclusion of relevant studies published in other databases owing to this high interdisciplinarity. However, efforts have been made to minimize this limitation using comprehensive search strings, snowballing, and asking colleagues to identify additional relevant literature. In addition, this review also includes interdisciplinary databases such as the more technical-oriented IEEE Xplore and the more pedagogical-oriented PubPsych.

It especially remains unclear whether all projects conducted especially with a more technical focus have been published in scientific journals at all. For future reviews, a more holistic approach should be taken to assess more results from projects that may not have been included in a publication.

In addition, there might be a lack of awareness that research in the engineering, gaming, and fitness spectrum has a direct connection with health-related issues. Thus, it seems possible that certain publications were not fully covered by our already broad search strategy or that promising interventions have not been related to health care yet. This should be mitigated in future studies, considering the growing attention to this young research field.

Another limitation is that this review focused on therapeutic medical interventions rather than on health interventions. AI and game-based approaches in the field of prevention and health promotion have not been included, although this is an important aspect of population health. Game-based approaches especially are used a lot in this field to reach the target groups [8,9,21,22,59-61].

Future Directions

In the near future, the potential of games, which is already established in the commercial games sector, should be applied to the field of serious games and AI. Adaptive game design can be suitable in health care to improve the intervention outcome via AI-driven health care games that assess the skills level of the patient and adapt the difficulty in feedback loops, which could lead to a better harmonization with traditional therapy sessions. NPCs could be used as virtual patients or other health care personnel or relatives to simulate the interprofessional working environment and to improve the interaction and communication with virtual patients [26,27,34].

Finally, the integration of AI and games should carefully consider the ongoing discussions regarding ethical, moral, and data protection issues. In particular, studies describing ethical issues using game-based approaches are scarce [62,63].

Analyzing the currently limited evidence with promising future possibilities in study design and quality, as well as a dynamic research field, it seems, at this stage, that another review should be conducted in the next few years to assess this rapidly growing research field.

Acknowledgments

Open access funding was provided by the open access publishing funds of Philipps-University Marburg and Bielefeld University.

Authors' Contributions

All authors were responsible for conceptualization, methodology, validation, and visualization. DT and JJS were responsible for data curation and formal analysis. DT and SK were responsible for investigation. SK was responsible for funding acquisition, project administration, resources, software, and supervision. DT and JJS wrote the original draft; all authors reviewed and edited the manuscript (contributions of the authors are based on CRediT [contributor roles taxonomy] [64]).

Conflicts of Interest

SK is the founder and a shareholder of MED.digital. All other authors declare no other conflicts of interest.

Abstract

Background: Serious games have emerged as an innovative educational strategy with the potential to significantly enhance the quality and effectiveness of cardiopulmonary resuscitation (CPR) training. Despite their promise, there remains a degree of controversy when comparing the advantages of serious games with traditional CPR training methods. This study seeks to provide a comprehensive assessment of the impact of serious games on CPR training and education by systematically analyzing the results of previous research.

Objective: This study aimed to assess the effect of serious games on CPR training and education by summarizing and pooling the results of previous studies.

Methods: We conducted a thorough and systematic search across 9 prominent web-based databases, encompassing the period from the inception of these databases until April 1, 2023. The databases included in our search were PubMed, Cochrane Library, Wiley Online Library, EBSCO (PsycInfo), SpringerLink, Chinese Biology Medicine Disc, Vip Journal Integration Platform, Wanfang Database, and Chinese National Knowledge Infrastructure. The studies selected adhered to the following criteria: (1) being a randomized controlled trial comparing serious games and traditional methods for CPR training; (2) having participants aged 12 years or older in CPR; (3) having an experimental group using serious games and a control group using nongame methods for CPR instruction; and (4) having outcomes including theoretical and skill assessments, compression depth, and rate. The Cochrane risk of bias assessment tool was used to evaluate the risk of bias. Data analysis was performed using RevMan (version 5.3; Cochrane Training), and mean differences (MDs) and standardized mean differences (SMDs) with 95% CIs were used to calculate continuous variables.

Results: A total of 9 articles were included, involving 791 study participants, of whom 395 in the experimental group taught CPR training using serious games and 396 in the control group taught CPR training using traditional methods. The results of our meta-analysis indicate that the use of serious games in CPR training yields outcomes that are comparable in effectiveness to traditional training methods across several key areas. Specifically, serious games demonstrated equivalence to traditional formats in theory assessment (SMD –0.22, 95% CI – 0.96 to 0.51; *P*=.55), skill assessment (SMD –0.49, 95% CI –1.52 to 0.55; *P*=.36), compression depth (MD –3.17, 95% CI –0.18 to 6.53; *P*=.06), and compression rate (MD –0.20, 95% CI –7.29 to 6.89; *P*=.96).

Conclusions: In summary, serious games offer a viable and effective CPR education approach, yielding results comparable to traditional formats. This modality is a valuable addition to CPR training methodologies. However, caution is warranted in interpreting these findings due to limited controlled trials, small sample sizes, and low-quality meta-analyzed evidence.

Introduction

Background

Out-of-hospital cardiac arrest (OHCA) is a critical medical emergency characterized by the sudden cessation of heart function, resulting in an abrupt loss of blood flow. OHCA incidents frequently occur in community settings, schools, homes, and public places [1]. Despite sustained efforts, OHCA survival rates remain disheartening, largely due to modifiable factors such as bystander cardiopulmonary resuscitation (CPR), automated external defibrillator (AED) use, and the timing of emergency medical services (EMS) intervention [2,3]. In the United States, OHCA affects over 88.8 adults per 100,000 adults annually, with a mere 9.0% discharge survival rate, as reported by the American Heart Association [4]. Similarly, in Europe, the annual incidence of OHCA among adults ranges from 67 to 170 per 100,000, with discharge survival rates varying from 0% to 18% [5]. In China, more than 540,000 individuals experience OHCA each year, but the survival rate remains at approximately 2% [6]. These statistics underscore that OHCA, despite regional disparities, has emerged as a substantial public health challenge, imperiling the well-being of citizens [7]. OHCA is typified by sudden respiratory distress, pulse cessation, and loss of consciousness, necessitating immediate and effective first-aid measures within the critical 4-minute window [8]. However, current prehospital EMS services often struggle to reach the scene promptly to address emergencies in public spaces [9]. Consequently, first responders (FRs), nonmedical professionals in public areas, shoulder the responsibility of on-site rescue efforts [10]. Swift and efficient basic life support interventions administered by FRs not only create a vital time buffer for EMS teams to arrive but also substantially elevate the chances of patients with OHCA surviving [11].

CPR, encompassing artificial respiration and chest compressions, stands as one of the simplest and most universally applicable techniques for basic life support during OHCA emergencies [12]. The quality of chest compressions holds immense significance in preserving organ perfusion. Consequently, the timely and effective administration of CPR plays a pivotal role in determining both the survival rate and neurological outcomes for patients with OHCA [3]. To enhance the widespread adoption of CPR and ensure that more individuals are proficient in this vital first-aid technique, the World Health Organization and the International Liaison Committee on Resuscitation endorsed the “Kids Save Lives” statement, which calls for CPR training for students, adolescents, and adults aged 12 years or older who already have the physical fitness and learning ability to understand and remember CPR skills to empower young people, including children aged 12 years, with CPR skills. Develop a generation of proactive and empowered community members who are expected to make a difference in emergency situations, especially in the context of OHCA, with the goal of increasing survival and improving long-term outcomes for patients with OHCA [13,14].

Serious games are increasingly used in medical education, encompassing medical theory instruction, clinical skills training, cognitive rehabilitation exercises, and patient health education. The integration of serious games into medical simulation programs is seen as a means to enhance the efficiency and effectiveness of training programs [15,16]. Otero-Agra et al [17] used serious games to instruct middle school students in CPR, revealing that 61.7% of participants acquired correct CPR techniques, with 93.4% achieving an average chest compression depth exceeding 50 mm. These results endorse serious games as effective tools for knowledge acquisition and the mastery of high-quality CPR skills. To optimize their use as an educational strategy, serious games must possess robust content and cater to the target audience. Integrating learning theory with game requirements enhances student engagement and ensures the efficacy of learning [18]. High fidelity is crucial, especially for medical students, as the knowledge and skills acquired in serious games will be applied in future clinical practice involving real patients. High-fidelity serious games bridge the gap between virtual gaming scenarios and clinical reality, boosting rescue confidence and self-efficacy [19]. Creutzfeldt et al [20] used serious games based on massively multiplayer virtual worlds technology to train 36 high school students in CPR. After 90-120 minutes of game-based sessions, participants reported a significant increase in self-efficacy, endorsing the effectiveness of serious games for CPR instruction. Moreover, serious games can incorporate adaptive learning features, adjusting difficulty and content based on the learner’s proficiency, ensuring tailored learning for individuals with varying CPR skill levels [21].

The incorporation of serious games into CPR training aims to enhance the learning process by rendering it more engaging, interactive, and effective. Compared to conventional methods relying on lectures, videos, and hands-on practice, serious games make the learning experience more enjoyable, interactive, and motivation-driven, integrating features such as scores, levels, and rewards [21,22]. Notably, serious games for CPR training are user-facing, offering immediate training opportunities, flexible learning schedules, and detailed real-time feedback on CPR performance [23]. In contrast, traditional teaching models often limit training opportunities, providing delayed feedback, particularly in large-scale group activities where individual feedback is frequently overlooked [24]. A systematic review by Lim et al [25] underlines that the absence of regular retraining and effective feedback in traditional CPR education can impact skill retention. Serious games address these shortcomings by providing continuous opportunities for practice and feedback. Moreover, serious games support collaborative learning, enabling learners to respond jointly to virtual CPR scenarios and develop teamwork and communication skills. They also offer diverse immersive first aid scenarios with varying causes of cardiac arrest, an aspect unattainable in traditional teaching formats [16,26]. This multifaceted approach not only compensates for the deficiencies in traditional methods but also promotes a dynamic and engaging learning environment in CPR training. Considering the advantages mentioned above, the 2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care recommended the incorporation of serious games into CPR training and education to enhance teaching methods and improve instructional quality, taking into account advancements in training equipment and teaching formats [27]. However, Dankbaar [28] concluded that serious games have limitations in terms of time and their ability to provide learners with sufficient knowledge acquisition and complex skill improvement. In summary, there exists a degree of controversy regarding the impact of serious games on CPR training and education. Therefore, we aimed to conduct a meta-analysis to determine the effectiveness of serious games in CPR training and education.

Research Gap and Aim

While numerous researchers have explored and experimented with serious games for CPR training, published randomized controlled trial (RCT) studies have explored and experimented with the effect of serious games applied to CPR training, and their effectiveness has been proven and supported [16,29]. However, due to the limitations of research, the generalization of research conclusions is affected. Specifically, (1) these RCTs were single-center studies with small sample sizes; (2) specific serious games limit the reliability of the findings in different settings of serious games or target populations; (3) outcomes were mostly assessed by questionnaires, and there were a lack of reliable, automated, and repeatable methods to measure their efficacy; and (4) there is a lack of methodological specifications and standard protocols for the use of serious games. Furthermore, there is a lack of systematic evaluation or meta-analysis of the effectiveness of serious games-based CPR training. Consequently, it is necessary to quantitatively analyze the objective effect of serious games–based training through meta-analysis. In view of this, we conducted a meta-analysis to comprehensively evaluate the effect of serious games on CPR training and teaching.

Methods

Overview and Registration

This systematic review adheres to the guidelines set forth by the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [30] and was registered in advance in the PROSPERO (International Prospective Register of Systematic Reviews) database (registration number CRD42023423089).

Search Strategy

Our search was conducted in several databases, including PubMed, Cochrane Library, Wiley Online Library, EBSCO (PsycInfo), and SpringerLink. Besides, Chinese databases, including the China National Knowledge Infrastructure (CNKI), China Biomedical Literature Database, VIP Journal Integration Platform, and Wanfang Database, were searched. The search was conducted from the inception of the databases until April 1, 2023. We limited the publication language to English and Chinese. English search terms included "serious game," "gam*," "cardiopulmonary resuscitation," "CPR," "basic life support," "BLS," "first aid training," "resuscitation education," "emergency skill," etc. The search involved a combination of subject terms and free words, with a manual retrospective search of references and associated literature to ensure a comprehensive search of relevant studies. Multimedia Appendix 1 provides detailed information on the search strategies, including search terms, and the process used.

Eligibility Criteria for This Review

The eligibility of studies was assessed based on the following criteria: (1) the study type should be an RCT comparing the effectiveness of serious games with other traditional training methods for teaching CPR; (2) the study population should include participants aged 12 years or older who participated in CPR training or first aid training that covered basic life support for CPR; (3) interventions in the experimental group should involve the use of serious games for CPR training instruction, while the control group should receive other methods of CPR theory and skills training instruction excluding serious games, with no limitations on the types of games or software used; and (4) outcome measures should include one or more of the indicators of theoretical assessment, CPR skill assessment, compression depth, and compression rate. Additionally, duplicate or multiple manuscripts, literature in languages other than Chinese or English, literature with inaccessible full text, incomplete or missing data, improper data collection, or errors in statistical methods were excluded.

Screening Process

Two authors (PC and PY), who were trained in evidence-based methods, independently conducted the screening of literature and extraction of data. All references were managed using EndNote X9 (Clarivate), a reference management software. After removing duplicates, the remaining references were first screened based on titles and abstracts. Subsequently, full-text screening was performed independently by the authors in duplicate to determine the inclusion of literature. Disagreements were resolved through discussion or adjudication by a third author (HZ).

Quality Assessment

The Cochrane handbook's criteria for assessing the risk of bias in RCTs were used to evaluate the methodological quality of the trials [31]. The assessment covered various aspects, including selection bias, concealment of the allocation scheme, implementation bias, measurement bias, missed visit bias, reporting bias, and other biases. Each item was categorized as "low risk of bias," "unclear," or "high risk of bias." In cases where differing opinions arose, a third author (HZ) was involved to reach a consensus.

Data Extraction

For data extraction, we used Excel (2010; Microsoft Corporation) to create a standardized form. The form included the following information: (1) basic details such as the first author, publication year, and country of the study; (2) population characteristics, sample size, and information about the serious games used in training and teaching; (3) specific interventions for the test and control groups; and (4) outcome measures and the tools used for measurement.

Statistical Analysis

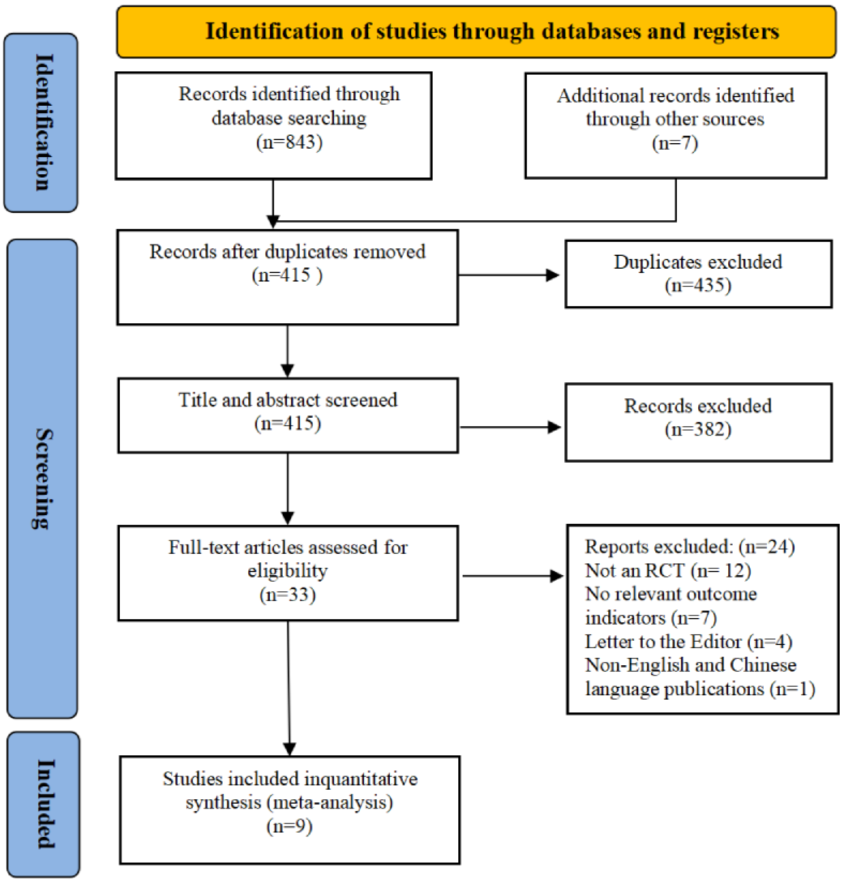
Data analysis was carried out using RevMan (version 5.3; Cochrane Training). To assess heterogeneity, the Q test and the I^2 test were used. If the resulting *P* value was greater than or equal to .1 and I^2 was less than or equal to 50%, it indicated low heterogeneity among the findings, leading to the selection of the fixed-effects model for meta-analysis. Otherwise, the random-effects model was used. When comparing groups, continuous variables were analyzed using mean difference (MD) if the same measurement instrument was used or standardized mean difference (SMD) if different instruments were used. Both effect measures were reported with 95% CIs. For continuous data that did not follow a normal distribution in the included studies and were expressed as medians, extreme values, or quartiles, a specific web-based formula calculator developed by Professor Luo et al [32] from Hong Kong Baptist University was used. This calculator, designed for meta-analysis data conversion, enabled statistical estimation of the data. Leave-one-out analysis was used to conduct sensitivity analysis, that is, omitting one study at a time from the meta-analysis and examining the impact on the overall effect size, then judging the robustness and reliability of the results and exploring the sources of heterogeneity [33]. Statistical significance was determined at a $P<.05$. The level of evidence was evaluated using the GRADEpro GDT web-based tool.

Results

Study Selection

After conducting a comprehensive search across various databases, a total of 843 RCTs were found. Additionally, 7 more studies were obtained by snowballing. Following the removal of duplicates, 415 articles were screened based on their titles and abstracts. Out of these, 382 articles were excluded, and the remaining 33 articles were examined in their entirety. Ultimately, a total of 9 full-text articles were considered for quantitative synthesis. This included 5 papers in English and 4 papers in Chinese. More specific information can be found in the study's PRISMA flowchart (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the selection process. RCT: randomized controlled trial.



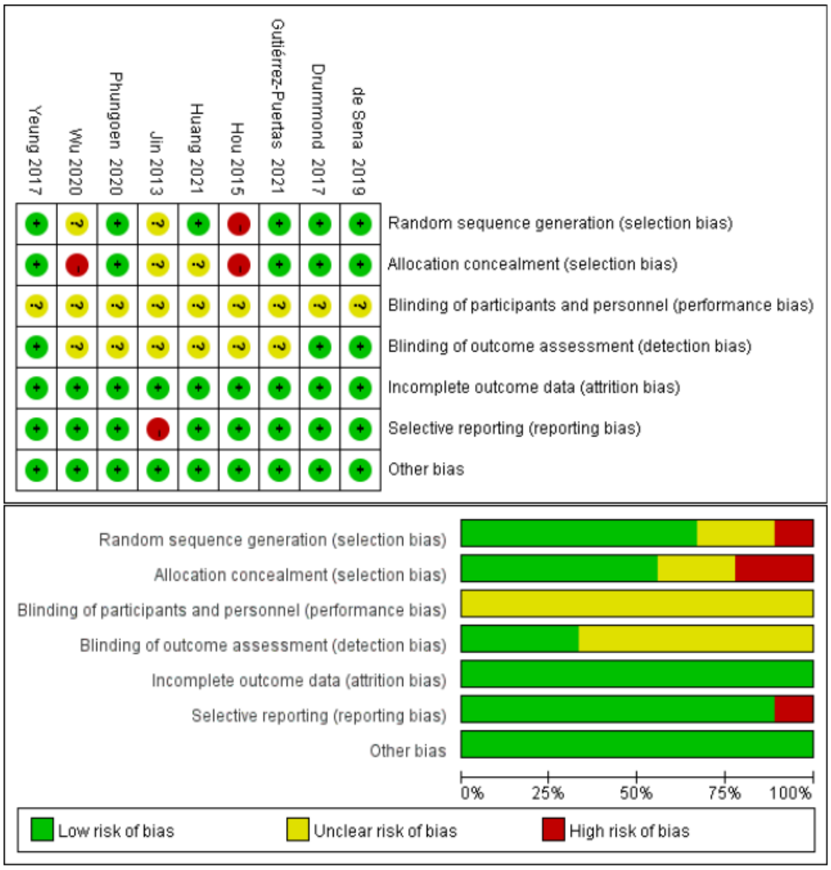
Characteristics of Included Studies

We included 9 RCTs [34-42] from 6 countries. There were no statistical differences in general information between the trial and control groups in each study. A total of 791 study participants were included, with 395 in the experimental group taught CPR training using serious games and 396 in the control group taught CPR training using traditional methods. Additional information can be found in Multimedia Appendix 2 [34-42].

Quality Assessment

The risk of bias evaluation of the included literature is presented in Figure 2 [34-42] (the colors green, yellow, and red in the figure mean “low risk of bias,” “unclear risk of bias,” and “high risk of bias,” respectively). The quality of the included studies was found to be acceptable. In 6 RCTs [36-38,40-42], they described the generation of random sequences, of which 5 RCTs [36-38,40,41] described methods of allocation concealment. Due to CPR training and teaching, it was not possible to blind participants. In 3 RCTs [36-38], they applied the blinding method for researchers. Additionally, in 1 RCT [34], they had a high risk of reporting bias, and all 9 RCTs had complete data and did not have any other bias.

Figure 2. Methodological quality assessment of risk of bias for the included trials.

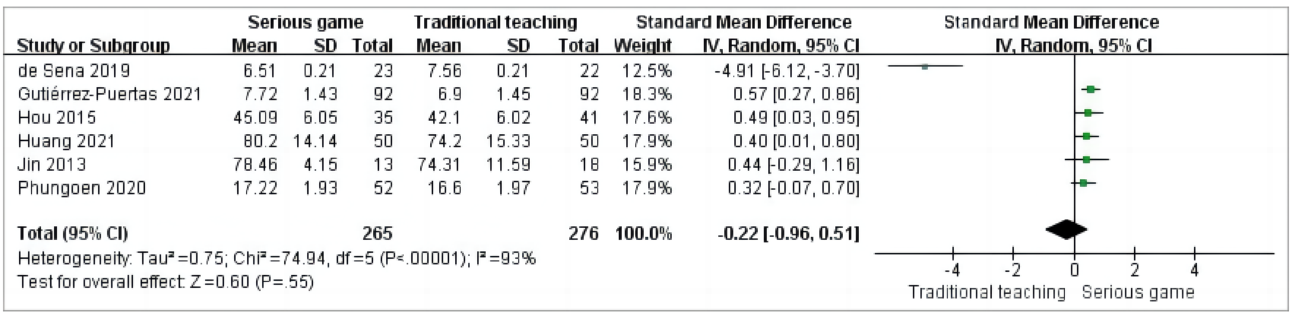


Meta-Analysis Results

The Effect of Serious Games Teaching on CPR Theory Performance

In the analysis, 6 out of the 9 studies [34,35,38,40-42] used posttraining CPR theory assessment as an outcome measure in RCTs. The pooled results revealed significant heterogeneity among the studies (P<.001; I^2=93%), necessitating the use of a random-effects model for the meta-analysis. Figure 3 [34,35,38,40-42] demonstrates that there was no significant disparity in the theory assessment between the 2 groups under investigation (SMD –0.22, 95% CI –0.96 to 0.51; P=.55).

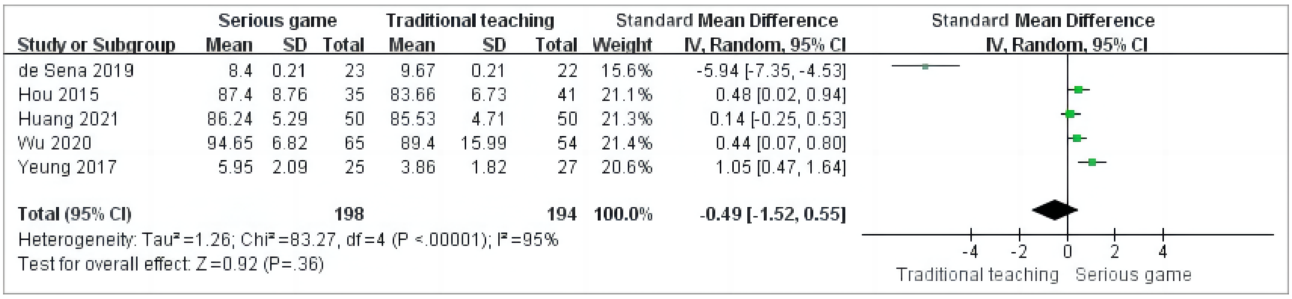
Figure 3. Meta-analysis of the effect of serious games on theory assessment.



The Effect of Serious Games Teaching on the Performance of CPR Skills Operations

Posttraining CPR skill manipulation performance was assessed as an outcome indicator in 5 RCTs [35,36,38,39,42] out of the 9 studies included. Meta-analysis was conducted using a random-effects model due to heterogeneity among the studies (P<.001; I^2=95%). The results indicated that there was no significant difference in skills assessment between the 2 study groups (SMD –0.49, 95% CI –1.52 to 0.55; P=.36). This suggests that the use of serious games for CPR training did not lead to a significantly different skill level compared to other traditional training methods (Figure 4 [35,36,38,39,42]).

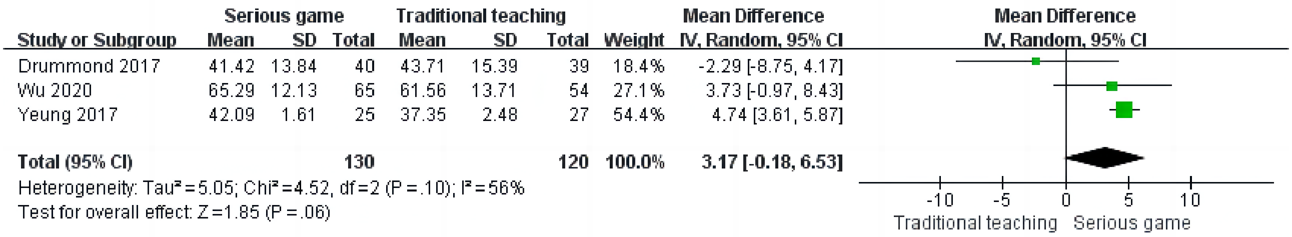
Figure 4. Meta-analysis of the effect of serious games on skill assessment.



The Effect of Serious Games Teaching on the Depth of CPR Compression

A total of 3 studies [36,37,39] presented findings on the impact of serious games on CPR compression depth. The assessment of heterogeneity demonstrated variability among the included studies (P=.10; I^2=56%), necessitating the application of a random effects model. The analysis depicted in Figure 5 [36,37,39] revealed that the disparity between the 2 groups did not reach statistical significance (MD 3.17, 95% CI –0.18 to 6.53; P=.06).

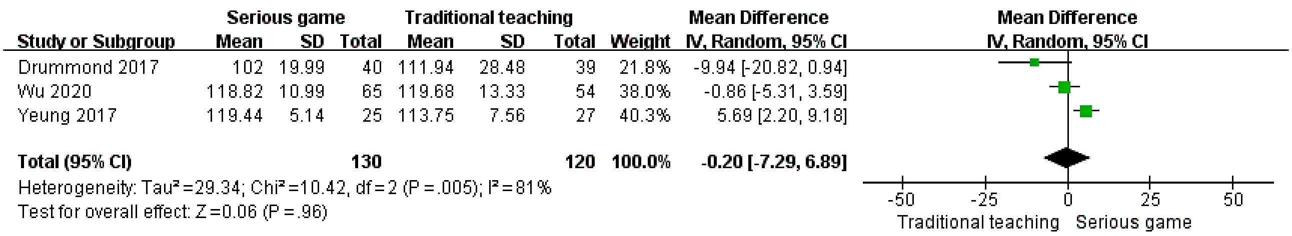
Figure 5. Meta-analysis of the effect of serious games on cardiopulmonary resuscitation (CPR) compression depth.



The Effect of Serious Games Teaching on the Frequency of CPR Compression

A meta-analysis was performed on 3 studies [36,37,39] that investigated the impact of serious games training on the frequency of CPR compression. Due to the variation among these studies (P=.005; I^2=81%), a random effects model was used. The results, as illustrated in Figure 6 [36,37,39], indicated that there was no significant difference in the theory of CPR compression rate between the 2 study groups (MD –0.20, 95% CI –7.29 to 6.89; P=.96).

Figure 6. Meta-analysis of the effect of serious games on cardiopulmonary resuscitation (CPR) compression frequency.



Sensitivity Analysis

We conducted separate analyses using both fixed effects and random effects models to examine the SMD, MD, and 95% CI of each model. By systematically excluding studies one by one, when the study by de Sena et al [38] was excluded, we observed a decrease in heterogeneity from 93% to 0% for theoretical assessment (Figure 7 [34,35,40-42]) and from 95% to 54% for skill assessment (Figure 8 [35,36,39,42]), respectively. This indicates that the study conducted by de Sena et al [38] may have contributed to the observed heterogeneity. In the meta-analysis of CPR compression depth, heterogeneity decreased from 56% to 0% after the exclusion of the study by Drummond et al [37], indicating that this study was the source of heterogeneity (Figure 9 [36,39]). After the exclusion of the study by Yeung et al [36], the heterogeneity of the meta-analysis on compression frequency of CPR decreased from 81% to 56%, indicating that this study was one of the sources of heterogeneity (Figure 10 [37,39]).

Figure 7. Sensitivity analysis of meta-analysis of cardiopulmonary resuscitation (CPR) theory performance.

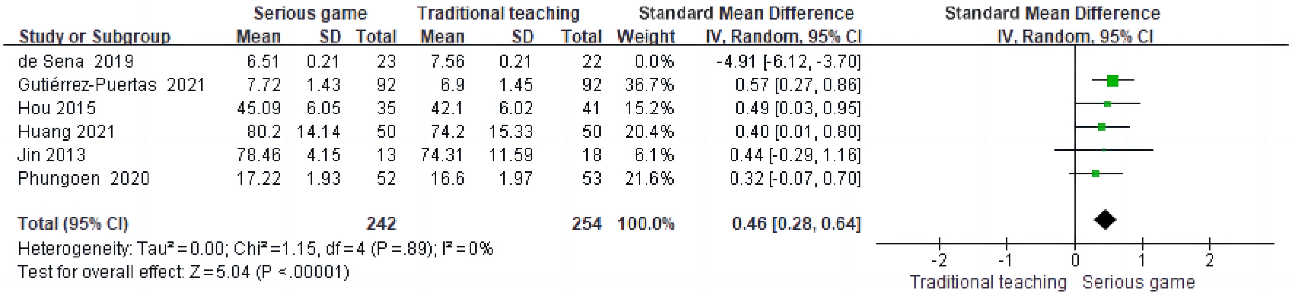


Figure 8. Sensitivity analysis of meta-analysis of cardiopulmonary resuscitation (CPR) skills operations.

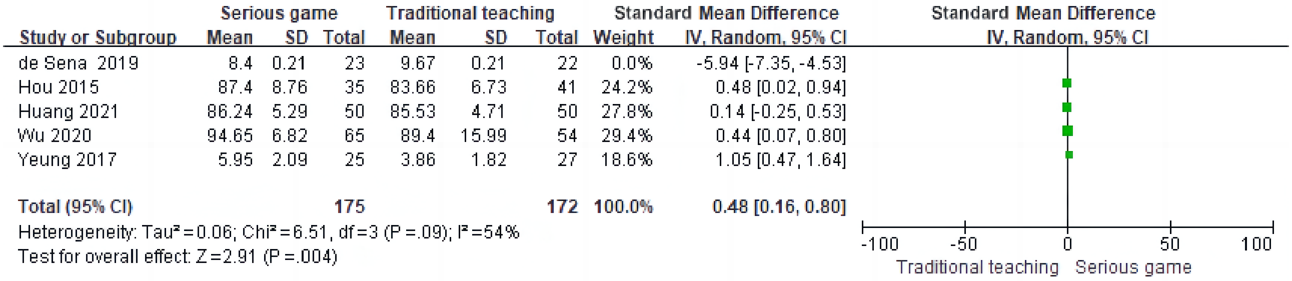

Figure 9. Sensitivity analysis of meta-analysis of cardiopulmonary resuscitation (CPR) compression depth.

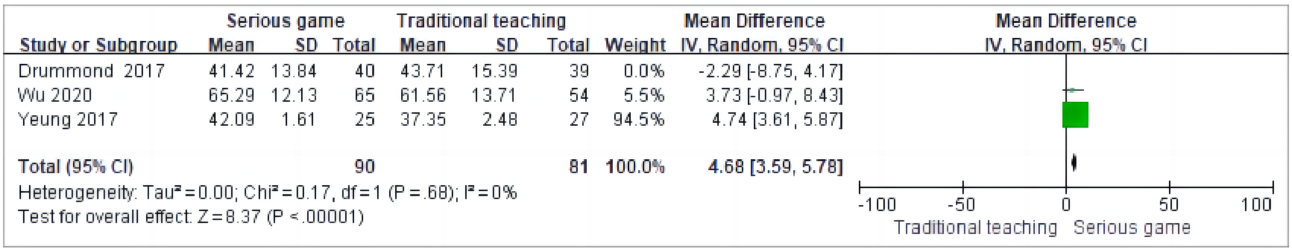

Figure 10. Sensitivity analysis of meta-analysis of cardiopulmonary resuscitation (CPR) compression frequency.

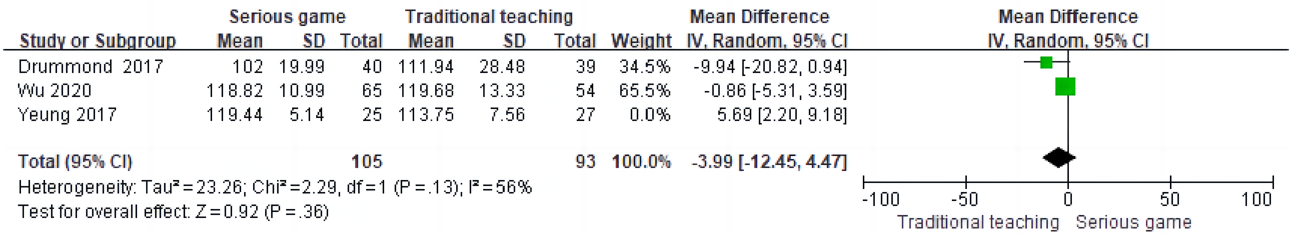

GRADE Evidence Quality Levels

Table S1 in Multimedia Appendix 3 presents the GRADE (Grading of Recommendations, Assessment, Development, and Evaluations) system evidence level for each outcome indicator in the meta-analysis of this study. The 4 outcome indicators considered were theory assessment, skill assessment, compression depth, and compression frequency.

Discussion

Principal Findings

This study systematically evaluated the efficacy of serious games-based training in CPR education, drawing upon data from 9 studies with a total of 791 participants. Our findings reveal no significant differences in theoretical exam scores, skill assessment scores, compression depth, or compression frequency between serious games-based and traditional CPR training methods. This suggests that serious games offer a highly effective alternative for CPR education. In alignment with the 2020 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care [27], which recommend the incorporation of serious games into CPR education, our results underscore the positive impact of virtualized, gamified learning models on knowledge acquisition and CPR skill mastery. Theory and skills assessments are pivotal components of CPR training, serving as key indicators of training effectiveness and student proficiency. Our meta-analysis demonstrates that serious games-based CPR training is on par with traditional methods in enhancing both knowledge acquisition and skill levels. Consequently, serious games represent a valuable addition to the spectrum of CPR teaching and training methods, fostering innovation and aligning with the American Heart Association's guidelines for modernizing teaching tools and approaches.

Comparison With Previous Work

This study aligns with a previous meta-analysis [43], indicating that both lay and medical school students exhibit enhanced knowledge following web-based digital resuscitation training. Moreover, they demonstrate comparable cognitive outcomes to those undergoing traditional training sessions. The inclination of younger individuals toward serious games for acquiring new skills stems from their immersive and interactive nature, offering a secure trial-and-error environment [44]. This, coupled with engaging and positive learning experiences, reduces reliance on educational resources and fosters active, independent learning—especially when conventional training methods are inaccessible. This approach helps in sustaining knowledge levels, preventing decay over time, and attaining learning outcomes equivalent to traditional education forms [45]. Despite these benefits, serious games' applications for CPR training face challenges, presenting a mixed landscape concerning usability and enjoyment quality. Issues range from outdated guidelines and unupdated advice to overly detailed, professional information hindering learning efficacy. Such drawbacks may discourage public engagement with CPR learning [46]. For nonmedical learners, serious games must ensure acceptable usability, simplifying the comprehension and retention of CPR theoretical knowledge. Regular updates aligning with the latest guidelines can transform serious games into dynamic electronic textbooks [46,47]. To maximize the potential of serious games over traditional training, it is crucial to identify and evaluate functions that motivate learners to increase frequency and actively embrace knowledge updates. This strategic approach could position serious games as a superior alternative for enhancing the theoretical understanding of CPR, offering distinct advantages over traditional training methods [46,48].

Numerous guidelines [27,49-51] underscore the primary goal of CPR training: imparting participants with the skills necessary for high-quality CPR. This involves maintaining the correct compression rate and depth, ensuring thoracic recoil, and minimizing interruptions and hyperventilation. However, traditional training methods have presented challenges, particularly for nonmedical personnel [52,53], in mastering these vital competencies. Previous studies [52,54] have noted that simulated scenarios and repetitive practice often fall short of achieving adequate compression depth and frequency. Aksoy [55] and Siqueira et al [56] propose that a CPR teaching mode based on serious games could enhance learners' motivation and attitude, consequently improving compression quality. This study echoes Lau et al's [57] systematic review, indicating equivalence between serious games and traditional training methods in enhancing compression depth and frequency. However, electronic CPR training, including serious games, may not independently enhance skills without some influence from instructors, particularly for beginners. In other words, teacher involvement remains crucial to refining CPR skill performance through serious games training. Lim et al [25] discovered that content learned in serious games may not seamlessly transfer to skill operations during assessments, particularly for students with autonomous learning based on serious games. Scores in the pressing position, crucial for CPR quality, were notably worse than those in traditional training. Factors such as incorrect anatomical positions directly impact compression quality, making it challenging to achieve better performance in practical measures such as compression depth and frequency. While there was no significant difference in CPR compression skill or rate between the 2 training models, serious games-based CPR training revealed imperfections. To address this, integrating and emphasizing the impactful elements and advantageous attributes of traditional training into serious games may compensate for their shortcomings in skill practice. This approach has the potential to amplify the comparative advantages of serious games in CPR training.

In summary, the results of this study are similar to those of similar previous systematic reviews or studies. Nevertheless, given the limited number of studies included in this meta-analysis and the low GRADE evidence level, these results warrant cautious interpretation. Therefore, we recommend future CPR training efforts prioritize conducting high-quality, large-sample studies. This will enable a more comprehensive analysis of the effectiveness of serious games-based training, providing substantial evidence for the refinement of guidelines and the development of related teaching methodologies.

Strengths and Limitations

Strengths

This review compensates for the shortcomings of the previous literature in English by focusing on all types of serious games and conducting a comprehensive search of massive Chinese databases. Certainly, this study was conducted in strict accordance with highly recommended guidelines (ie, PRISMA), with early registration of the protocol for the systematic review and final grading of the evidence based on the GRADEpro GDT web-based tool, so it can be considered a robust, high-quality review. In addition, the meta-analysis conducted in this study involved 9 RCTs [34-42]. These RCTs provided detailed information on the study population, training protocol, serious games used, and measurement tools for outcome indicators. As for blinding implementation, it was challenging to blind interventionists due to the nature of CPR teaching training, which resulted in some degree of implementation bias. On the other hand, blinding the measurer effectively prevented measurement bias, particularly when assessing CPR theoretical knowledge and skills. Objective outcome indicators such as CPR compression depth and frequency, as recorded by the simulator, were less susceptible to measurement bias. The literature also addressed missed visits, had a low risk of selective reporting bias, and demonstrated baseline comparability between groups. Therefore, the included literature was of high quality, and the findings can be considered credible.

Limitations

This study acknowledges several limitations that merit consideration. First, our research only encompassed studies available in Chinese and English, which may introduce a linguistic bias. Second, heterogeneity in our meta-analysis results emerged due to variations in study populations, the use of different serious games, and diverse tools used to measure outcome indicators. Despite our efforts to explore the sources of heterogeneity through sensitivity analysis, a complete explanation remained elusive. In particular, it is worth noting that the use of different instruments by the included studies to evaluate training outcomes may have influenced the judgment of the results. Third, the relatively small number of included studies prevented us from conducting tests for publication bias. Additionally, some data underwent statistical transformations during the meta-analysis, potentially influencing the accuracy of the results. Lastly, this study focused primarily on CPR theory assessment, skill evaluation, compression depth, and compression rate as outcome indicators, without delving into knowledge and skill retention post-training, trainees' self-efficacy, or other facets of compression quality.

Implications for Future Research and Practice

Serious games, as an innovative model for CPR teaching and training, offer a promising avenue for first aid education, catering to diverse populations. However, this approach is still in its developmental and exploratory phases, and its cost-effectiveness warrants discussion. Future research should consider incorporating outcome indicators from the field of health economics to address economic barriers and promote the adoption of serious games in professional medical education and broader first aid training. Additionally, many studies lack standardized training specifications for serious games, including training duration, frequency, trainer intervention levels, and evaluation methods and tools for assessing training effectiveness. While serious games are recommended for CPR education, the specific details of this training mode require further standardization. Moreover, the quality of serious games, which serve as the platform for CPR training, significantly impacts training effectiveness. Developing serious games that align with international guidelines and cater to the diverse characteristics of trainees is undoubtedly challenging but essential. In conclusion, future research should prioritize conducting multicenter, large-sample RCTs to advance our understanding of the potential of serious games in CPR education.

Conclusion

This study conducted a meta-analysis of RCTs to assess the efficacy of serious games in CPR training. The findings indicate that serious games are equally effective as traditional training methods in enhancing CPR theory assessment and skill evaluation. Meanwhile, no significant differences emerged between serious games and traditional training methods regarding CPR compression depth and frequency. Notably, the current body of high-quality studies on serious games in CPR training is limited, often characterized by small sample sizes. Therefore, future research should prioritize conducting additional high-quality RCTs to provide further evidence and offer a more comprehensive understanding of the impact of serious games in CPR training and education.

Abstract

Background: Several electronic interventions have been used to improve glycemic control in patients with diabetes. Electronic interactive games specific to physical activity are available, but it is unclear if these are effective at improving glycemic control in patients with diabetes.

Objective: This study aimed to determine the effects of electronic game–based interventions on glycemic control in patients with diabetes.

Methods: Relevant studies that were published before April 1, 2023, were searched from 5 databases: PubMed, Embase, Web of Science, Scopus, and Cochrane Library. Eligibility criteria included prospective studies examining the relationship between electronic games with physical activities or diet education and glycemic control as the outcome. The risk of bias was assessed using the Cochrane risk-of-bias tool. All analyses were conducted using RevMan5.4.1. Depending on the heterogeneity across studies, the pooled effects were calculated using fixed-effects or random-effects models.

Results: Participants from 9 studies were included and assessed. Glycated hemoglobin (HbA_{1c}) and fasting blood glucose improved in the intervention group, although the analysis revealed no significant reduction in HbA_{1c} (−0.09%, 95% CI −0.29% to 0.10%) or fasting blood glucose (−0.94 mg/dL, 95% CI −9.34 to 7.46 mg/dL). However, the physical activity of individuals in the intervention group was significantly higher than that of those in the control group (standardized mean difference=0.84, 95% CI 0.30 to 1.38; P=.002). Other outcomes, such as weight and blood lipids, exhibited no significant improvement (all P>.05).

Conclusions: Electronic games had a good impact on participants' physical activity and offered an advantage in glycemic control without reaching statistical significance. Electronic games are convenient for reminders and education. Low-intensity exercise games may not be considered a better adjuvant intervention to improve diabetes self-management care.

KEYWORDS
electronic game; physical activity; diet; diabetes mellitus; glycemic control

Introduction

Diabetes mellitus is one of the 4 major noncommunicable diseases and is also among the top 10 global causes of death. Throughout the world, the number of patients with diabetes mellitus is increasing, probably due to changes in lifestyle. According to the International Diabetes Federation, in 2021, approximately 536.6 million adults (aged 20-79 years) were living with diabetes; this is expected to rise to 12.2% in 2045 [1]. Because of the rise in type 1 and type 2 diabetes, the burden of health care expenditures and its complications continues to increase, whereas the complications are the main causes of morbidity and mortality [2]. To address the health challenge resulting from diabetes, effective and efficient management is needed [3-5].

Lifestyle management, an efficacious method for diabetes prevention [6], is a fundamental aspect of diabetes care. It includes diabetes self-management education and support, medical nutrition therapy, physical activity, smoking cessation counseling, and psychosocial care [7]. Food intake and physical activity are associated with significantly improved control of diabetes [8]. With advances in technology, lifestyle management incorporating novel technologies and formats meets the needs of various populations for diabetes treatment [9]. New methods, such as electronic games and wearable devices, aim to contribute to better patient compliance [10].

It has been reported that electronic games can help players learn more about healthy diets and encourage exercise [11,12]. Although they play a role as facilitators in motivating and accelerating physical activity, they offer little benefit to patients with chronic disease [13]. Previous systematic reviews have evaluated the impact of app-based or electronic health interventions to support changes in blood glucose management, physical activity, or diet [9,14,15]. However, previous papers analyzed relatively few articles or articles that were not solely on using games. They also used educational or regulation applications, robots, or virtual worlds that do not contain game elements. Electronic games specific to physical activity and dietary education are available; however, we currently lack an understanding of how effective electronic games can be for glycemic control.

In this study, we performed a comprehensive literature search to select studies on the effects of electronic game–based interventions on glycemic control in patients with diabetes for meta-analysis. Electronic gaming interventions are defined as containing an element of gaming that involves virtual reality, serious gaming, or exergaming [15].

Methods

Data Sources and Search Strategy

This review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement and its associated checklist (Multimedia Appendix 1). Relevant studies that were published before April 1, 2023, were searched from 5 databases: PubMed, Embase, Web of Science, Scopus, and Cochrane Library. The references of the included studies were hand-searched to identify any additional articles. The following terms were used during the search: (“Diabetes” OR “diabetic” OR “diabetes mellitus” OR “glycemic control” OR “glucose control” OR “glucose”) AND (“game” OR “gamification” OR “exergaming” OR “avatar” OR “wii” OR “virtual” OR “konami” OR “wii-fit” OR “kinect” OR “tierone” OR “video-game” OR “serious-games” OR “serious video-games” OR “Augmented reality” OR “mixed reality” OR “second life” OR “TierOne” OR “Konami Dance Dance Revolution” OR “Sony Eyetoy” OR “Microsoft Kinec”). Detailed search strategies for each database are given in Multimedia Appendix 2. The reference lists of the searched articles and the relevant reviews were then screened to identify any pertinent studies.

Study Selection

Studies included in this meta-analysis met the following criteria: (1) participants were diagnosed as having type 1 diabetes or type 2 diabetes; (2) the articles were published in English or Chinese; (3) the articles presented the electronic management intervention with a gaming element, such as a virtual reality game, serious game, or exergame; and (4) the outcome indicators were blood glucose and glycated hemoglobin (HbA_{1c}).

Studies that met the following criteria were excluded: (1) participants had gestational diabetes mellitus, had other special types of diabetes mellitus, underwent surgery, had an operation, or were in the emergency department; (2) participants had a previous history of mental illnesses, eating disorders, or cancer; (3) the management intervention was only based on an online, mobile, or virtual application but did not use a gaming element; and (4) articles that were protocols, conference abstracts, case reports, reviews, or meta-analyses.

Articles were screened in a 2-step process. First, all titles and abstracts were examined by 2 investigators. Any citations that clearly did not meet the inclusion criteria were excluded. Second, all abstracts and full-text articles were examined independently by 2 investigators. Any disagreements in the selection process were resolved through discussion with a third investigator.

Risk of Bias

The included trials were independently assessed by 2 investigators for the risk of bias using the Cochrane risk-of-bias tool [16]. An assessment was performed across 5 domains of bias (sequence generation, allocation concealment, blinding, incomplete outcome data, and selective reporting). The risk of bias was assessed as either low (proper methods taken to reduce bias), high (improper methods creating bias), or unclear (insufficient information provided to determine the bias level). All discrepancies and disagreements were resolved through consensus or, where necessary, by a third author.

Data Extraction

A Microsoft Excel table was used to extract data on the year of publication, country, sample size, participant characteristics, study setting and design, intervention and control arms, duration, and outcome data. The main outcomes included HbA_{1c} or fasting blood glucose (FBG). The secondary outcomes included daily steps (regarded as a physical activity outcome), blood pressure, and weight, among others. The data were obtained from the original text and attachments supplied. Data from different studies were converted to common units. Data extraction was carried out by 2 reviewers independently. All discrepancies and disagreements were resolved through consensus.

Missing Data

Study authors were contacted by email where there were missing or unclear data (for instance, relating to the primary outcome). Studies for which insufficient primary data were available (eg, missing data cannot be obtained) were excluded from analysis but not from the review.

Data Synthesis and Quality Assessment

All analyses were conducted using RevMan5.4.1 (Cochrane). Data were expressed as the mean difference (MD) and 95% CI and pooled using fixed-effect or random-effects models according to the heterogeneity. A random-effects model assumes that the study estimates are estimating different, yet related, intervention effects and thus incorporates the heterogeneity among studies. This is a more appropriate method to pool studies that may differ slightly in the distribution of risk factors, population, size, and outcomes.

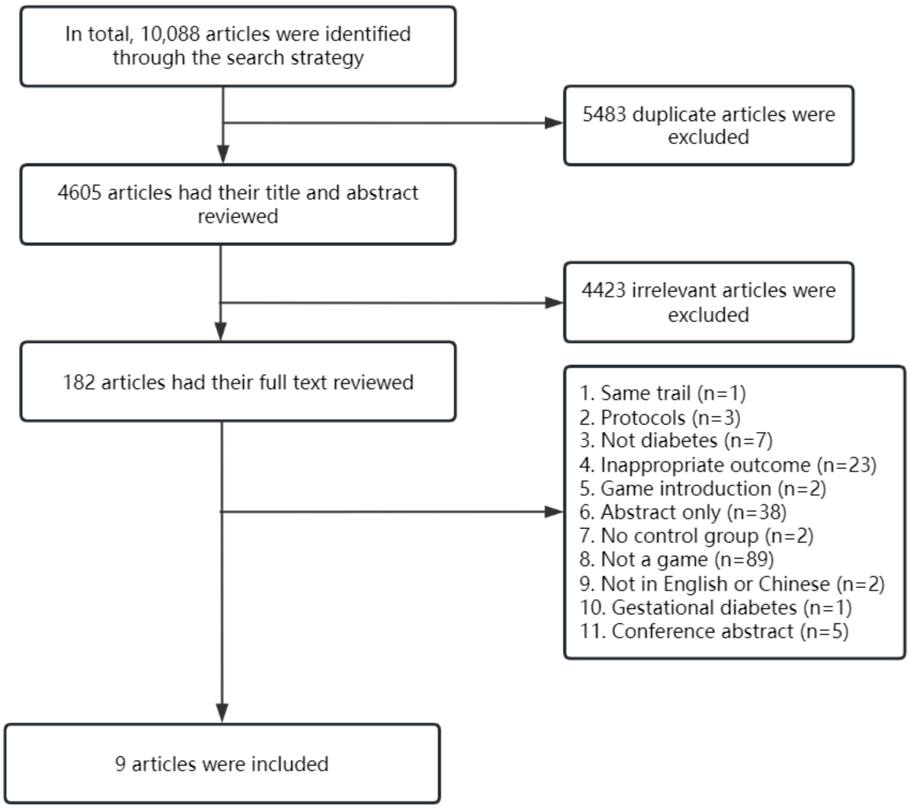
Heterogeneity was assessed using a χ^2 test and quantified using the I^2 statistic. Significance for the heterogeneity was set at $P<.05$, with an $I^2>50\%$ considered to be evidence of high heterogeneity, which prompted us to use the random-effects model to pool the data.

Results

Overview

Our search identified 10,088 articles, of which 4605 were screened after removing duplicate records. Of these, 182 were identified for further evaluation. Of these, 173 were excluded, resulting in 9 included studies (Figure 1). Of the excluded articles, 18 were excluded because they only had abstracts and we could not access the original text and data.

Figure 1. Flowchart of the study selection process.



The results of the remaining 9 studies, comprising 913 participants and 747 cases of type 2 diabetes, were included in the meta-analysis [17-25]. The characteristics of all 9 studies are shown in Multimedia Appendix 3 [17-25]. The duration of trials ranged from 1 month to 1 year. Of the 9 studies, 4 were undertaken in the United States [18,21,23,25], 2 in Europe [17,20], and 3 in Asia [19,22,24]. Of the 9 studies, 3 assessed FBG and 8 assessed HbA_{1c}.

The studies included 2 non–randomized controlled trials (RCTs) and 7 RCTs, the quality of which was assessed using the Cochrane risk-of-bias tool. We determined that 3 studies were of high quality, whereas 4 were of moderate quality and 2 were of low quality (Figures 2 and 3 [17-25]). The 2 non-RCTs were not random and the allocations were unclear. Blinding was difficult in game interventions; 1 study was unblinded [25] and 4 were unclear, but the studies made an effort to blind either patients or personnel. One study was not blinded to the outcome assessment, but it was still analyzed as low risk, considering its main outcome was the objective index. The 9 studies had no elective outcome reporting.

Figure 2. Risk-of-bias graph showing the authors' judgments about each risk-of-bias item presented as percentages across all the included studies. A total of 9 trials were assessed for risk of bias.

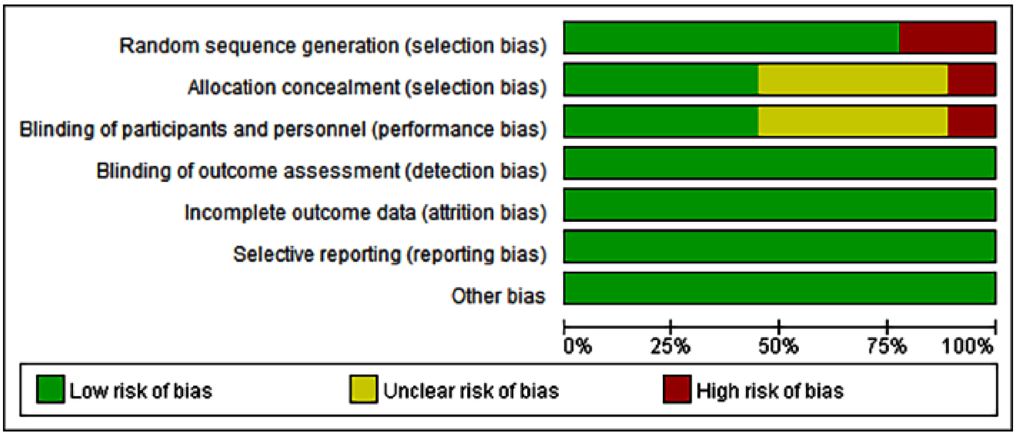


Figure 3. Risk-of-bias summary showing the authors' judgments about each risk-of-bias item for each included study. Green "+": low risk of bias; red "–": high risk of bias; yellow "?": unknown risk of bias.

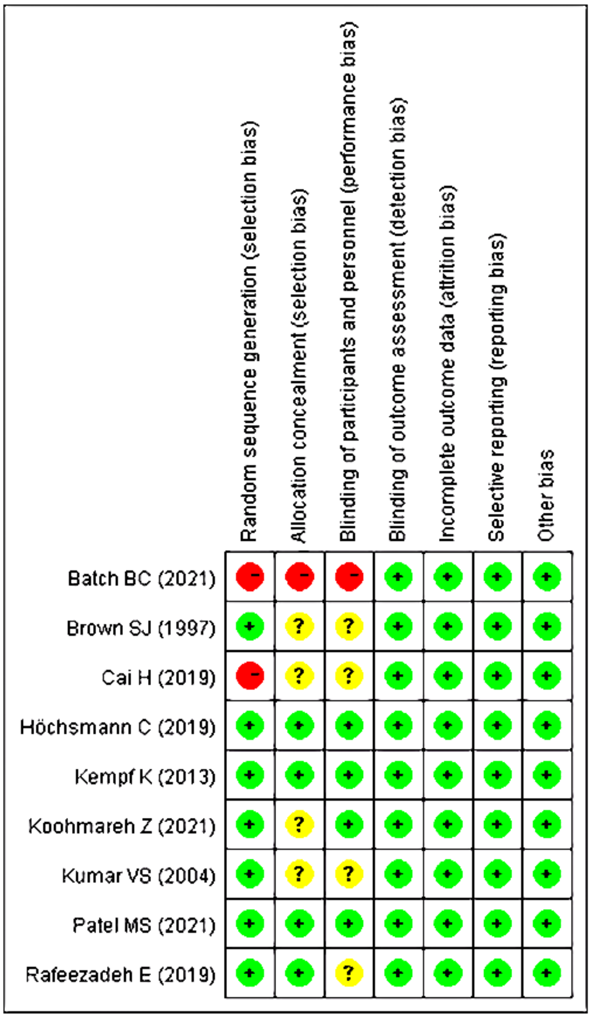


Publication bias was not assessed for any outcome as <10 trials were available.

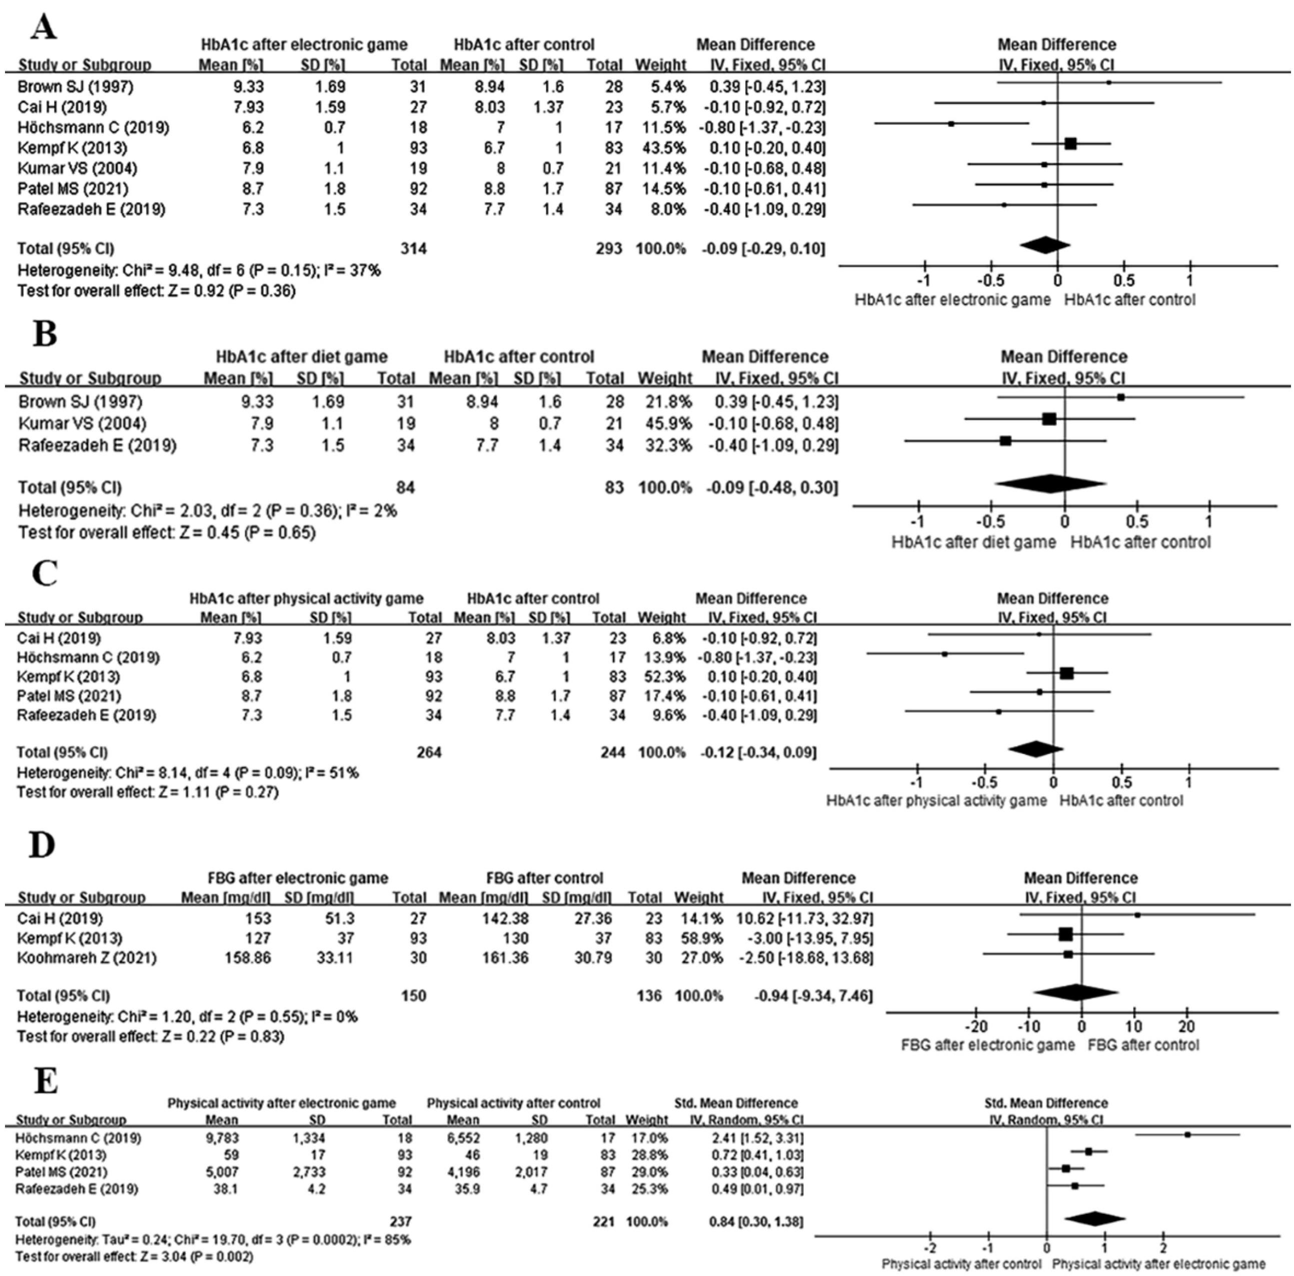
Meta-Analysis

HbA_{1c} Level

A total of 8 articles had HbA_{1c} testing but 1 did not provide postintervention data [25]. We sent an email to the author with a request to provide the raw data but received no reply.

As shown in Figure 4A [17,21,23-25], this analysis showed a clinically important improvement in HbA_{1c}, but there was no significant reduction after the intervention among individuals with diabetes mellitus (7 studies; n=607; MD=−0.09%, 95% CI −0.29% to 0.10%; I^2=37%; P=.36). Figure 4B shows the change in HbA_{1c} after a diet-based game intervention (3 studies; n=167; MD=−0.09%, 95% CI −0.48% to 0.30%; I^2=2%; P=.65). Figure 4C shows the change in HbA_{1c} after a physical activity–based game intervention (5 studies; n=508, MD=−0.12%, 95% CI −0.34% to 0.09%; I^2=51%; P=.27).

Figure 4. Meta-analysis of the effect of electronic games on HbA_{1c}, FBG, and physical activity. (A) HbA_{1c} after a diet intervention or physical activity intervention; (B) HbA_{1c} after a diet intervention; (C) HbA_{1c} after a physical activity game intervention; (D) FBG after an electronic game intervention; and (E) physical activity after an electronic game intervention. FBG: fasting blood glucose; HbA_{1c}: glycated hemoglobin; IV: inverse variance; Std.: standardized.



Fasting Blood Glucose Level

The meta-analysis showed that the FBG level of the intervention groups was not statistically different from that of the control groups (3 studies; n=286; MD=−0.94 mg/dL, 95% CI −9.34 to 7.46 mg/dL; I^2=0%, P=.83; Figure 4D).

Physical Activity

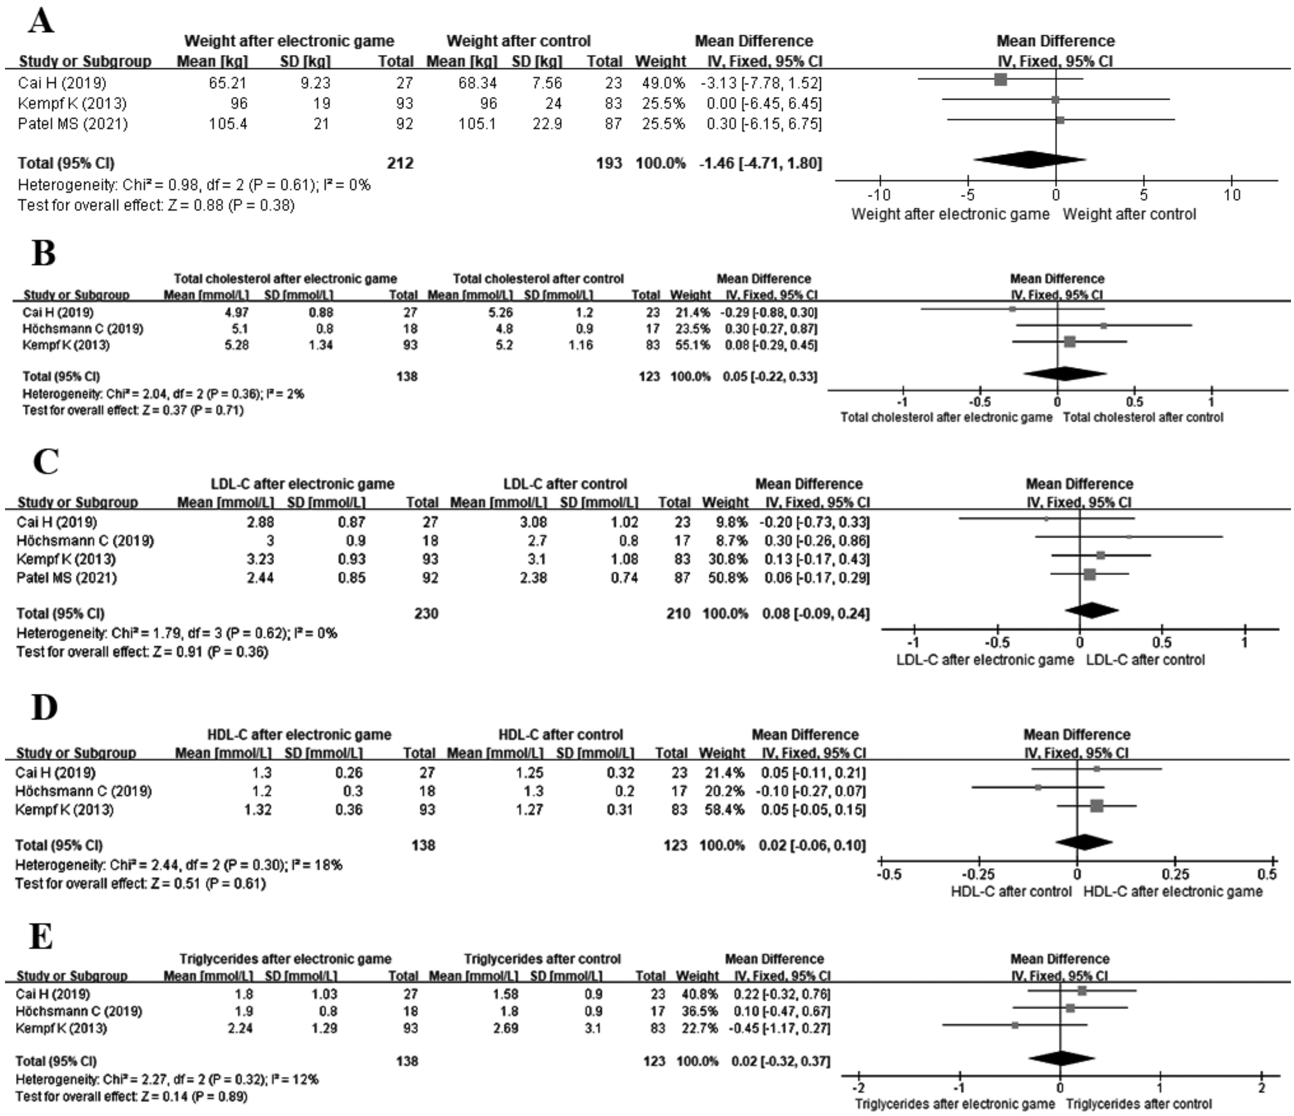
Of the 7 RCTs, 2 assessed self-reported physical activity and 2 counted participants' daily steps during the intervention to assess the patients' physical activity. Because of the differences in measurement instruments, we calculated standardized mean differences (SMDs). These results were statistically heterogeneous with respect to the effect (χ^2_3=19.70; P<.001; I^2=85%); we found a significant increase in physical activity above baseline in the intervention groups. Moreover, participants assigned to the intervention groups increased their physical activity significantly more than participants in the control groups (SMD=0.84; 95% CI 0.30 to 1.38; P=.002; Figure 4E).

Weight

Weight also trended toward decreases in the intervention groups, with an MD of −1.46 kg (95% CI −4.71 to 1.80 kg; Figure 5A

[17-19]). However, the decreases did not reach statistical significance (P=.38).

Figure 5. Meta-analysis of the effect of electronic games on (A) weight, (B) total cholesterol, (C) LDL-C, (D) HDL-C, and (E) triglycerides. HDL-C: high-density lipoprotein cholesterol; IV: inverse variance; LDL-C: low-density lipoprotein cholesterol; Std.: standardized.



Blood Lipids

There was no significant reduction in total cholesterol (3 studies; n=261; MD=0.05 mmol/L, 95% CI −0.22 to 0.33 mmol/L; I^2=2%; P=.71; Figure 5B), low-density lipoprotein cholesterol (4 studies; n=440; MD=0.08 mmol/L, 95% CI −0.09 to 0.24 mmol/L; I^2=0%; P=.36; Figure 5C), high-density lipoprotein cholesterol (3 studies; n=261; MD=0.02 mmol/L, 95% CI −0.06 to 0.10 mmol/L; I^2=18%; P=.61; Figure 5D), or triglycerides (3 studies; n=261; MD=0.02 mmol/L, 95% CI −0.32 to 0.37 mmol/L; I^2=12%; P=.89; Figure 5E) after the intervention among patients with diabetes mellitus.

Discussion

Principal Findings

This study demonstrated that electronic interactive games were associated with a good impact on participants' physical activity. However, we found that electronic interactive games did not present a significant benefit for HbA_{1c} levels, FBG levels, weight, or blood lipids compared to the control group. The game interventions were intended for education to manage diabetes through games.

Effects of Diet Education Games on Blood Glucose

Plant-based diets and exercise are major diabetes-protective factors [26]. The Da Qing Diabetes Prevention Study showed an overall 51% reduction in diabetes incidence in participants after a 6-year intervention with diet, exercise, or both; its 30-year follow-up showed that lifestyle interventions reduced the incidence of serious diabetes complications and diabetes-related mortality [27]. However, Hemmingsen et al [28] did not find firm evidence that diet alone or physical activity alone influences the risk of type 2 diabetes mellitus or its associated complications in people at increased risk of developing type 2 diabetes mellitus compared to standard treatment [28]. The trials included in this study had little data on the impact of games on diet, and only 3 articles evaluated participants' postintervention diet. From the results, education through games was effective, although the improvements in glycemic control were not statistically significant. The most important reason was that the 3 trials studied patients with type 1 diabetes mellitus aged 8 to 18 years. The games provided diabetes-related diet education to the patients, but family-based diet intervention may also not impact glycemic control [29].

Effects of Games Related to Physical Activity on Blood Glucose

Physical activity with different intensities impacts glycemic control in individuals with diabetes. Of the included studies, 4 trials [17,18,20,24] assessed physical activity by daily steps or self-reported activity, and this analysis found a significant increase. These results are consistent with findings from other meta-analyses showing increased physical activity among patients with chronic disease [30-32]. Some studies find positive effects with low-intensity physical activity, although these are not reflected by a decrease in HbA_{1c} or FBG in patients with type 2 diabetes [33-35]. A meta-analysis showed that high-intensity interval exercise significantly reduced HbA_{1c} levels compared to no or low-intensity exercise [36]. Low exercise intensity in the 9 studies we included may be the reason why there was no significant difference in HbA_{1c} and FBG in patients with diabetes between the groups. However, the games in the virtual reality group were relatively novel, which was very helpful for improving cognition, physical skills that are directly involved in functional abilities, and enthusiasm for sports [19].

The study by Höchsmann et al [20] contributed a substantial amount of heterogeneity; without this study, I^2 was 11%. The high heterogeneity may have been caused by the baseline of the participants in this trial being better than those in the other trials. In their trial, Höchsmann et al [20] used a dilapidated garden to symbolize the patient's physical condition, and exercise and daily physical activity execution were tracked by mobile phones, allowing for feedback. After 24 weeks of intervention, there was no significant change in HbA_{1c} levels in the intervention group, while HbA_{1c} levels in the control group receiving 1-time lifestyle counseling increased. In the trial, the intervention group had a higher increase in daily steps than the control group, providing evidence that physical activity can be encouraged by electronic games.

Effects of Games on Blood Lipids, Blood Pressure, and BMI

In our study, game-based intervention resulted in no significant decrease in blood lipids in patients with diabetes. Only 2 trials reported the outcomes of blood pressure [17,20] and BMI [17,19], and the 2 indexes were both reduced. Systolic blood pressure was below 140 mm Hg but above 130 mm Hg, which is still high for patients with diabetes. Treatment with medication may be indispensable.

Effects of Games on Weight

Lifestyle intervention can be effective for achieving clinically important reductions in body weight [37,38]. It has been demonstrated that electronic game activities are engaging, which encourages their use on a regular basis, improving the long-term outcome of a treatment for obesity [39,40]. However, an intervention using a different avatar did not improve physical activity practice or self-efficacy expectations [41]. Gomez et al [42] showed that high exercise intensity from active electronic games elicited significant increases in energy expenditure. In this study, electronic games did not result in significant weight reduction, and BMI was reduced slightly in 2 trials. Possible reasons include insufficient physical activity and that participants did not strictly control their diet. Whether electronic games are beneficial for weight control by encouraging appropriate intensity exercise in patients with diabetes requires more clinical evidence in the future.

The reasons for the lack of significant results in this meta-analysis may be as follows. First, participants in the control groups were also familiar with what the game taught. Second, patients with type 2 diabetes mellitus in the intervention groups, who were all older than 40 years, could not make full use of electronic devices and adapt to the games. Third, for exercise-based interventions, not all studies involved regular exercise monitoring for participants and established appropriate feedback or interaction mechanisms.

Limitations and Future Directions

This study had several limitations. First, not every included study reported the HbA_{1c} and FBG levels. Some excluded studies had relevant interventions but did not observe blood glucose changes or failed to give detailed trial data results. Second, the studies that were included in this meta-analysis were not homogeneous. Different games or game mechanisms were used in different patient populations. The number of participants was not large in several of the included studies, and each study used different games. Therefore, it is difficult to conduct detailed hierarchical verification of the effects of different games on blood glucose. We strived to ensure that the included studies were high-quality RCTs with strict inclusion and exclusion criteria, excluding nongaming electronic interventions. Existing studies have evaluated the effectiveness of electronic games as an alternative for traditional diabetes education. As diabetes continues, it is necessary to promote this management model. However, future studies should not only design the game in terms of increased knowledge and improved self-management but should encourage enhanced physical activity intensity.

Conclusion

As an alternative treatment tool in diabetes management, the studies on electronic games explored in this study showed a clinical improvement in glycemic control and weight control, although this improvement was not superior to that observed in the control participants. Thus, such interventions may complement existing treatment courses for diet, self-management education, and high-intensity physical activity to potentially increase the compliance of patients with diabetes. More new technologies can be used for diabetes control, and electronic games can be designed for different groups of patients with diabetes. For example, immersive virtual reality is an emerging strategy to enhance exercise performance for young patients with diabetes, and the metaverse may be a new community enabling older patients to form new social connections and share their experiences of living with diabetes. Interactive exercise games can be used in children to increase interest in education and family companionship time, and thus improve exercise compliance.

Acknowledgments

This work was supported by grants from the National Natural Science Foundation of China (grants 82170796 and 82003370), the Natural Science Foundation of Guangdong province (grant 2019A1515012225), the Science and Technology Plan of Guangdong province (grant 2022A0505030005), and Science and Technology Program of Guangzhou (grants 202102020165 and 2024A04J9990).

Authors' Contributions

Y Cheng conceived the idea of the overview and wrote the protocol and full overview. WY and YH developed the concept and details of the overview (ie, participants, intervention, comparison, outcomes). WY and Y Chen carried out searches and selected reviews for inclusion (YH acted as an arbitrator). WY and SY carried out the assessment of methodological quality (YH acted as an arbitrator). WY and SY extracted the data and interpreted the initial findings. YH and Y Chen directed data analyses. WY, YH, LY, and Y Cheng formulated the focus of the discussion and made suggestions for future studies. All authors were involved in the interpretation of the results and in approving the final review.

Abstract

Background: The effectiveness of virtual reality (VR) therapy in adults with chronic spinal pain (CSP) is unclear.

Objective: This study was conducted to compare the effectiveness of VR therapy and other therapies in adults with CSP, especially patients with inflammation-related pain.

Methods: PubMed, Web of Science, Cochrane Library, Embase, and CINAHL databases were searched up to November 11, 2023. Randomized controlled trials (RCTs) comparing adults with CSP receiving VR therapy with those receiving other therapies were included. The trial registration platform as well as the reference lists of included studies and previous systematic reviews and meta-analyses were manually searched. Two independent reviewers performed study selection, data extraction, risk-of-bias assessment, and evaluation of the quality of the evidence. The weighted mean difference (WMD) was used as the effect size used to synthesize the outcome measure.

Results: In total, 16 RCTs involving 800 participants were included in this meta-analysis. The pooled data from 15 (94%) RCTs including 776 (97%) participants showed that VR therapy was superior in improving pain intensity (WMD=–1.63, 95% CI –2.11 to –1.16, P<.001, I^2=90%) and reducing inflammatory markers, including C-reactive protein (WMD=–0.89, 95% CI –1.07 to –0.70, P<.001, I^2=0%), tumor necrosis factor-alpha (WMD=–6.60, 95% CI –8.56 to –4.64, P<.001, I^2=98%), and interleukin-6 (WMD=–2.76, 95% CI –2.98 to –2.53, P<.001, I^2=0%). However, no significant differences were found in terms of the spinal range of motion (ROM), disability level, or fear of movement. In addition, 10 (63%) of the included RCTs had a high risk of bias.

Conclusions: VR therapy may be an effective and safe intervention for reducing symptoms in patients with CSP, as it is shown to exert significant analgesic effects and beneficial improvements in inflammatory factor levels. However, this approach may not have significant effects on the spinal ROM, disability level, or fear of movement. Notably, the quality of the evidence from the RCTs included in this study ranged from moderate to low. Therefore, we recommend that readers interpret the results of this study with caution.

KEYWORDS
virtual reality; chronic spinal pain; inflammation-related pain; systematic review; meta-analysis

Introduction

Chronic spinal pain (CSP), which most commonly includes chronic low back pain (CLBP) and chronic neck pain (CNP), is the leading cause of years with disability worldwide [1,2] and constitutes the most frequent reason for patients to seek medical care in any given year. The lifetime prevalence of low back pain (LBP) is 84%; more specifically, the lifetime prevalence of CLBP is 23%, and LBP accounts for approximately 11%-12% of cases of disability [3]. CSP is recognized as a biopsychosocial syndrome [4]. Prolonged pain can lead to anxiety, depression, and other negative emotions and is particularly significant in patients with CSP, as it is associated with decreased quality of sleep and reduced physical activity, thus placing tremendous strain on health care systems and world economies [5].

Previous studies have reported that an intervertebral disc undergoes aging or pathological changes in the adjacent region in patients with CSP, exposing cells within the nucleus pulposus to macrophages, resulting in an inflammatory response that might trigger pain [6,7]. The guidelines recommend that nonsteroidal anti-inflammatory drugs (NSAIDs) be the primary choice for patients with chronic pain [8]. However, compared with a placebo, NSAIDs can reduce CSP by controlling the level of inflammation but do not achieve clinically important efficacy [9]. Additionally, long-term use may be associated with adverse effects (eg, gastrointestinal reactions, hepatic and renal damage, and cardiovascular risk) [10]. Several studies have shown that conventional nonpharmacological therapies, such as spinal manipulation, acupuncture, exercise therapy, yoga, and cognitive-behavioral therapy, are beneficial for reducing CSP and improving psychological symptoms but have limited effects (small to moderate) [11-14]. Effective cognitive-behavioral therapies are not widely accessible due to the reliance on therapist experience, and the long-term effectiveness of these therapies remains unclear [15]. Notably, the majority of patients with CSP have goals of pain management (using ongoing care) rather than "curing" (care with a specific end) for their therapeutic care because of the complexity of the causes of chronic pain [16]. Thus, pain management is as important as the control of inflammation levels for patients with CSP. There is an urgent need for an alternative analgesic nonpharmacological and anti-inflammatory strategy for patients with CSP.

Virtual reality (VR) is typically characterized by low cost, easy availability, reusability, and personalized customization; VR therapy has been used as an alternative approach for pain management in various populations, such as individuals with spinal cord injuries, burns, and phantom limb pain [17-19]. VR can be categorized into 2 types: nonimmersive virtual reality (NIVR) and immersive virtual reality (IVR). NIVR is managed using a computer or console gaming system and a 2D interface device (mouse, keyboard, or gamepad, joystick), and patients do not need to be fully immersed in a virtual environment for experience [20].With the use of professional equipment, hardware, and configuration of the corresponding software, IVR can mimic reality by enabling the user to interact with the virtual environment [21]. A recent study demonstrated that regular exercise with the use of VR might be related to a decrease in inflammation in participants undergoing chronic hemodialysis [22], and inflammatory arthritis–targeting innovative teaching approaches based on VR technology are considered feasible [23]. There is limited evidence regarding the beneficial effects of VR therapy on pain in patients with CNP [24] and CLBP [25,26]; furthermore, there is insufficient focus on inflammatory factors. Therefore, this study aimed to investigate the potential efficacy of VR in reducing pain intensity and the levels of inflammatory factors in patients with CSP, thereby providing an updated summary of the existing evidence.

Methods

Study Protocol and Registration

This systematic review and meta-analysis was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines. The PRISMA checklist is given in Multimedia Appendix 1. The study protocol was registered in the PROSPERO database (CRD42022382331). The *Cochrane Handbook for Systematic Reviews of Interventions* (version 5.1.0) was followed [27].

Search Strategy

Search Sources

PubMed, Web of Science, Cochrane Library, Embase, and CINAHL electronic databases were searched from inception to November 11, 2023, to identify relevant studies. The reference lists of the included studies, as well as systematic reviews and meta-analyses that examined the efficacy of VR in patients with CSP, were manually searched for additional eligible studies. The trial registration platform ClinicalTrials was also searched for ongoing studies that reported sufficient data on the efficacy of VR for CSP.

Search Terms

The studies on VR for CSP were identified by formulating appropriate search terms. These terms were selected based on the target population (spinal pain, neck pain, thoracic pain, back pain, LBP, sacral pain, and intervertebral disc pain), target intervention (eg, VR), and target study design (eg, randomized controlled trial [RCT]). The detailed search strategy is shown in Multimedia Appendix 2.

Study Eligibility Criteria

The inclusion criteria were as follows:

- Participants: adults older than 18 years with chronic pain (more than 12 weeks) in the spinal region were included, except those who were receiving analgesic medication and who had cancer-related pain or neuropathic pain (eg, neuropathic pain after spinal cord injury, herniated disc with compression, sciatica, or lumbosacral radiculitis).

- Intervention: VR therapy.
- Comparisons: sham stimulation, usual care, and conventional treatment.
- Outcomes: pain intensity, inflammatory markers (eg, C-reactive protein [CRP], tumor necrosis factor-alpha [TNF-α], and interleukin [IL]-2, IL-4, and IL-6), fear of movement, spinal range of motion (ROM), and disability level.
- Study design: RCT.

No restrictions were imposed on language or publication date.

Study Selection

The retrieved studies were imported into Endnote X9 software (Clarivate), which was used to eliminate duplicate studies. Two independent reviewers (authors TTZ and FW) performed the initial screening of the literature by reading the titles and abstracts of all retrieved studies, and studies that did not meet the inclusion criteria were excluded. Next, the full texts of the remaining studies were screened. Any disagreements were resolved by negotiation and discussion with a third reviewer (author XZ).

Data Extraction

Two independent reviewers (authors FW and XL) extracted detailed information, including the name of the first author, the year and country of publication, the language of publication, study design, the number of included subjects (% female), diagnosis, and outcome indicators. Information about the characteristics of the interventions, including dose, frequency, and duration, was also collected for both the VR group and the control group. The sample size and mean (SD) of the outcome indicators in each group were collected. When the same group of participants was reported in different studies, the group with the largest sample size was selected for inclusion in this review to avoid duplicate publications [28]. For information that could not be confirmed, the authors were contacted by email. The 2 reviewers cross-checked the data at the end of the extraction, and any disagreements were resolved by negotiation.

Risk-of-Bias Assessment

The methodological quality of the included studies was independently assessed by 2 reviewers (authors XL and ZFH) using the Cochrane Risk of Bias tool, and the studies were classified as having a low, unclear, or high risk of bias [29]. Disagreements were resolved by consulting a third reviewer (author QD). The Egger test and funnel plots generated with Stata 14.0 software (StataCorp) were used to evaluate potential publication bias. The trim-and-fill method was used to adjust for funnel plot asymmetry due to publication bias [30]. Sensitivity analyses were performed by removing each study separately to assess the robustness of the results [29]. The overall strength of the evidence was assessed using the Grading of Recommendations, Assessment, Development and Evaluation (GRADE) criteria [31].

Meta-Analysis and Subgroup Analysis

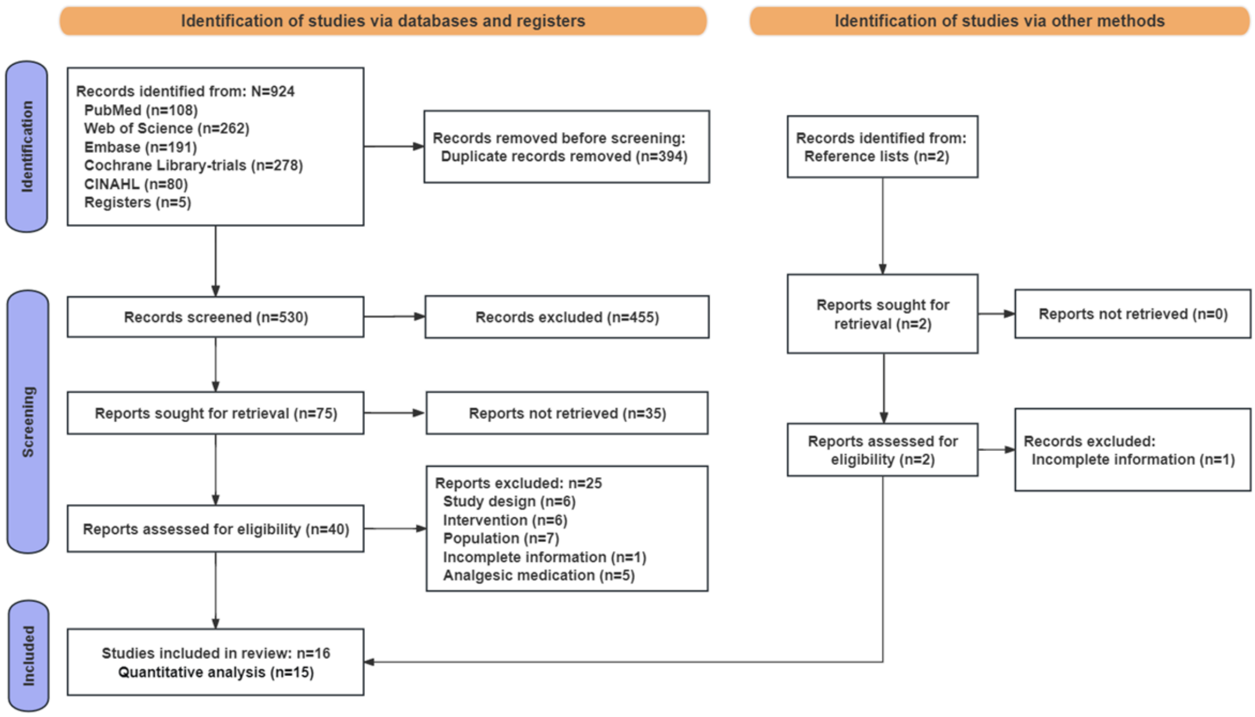
This systematic review and meta-analysis were performed using Review Manager software 5.4 (Informer Technologies) and Stata 14.0 software. Heterogeneity was tested using the I^2 statistic. A fixed effects model was selected for the outcome indicators if I^2<50%, while a random effects model was used when there was significant statistical heterogeneity (I^2>50%, P<.05). The effect size used to synthesize the outcome measure was the weighted mean difference (WMD). Three subgroup analyses were performed to explore the possible causes of heterogeneity among the studies: the region of CSP (CNP vs CLBP), VR types (IVR vs NIVR), and treatment duration (<4 weeks vs ≥4 weeks).

Results

Search Results

A total of 924 records were obtained from the 5 databases and the trial registration platform. A total of 394 (42.6%) duplicates were identified and removed using Endnote X9 software. After screening the titles and abstracts, 40 (7.5%) of the remaining 530 RCTs were retained, and 490 (92.5%) were excluded for the following reasons: (1) the study population included patients without CSP, (2) the intervention did not use VR therapy, (3) the type of study was a non-RCT, (4) the information was incomplete, and (5) the patients also received analgesic medication. Of the 40 studies, 15 (38%) were retained after reading the full text and 25 (62%) were excluded for the following reasons: (1) the study population included patients without CSP, (2) the intervention did not use VR therapy, (3) the type of study was a non-RCT, (4) the information was incomplete, and (5) the patients also received analgesic medication. Two additional RCTs were retrieved from the reference lists of the included studies. One RCT was retained after the full text was read, and the other was excluded due to incomplete information. A total of 16 studies were included in this review, 15 (94%) of which reported sufficient data (eg, mean [SD], sample size) on the analgesic effect of VR for CSP. Therefore, 15 studies were included in the meta-analysis. The PRISMA flowchart of selecting the included studies is shown in Figure 1.

Figure 1. PRISMA flowchart: database and clinical trial register search and other sources. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analysis.



The CSP reported in the included studies included CLBP [32-43] and CNP [44-47]. All patients had chronic pain that persisted for more than 3 months. The sample size varied from 8 to 90 participants, and the mean age ranged from 18 to 85 years. The characteristics of all the studies are summarized in Table 1.

Table 1. Characteristics of the included studies [32-47].

[f]VR: virtual reality.
[g]NPRS: Numerical Pain Rating Scale.
[h]VAS: Visual Analogue Scale.
[i]NWE: Nintendo Wii exercise.
[j]VRE: virtual reality exercise.
[k]NRS: Numeric Rating Scale.
[l]TSK: Tampa Scale for Kinesiophobia.
[m]CNP: chronic neck pain.
[n]NDI: Neck Disability Index.

The types of VR interventions included IVR [32,35,42,44-47] and NIVR [33,34,36-41,43], which were classified based on the degree of isolation participants experienced when interacting with the virtual environment during VR therapy. NIVR uses a wall-mounted screen or a computer monitor as the vehicle for VR content, while IVR uses a headset or head-mounted display [48]. Compared to NIVR, IVR can increase the user's sense of presence by improving immersion through the addition of auditory or haptic feedback [49]. The duration of a single VR session ranged from 2 to 40 minutes, and the frequency of treatment ranged from 5 to 7 times a week; all the included studies ranged in duration from a single exercise session to 8 weeks. For the control groups, 5 (31%) studies performed conventional balance function training [33,34,38-40], 5 (31%) performed conventional physical therapy [36,37,41,46,47], 2 (13%) performed core training [43,44], and the remaining conducted treatments, including sham VR [32], conventional multimodal pain therapy [42], waiting lists [45], and standard care [35]. The intervention details are summarized in Table 2.

Table 2. Characteristics of the intervention protocols used in the included studies [32-47].

First author	Intervention group	Control group	Device	Duration
Garcia et al [32]	Ease VR[a], IVR[b], interactive, pain education, relaxation/interception, mindful escape, pain distraction games, dynamic breathing performed 56 times (2-16 minutes each time, average of 6 minutes, 1 time/day)	Sham VR, NIVR[c], not interactive, displayed 2D nature footage with neutral music, 20 videos rotated over 56 sessions, performed 56 times (2-16 minutes each time, average of 6 minutes, 1 time/day)	Pico G2 4K all-in-one head-mounted VR device	8 weeks
Nambi et al [33]	VR group: sit in the virtual platform and select firing game executed by trunk movements (flexion, extension, and lateral flexion; 30 minutes/day, 5 times/week, for 4 weeks); heat modality (20 minutes); therapeutic ultrasound (25 minutes)	Conventional balance function training, traditional active balance exercise for abdominal and back muscles (5 times/week for 4 weeks); heat modality (20 minutes); therapeutic ultrasound (25 minutes)	VR group: Pro-Kin system PK 252 N (TecnoBody)	4 weeks
Nambi et al [34]	VRT: shooting game (30 minutes, 5 days/week, for 4 weeks); home-based exercise; hot-pack therapy (20 minutes); ultrasound (frequency 1 MHz, intensity 1.5 W/cm^2 in continuous form for 5 minutes)	Conventional balance function training: standardized conventional exercises actively involving abdominal, deep abdominal, and back muscles (30 minutes/session, 5 days/week, for 4 weeks); hydrocollator packs (20 minutes/session); continuous ultrasound (frequency 1 MHz, intensity 1.5 W/cm^2) at the low back region (5 minutes, 5 days/week, for 4 weeks)	VRT: Pro-Kin system (TecnoBody)	4 weeks
Yalfani et al [35]	Fishing, boxing, tennis, football, bowling, beat saber, audio shield, and skiing (30 minutes, 3 times/week, for 8 weeks)	Standard care.	VR: HTC Vive virtual reality system	8 weeks
Park et al [36]	NWE[d]: using the Nintendo Wii exercise program, including the wakeboard, Frisbee dog, jet ski, and canoe games. Participants chose which Nintendo Wii sports program to perform and took a 2-minute break every 10 minutes (30 minutes/session, 3 times/week, for 8 weeks)	Conventional physical therapy: using physical agent modalities, such as a hot pack (30 minutes); interferential current therapy (15 minutes); deep heat with ultrasound (5 minutes)	VR: Nintendo	8 weeks
Afzal et al [37]	Kinetic exergames (trunk slide flexion, sitting to avoid obstacles, jumping and combined movement of arms, for 5 minutes); after 30 seconds of rest, play body ball game for 5 minutes (3 sessions/week for a total of 12 sessions); routine physical therapy	Conventional physical therapy: heat therapy for 10 minutes, hamstring stretching, back-strengthening exercises (3 sessions/week for a total of 12 sessions)	VR: nonimmersive system with a kinetic device (model V.2), incorporated with red-green-blue (RGB) cameras and time-of-flight (TOF) sensor, attached with a liquid crystal display (LCD) screen	4 weeks
Nambi et al [38]	VRE[e]: virtual training exercises performed in the upright position, a car race game chosen from the list of games, and training given to focus on the back muscles. The participant was asked to sit on the moving game chair and instructed to watch the game on the desktop monitor (30 minutes/session, 5 days/week, for 4 weeks); hydrocollator packs (20 minutes/session); continuous ultrasound (frequency 1 MHz, intensity 1.5 W/cm^2) at the low back region (5 minutes, 5 days/week, for 4 weeks)	Conventional balance function training: standardized conventional exercises actively involving abdominal, deep abdominal, and back muscles (30 minutes/session, 5 days/week, for 4 weeks); hydrocollator packs (20 minutes/session); continuous ultrasound (frequency 1 MHz, intensity 1.5 W/cm^2) at the low back region (5 minutes, 5 days/week, for 4 weeks)	VRE: Pro-Kin system (TecnoBody)	4 weeks

First author	Intervention group	Control group	Device	Duration
Nambi et al [39]	Virtual reality training (VRT): shooting game, sitting on a virtual platform and visualizing the game on the computer display screen (30 minutes each time, 5 times/week, for 4 weeks); heat modality (20 minutes); therapeutic ultrasound (frequency 1 MHz, intensity 1.5 W/cm^2; 5 minutes); home-based exercise (10 repetitions, bottom-to-heel stretch, opposite arm/leg raise, back extension, bridging, knee rolling; 2 times/day for 4 weeks)	Conventional balance function training: active isotonic and isometric exercises for abdominal, deep abdominal, and back muscles (10-15 repetitions/day, 5 days/week for 4 weeks; stretching focused on each muscle group for 3 repetitions for 10 seconds per muscle group); heat modality (20 minutes); therapeutic ultrasound (frequency 1 MHz, intensity 1.5 W/cm^2; 5 minutes); home-based exercise (10 repetitions, bottom-to-heel stretch, opposite arm/leg raise, back extension, bridging, knee rolling; 2 times/day for 4 weeks)	VR: Pro-Kin system PK 252 N (Pelvic Module balance trunk MF; TecnoBody)	4 weeks
Nambi et al [40]	VRT: shooting game, sitting on a virtual platform and visualizing the game on the computer display screen (30 minutes each time, 5 times/week, for 4 weeks); heat modality (20 minutes); therapeutic ultrasound (frequency 1 MHz, intensity 1.5 W/cm^2; 5 minutes)	Conventional balance function training: active isotonic and isometric exercises for abdominal, deep abdominal, and back muscles (10-15 repetitions/day, 5 days/week for 4 weeks; stretching focused on each muscle group for 3 repetitions for 10 seconds per muscle group); heat modality (20 minutes); therapeutic ultrasound (frequency 1 MHz, intensity 1.5 W/cm^2; 5 minutes)	VR: Pro-Kin system PK 252 N (Pelvic Module balance trunk MF; TecnoBody)	4 weeks
Matheve et al [41]	2 different games (2 minutes each); single-session intervention, 2 × 2 minutes of pelvic tilt exercises in the sagittal plane, with 30 seconds of rest in between, through a wireless motion sensor	Conventional physical therapy: 2 different games (2 minutes each); single-session intervention, 2 × 2 minutes of pelvic tilt exercises in the sagittal plane, with 30 seconds of rest in between	VR: wireless motion sensor (Valedo Pro, Hocoma)	Single exercise session
Stamm et al [42]	Multimodal pain therapy in VR (movement therapy and psychoeducation), training session including 12 exercises, structured as follows: (1) warm-up (training of upper and lower extremities), (2) main part (strengthening of abdominal and back muscles, core stability), (3) cool-down (stretching, progressive muscle relaxation), (4) psychoeducative units (topics: physiology of pain, pain management, stress management, everyday training), 3 times/week for 30 minutes	Conventional multimodal pain therapy: chair-based group exercises and psychoeducation in a group setting), 3 times/week for 30 minutes	VR: head-mounted display headset using the ViRST VR app	4 weeks
Monteiro-Junior et al [43]	Virtual physical training (8 exercises, 30 minutes each time, with 3 weekly sessions lasting 90 minutes each), lasted 8 weeks, 3 times weekly/session	Core training: postures adopted by participants for 15-30 seconds or according to the capacity of each; 10-15 seconds between postures (ie, bridges), with each performed 3 times, lasted 8 weeks, 3 times weekly/session	VR: Wii Balance Board (WBB; Nintendo)	8 weeks
Cetin et al [44]	VR exercises: VR apps that allowed neck movements in all directions, motor control (MC) exercises (20 minutes and then VR for 20 minutes, 5 repetitions for each exercise; 40 minutes/session, 3 sessions/week, for 6 weeks, total of 18 sessions)	Core training: strengthening of deep cervical flexors (DCFs), deep cervical extensors (DCEs), and axioscapular muscles; stretching exercises; and postural correction exercises (40 minutes, 10 repetitions for each exercise, 3 sessions/week, for 6 weeks, total of 18 sessions)	VR: Oculus Go VR glasses, 2 VR apps installed: “Ocean Rift” and “Gala 360”	6 weeks

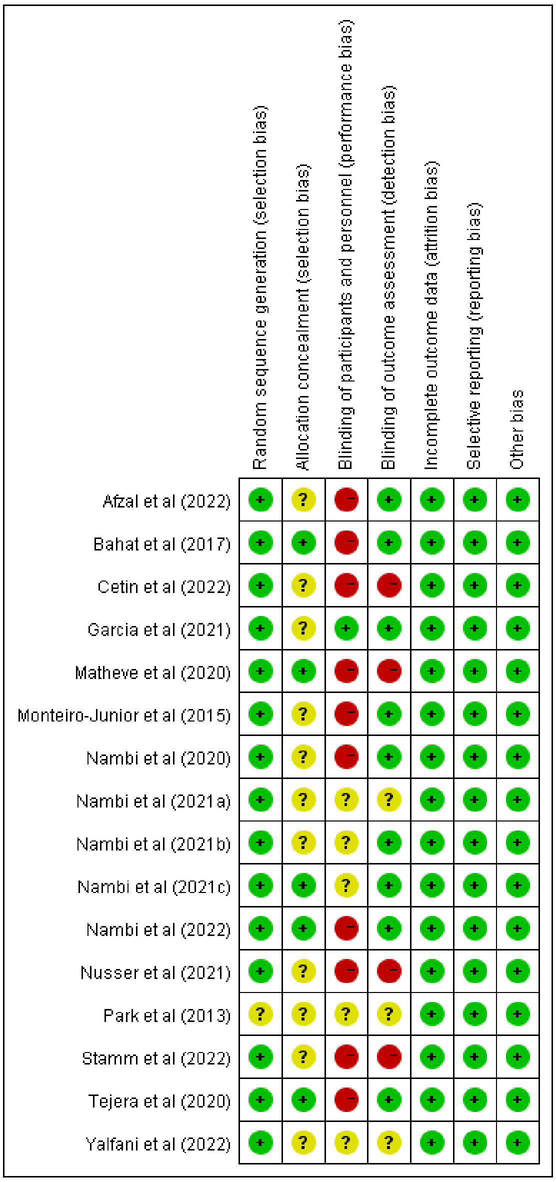
The risk of bias in the 16 (100%) studies included in the meta-analysis is presented in Figure 2. Overall, 10 (63%) studies showed a high risk of bias. In addition, 15 (94%) RCTs generated an adequately randomized sequence, and 9 (60%) of them were analyzed using a blinded method for outcome measurement. Ratings using the GRADE methodology for all outcome measurements were inconsistent and ranged from moderate to low quality (Multimedia Appendix 3). Therefore, the quality of evidence from most studies was classified as fair.

Figure 2. Cochrane risk-of-bias summary for included studies.



Primary Outcome

Pain Intensity

All 16 (100%) studies (800 patients) reported pain intensity: 9 (56%) used the Visual Analogue Scale (VAS) [34-38,40,44,45,47], 2 (13%) used the Numerical Pain Rating Scale (NPRS) [33,41], 3 (19%) used the Numeric Rating Scale (NRS) [42,43,46], and 1 (6%) used the Defense and Veterans Pain Rating Scale (DVPRS) [32]. The random effects model revealed that compared with the control treatment, the VR intervention significantly reduced pain intensity (WMD=–1.63, 95% CI –2.11 to –1.16, $P<.001$, I^2=90%). Clinical differences between groups were significant, and as suggested, the minimal clinically important difference (MCID) threshold on the VAS for LBP was set at a 1.5-point reduction [50]. Given the significant heterogeneity observed (I^2=90%), we performed subgroup analyses to investigate the source of heterogeneity based on the different regions, VR types, and treatment durations.

VR had a good analgesic effect on both CNP and CLBP groups compared with the control group. The results did not significantly differ among the subgroups (WMD=−1.63, 95% CI −2.11 to −1.16); see Figure 3. Moreover, a total of 7 (44%) studies demonstrated that IVR significantly improved CSP (WMD=–1.50, 95% CI –2.45 to –0.55, $P<.001$, I^2=80%) [32,35,42,44-47]. Another 8 (50%) studies showed that NIVR improved CSP substantially (WMD=–1.50, 95% CI –2.45 to –0.55, $P<.001$, I^2=90%) [33,34,36-38,40,41,43]; see Figure 4. The subgroup analyses also revealed significant differences between treatment durations of <4 weeks (WMD=–1.41, 95% CI –2.12 to –0.69, P=.001, I^2=0%) and ≥4 weeks (WMD=–1.65, 95% CI –2.16 to –1.14, $P<.001$, I^2=91%) in terms of the analgesic effect of VR treatment on CSP (Multimedia Appendix 4).

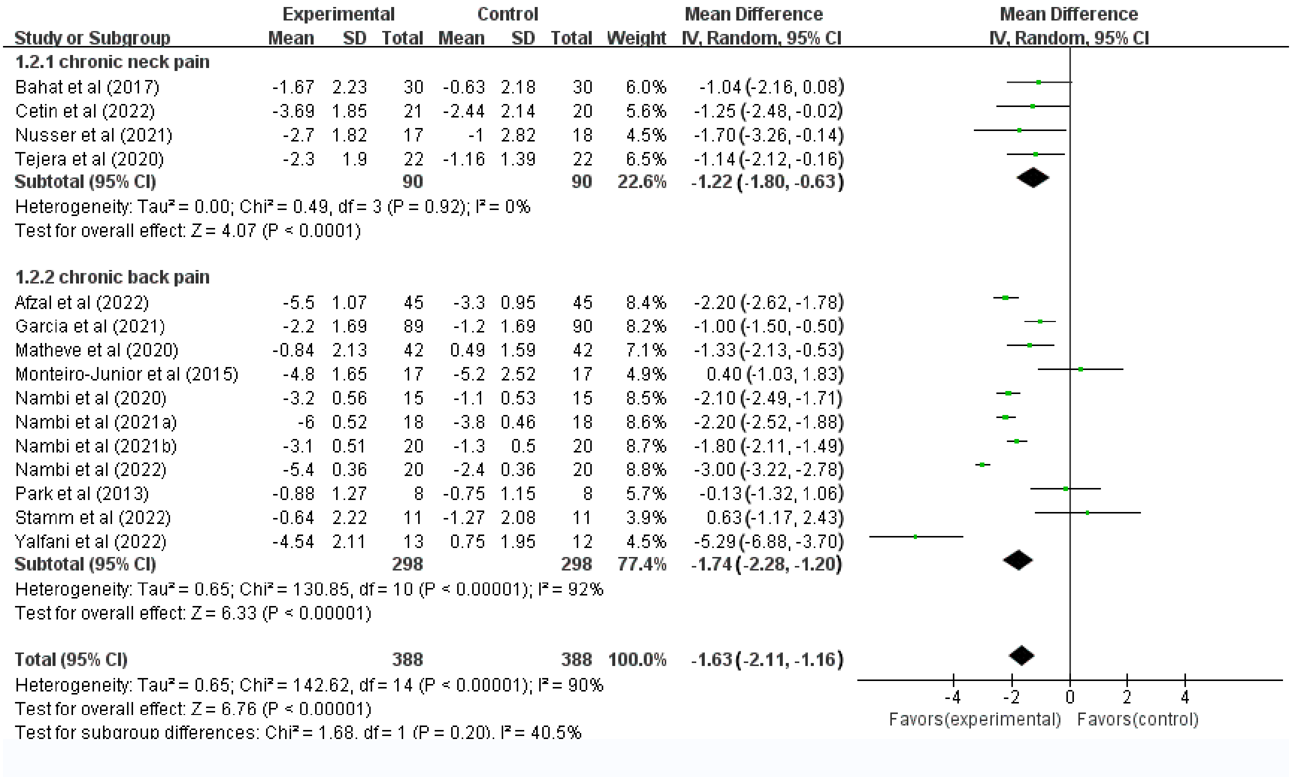

Figure 4. Forest plots of the effect of VR compared with other treatments on pain intensity in patients with CSP: subgroup analysis of posttreatment effectiveness for the VR intervention type. CSP: chronic spinal pain; VR: virtual reality.

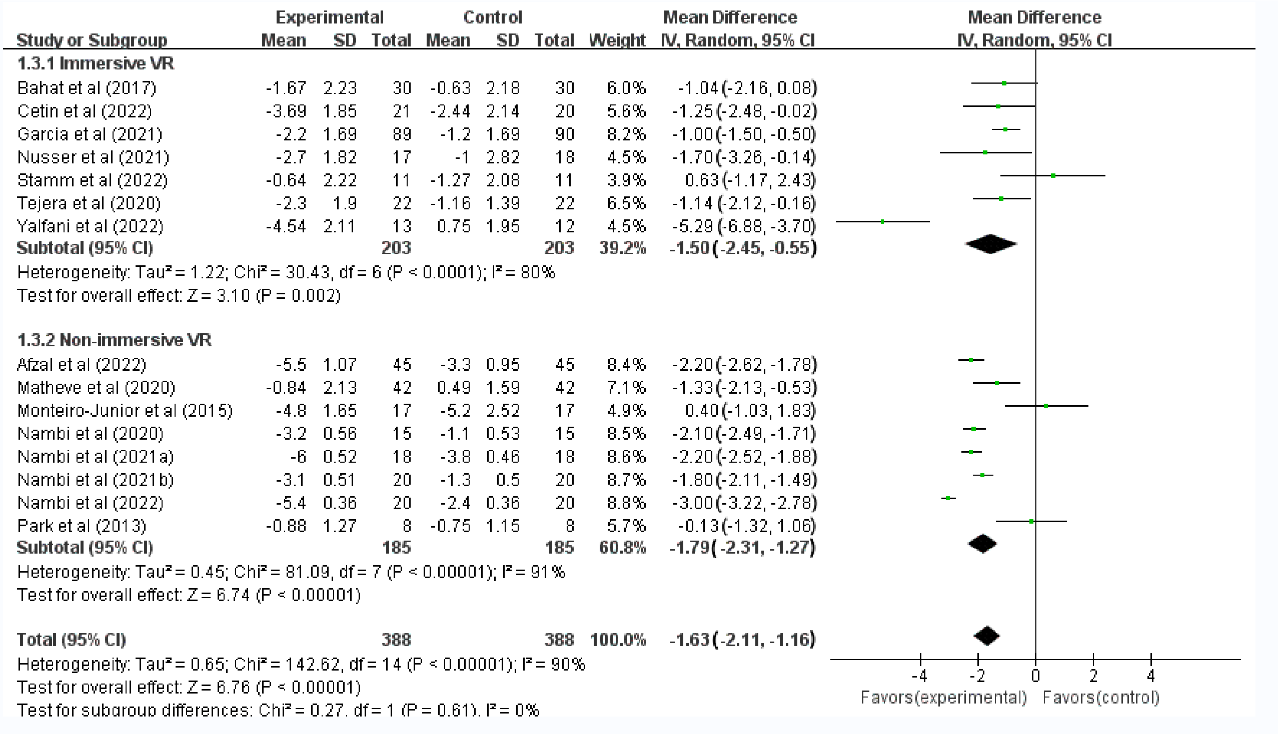

Secondary Outcomes

Inflammatory Markers

Patients with CSP develop a systemic inflammatory response and have elevated levels of inflammatory markers in the blood [51]. Two studies (62 patients) focused on the levels of inflammatory markers (eg, CRP, TNF-α, IL-2, IL-4, and IL-6) by collecting 10 mL of venous blood [38,39]. The results showed that VR therapy significantly improved the level of CRP (WMD=–0.89, 95% CI –1.07 to –0.70, *P*<.001, I^2=0%), TNF-α (WMD=–6.60, 95% CI –8.56 to –4.64, P<.001, I^2=98%), and IL-6 (WMD=–2.76, 95% CI 2.98 to –2.53, P<.001, I^2=0%). No significant differences were found between the IL-2 and IL-4 subgroups (Figure S1 in Multimedia Appendix 5).

Fear of Movement

Four studies (162 patients) reported fear of movement according to the 11-item or 17-item Tampa Scale of Kinesiophobia (TSK-11 or TSK-17, respectively) [42,47]. No significant differences were found in either the TSK-11 (WMD=–0.81, 95% CI –4.48 to 2.86, P=.66, I^2=0%; Figure S2 in Multimedia Appendix 5) or TSK-17 (WMD=–9.66, 95% CI –22.01 to 2.68, P=.13, I^2=97%; Figure S3 in Multimedia Appendix 5).

Spinal Range of Motion

Three studies reported changes in the ROM of the neck in 4 directions before and after the intervention [45-47]. No significant differences were found between the groups in terms of flexion (WMD=2.67, 95% CI –2.31 to 7.64, P=.29, I^2=61%), extension (WMD=3.92, 95% CI –2.17 to 10.0, P=.21, I^2=48%), right rotation (WMD=–0.22, 95% CI –4.38 to 3.95, P=.92, I^2=0%), or left rotation (WMD=0.08, 95% CI –3.90 to 4.05, P=.97, I^2=42%); see Figure S4 in Multimedia Appendix 5.

Disability Level

Three studies (139 patients) reported disability levels in patients with CNP by using the Neck Disability Index (NDI) [45-47], a 10-item questionnaire that assesses self-reported disability related to CNP. Higher scores on the NDI indicate higher levels of disability. No significant differences were found in the pooled analysis of 3 (19%) studies (WMD=–2.66, 95% CI –5.47 to 0.15, P=.06, I^2=48%); see Figure S5 in Multimedia Appendix 5.

Adverse Events

One study reported that after 1 month of intervention, patients experienced nausea and motion sickness [32], two studies reported that there were no adverse events [33,37], and the remaining studies did not mention adverse events. The overall dropout rate was 4.25% (17/400) in the intervention group and 3.75% (15/400) in the control group.

Publication Bias and Sensitivity Analysis

The Egger test indicated significant publication bias in the results for pain intensity (P=.03; Figure 5). The sensitivity analysis for pain intensity revealed that removing each study separately did not significantly affect the pooled results, thus indicating that the results are robust (Figure 6). The trim-and-fill method was performed, and it was estimated that there were 4 missing studies. The pooled estimates (95% CIs) calculated for the fixed effects model and the random effects model were –2.30 (–2.42 to –2.18) and –2.06 (–2.50 to –1.61), respectively (Figure 7). No significant changes in the results were observed before or after pruning or filling, indicating that our results are robust and plausible.

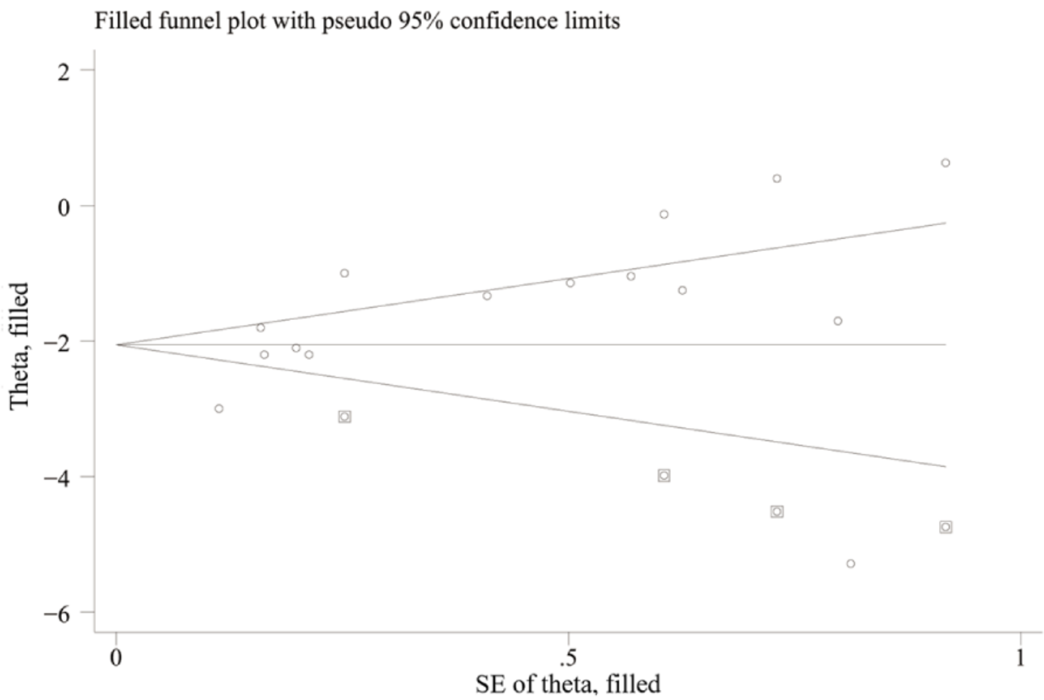
CSP: chronic spinal pain; VR: virtual reality.



Discussion

Principal Findings

The primary purpose of this meta-analysis was to compare the relative efficacy of VR therapy and other therapies (eg, conventional therapy, sham stimulation, and standard care) for treating CSP. The results indicated that VR therapy can effectively relieve CSP. The results of subgroup analyses showed that VR is a beneficial pain management strategy for patients with CNP and CLBP. For different types of VR, subgroup analyses showed that compared to the control group, IVR and NIVR both significantly improved CSP. No statistically significant differences were found between patients who underwent VR treatments for a duration of <4 weeks and a duration of ≥4 weeks. VR was associated with a significant improvement in inflammatory marker levels but not in the fear of movement, spinal ROM, or disability level. VR was found to be well tolerated among these patients.

Discussion of the Results

The primary result suggested that VR reduces self-reported pain intensity, which might be explained by several implicating mechanisms [52,53]. A previous study reported that abdominal muscle strength is significantly lower in people with LBP [54], and a lack of strength in the core trunk muscles can lead to a decrease in intra-abdominal pressure, affecting spinal stability [55]. VR, as a novel human-computer interaction approach, can stimulate and mobilize the sensory system during training and results in changes in neuroplasticity and enhanced performance of relevant muscle groups, promoting a new motor learning process and leading to increased spinal stability [37,56], which would benefit pain relief. Furthermore, previous studies have reported that an intervertebral disc undergoes aging or pathological changes in the adjacent region in patients with CSP, exposing cells within the nucleus pulposus to macrophages, resulting in an inflammatory response that might trigger pain [7,8]. VR therapy may enhance the activity of disc fibroblasts and increase the thickness of the multifidus muscle [39,57], which is beneficial for relieving pain intensity. Furthermore, pain is an unpleasant subjective sensation associated with actual or potential tissue damage and is correlated with the degree of patient attention given to the pain area [58-61]. The various virtual game environments and real-time feedback methods are the most eye-catching features in the VR training process; these methods can be used to attract the patient's visual and auditory attention to achieve motor performance, while relatively less attention has been given to the effects of VR on pain [62,63].

Although the high heterogeneity of the primary outcome and the results of the subsequent subgroup analyses suggest that the region of CSP, VR type, and treatment duration may play a role in the heterogeneity, the results of the sensitivity analysis indicate that these differences are more likely to be caused by 6 studies [33-35,37,38,40], which included participants of different ages.

VR therapy significantly improved the levels of inflammatory markers, including CRP, TNF-α, and IL-6. Numerous studies have previously reported an association between CSP and changes in inflammatory cytokines, such as IL-1 and TNF-α, which are thought to be closely related to the pathogenesis of disc herniation and degeneration [64,65]. Similarly, Nambi et al [66] reported that 4 weeks of VR training could significantly decrease pain intensity, increase functional impairment, and improve CRP, TNF-α, IL-2, IL-4, and IL-6 levels. However, the limited number and low quality of the included studies need to be noted, and further RCTs with large samples and rigorous study designs are needed to elucidate these results.

Patients with CSP may engage in fear/avoidance behaviors to avoid pain and protect themselves by limiting spinal motion, which ultimately affects spinal mobility and the speed of movement [67,68], with the degree of pain catastrophizing being proportional to the degree of disability [69,70]. However, we found no statistically significant differences in fear avoidance beliefs after the VR intervention but at the 3-month follow-up [47]. A systematic review and meta-analysis reported that VR therapy enhances spinal ROM and physical functioning in patients with CNP [26]. We failed to observe significant differences in the spinal ROM or disability level after VR intervention compared to those in the control group, which may be attributed to the relatively short duration (0-8 weeks) of the VR intervention (the reported mean duration was 4.81 weeks).

Limitations

Several limitations need to be addressed in this meta-analysis. First, the pooled analysis of the studies may be imprecise due to the large heterogeneity and the low quality of evidence from most of the included studies, and the results should be interpreted with caution. Second, the optimal duration of treatment for CSP could not be determined. Third, the effectiveness of VR therapy in patients with CSP and its analgesic effects in long-term follow-up must be further explored in high-quality studies. Fourth, indicators related to quality of life, such as depression and anxiety, should be emphasized and investigated in depth in future studies of patients with CSP.

Conclusion

VR therapy is an innovative and effective analgesic method that has beneficial effects on inflammatory markers in patients with CSP compared to other therapies (sham stimulation, usual care, conventional treatment). However, this approach may not have significant effects on the fear of movement, spinal ROM, or disability level. Notably, the quality of the evidence from the RCTs included in this study ranged from moderate to low. Therefore, we recommend that readers interpret the results of this study with caution. Future trials with large sample sizes, rigorous designs, and long-term follow-up periods are needed to explore the clinical significance of these differences and key issues in patients with CSP and to elucidate the underlying mechanisms of VR.

Data Availability

All data generated or analyzed during this study are included in this published paper and its supplementary information files.

Authors' Contributions

All authors contributed to the writing and redrafting of the manuscript. QD and XZ had the original idea. TZ and FW performed the literature search, XL and ZH assessed the risk of bias; YS, YF, and LZ rated the certainty of the evidence for each outcome; and XL and FW undertook data collection. The results were analyzed, interpreted, and discussed by XZ and QD. All authors contributed to the conception and design of the study, the analysis and interpretation of data, and the drafting and revising of the manuscript and have approved the final version.

Abstract

Background: The increasing prevalence of autism spectrum disorder (ASD) has driven research interest on the therapy of individuals with autism, especially children, as early diagnosis and appropriate treatment can lead to improvement in the condition. With the widespread availability of virtual reality, augmented reality (AR), and mixed reality technologies to the public and the increasing popularity of mobile devices, the interest in the use of applications and technologies to provide support for the therapy of children with autism is growing.

Objective: This study aims to describe the literature on the potential of virtual reality, AR, and mixed reality technologies in the context of therapy for children with ASD. We propose to investigate and analyze the temporal distribution of relevant papers, identify the target audience for studies related to extended reality apps in ASD therapy, examine the technologies used in the development of these apps, assess the skills targeted for improvement in primary studies, explore the purposes of the proposed solutions, and summarize the results obtained from their application.

Methods: For the systematic literature review, 6 research questions were defined in the first phase, after which 5 international databases (Web of Science, Scopus, ScienceDirect, IEEE Xplore Digital Library, and ACM Digital Library) were searched using specific search strings. Results were centralized, filtered, and processed applying eligibility criteria and using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The results were refined using a technical and IT-oriented approach. The quality criteria assessed whether the research addressed ASDs, focused on children's therapy, involved targeted technologies, deployed solutions on mobile devices, and produced results relevant to our study.

Results: In the first step, 179 publications were identified in Zotero reference manager software (Corporation for Digital Scholarship). After excluding articles that did not meet the eligibility or quality assessment criteria, 28 publications were finalized. The analysis revealed an increase in publications related to apps for children with autism starting in 2015 and peaking in 2019. Most studies (22/28, 79%) focused on mobile AR solutions for Android devices, which were developed using the Unity 3D platform and the Vuforia engine. Although 68% (19/28) of these apps were tested with children, 32% (9/28) were tested exclusively by developers. More than half (15/28, 54%) of the studies used interviews as an evaluation method, yielding mostly favorable although preliminary results, indicating the need for more extensive testing.

Conclusions: The findings reported in the studies highlight the fact that these technologies are appropriate for the therapy of children with ASD. Several studies showed a distinct trend toward the use of AR technology as an educational tool for people with ASD. This trend entails multidisciplinary cooperation and an integrated research approach, with an emphasis on comprehensive empirical evaluations and technology ethics.

Introduction

Background

In recent years, there has been increased interest in using technology to address the unique challenges faced by individuals with autism spectrum disorder (ASD). Among the various technological approaches, extended reality (XR), which includes augmented reality (AR) and virtual reality (VR), has emerged as a promising solution for intervention and therapy in children with ASD. XR offers the potential to create immersive and engaging environments that can address the specific needs of individuals on the autism spectrum, assisting them with communication, social interaction, and skill development. As a result, researchers and practitioners have explored the development of XR-based mobile apps tailored to the therapy of children with ASD.

However, the rapid growth in this field has spawned a multitude of XR-based mobile app solutions, each claiming unique benefits and features. With this proliferation of interventions, it is important to comprehensively assess the current landscape of XR-based mobile apps for the therapy of children with ASD, not only to strengthen existing knowledge in the field but also to provide critical insights into the research field.

In light of these considerations, this systematic literature review aimed to explore and assess the current status of XR-based mobile app solutions for the therapy of children with ASD. By synthesizing evidence from existing studies, this review aimed to provide an updated overview of the field, identify research gaps, and provide valuable insights. In this endeavor, this review aimed to contribute to the advancement of knowledge and practice in the field of XR-based interventions for ASD therapy, ultimately aiming to improve the quality of life of children on the autism spectrum and their caregivers.

ASD is a neurological condition that has a significant negative impact on a person's social, verbal, and physical abilities. Researchers claim that ASD is typically discovered around the third year of life [1], but it can be identified and diagnosed as early as the age of 18 months [2]. According to a study from 2022, a total of 1% of infants have ASD [3]. On the basis of studies conducted over the past 50 years, the World Health Organization predicts a global increase in the prevalence of ASD [3].

Researchers consider 3 techniques that could be used to facilitate the evaluation of this condition's prevalence: providing diagnostic tools, enhancing diagnostic standards, and increasing public awareness of ASDs [4].

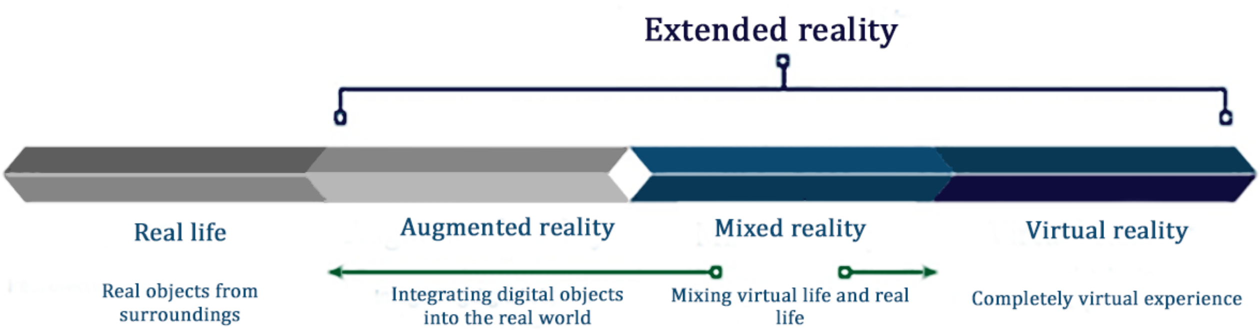
On the basis of each individual's verbal IQ and level of language delay, the diagnosis assesses the severity of the disorder (mild, moderate, or severe) [5], which can estimate the extent to which daily life is affected. Many people with ASD are timid, have difficulty communicating, or experience anxiety when engaging in casual conversation. Despite their communication and social skill deficits, individuals with ASD have demonstrated a preference for technology [6]. Furthermore, the use of technology in behavioral therapy for people with ASD has the additional advantage of being cost-effective in terms of both caregiver and treatment facility expenses [7]. In addition, various studies have shown that individuals with ASD respond better to visual stimuli than to other sensory stimuli [8]. The findings of these studies have led to various applications of technology in digital behavioral treatment.

XR, AR, VR, and Mixed Reality

As evidenced, the evolution of IT has accelerated in recent years. According to the study by Abad-Segura et al [9], rapid technological advancements have caused a significant and positive shift in how people view modern living.

The relatively new term XR refers to the entire spectrum from AR to VR, including mixed reality (MR; Figure 1 [10]).

Figure 1. The extended reality concept [10].



AR is a technology that enables real-time interaction and integration of 3D virtual models into the physical world [11]. Although the first portable AR system was developed in 2003 [12], AR did not acquire widespread acceptance and public awareness until the release of the mobile game Pokémon GO [13] in 2016. Despite the various implementation challenges, AR has many potential applications. In addition to applications in specific domains such as industry, construction, or medicine, as well as in advertising and commerce, education, and gaming [14], AR can be used by a broader audience for everyday tasks such as finding information about nearby points of interest, navigation, and assistance while following a route [14]. Most of these apps are now accessible owing to advances in mobile device technology and the spread of smart mobile phones. AR facilitates behavioral therapy by enhancing the experiences and abilities of people with ASD and establishing an integrated learning environment that enables the visualization of educational materials in 3D and engaging manipulation of real-world objects [15]. By generating "physical" structures to improve specific skills, AR fosters the imagination of patients with ASD without impairing it [16,17]. Moreover, AR can be used to create more engaging and appealing user interfaces, thereby eliminating the need for conventional input devices such as a keyboard and mouse [18]. AR technology is typically accessed using various devices and platforms. Among the widely used platforms and tools for developing AR apps are Unity, Unreal Engine, ARCore, and HP Reveal.

As described in the study by Azuma [11], VR is a computer-generated environment that simulates real-life scenarios, creating an immersive and interactive experience. This means that the users are placed in a completely virtual world, which can be similar to or different from the real one. This technology requires specialized equipment, such as VR headsets or glasses to enable users to see and interact with the virtual environment.

As seen in the studies by Bursali and Yilmaz [19] and El-Jarn and Southern [10], MR is situated between AR and VR, integrating the 2 technologies to provide the user with a unique and captivating experience in real time. It can be difficult to precisely define the limits of MR as they depend on the devices and equipment used as well as the extent to which VR or AR is incorporated into the final product. A model describing the integration of digital objects from the physical world into the virtual world is shown in the study by Milgram and Kishino [20], which also presented a taxonomy for MR, stating that it can be defined as a part of the human-computer interface field, which integrates VR and AR elements to create an environment in which virtual and real objects coexist and interact.

To be used, technologies from the XR spectrum require specific hardware with an optical sensor [19]. In addition, well-known technology companies such as Google, Facebook, Apple, Amazon, and Microsoft have significantly contributed to the development of AR tools and services [21,22], including handheld devices; holographic screens (Microsoft HoloLens); and heads-up displays, which are mainly designed for MR, tablets, and mobile devices (smartphones).

The development of collaborative XR, which enables simultaneous communication and collaboration among multiple users, is one of the research trends in the field of XR [23].

Given the benefits that AR, VR, and MR can offer as a new mode of human-computer interaction and the fact that these technologies are becoming ubiquitous and part of our daily lives, this systematic review aimed to describe how these technologies can be used in the therapy of children with ASDs.

Methods

Overview

According to Kitchenham [24], a systematic literature review is a method for identifying, evaluating, and interpreting all available research relevant to a field of study as well as answering specific research questions (RQs). We conducted this research following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [25] and the recommendations suggested by Kitchenham [24].

To conduct this literature review, several well-known scientific databases were queried, and publications containing relevant information for our analysis were filtered. We defined RQs and provided answers to each of them, thus achieving our proposed objective.

Search Strategy

According to the considered methodology, the following 7 RQs were formulated. These questions consider aspects relevant to the understanding of concepts important to this study:

1. What is the papers' distribution over time? (RQ 1)
2. What category of people are the studies aimed at? (RQ 2)
3. Which technologies are used with XR or any of its subdivisions to develop apps for ASD therapy? (RQ 3)
4. What skills were targeted for improvement in primary studies? (RQ 4)
5. What are the purposes for which the proposed solutions were used? (RQ 5)
6. What are the results obtained using the proposed solutions? (RQ 6)

To study the literature and answer the aforementioned questions, we searched for scientific publications using various academic research databases. Our study primarily focused on the technical aspects of mobile app solutions using XR for autism therapy. To comprehensively cover our research domain, we chose to use multidisciplinary scientific databases—Scopus, ScienceDirect, and Web of Science—along with 2 databases particularly relevant to computer science, namely, IEEE Xplore Digital Library and ACM Digital Library. From these sources, we only considered publications that were relevant in computer science–related categories, such as technology, engineering, and computer science, excluding categories related to medicine, chemistry, or neurosciences considering that the RQs were focused not only on the available apps but also on their technical details. The functionalities, the technologies used, and the entire process of their development also constituted an objective. Thus, the approach from a technical point of view and the development of these apps were followed. This was done using the results refinement interface available in the aforementioned databases. Initially, to view and analyze the results of queries conducted using the considered search strings, the search was not limited to a particular time.

Given the topic of this study, we aimed to query scientific databases so that the resulting list of publications would meet the following criteria:

1. Reference to ASDs
2. Consideration of one of the technologies that are part of the concept of XR (VR, AR, or MR)
3. Addressing mobile apps
4. Aim to develop solutions for the therapy of children

The literature was searched using keywords relevant to achieving the proposed objectives: *autism*, *autistic*, *ASD*, *virtual reality*, *augmented reality*, *extended reality*, *mixed reality*, *mobile application*, and *children*.

Following the analysis of these keywords, the query process was extended by including the following terms: *Autis**, *VR*, *AR*, *MR*, *XR*, *Mobile app**, *Smartphone app**, *Child**, *Infan**, *Toddler**, *Preschool**, *Kid**, and *Juvenile*. In the aforementioned list, an asterisk stands for any number of characters at the end of the current string (eg, *Preschool** refers to *Preschool*, *Preschooler*, and *Preschoolers*).

Information Sources

Depending on the search options available in each database considered, specific search strings were defined for querying the databases (Table 1). These query strings were defined using advanced search functions and appropriate operators. The search of Web of Science and Scopus publications was performed by title, abstract, and keywords, and IEEE Xplore Digital Library, ScienceDirect, and ACM Digital Library were searched using a general search. The queries were executed on December 18, 2022.

Table 1. The search strings used for querying the databases (N=219).

Item	Database	Search string	Returned results, n (%)
1	Web of Science	(TS=(Autis*) OR TS=(ASD)) AND (TS=(virtual reality OR VR) OR TS=(augmented reality OR AR) OR TS=(mixed reality OR MR) OR TS=(extended reality OR XR)) AND (TS=(mobile app* OR smartphone app*)) AND (TS=(child* OR infan* OR toddler* OR preschool* OR kid* OR juvenile))	45 (20.5)
2	Scopus	(TITLE-ABS-KEY (autis*) OR TITLE-ABS-KEY (asd)) AND (TITLE-ABS-KEY ("virtual reality" OR vr) OR TITLE-ABS-KEY ("augmented reality" OR ar) OR TITLE-ABS-KEY ("mixed reality" OR mr) OR TITLE-ABS-KEY ("extended reality" OR xr)) AND (TITLE-ABS-KEY ("mobile app*" OR "smartphone app*")) AND (TITLE-ABS-KEY (child* OR infan* OR toddler* OR preschool* OR kid* OR juvenile))	32 (14.6)
3	IEEE Xplore Digital Library	(Autis* OR ASD) AND (Augmented reality OR AR OR Mixed reality OR MR OR Extended Reality OR XR OR Virtual Reality OR VR) AND (Mobile OR Tablet OR Smartphone OR Phone OR Smartglass) AND (App* OR Solution*) AND (child* OR kid* OR infan* OR preschool* OR juvenile OR toddler*)	26 (11.9)
4	ScienceDirect	("Autism Spectrum Disorder" OR "ASD") AND ("Augmented reality" OR "Mixed reality" OR "Extended reality") AND ("App OR Application") AND ("kids OR children")	48 (21.9)
5	ACM Digital Library	[[All: "autis*"] OR [All: "asd"]] AND [[All: "augmented reality"] OR [All: "mixed reality"] OR [All: "virtual reality"] OR [All: "extended reality"]] AND [All: "mobile"] AND [[All: "app"] OR [All: application]]	68 (31.1)

Eligibility Criteria

The papers obtained by querying scientific databases had an interdisciplinary nature. However, our study took a technical and IT-focused approach to mobile app solutions using XR for autism therapy. Therefore, we needed to refine the results by considering inclusion and exclusion criteria. As previously stated, no constraints were imposed on the publication dates of the articles during the search conducted in the scientific databases. Nevertheless, considering the significant progress in mobile device capabilities and their widespread use over the last decade, which have facilitated the development and growth of the global use of XR-based mobile apps for therapeutic purposes, we focused our investigation on the period following 2012 [26,27]. In line with our technical focus on mobile app solutions using XR for the therapy of children with ASD, we refined the search results across the 5 considered databases, prioritizing computer science–related domains. We deliberately excluded categories related to medicine, chemistry, or neurosciences as our RQs focused on both the available apps and their technical details.

Before centralizing the results for analysis, they were refined according to the inclusion and exclusion criteria. The inclusion criteria were as follows:

1. Articles published in English
2. Articles published after 2012

The exclusion criteria were as follows:

1. Book chapters
2. Paper tables of contents
3. Articles published in languages other than English
4. Results on the topics of medicine, chemistry, or neurosciences

After initial processing, the database searches returned the number of results presented in Table 2.

Table 2. Results obtained after initial data processing (N=179).

Database	Results, n (%)
Web of Science	43 (24)
Scopus	22 (12.3)
IEEE Xplore Digital Library	25 (14)
ScienceDirect	41 (22.9)
ACM Digital Library	48 (26.8)

Selection Process

During the selection process, the PRISMA guidelines were considered [25]. These guidelines outline 3 steps: identification (centralizing the results and excluding duplicate publications), screening (review of titles and abstracts and testing eligibility), and inclusion (the publications identified as answering the proposed RQs). The PRISMA 2020 checklist is available in Multimedia Appendix 1. The Zotero reference manager software (Corporation for Digital Scholarship) was used to perform the specified steps. In the first step, 179 publications resulting from the search of the 5 considered databases were imported, after which duplicate publications (n=20, 11.2%) and some conference papers (n=4, 2.2%) were removed. For the next step, 86.6% (155/179) of the publications were considered. To enable author collaboration, the data were imported into Google Sheets. In total, 2 reviewers (M-VT and CET) conducted an independent screening of publications for inclusion based on title and abstract analysis. Studies meeting the eligibility criteria according to both reviewers were then considered for full-text screening. Any disagreements were discussed face-to-face between the reviewers, and a third party was involved to help reach unanimity where necessary. The same process was implemented for the full-text review with the assistance of a third reviewer (SV).

After reviewing the titles and abstracts, a total of 41.9% (65/155) of the publications were excluded as they did not address the proposed topic, focusing either on another condition or on other technologies.

Despite the high quality of the publications, as evidenced by their indexing in prestigious international databases, the analysis included a full text review (where available) of the remaining 58.1% (90/155) of the publications, and the following quality assessment criteria were applied to ensure their relevance to the RQs considered. Articles with no full text accessible were excluded. The following quality criteria (QCs) were applied to 78 publications:

1. Does the research topic address ASDs? (QC 1)
2. Does the study address children’s therapy? (QC 2)
3. Does the study include one of the technologies targeted in this review? (QC 3)
4. Is the solution deployed on a mobile device? (QC 4)
5. Are the results relevant to this review? (QC 5)

Given the nature of the research and its objectives, the 5 QCs that were developed specifically to achieve the goals of the research were used to evaluate the studies’ quality by 2 authors. Each publication was carefully reviewed and assigned a score from 0 to 2 measuring the extent to which it corresponded to the quality assessment criteria and to the subject of this study (0=no; 1=partially; 2=yes). Thus, the maximum score for a paper could be 10. After that, the data were combined for further analysis using Microsoft Excel (Microsoft Corp). After consolidation, a score with a decimal part (eg, 1.5) was rounded up to the nearest integer for better inclusion.

After reviewing the full texts, 3 publications were found to be not written in English, and in other publications, ASD was not addressed (only mentioned), other technologies were addressed, or the proposed solution was not clearly described and the results were inconclusive (see the sample in Figure 2; the entire table is available in Multimedia Appendix 2 [28-104]).

Following this, only publications with a score of ≥7 were evaluated as they adequately addressed the RQs. The type of publication, whether it was a review or aimed at developing an app, was also noted. Systematic literature review publications were investigated to identify any references that could be added to this study, but they were removed from the list after being reviewed. The entire publication selection process is illustrated in Figure 3.

Figure 2. Screenshot of the quality assessment of the papers.

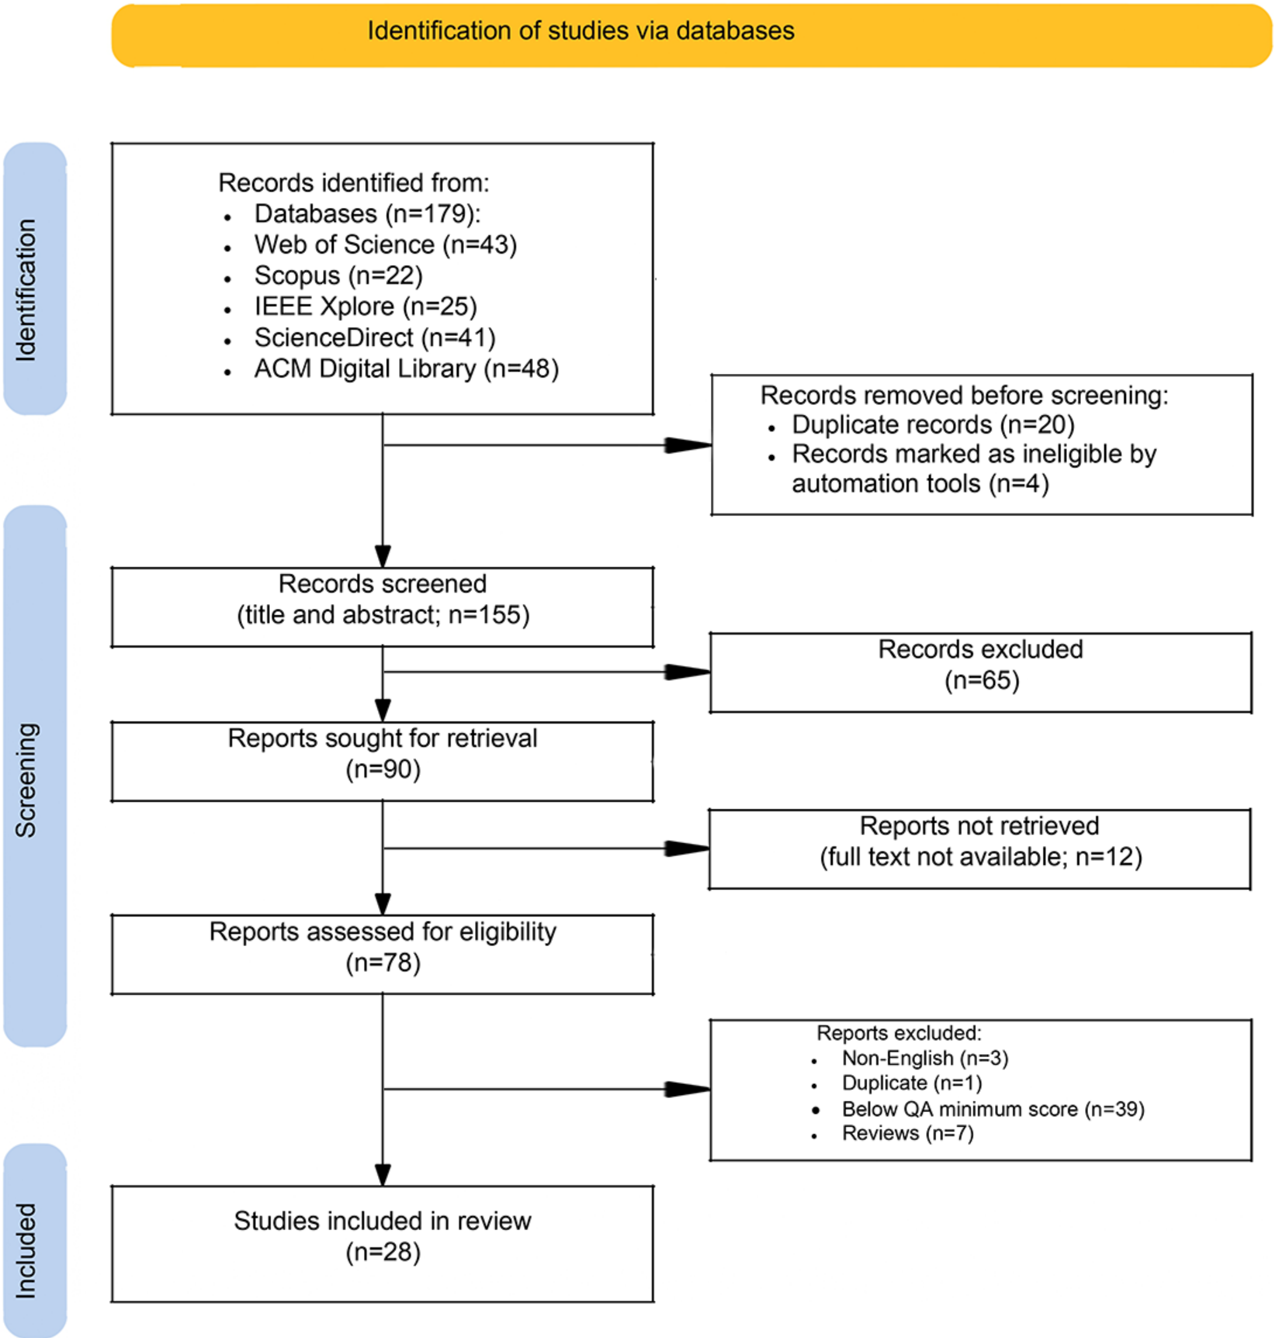
Figure 3. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. QA: quality assessment.



Synthesis Methods

The data extraction process was carried out to methodically address the stated RQs. Initially, a single reviewer handled the task of data extraction, leveraging the analytical capabilities of Microsoft Excel to facilitate a structured and organized approach to data collection and analysis. The same tool was used for data organization and representation. Within this app, a comprehensive table was constructed in which the rows were designated to the considered references and data corresponding to individual RQs were entered into separate columns, fostering a systematic representation of the data obtained. Subsequently, to enhance the reliability and validity of the data integration process, a second reviewer performed a verification of the initially extracted data. This encompassing procedure ensured a high degree of accuracy and reduced potential discrepancies, thus guaranteeing the integrity of the data.

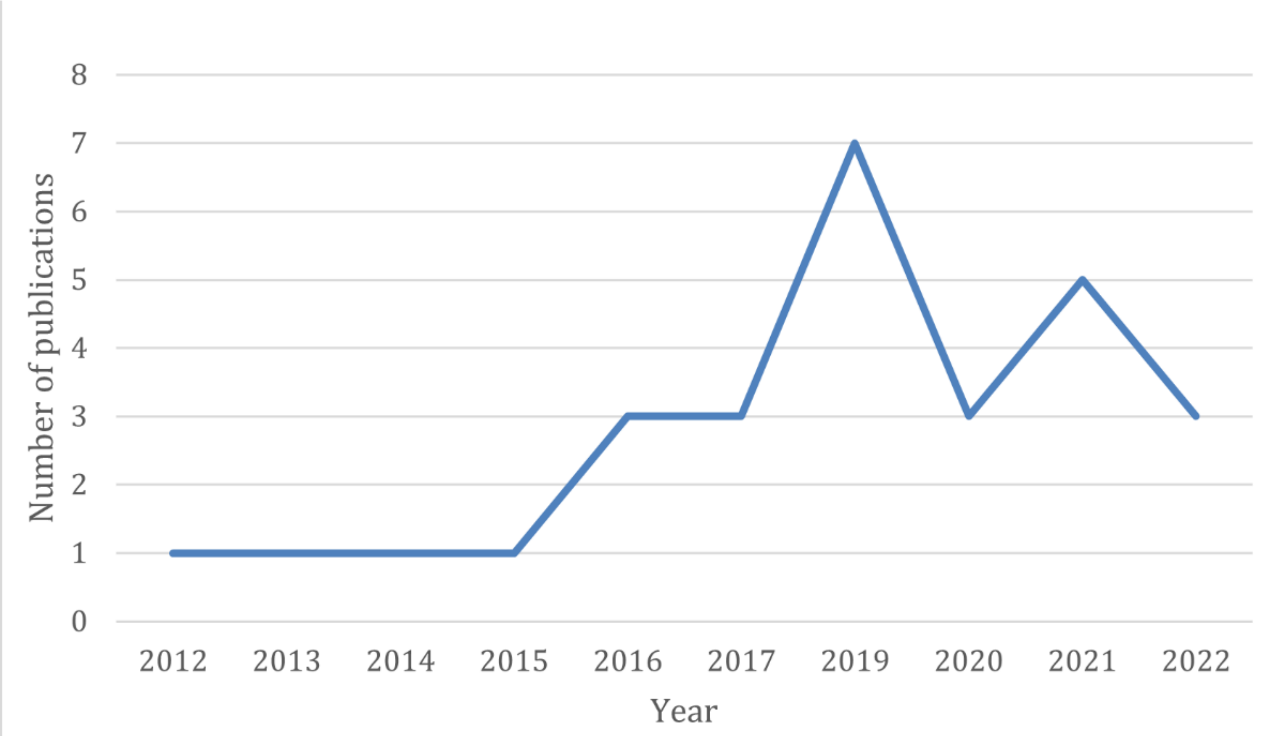
Results

As a result of applying the PRISMA guidelines, a total of 28 publications were considered in this study to address the RQs.

RQ 1: What Is the Papers' Distribution Over Time?

Considering the time range for paper analysis, Figure 4 depicts the time distribution of publications over the period of 2012 to 2022.

Figure 4. Time distribution of the reviewed publications.



Analyzing Figure 4, we can see an increasing trend in the number of publications starting in 2015, with the maximum value being reached in 2019. This denotes an increasingly high interest in these technologies. The number of publications decreased again in 2020, probably because of the pandemic, which limited human interaction and prevented the development and testing of apps dedicated to children with autism.

Regarding the types of publications, more than half (17/28, 61%) were presented at conferences, and 39% (11/28) were articles published in specialized scientific journals.

RQ 2: What Category of People Are the Studies Aimed at?

The analysis of the considered publications revealed that 43% (12/28) [29,31-33,36,39,43,44,47,50,51,53] stated that they were about children without mentioning the number of participants or their ages. Textbox 1 summarizes the data obtained.

The paper by Xia et al [47] addressed people with autism without mentioning whether they were children or adults, and the study by Wang et al [54] only involved adults but was of interest because the proposed solution can be applied to children as well.

In addition, the studies by Zheng et al [38], Escobedo et al [46], and Voss et al [49] included children both with and without ASD to compare the results and the process recorded in both cases.

Textbox 1. Number and age of the children involved in the studies.

- Hashim et al [28]: 6 children aged between 5 and 12 y
- Machado et al [29]: children—age not stated
- Tang et al [30]: children aged <4 y and between 4 and 8 y; number not mentioned
- Selvarani et al [31]: children—age not stated
- Abou El-Seoud et al [32]: children—age not stated
- Vullamparthi et al [33]: children—age not stated
- Singh et al [34]: children aged between 9 and 12 y
- Chen et al [35]: 6 teenagers aged between 11 and 13 y
- Tang et al [36]: children—age not mentioned
- Giraud et al [37]: 12 children aged between 5 and 9 y
- Zheng et al [38]: 12 children, 6 with autism spectrum disorder (ASD) and 6 with typical development
- Pradibta and Wijaya [39]: children—age not stated
- Nubia et al [40]: 6 children (5 boys and 1 girl) aged between 3 and 9 y
- Sait et al [41]: 9 children aged between 4 and 12 y
- Wan et al [42]: 10 children aged between 3 and 8 y
- Kavitha et al [43]: children—age not stated
- Silva et al [44]: children—age not stated
- Kalantarian et al [45]: 8 children aged between 6 and 12 y
- Escobedo et al [46]: unknown number of children aged between 8 and 11 y, including 3 children with autism
- Xia et al [47]: mainly people with autism
- Amado et al [48]: children aged between 7 and 9 y; number not indicated
- Voss et al [49]: 20 children with ASD and 20 children without ASD
- Washington et al [50]: 14 families
- Gulati and Handa [51]: children—age not stated
- Escobedo et al [52]: 12 children and 7 teachers
- Bouaziz et al [53]: children—age not stated
- Wang et al [54]: 4 adults, but the system was suitable for children as well
- Gelsomini et al [55]: 5 children (2 with mild ASD, 2 with medium ASD, and 1 with psychomotor retardation)

RQ 3: What Technologies Are Used With XR or Any of Its Subdivisions to Develop Apps for ASD Therapy?

AR mobile apps for therapy for children with ASD typically used a combination of the following technologies:

1. Mobile devices such as smartphones and tablets equipped with cameras; displays; and sensors such as accelerometers, gyroscopes, and GPS
2. AR software development kits such as ARKit, ARCore, and Vuforia, which provide the tools and framework needed for developing AR apps
3. Graphical and game engines such as Unity and Unreal Engine for 3D model development and creating animations and interactive environments
4. Natural language processing and speech recognition technologies for creating voice-activated AR experiences
5. Computer vision and image-processing techniques for real-time object tracking and recognition of objects, faces, and gestures
6. Machine learning algorithms for customizing the AR experience based on the child's performance and preferences
7. Cloud computing infrastructure for data storage, management, and analysis of therapy progress

Of the 28 analyzed publications, 22 (79%) addressed a solution from the spectrum of AR implemented on mobile devices such as smartphones owing to their processing power and integrated sensors that make them suitable tools for implementing apps without the need for additional and sophisticated equipment. In addition, the papers by Giraud et al [37], Sait et al [41], Gulati and Handa [51], and Gelsomini et al [55] presented solutions based on VR. Although the articles by Wan et al [42] and Kalantarian et al [45] did not present an AR or VR solution, the methodology addressed and the results obtained show the potential for research in this area. Textbox 2 summarizes information about the technologies and platforms used for app development.

Unity 3D and Vuforia were among the most common platforms used in the development of AR apps for mobile devices, with the Android operating system often mentioned. Several studies (6/28, 21%) [29,38,41,49,51,55] used wearable devices such as Google Glass, Oculus Go, Google Cardboard, Leap motion sensors, and E4 wearable sensors along with the mentioned technologies. Interactive cards were also used as markers to overlay virtual content.

Textbox 2. Technologies and platforms used.

- Hashim et al [28]: interactive cards, augmented reality, and smartphones
- Machado et al [29]: augmented reality based on smart glasses and Android, web platform, Node.js, eye tracker, sensors, and Amazon Alexa
- Tang et al [30]: augmented reality and Google TensorFlow
- Selvarani et al [31]: interactive cards, augmented reality based on markers, Vuforia, Android smartphone, and Unity 3D
- Abou El-Seoud et al [32]: augmented reality based on markers, smartphones, and the Aurasma framework
- Vullamparthi et al [33]: smartphone, Android, augmented reality, and QR codes
- Singh et al [34]: desktop app and augmented reality
- Chen et al [35]: Vuforia and smartphone or tablet PC
- Tang et al [36]: Google TensorFlow, augmented reality, and smartphone or PC
- Giraud et al [37]: virtual reality (VR) and Unity 3D
- Zheng et al [38]: augmented reality, Microsoft Kinect, and portable E4 sensor
- Pradibta and Wijaya [39]: interactive cards, augmented reality, Android smartphone, and Adobe for animation and graphic illustration
- Nubia et al [40]: augmented reality, Android tablet PC, Unity 3D, Vuforia, and Blender
- Sait et al [41]: VR, Unity 3D, and VR glasses (Oculus Go)
- Wan et al [42]: system that can be implemented on a PC, smartphones or robots; no use of augmented reality or VR
- Kavitha et al [43]: augmented reality, Android smartphone, Vuforia, and ARCore
- Silva et al [44]: augmented reality, smartphone or tablet PC, and Vuforia
- Kalantarian et al [45]: Android smartphone; no VR or augmented reality
- Escobedo et al [46]: augmented reality and Android smartphone
- Xia et al [47]: augmented reality, Android or iOS smartphone, React, Node.js, and Python for object recognition
- Amado et al [48]: augmented reality, Vuforia, Unity 3D, Android smartphone, Balsamiq Mockups 3, and Tinkercad
- Voss et al [49]: augmented reality, Android smartphone, and Google Glass
- Washington et al [50]: Google Glass and Android smartphone
- Gulati and Handa [51]: VR, Leap motion sensors, and VR camera
- Escobedo et al [52]: augmented reality, smartphone or tablet PC, PC server, MySQL database, and HTTP
- Bouaziz et al [53]: interactive cards, augmented reality, smartphone, and Vuforia
- Wang et al [54]: augmented reality, tablet PC or smartphone, Unity 3D, and Vuforia
- Gelsomini et al [55]: VR, Google Cardboard, smartphone, and Unity 3D

RQ 4: What Skills Were Targeted for Improvement in Primary Studies?

Owing to the deficiencies of children with ASD, the aim was to improve some basic skills such as the following:

1. Communication and language development
2. Social interaction and play skills
3. Fine and gross motor skills
4. Emotional regulation and collaborative strategies
5. Cognitive and problem-solving abilities
6. Attention and ability to follow instructions
7. Independence and self-help capabilities

Table 3 presents the number of publications aimed at improving basic skills.

A total of 25% (7/28) of the publications [28,30,33,36,40,49,52] focused on improving communication skills such as English vocabulary learning [28]; word learning using automatic object recognition through an app based on the TensorFlow library that can be used either when connected to the internet or offline [29]; speaking, reading, and associating images using an app that allows for customization of lessons by parents or therapists [33]; and communication and socialization by delivering certain cues through smart glasses [49]. Textbox 3 details the skills targeted in the studies.

Table 3. Targeted learning skills (n=28).

Skill	Studies, n (%)
Religious skills	1 (3)
Daily activities, meal preparation, toothbrushing, and eating	3 (11)
Cognitive or attention	2 (7)
Expressing emotions or social skills	5 (18)
Environment adaptation	1 (3)
Motor skills	2 (7)
Task training	1 (3)
General skills	3 (11)
Number learning	1 (3)
Object recognition	2 (7)
Communication or vocabulary	7 (25)

Textbox 3. Skills aimed to be improved.

- Hashim et al [28]: communication skills; learning English vocabulary, pronunciation, and articulation skills
- Machado et al [29]: daily routine activities (preparing meals)
- Tang et al [30]: word learning and object recognition
- Selvarani et al [31]: number learning
- Abou El-Seoud et al [32]: general skills; the user can choose the augmented reality (AR) content to be displayed
- Vullamparthi et al [33]: speaking abilities, reading, image associations, and activity scheduling
- Singh et al [34]: procedural task fulfillment
- Chen et al [35]: expressing emotions and social abilities
- Tang et al [36]: object recognition and vocabulary learning skills
- Giraud et al [37]: motor and social skills
- Zheng et al [38]: toothbrushing abilities
- Pradibta and Wijaya [39]: religious abilities—prayers
- Nubia et al [40]: communication abilities
- Sait et al [41]: adaptation to a new or unfamiliar environment
- Wan et al [42]: cognitive skills and practicing facial emotions
- Kavitha et al [43]: general skills; the user can choose the AR content to be displayed
- Silva et al [44]: social and general skills
- Kalantarian et al [45]: expressing emotions and social abilities
- Escobedo et al [46]: social skills in real-life situations, building and maintaining social relationships, improving conversational ability, and managing behavior and emotions
- Xia et al [47]: social and self-help abilities (shopping)
- Amado et al [48]: cognitive skills
- Voss et al [49]: social and communication abilities
- Washington et al [50]: expressing emotions
- Gulati and Handa [51]: motor, focusing, and general skills
- Escobedo et al [52]: object recognition
- Bouaziz et al [53]: self-help skills (feeding)
- Wang et al [54]: attention skills
- Gelsomini et al [55]: general skills (attention, concentration, and understanding) and narration

Some studies (3/28, 11%) focused on the development of self-help skills such as preparing meals with the help of smart glasses, receiving real-time information about the steps to follow [29], brushing teeth [38], or eating [53]. By improving the skills aimed at in the studies considered in this review and developing skills that can improve the deficiencies present in children with ASD, the social inclusion of children with ASD was pursued.

RQ 5: What Are the Purposes for Which the Proposed Solutions Were Used?

Using at least one of the technologies targeted in this review, the solutions presented in these publications were used to assist children with ASD. Developed for use by both therapists and parents at home or in specialized medical centers, these solutions aimed to improve certain fundamental aspects of the lives of children with autism. Textbox 4 presents information related to the reasons for which the apps were developed.

Hashim et al [28] created an app for the development of children's English vocabulary, which could potentially be used with other languages as well. The solution proposed in the paper by Machado et al [29] used multiple technologies to allow the therapist to model activities using a web platform and provide hints to users via smart glasses. It also works as an attention-monitoring tool via an eye tracker so that activities can be evaluated and improved. The study by Tang et al [30] addressed the problem of communication through automatic object recognition using a smartphone and display of virtual content (object names) on the screen. This app works either when connected to the internet or offline. A similar approach was observed in the study by Selvarani et al [31], in which children could learn numbers by scanning notebooks using their mobile devices, after which the relevant content was displayed on the screen.

Textbox 4. The purpose of the developed apps.

- Hashim et al [28]: the Areal-Vocab app was developed to help children with autism improve their English vocabulary.
- Machado et al [29]: the aim was to develop an assistive app using augmented reality (AR) based on smart glasses and a visual attention analysis tool to help people with autism in daily tasks by providing complementary information (eg, to pick up the knife and then cut the strawberries). The therapist can model the activity.
- Tang et al [30]: the researchers intended to develop a mobile app for children with autism that could run either connected to the internet or offline that would improve word learning skills by using object recognition.
- Selvarani et al [31]: the aim was to help children with autism learn numbers by scanning an interactive card using the app so that complementary video and audio content is displayed on the screen.
- Abou El-Seoud et al [32]: the aim was to develop a framework to help parents or educators use AR in a personalized way by choosing what type of AR educational content to display over a printed marker representing a familiar cartoon character.
- Vullamparthi et al [33]: a tool was developed that included an interface for parents or educators to scan a QR code and create various lessons and an interface for children. It used the smartphone camera, an Android apk (Android application package), a web page, a database, and Jakarta server pages.
- Singh et al [34]: the paper was a comparative study that aimed to explore the effectiveness of AR in the execution of tasks among less privileged children (who have had minimal interaction with technology), healthy but younger children, and children with autism.
- Chen et al [35]: the researchers developed a Vuforia-based AR app that can be deployed on Android or iOS devices (smartphones or tablets). This app can scan storybooks (with images captured from videos) and overlay relevant content to assist children with autism in expressing and understanding emotions and developing social skills.
- Tang et al [36]: the aim was to develop a tool for children with autism that can recognize objects and display their names.
- Giraud et al [37]: the study aimed to involve children with autism in common actions (moving furniture) by interacting with a virtual character projected on a tactile magnetized surface.
- Zheng et al [38]: the goal was to develop an AR system (Cheerbrush) that could teach children with autism how to brush their teeth considering how important this is to stay healthy and avoid dental procedures. It uses Kinect to capture the user’s movement, a 3D-printed toothbrush to assess brushing skills, a monitor to view the surroundings, and an avatar. It also uses a wristband to assess children’s stress while using the app.
- Pradibta and Wijaya [39]: the aim was to help children with autism learn daily prayers. The goal was to develop an app that contains animated learning materials in the form of daily prayers from the Islamic religion.
- Nubia et al [40]: the aim was to help children with autism communicate better using an app that can identify human-recognizable objects such as animals, fruits, or other common objects and match them with specific sounds.
- Sait et al [41]: the goal was to develop a virtual reality (VR) framework in which the teacher can enter information about the child and prepare scenes that can be watched by a child wearing VR glasses. The main objective was to familiarize children with autism with places such as school, the schoolyard, and the classroom by previously visualizing the environment.
- Wan et al [42]: the aim was to help children with autism recognize, practice, and express emotions such as happiness, sadness, fear, or anger.
- Kavitha et al [43]: the aim was to help children with autism recognize objects or animals by rendering 3D content over certain images.
- Silva et al [44]: the aim was to help reduce the isolation of children with autism by encouraging them to explore the world with the help of an app based on geolocation and AR.
- Kalantarian et al [45]: the goal was to help children with autism learn to express their emotions. Guess what? is an Android mobile app similar to Heads up!, a game in which a parent holds the smartphone with the screen facing the child, the child imitates what they see, and the parent tries to guess the simulated emotion.
- Escobedo et al [46]: the paper describes the design and development of the MOSOCO app, which is a mobile app that provides real-time support and guidance to children with autism in practicing social skills. The app uses AR technology to overlay social hints directly into the child’s real environment, allowing them to practice social skills in real-life situations.
- Xia et al [47]: the app provided step-by-step guidance for people with autism to go shopping by augmenting real shopping scenes using object recognition, barcode reading, and automatic classification.
- Amado et al [48]: the main objective was to develop an AR mobile app to be used by parents of children with autism for their therapy during the pandemic, when human interaction was limited.
- Voss et al [49]: the system described in the paper aimed to help people with autism spectrum disorder improve their social skills by providing discrete real-time social cues via wearable technology. Social cues are provided directly in the wearer’s field of vision using AR technology and are intended to help the wearer navigate social situations and improve their social interactions and communication skills.
- Washington et al [50]: the goal was to develop an app that runs on an Android smartphone (used by a parent) that is connected to a Google Glass device worn by the child. Social cues are delivered to the glasses based on emotions recognized by the mobile app, which also records the session (video only for privacy reasons). The activities are gamelike—catch the smile, guess the emotions, and unstructured activities.
- Gulati and Handa [51]: the aim was to develop a VR game to improve reading, basic math, and spelling. Motor skills are improved by reading gestures and helping coordinate them with the eyes using the Leap motion sensor.

- Escobedo et al [52]: the aim was to create an app that can identify objects that are tagged and display relevant content over them, such as text, 3D models, vibrations, video, or audio, and the user can receive a reward. The main architecture is composed of a module called therapy manager, an ambient notification system, and a tag manager.
- Bouaziz et al [53]: the aim was to develop an app dedicated to children with autism that teaches them how to eat by scanning an interactive card and displaying on top of it a 3D character depicting the targeted skill.
- Wang et al [54]: the aim was to help adults with autism be more focused by performing certain tasks, such as rearranging objects in a scene.
- Gelsomini et al [55]: the aim was to develop a VR mobile app for smartphones that can be used with Google Cardboard, helping children with autism understand activities through storytelling and allowing caregivers to customize the content using a web app, monitor children's attention, and analyze statistics.

The apps developed in the studies by Abou El-Seoud et al [32] and Vullamparthi et al [33] aimed to go through some lessons that parents and educators could customize by accessing a web platform so that they could choose which type of content to display when the app detected an object in the visual area. The study carried out by Singh et al [34] compared the effects of apps that use AR to perform certain tasks in both children with ASD and children with typical development. Religious activities were also included in one study [39], which presented an app containing animated materials that helped children learn prayers.

Given the fact that children with autism typically experience difficulties adapting to a new environment, Sait et al [41] aimed to develop an app that uses VR, VR glasses, and a web platform in which therapists can enter information about each child and set up custom scenes, such as a classroom, to be viewed virtually and get used to. In addition to the goal of conducting basic activities, Xia et al [47] developed an app to guide individuals with autism with grocery shopping step by step.

RQ 6: What Are the Results Obtained Using the Proposed Solutions?

Depending on the proposed solution and the objectives of the studies, the results were different, but in general, where the app was tested, encouraging results were obtained, with the remark that these were to be improved and tested more thoroughly. In cases in which the app was not tested with the intended audience but was proven to function, it was deemed to have potential. Textbox 5 summarizes the results obtained in each study.

Upon analyzing the results of the studies included in this review, it was found that only 68% (19/28) of the apps were tested with children with autism, whereas 32% (9/28) were tested only by the developers for functionality purposes. Regarding the methods used to quantify the results, 54% (15/28) of the studies used interviews, and only 14% (4/28) of the studies used an assessment method based on assigning a score according to the degree of skill improvement after using the apps.

Textbox 5. Summary of the results.

- Hashim et al [28]: children and their parents or educators in the study used the app and reported positive results based on interviews: "Helps listen and understand instructions, helps maintain attention longer, helps with pronunciation and enunciation, helps keep them engaged and interested to learn the vocabulary in depth."
- Machado et al [29]: the app has great potential considering the fact that smart glasses can very easily transpose the user into the world of augmented reality (AR) and help them by displaying complementary information, as well as giving feedback to the therapist. It has been tested by developers but has not been tested with children with autism, so it does not show quantifiable results.
- Tang et al [30]: the first pilot study was conducted on a university campus with neurotypical children and adults, who provided positive feedback and showed a lot of interest. The second study was conducted in a special education unit involving 2 groups: one with children aged <5 y and one with children aged between 6 and 8 y. It was noticed that the younger children had difficulty using the app, but it was well received by the older children. Positive feedback was also provided by parents and teachers, pointing out that the offline module required improvement.
- Selvarani et al [31]: the app (NUM09) is functional but has not been tested on children with autism with quantifiable results.
- Abou El-Seoud et al [32]: a total of 3 patients with autism, together with their instructors, performed a usability test. According to responses to a questionnaire, the system can improve communication, concentration, and attention and is easy to use.
- Vullamparthi et al [33]: this study developed an Android smartphone app that helps children with autism and their parents or therapists create personalized lessons to improve basic skills such as reading, writing, or picture recognition. A workshop was held, and positive feedback from parents was reported. There are no quantifiable results.
- Singh et al [34]: the main task was to complete a tangram puzzle. In the first stage, the involved children did not solve the puzzle without clues involving AR, but it was reported that solving took longer in the AR training mode. In the first study, children aged 9 to 12 y rated the desktop-based instruction mode as the least preferable, whereas the performance using the AR mode was superior. In the second study, 4 children with autism followed the same procedure but had difficulty using the AR-based solution, resulting in poorer performance on the task.
- Chen et al [35]: the app was tested in a dedicated room equipped with a computer, a 52-inch monitor, and 8 tablets. The therapist showed the children the app and asked them to look at the pictures, answer some questions, and use the tablet to access the AR content by pointing it at the picture with the app running in the background. Positive feedback was reported from the children, who were curious and eager to discover new visual cues, showing interest in the facial expressions, gestures, and related activities of the characters. The children had low scores on the initial assessment, but all 6 scores increased significantly after the app intervention. The most dramatic improvement was in one child, from 30% to 89.5%.
- Tang et al [36]: the app works, but it has not been tested on children with autism with quantifiable results.
- Giraud et al [37]: 12 children with autism spectrum disorder (ASD; including 2 girls) aged between 5 and 9 y participated in the study for a period of 3 mo. In total, 7 of the children showed little conversational language. A 3-stage experiment was conducted (familiarization, moving an object with an agent following the child, and training with an agent that the child follows). Preliminary results were encouraging: one-third of the children completed the training, another third needed device adjustments, and some had difficulty using the system.
- Zheng et al [38]: to evaluate the system, 6 children aged between 3 and 6 y (3 with ASD and 3 without ASD) were involved in an experiment comparing the results. It was noted that all the children were able to complete the training sessions, but the children with ASD were clearly more engaged and interested. After training, the most notable improvements were observed in children with autism. During an interview, both children and parents said that they liked the app and that it helped them improve their toothbrushing skills.
- Pradibta and Wijaya [39]: no proof of testing with children with autism and no quantifiable results.
- Nubia et al [40]: by playing relevant sounds in line with images, the app helped children improve their learning skills compared with traditional methods. A 14% increase in attention and a 9% increase in verbal language were reported.
- Sait et al [41]: the system was used by 9 children with autism who benefited from the help of therapists who guided them in adjusting the Oculus Go headset and using the app (AutiVE). One of the issues was the virtual reality (VR) headset itself and the VR environment, but the website provided had a video explaining them. In total, 8 of the children eventually accepted the device. There were some improvements in learning skills, but no detailed statistics were mentioned.
- Wan et al [42]: the children completed a 20-min training session each day for 4 consecutive days. A total of 6 participants showed improvement in proficiency in operating the system, 5 of 6 completed all tasks, and 4 of 6 showed improvements in expressing emotions. Children aged <5 y found the app difficult and did not perform in a satisfactory manner.
- Kavitha et al [43]: the app works, but it has not been tested with quantifiable results.
- Silva et al [44]: an app similar to Pokémon GO was developed in which users can find "monsters" in certain areas and, by clicking on them, find relevant information. The concept of gamification was used, but the system was not validated with real users with autism.
- Kalantarian et al [45]: the solution was tested with 8 children, all boys, playing up to 5 games in 1 session. In total, 94%, 81%, 92%, and 56% of the emotions were labeled correctly as disgust, neutrality, surprise, and fear, respectively.
- Escobedo et al [46]: the app was evaluated over 7 wk. Interview results revealed that the app was well received by children with autism and their therapists and that it was effective in helping children practice and improve their social skills in real-world situations. The authors reported that users were able to use the app easily and that the AR technology was effective at providing children with real-time support and feedback. The study also showed that the app was well accepted by therapists, who found it a useful tool for their patients' therapy.
- Xia et al [47]: the app, called ParaShop, was tested by a nonprofit organization that helps people with disabilities. Staff said that the app helped people with autism buy their groceries, but the number of participants or other details were not mentioned.

- Amado et al [48]: a case study was conducted using Google Forms asking parents to answer questions related to their children (eg, age, gender, and whether the parents lived together). Several studies with parents were conducted, and then the app was developed based on their responses and requirements. In the last stage of the case study, 5 questions were posed about the final prototype of the app. The survey revealed that 46.2% of parents were satisfied and 23.1% were very satisfied. Overall, the mobile app received positive feedback from respondents.
- Voss et al [49]: the research entailed a study involving 20 participants with ASD and 20 participants without ASD who used a system called Superpower Glass over a 4-mo period. The results showed that the participants found the social cues useful in situations and improved their social interactions and communication skills. The study also assessed the acceptability and usability of the system, and the results suggest that it was well received by participants and easy to use.
- Washington et al [50]: the app was tested by families, and they reported that it was useful, with some of them recording the sessions and then showing them to the children to see how they behaved for further improvement. Overall, based on interviews, parents reported positive outcomes.
- Gulati and Handa [51]: the concept of gamification was used; it has potential, but it has not been tested in children with autism. To play the game, a dedicated gaming room and specific equipment are required.
- Escobedo et al [52]: the app (Mobis) was tested with 7 teachers caring for 12 children with autism aged between 3 and 8 y. The researchers conducted weekly interviews with the teachers, keeping in mind that only 3 out of 12 children were able to properly pronounce words. The duration of the observation was 54 h. Participants were reported to find Mobis "exciting, useful, and easy to use." Students improved their motor skills by focusing the camera on the target. Mobis increased the time that students stayed on task by 20% and motivated them to use the app as they were excited to discover new objects in their environment. Selective attention improved by 62%, and sustained attention improved by 45%. Mobis also induced positive emotions and taught behavioral skills such as tolerance.
- Bouaziz et al [53]: no proof of testing with children with autism and no quantifiable results.
- Wang et al [54]: the app was developed for demonstrative purposes only; it has not been tested with quantifiable results.
- Gelsomini et al [55]: the solution (Wildcard) was tested in a special unit with 5 children with autism during 8 individual therapy sessions. Therapists reported improvements in children's attention and cognitive skills, but the paper only reported qualitative data. Therapists were excited to be able to customize each VR session and noted that patients embraced the app and found it engaging.

Discussion

Principal Findings

The analysis revealed an increasing trend in publications starting from 2015, reaching its highest point in 2019 and followed by a decline in 2020, potentially because of the pandemic. Most of the papers (17/28, 61%) were presented at conferences and largely focused on AR solutions (22/28, 79%) for mobile devices to assist children with ASD in enhancing basic skills and fundamental life aspects. Notably, Unity 3D and Vuforia emerged as popular development platforms. Although a substantial percentage of publications (13/28, 47%) did not provide details on participating children, most of the identified participants were aged between 3 and 13 years. Developed for use by both therapists and parents at home or in specialized medical centers, these solutions showed encouraging preliminary results but underscore the necessity for further, more extensive testing, particularly as a significant portion (9/28, 32%) were only developer tested.

Main Directions of Research

Upon examining the scientific publications included in our study, several main directions for the use of XR to support children with autism can be identified.

One notable topic is the use of AR in the area of language skills and vocabulary learning in children with autism. Researchers in some studies (3/28, 11%) [28,30,43] focused on the development of AR-based mobile apps that facilitate word learning and object recognition through techniques such as deep learning and automatic object recognition.

Another topic addressed in some studies (3/28, 11%) [29,39,53] was the use of smart glasses or wearable devices to support children with autism in social interactions. These devices provide real-time visual cues and information to enhance communication and social interaction skills.

The use of AR occupational therapy and the development of cognitive skills in children with autism were explored in some studies (3/28, 11%) [31,38,46], which proposed AR-based apps to aid children in learning numbers, teeth-brushing skills, or environmental adaptation skills.

Furthermore, it was stated that the apps specifically designed for children with ASD should be tested with a target group of children, and the results should be quantified in a pertinent manner given that a large part of the findings were obtained through interviews.

Personalization and adaptability are other key aspects of developing mobile apps, as shown in the studies by Wan et al [42], Kalantarian et al [45], and Washington et al [50]. These publications addressed the development of personalized systems and apps to maximize the therapeutic and educational benefits for children with autism.

Some studies (3/28, 11%) [32,34,52] also examined the use of AR to provide individual support for people with autism and cognitive impairment. These studies proposed AR-based frameworks and approaches to assist individuals with autism in various activities and tasks, such as training in procedural tasks, perception and recognition of facial emotions, or assistance in real-life situations.

In addition, some studies (3/28, 11%) [35,37,55] investigated the use of AR in the context of education and social skill development. These studies focused on the use of interactive books, serious games, or training apps to support children with autism in understanding and interpreting facial expressions, social cues, and social interactions.

The use of AR in the context of learning in a geographical environment or learning environmental coping skills was addressed in some studies (3/28, 11%) [40,41,47]. These studies proposed AR-based apps to assist children with autism in exploring and learning in a geographical environment or in developing adaptive skills applicable to different situations and contexts.

A relatively small number of studies (6/28, 21%) [34,38,46-48,52] focused on VR-based approaches for apps, indicating a shift toward the adoption of AR owing to its lower cost and greater usability. Using VR, the study by Abou El-Seoud et al [32] evaluated joint action (moving furniture) abilities using a virtual character, and the preliminary results were encouraging, with one-third of the children completing the training despite 7 of them having limited conversational language. Another issue addressed in the study by Tang et al [36] was adaptation to unfamiliar surroundings. Researchers reported improvements in learning abilities but stated that the equipment and VR environment posed the greatest challenges. The concept of gamification was integrated with VR in the study by Escobedo et al [46] to enhance reading, basic mathematics, and spelling. This app required a special room to run. Although this app has great potential, it has not yet been tested in children with ASD. In addition, an app using Google Cardboard and VR was developed to enhance the cognitive and attentional skills of children. Therapists expressed satisfaction with the outcomes as they were able to personalize each session using unique teaching methods.

User Interaction Perspectives

Overview

The interaction of children with ASD with XR devices, such as AR and VR platforms, brings forth a distinct set of considerations. The manner in which children with ASD use these devices can be influenced by their sensory sensitivities, motor skills, cognitive abilities, and preferences. Although the experiences can vary widely, the following are some ways in which children use XR devices and the challenges they may face.

Physical Interaction

Children use XR devices by interacting with touch screens, controllers, or wearable components. They may tap, swipe, or perform gestures to navigate through XR environments. However, children with fine motor difficulties may struggle with precise interactions, leading to accidental inputs or difficulties in selecting desired options.

Visual Engagement

Children engage visually with the XR content displayed on screens or through headsets. Visual stimuli can capture their attention and spark interest. Nonetheless, those with sensory sensitivities may experience sensory overload or visual discomfort if the content is excessively bright, flashy, or overwhelming.

Spatial Awareness

XR experiences often involve spatial interactions such as moving through virtual environments or manipulating virtual objects. Children's spatial awareness skills can influence their ability to navigate these environments. Some children may find it challenging to grasp the concept of a virtual space, leading to disorientation.

Auditory Response

Many XR apps incorporate auditory cues, sound effects, or voice instructions. Children may respond to auditory prompts by vocalizing or reacting physically. However, children who are sensitive to loud or sudden sounds may experience distress in XR environments with intense auditory stimuli.

Attention and Engagement

Children's level of attention and engagement with XR content can vary. Some may become deeply immersed and engaged, whereas others may have difficulty sustaining their attention because of the novelty of the experience or sensory distractions.

Preferences and Comfort

Children's preferences for certain types of interactions or content can influence their engagement. Some children may appreciate exploring virtual worlds, whereas others may prefer more structured or repetitive activities. Ensuring a variety of XR experiences allows for accommodating different preferences.

Transition Challenges

Transitioning between the real world and the XR environment can be challenging for some children. They may have trouble understanding that the virtual elements are not physically present or struggle with transitioning back to reality after prolonged XR use.

Response Variability

Children with ASD may respond to XR experiences differently across sessions. Factors such as mood, sensory sensitivities, and cognitive states can influence their interactions. Some days, children may be more receptive to XR, whereas on other days, they may be less engaged or overwhelmed.

Calibration and Setup

XR devices require proper calibration and setup for optimal interaction. Children may need assistance in adjusting headsets, ensuring proper alignment, or calibrating controllers. Technical difficulties can lead to frustration or disengagement.

Challenges

The identified challenges are as follows:

1. Individualized learning needs: a prevalent challenge across the studies in this review was catering to the diverse learning preferences and abilities of children with ASD. For instance, Hashim et al [28] faced the task of addressing the specific needs of children with mild ASD. Similarly, the studies by Abou El-Seoud et al [32] and Singh et al [34] addressed the challenge of tailoring their AR experiences to suit varying preferences and capabilities.

2. Transferability and generalization: a common limitation is the transfer of learned skills to real-world scenarios. As seen in the studies by Tang et al [36] and Giraud et al [37], researchers have encountered challenges in translating acquired skills into practical applications. In addition, studies such as those by Chen et al [35] and Kavitha et al [43] noted limitations in transferring learned skills beyond the AR context, possibly owing to the variations in real-world stimuli.
3. Technical feasibility and personalized support: technical feasibility and ongoing support emerged as challenges in some studies [29,38]. Maintaining the functionality of AR-based smart glasses and ensuring accurate real-time feedback for toothbrushing techniques required continuous technical support.
4. Sensory overload and individualization: sensory sensitivities and the need for individualized solutions were prominent challenges. Sait et al [41] encountered the challenge of designing virtual environments that cater to sensory sensitivities, whereas studies such as the one by Voss et al [49] highlighted the importance of unobtrusive cue presentation in wearables for children with ASD.
5. Cognitive adaptation and user adoption: cognitive adaptation and user adoption challenges were evident in some studies [48,52]. Designing tasks that effectively target cognitive skills and maintaining user engagement over time were key considerations.
6. Ethical implications of data handling: as AR interventions involve interactions and data collection, ethical considerations are paramount. The study by Wan et al [42] delved into recognizing facial expressions, which raises ethical concerns related to data privacy and security. Ensuring that data-handling protocols adhere to ethical standards becomes crucial, underscoring the need to protect sensitive user information while deriving meaningful insights from the interactions.
7. Cross-cultural adaptation and applicability: given the diversity of cultures and languages, ensuring the cross-cultural adaptation and applicability of AR interventions becomes a notable challenge. The study by Wang et al [54], which explored mobile AR for attention improvement in adults with ASD, highlights the importance of adapting interventions to diverse cultural contexts. This challenge emphasizes the need for cultural sensitivity and the localization of content to ensure that interventions are universally accessible and effective.
8. Long-term impact measurement: measuring the long-term impact of AR interventions and tracking the progress of children over time poses significant challenges, as pointed out in the study by Escobedo et al [46], which emphasized the importance of assessing the sustained effects of interventions beyond short-term interactions. This challenge underscores the necessity of devising reliable methodologies for gauging the lasting benefits of AR interventions and understanding how these interventions contribute to the developmental trajectory of children with ASD.

In the realm of AR apps for children with ASD, studies have striven to engage children through various interaction modes while tackling shared challenges. The diverse engagement strategies and the collective endeavor to overcome common limitations underscore the continuous efforts to create meaningful and effective AR-based interventions for this unique demographic.

Research in this area demonstrates an interdisciplinary approach involving collaboration among specialists in education, IT, and mental health. This is illustrated by the diversity of authors and publications included in this review, suggesting that integrating AR, VR, and MR into ASD pedagogy requires a comprehensive approach that considers multiple aspects—from technology design to educational and mental health psychology. It was also specified that the apps aimed at children with ASD should be tested with a target group of children and that the results should be quantified in a more relevant manner given that a large part of the reported results was obtained only through interviews. The analysis of the studies indicates a trend in research toward the use of diverse and innovative study methods, such as using both quantitative and qualitative methods to investigate the impact of AR, VR, and MR on people with ASD.

Furthermore, the analyzed publications suggest that the development and implementation of AR-, VR-, and MR-based technologies extend beyond academia or research, involving partnerships with the private sector and local communities. This demonstrates the awareness of the need to transfer research findings into practice to have a direct impact on people with autism.

Limitations

Considering the publications reviewed in this study, several limitations were identified regarding the development and testing of AR-, VR-, and MR-based mobile apps:

1. Sample size: some studies involved small samples of participants, which may have limited the generalizability of their results to a larger population of children with autism. The involvement of a limited number of participants in many studies can be attributed to the unique characteristics of the target population—children with ASD. The diversity in ASD manifestation, severity, and individualized needs necessitates careful participant selection. Moreover, recruitment challenges, ethical considerations, and the resource-intensive nature of working with children with ASD contribute to the small sample sizes. However, this limitation was often acknowledged in the papers, along with the understanding that the findings may not be easily generalizable to the broader population with ASD.
2. Study duration: the duration of the studies included in this review varied from short testing sessions to several weeks or months. The short duration of many studies was due to practical constraints and the inherent complexities of conducting research involving children with ASD. Longitudinal studies involving children with ASD can present challenges in terms of participant retention, compliance, and data collection consistency over extended periods. In addition, the rapid pace of technological advancements may affect the relevance of the findings if studies are conducted over prolonged durations. However, the researchers did recognize the limitations imposed by

short study durations and provided justifications for the chosen time frames.

3. Diversity of diagnosis and level of functioning: autism is a disorder with a wide variety of symptoms and levels of functioning, which adds complexity and variability to the research.
4. Standardized outcome assessment: some studies did not use standardized outcome assessment tools, which may have affected the comparability and validity of the obtained results.
5. Availability and accessibility of technology: although the presented studies demonstrate the potential of AR technology to support children with autism, it is important to consider the availability and accessibility of this technology in real-world settings. The cost, infrastructure, and availability of AR devices and apps may be limiting factors in the widespread adoption of this technology.

The relatively small sample sizes and short durations commonly observed in many studies involving children with ASD and XR interventions are notable aspects of the research landscape. Although solutions to these issues were not always addressed in the papers, they remain ongoing areas of consideration for researchers in the field. In the selected papers, although some discussions and considerations regarding the challenges of small sample sizes and short study durations were present, comprehensive solutions were not elaborated on. The researchers often acknowledged these limitations and offered potential insights or recommendations, but definitive solutions were not always a primary focus of the papers, the primary focus being on the technical details and potential outcomes of their approach.

In addition, this study itself has several limitations, which should be considered for further research:

1. Limited number of databases queried: despite using comprehensive search strategies, it is possible that some relevant studies were omitted because they were published in nonindexed or less accessible sources.
2. Field evolution: this field of study is rapidly evolving, and new research may have been published since the literature search was conducted. Consequently, this review may not capture the most recent evidence and emerging trends in the field.
3. No distribution of publication authors: this review did not present information on the regional distribution of authors or the origin of the apps and systems, disregarding the influence of cultural differences on the development of these types of apps.
4. Lack of security analysis: this study did not analyze the security issues associated with the proposed solutions.
5. Absence of cost information: no information regarding the cost of the presented solutions could be identified.

Conclusions

This study aimed to conduct a systematic review of the specialized scientific literature in terms of applications, devices, and technologies relevant to the development of AR-, VR-, and MR-based mobile apps dedicated to the therapy of children with ASDs, an objective that was successfully achieved. At the beginning of this paper, the general concept of ASD was presented, after which the RQs and inclusion and exclusion criteria were defined and the results of applying the PRISMA guidelines for the selection of publications to be reviewed were reported. The answers to the RQs were discussed. At the end of the paper, the limitations of the research were presented.

Although the concepts of AR, VR, and MR are not entirely new, their use in the development of therapeutic apps for children with autism has only recently gained popularity. The findings documented in various publications indexed in 5 scientific databases emphasize the suitability of these technologies for such therapy, thereby warranting further in-depth research and the future development of apps based on these technologies. The studies indicated a clear trend toward the use of AR, VR, and MR technologies as a pedagogical tool for people with ASD. This trend involves multidisciplinary collaborations and an integrated approach to research, with a focus on empirical evaluations and ethics regarding the use of technologies. As the field advances, it is essential that research and practice continue to be guided by a balanced and integrated approach that considers both the technological possibilities and the needs and rights of individuals with ASD. However, there are still many issues that require further exploration and research.

Moreover, the publications studied illustrate a wide range of research areas related to the use of AR, VR, and MR in the context of ASD, as well as a variety of methodological and theoretical approaches adopted by the researchers. This suggests that the field is in a phase of rapid growth and diversification, with a wealth of opportunities for future research and development.

All data generated or analyzed during this study are included in this published article (and its multimedia appendices).

Authors' Contributions

M-VT and CET were involved in the concept and design of this review. All authors made substantial contributions to the analysis, preparation, interpretation, and organization of the data. The final manuscript was read, revised, and approved by all the authors.

Conflicts of Interest

None declared.

Abstract

Background: Neuropsychological assessments traditionally include tests of executive functioning (EF) because of its critical role in daily activities and link to mental disorders. Established traditional EF assessments, although robust, lack ecological validity and are limited to single cognitive processes. These methods, which are suitable for clinical populations, are less informative regarding EF in healthy individuals. With these limitations in mind, immersive virtual reality (VR)–based assessments of EF have garnered interest because of their potential to increase test sensitivity, ecological validity, and neuropsychological assessment accessibility.

Objective: This systematic review aims to explore the literature on immersive VR assessments of EF focusing on (1) EF components being assessed, (2) how these assessments are validated, and (3) strategies for monitoring potential adverse (cybersickness) and beneficial (immersion) effects.

Methods: EBSCOhost, Scopus, and Web of Science were searched in July 2022 using keywords that reflected the main themes of VR, neuropsychological tests, and EF. Articles had to be peer-reviewed manuscripts written in English and published after 2013 that detailed empirical, clinical, or proof-of-concept studies in which a virtual environment using a head-mounted display was used to assess EF in an adult population. A tabular synthesis method was used in which validation details from each study, including comparative assessments and scores, were systematically organized in a table. The results were summed and qualitatively analyzed to provide a comprehensive overview of the findings.

Results: The search retrieved 555 unique articles, of which 19 (3.4%) met the inclusion criteria. The reviewed studies encompassed EF and associated higher-order cognitive functions such as inhibitory control, cognitive flexibility, working memory, planning, and attention. VR assessments commonly underwent validation against gold-standard traditional tasks. However, discrepancies were observed, with some studies lacking reported a priori planned correlations, omitting detailed descriptions of the EF constructs evaluated using the VR paradigms, and frequently reporting incomplete results. Notably, only 4 of the 19 (21%) studies evaluated cybersickness, and 5 of the 19 (26%) studies included user experience assessments.

Conclusions: Although it acknowledges the potential of VR paradigms for assessing EF, the evidence has limitations. The methodological and psychometric properties of the included studies were inconsistently addressed, raising concerns about their validity and reliability. Infrequent monitoring of adverse effects such as cybersickness and considerable variability in sample sizes may limit interpretation and hinder psychometric evaluation. Several recommendations are proposed to improve the theory and practice of immersive VR assessments of EF. Future studies should explore the integration of biosensors with VR systems and the capabilities of VR in the context of spatial navigation assessments. Despite considerable promise, the systematic and validated implementation of VR assessments is essential for ensuring their practical utility in real-world applications.

Introduction

Background

Executive functioning (EF) has long been a focus of neuropsychological assessment because of the significant role it plays in everyday functioning. EF is an umbrella term for higher-order cognitive skills used to control and coordinate a wide range of mental processes and everyday behaviors [1-5], including "...mentally playing with ideas; taking the time to think before acting; meeting novel, unanticipated challenges; resisting temptations; and staying focused" [6]. Although a universally accepted definition of EF does not exist [5], there is agreement on the attributes of 3 core executive functions: inhibition, cognitive flexibility, and working memory [2,4,6]. These core executive functions support other higher-order executive functions such as reasoning, planning, and problem-solving [6-8]. As EF impairment has been linked to a variety of mental disorders [9], it is often considered a transdiagnostic risk factor [10].

Although traditional methods used to assess EF are popular [11,12] and well validated [13], they have been criticized for their lack of ecological validity [14,15]. Ecological validity, within the scope of this study, is defined as the "functional and predictive relationship between the person's performance on a set of neuropsychological tests and the person's behavior in a variety of real world settings" [16]. Specifically, we interpret ecological validity as comprising 2 principal components: representativeness—the degree to which a neuropsychological test mirrors the demands of a person's daily living activities that it aims to evaluate [17], sometimes referred to as *verisimilitude* [18]—and generalizability—the extent to which test performance predicts an individual's functioning in their daily living activities [17], also known as veridicality [18].

Traditional assessments tend to take a "construct-led" approach, with each test intended to isolate a single cognitive process in an abstract measure. This process of abstraction may limit the ecological validity of the measure by resulting in poor alignment between the test outcomes and real-world functioning. In turn, this produces a large amount of variance in EF that is unaccounted for by traditional tasks. For example, Chaytor et al [19] noted that traditional EF tests accounted for only 18% to 20% of the variance in the everyday executive ability of participants. This lack of explained variance may be attributed to the nature of the testing environment, the constructs assessed in isolation, the participant's affective state, and the compensatory strategies available to the participant [19]. A related methodological issue, known as the "task impurity problem" [4,20], indicates that the score on an EF task usually reflects not only the systematic variance attributable to the specific aspect of EF targeted by that task but also the (1) systematic variance across multiple types of EF tasks, (2) systematic variance attributable to non-EF aspects of the task, and (3) nonsystematic (error) variance (see the study by Snyder et al [10] for a detailed review). Outside the testing environment, the process of making a decision or planning and eliciting goal-directed behavior in everyday life is often highly dynamic and influenced by numerous internal and external factors [13,14]. Therefore, an ecologically valid assessment tool will need to include relevant contextual, dynamic, and multidimensional features such as affect and physiological state, which traditional assessments cannot include.

Furthermore, although traditional EF assessment tools may be appropriate for clinical populations, they generate less information about functioning in relatively healthy individuals. For example, the Trail-Making Test (TMT) has routinely been administered as a neuropsychological assessment of driving performance. Although some studies have demonstrated a relationship between the two [21,22], others have shown no relationship [23], particularly in nonclinical populations [24,25]. Thus, although traditional tools are adequate for detecting more severe EF impairments, they are less effective in detecting subtle changes in EF and early decline. Increased test sensitivity to detect subtle intraindividual changes may enable better detection of the prodromal stages of cognitive decline. Early detection is important as it enables early intervention, which may in turn improve prognosis. For example, sensitive detection can identify the prodromal stages of Alzheimer disease in seemingly healthy individuals [26] and mild cognitive decline up to 12 years before clinical diagnosis [27]. Similarly, in a situation in which an individual requires a capacity assessment for an activity, traditional assessments may have limited utility for nonclinical populations. The triangulation of multiple data sources such as biosensors may increase sensitivity to better identify subtle changes in capacity.

To address the shortcomings of poor ecological validity and test sensitivity, research on psychological assessment has begun to investigate virtual reality (VR) technology as a means of providing a more naturalistic environment for evaluating EF in clinical neuropsychological assessments. VR enables the development of custom-designed simulated environments that can replicate real-life environments, potentially increasing its ecological validity through representativeness. In addition, VR could increase engagement [28,29], reduce test time, and better integrate data from biosensors with in-task events that facilitate assessment. The following sections will expand on these points and consider the importance of validating and assessing the reliability of VR for EF assessment.

Ecological Validity and Representative Tests

There is an increasing emphasis on conducting EF assessments using tasks that resemble situations experienced in everyday life [30]. For example, the Multiple Errands Test (MET) [31] requires individuals to run errands in a real environment (eg, a shopping center). Empirical assessment of the MET has demonstrated its generalizability to daily functioning [32] and carer reports of daily functioning [33]. However, given that the MET is designed to be performed in real-life locations, it is impractical for routine administration by clinicians [34,35] and susceptible to the variable features of real-world environments that are outside experimental control. VR can mitigate these difficulties by maintaining the real-world environment without requiring travel while enabling fine-tuned control and uniform presentation of environmental characteristics [36]. Several studies [37-39] have investigated and developed platforms for this purpose, commonly known as the virtual MET.

Engagement

VR has the potential to enhance individual engagement more effectively than traditional pencil-and-paper or computerized tasks by offering a fully immersive experience [40]. Recognized as a crucial aspect of cognitive assessment, engagement can be improved through gamification, thereby improving task performance [41]. “Serious games,” defined as games intended for a variety of serious purposes, such as training, learning, stimulation, or cognitive assessment [42], have been shown to be more engaging than nongamified tasks [43-45]. The unique immersive environment of VR captures increased attention, leading to reduced average response times and response time variability [46]. Notably, recent studies using electroencephalography (EEG)-based metrics have shown greater attention elicited in immersive VR paradigms than in 2D computerized assessments [46]. This heightened immersion and engagement in VR may enhance the reliability of the measures by capturing a more accurate representation of an individual’s best effort.

Cybersickness

Despite their increased engagement, VR paradigms have the potential to induce cybersickness, which can threaten the validity of the paradigm. Cybersickness (ie, dizziness and vertigo) is akin to motion sickness but occurs in response to exposure to VR [47]. Previous research suggests that there is a negative relationship between cybersickness and cognitive abilities. For example, Nalivaiko et al [47] found that reaction times were moderately correlated (r=0.5; P=.006) with subjective ratings of nausea. Similarly, Sepich et al [48] found that participants’ accuracy on n-back task performance was weakly to moderately negatively correlated (r=−0.32; P=.002) with subjective cybersickness ratings. Therefore, there is reasonable concern that the potential benefits of engagement and ecological validity may be compromised if participants experience cybersickness.

Validity, Reliability, and Sensitivity

Arguably, the biggest threat to the utility of VR platforms is that many studies do not document their validity and reliability. A meta-analysis showed that VR assessment tools are moderately sensitive to cognitive impairment across neurodevelopmental, mental health, and neurological disorders [49], demonstrating their promising application in clinical settings. Borgnis et al [50] reviewed the VR-based tools for EF assessment that are currently available, illustrating the plethora of platforms developing in this field. The works by Negu et al [49] and Borgnis et al [50] highlight the utility of VR assessment tools to detect dysfunction and present the various tools in the literature created to investigate EF. Kim et al [51] provided an overview of the research trends using VR for neuropsychological tests and documented the cognitive functions assessed in each study. However, to the best of our knowledge, there is no overview or examination of the psychometric properties of these VR tools or how they are being evaluated.

Typically, novel measures and assessments are validated against current gold-standard tasks for concurrent validity [52]. Concurrent validity can be a reliable means of determining whether two assessments measure the same construct. However, concurrent validity can also occur when two tests contain the same problems, such as inaccurately measuring a particular construct in the same way. Sequentially, many VR tasks are being created from a “function-led” perspective but validated against “construct-led” tasks [53,54]. Given their different approaches, function-led and construct-led assessments should be validated in different ways or at least using several validation approaches. If function-led VR assessments improve upon the validity of current assessment methods, validation techniques may also need to go beyond comparisons with traditional assessments. For example, function-led VR assessments may be better validated against additional alternative methods, such as carer reports, real-life performance (eg, self-care, residence, transportation, and employment), and diagnostic trajectory [49] as opposed to validation through traditional (construct-led) assessment. Without incorporating tests of ecological validity, the potential advantages of VR may go unrecognized. Given the increasingly rapid development of VR neuropsychological assessments, it will be imperative to maintain high validation standards for these tools [55].

Establishing the reliability of novel VR EF assessments is also critical to the integrity of the outcomes. Reliability ensures that the measure yields consistent and repeatable results, a foundational element for test validity. Consequently, both reliability and validity ought to be evaluated for each measurement tool. Test-retest reliability, confirming consistency over time, should be accompanied by the interval between assessments and the correlation of the results. Internal consistency, typically measured using the Cronbach α, should also be reported for each target construct or domain of assessment. Importantly, for immersive VR EF assessments that evaluate multiple EF constructs, it is essential to report the α for each distinct construct rather than a collective coefficient. This is because the coefficient is intended to evaluate item consistency within a scale measuring a single construct; applying it across disparate constructs could be confusing and potentially misleading.

Consistency of Terminology

Finally, to ensure psychometric precision and build on previous research, EF assessment paradigms must adopt consistent terminology for their target assessment constructs. The field of EF, although of significant interest to both researchers and clinicians, is marked by varied terminology for identical constructs. This issue, longstanding in EF research (see the study by Suchy [5]; for a review, see the study by Baggetta and Alexander [56]), presents challenges to VR in the EF assessment field. For instance, inconsistent terminology hinders the synthesis of research findings. Diverse labels such as "impulsivity" and "impulse control" might, upon examination, refer to the same underlying construct. Consequently, researchers aiming to extend the literature on "impulsivity" might overlook pertinent studies or exclude valuable references because of terminological discrepancies.

This literature review sought to examine and discuss the development of the VR tools used to assess EF with a specific focus on evaluating their psychometric properties. The studies selected for inclusion in this review were those that developed assessment tools for EF either holistically or in part. The aims of this review were to (1) determine the components of EF assessed using VR paradigms, (2) investigate the methods used to validate VR assessments, and (3) explore the frequency and efficacy of reporting participants' immersion in and engagement with VR for EF assessment.

Methods

Our review methodology followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [57]. In line with the literature, EF was defined as a set of executive functions, including inhibition, cognitive flexibility, and working memory [2,4,6], that support other higher-order executive functions, such as reasoning, planning, and problem-solving [6,8].

Inclusion Criteria

Before conducting the literature search, the inclusion criteria were established. First, only peer-reviewed articles and conference proceedings (complete manuscripts) written in English would be included. Second, articles that detailed an empirical, clinical, or proof-of-concept study in which an immersive virtual environment (ie, using a head-mounted display, not a 2D computer screen) was reported to broadly investigate EF or higher-order cognition or that examined EF via a selection of one or more subconstructs (eg, inhibitory control and working memory) would be included. Finally, only articles with an adult participant population published after 2013 would be included. This temporal limit was based on the release date of the Oculus Rift Development Kit 1 as it was one of the first accessible products for public use of VR. Articles were identified through the EBSCOhost, Scopus, and Web of Science (WoS) citation databases. Scopus and WoS were chosen because of their prominence as citation databases [58]. To compensate for the bias toward engineering and natural science articles found through Scopus and WoS [59], EBSCOhost was searched for articles published in fields such as (clinical) psychology and medicine.

Search Strategy

Keywords were developed by identifying 3 main components that the relevant literature should include. The 3 components were based on "Virtual Reality," "Neuropsychological Tests," and "Executive Function." It was decided not to search for specific components of EF because of the lack of consensus in the field regarding its components. Rather, it was assumed that, if an article addressed EF or a component of EF, it would include "executive functioning" as a keyword in the title, abstract, or keywords. Other reviews looking broadly at VR paradigms have used similar search strategies [49].

In this study, key terms were developed by identifying synonyms for key components and concatenating them using the "AND" Boolean operator. The final keywords used for the search were as follows: (["virtual" OR "artificial" OR "simulated"] AND ["realit*" OR "world" OR "environment"]) AND ([neuropsych* OR function* OR cognit*] AND [(executive AND function*) OR (high* AND order AND cognit*)] AND [assessment]).

Literature queries made through EBSCOhost were limited to the following databases: Academic Search Complete, AgeLine, AMED, Applied Science and Technology Source, CINAHL, E-Journals, Health Source Consumer and Nursing/Academic Edition, MEDLINE, Mental Measurements Yearbook, Psychology and Behavioral Sciences Collection, and all variations of the American Psychological Association databases. Furthermore, for the search, 3 topic fields (ie, title, abstract, and subject terms) were used to paste the keywords. The 3 topic fields were concatenated using the "OR" Boolean operator. Using the Scopus database, we implemented a basic search in the article title, abstract, or keywords using the keywords. No additional limitations were applied. Our search in WoS included all databases, and the advanced search method was used wherein keyword searches in the article title, abstract, and keyword topic fields were concatenated using the "OR" Boolean operator (ie, Title=(keywords) OR Abstract=(keywords) OR Keywords=(keywords)).

The results for each database were exported to Covidence systematic review software (Veritas Health Information) [60], which removed duplicates. All abstracts were screened independently by the first author and the senior author to determine whether the contents met the inclusion criteria. Full-text screening was also performed by the same authors. Any disagreement was discussed by the first (RK), second (LK), and senior (KR) authors.

Data Extraction

The first and second authors completed the data extraction process by manually reviewing each manuscript; data items (see the following section) were recorded in a tabular format using Microsoft Excel (Microsoft Corp).

Data Items and Synthesis

Demographic details, qualitative descriptions of the VR paradigm, user experience, cybersickness, immersion and engagement details, and comparative measures for validation purposes were extracted (Multimedia Appendix 1 [53-55,61-76]).

A qualitative evaluation of the studies included in the review was performed, meaning that the content of each manuscript was assessed based on the reported target constructs or constructs relevant to EF and the extent to which the reported VR task was related to the assessment of the target construct or constructs. To do this, studies were categorized based on the construct they targeted through their VR paradigm as reported by the authors of the respective articles. If multiple constructs were assessed in a single study, the study was included for each construct. No inferences were made about which cognitive construct or constructs was assessed based on the tasks that were reported in the manuscripts. For example, if an article indicated only that they used a VR version of the Stroop test (ST) but did not disclose which construct it assessed using this test, the study was not categorized under inhibitory control or cognitive flexibility but under the general factor "executive functioning."

Next, it was indicated whether the articles explicitly or implicitly disclosed the way in which the comparative measures (such as particular metrics) were used to validate the VR paradigm. For instance, if the article directly stated a priori that they hypothesized a correlation between a VR task measuring inhibition and a validation task such as the ST, this was recognized as providing explicit validation for inhibition. Conversely, if an article indicated that participants completed the ST, which assessed inhibition and processing speed, and mentioned that the VR paradigm evaluated inhibition, it was considered to provide implicit validation for inhibition. Furthermore, traditional construct- and function-led assessments were identified from the text.

The (quantitative) results of the studies were screened to identify (1) the direction and strength of the relationship between traditional and VR assessments and (2) whether the results from all possible and a priori–defined comparisons were reported.

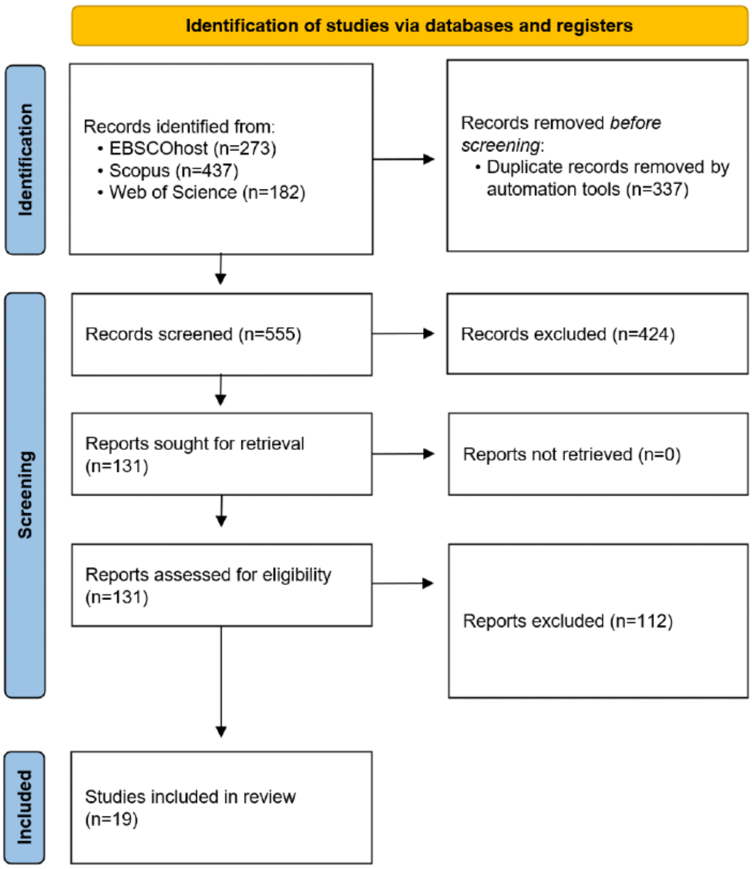
Finally, qualitative and quantitative tools used to evaluate beneficial and adverse effects of VR immersion were identified from the manuscripts and categorized in a tabulated format. The results of the studies were screened to identify whether they assessed the influence of the beneficial and adverse effects of VR immersion on task performance.

Results

Overview

Through WoS, EBSCOhost, and Scopus, 892 items were identified, from which the Covidence systematic review management platform [60] filtered 337 (37.8%) duplicates. A total of 555 unique articles remained, of which 424 (76.4%) were deemed irrelevant through abstract screening. The final 131 articles had their full texts screened, and 19 (14.5%) met the inclusion criteria. The systematic literature search process is shown in Figure 1.

Figure 1. Systematic review process and results from literature searches in EBSCOhost, Scopus, and Web of Science databases.



General EF

In total, 7 of the 19 (37%) of the reviewed studies assessed EF in general, meaning that the authors of these articles did not explicitly state which subconstruct of EF was targeted using the VR task. Table 1 shows which validation tasks were used in each study to measure EF.

Table 1. The validation tasks, authors, and total number of studies examining general executive functioning.

[i]The VR task was predominantly a sorting task for executive functioning assessment. The comparative assessments that validated this assessment were detailed under "executive function" broadly as the paper did not specify which components of the VR task the comparative tasks aimed to validate.

[j]The VR task was reported to assess executive functioning. The comparative assessments that validated this assessment were detailed under "executive function" broadly as the paper did not specify which components of the VR task the comparative tasks aimed to validate.

[k]OTS: One Touch Stockings of Cambridge.

[l]CANTAB: Cambridge Neuropsychological Test Automated Battery.

[m]VFT: verbal fluency test.

[n]N/A: not applicable.

Banville et al [61] immersed participants in a Virtual Multitasking Test (VMT), which was in principle designed to measure prospective memory and executive functions by having participants perform multiple tasks in a virtual apartment. However, this paper reported specifically on the task in which participants had to store groceries as fast as possible while also being attentive to other tasks, such as answering the phone or closing a window. Although the authors hypothesized that VMT scores would be correlated with neuropsychological assessments, such as mental flexibility, planning, and inhibition, it was not explicitly stated which metric of the VMT would be correlated with which neuropsychological assessment. Nonetheless, the authors identified that grocery storing time was correlated with the rule-break score on the Six Elements Test (r_{19}=−0.49; *P*=.04; *P* value as reported in the manuscript). Furthermore, the number of errors in storing fruits and vegetables was found to correlate with the perseveration score on the Zoo Map Test (r_{20}=0.53; *P*=.02; *P* value as reported in the manuscript) and reading speed during the second condition of the ST (r_{20}=0.44; *P*=.05; *P* value as reported in the manuscript).

Davison et al [62] immersed participants in a parking simulator and a chemistry laboratory where they had to park a vehicle, sort chairs, or locate items. Before immersion, participants completed the ST and the TMT versions A (TMT-A) and B (TMT-B). The authors identified that the completion time of the second level (Kendall τ=−0.32; *P*=.01; *P* value as reported in manuscript) and the number of levels completed in the parking simulator (τ=0.43; *P*<.01; *P* value as reported in manuscript) were correlated with participants' performance on the ST. In addition, the ST was correlated with seating arrangement metrics, such as time to place the first stool (τ=−0.33; *P*=.01; *P* value as reported in manuscript) and number of stools placed (τ=0.33; *P*=.02; *P* value as reported in manuscript), as well as with time to locate the first item in the chemistry laboratory (τ=−0.37; *P*=.01; *P* value as reported in manuscript). Correlations between the TMT-A or TMT-B and, for example, the number of completed parking levels (τ=−0.49; *P*<.01; *P* value as reported in the manuscript) or the number of items placed in the seating arrangement task in the chemistry laboratory (τ=−0.35; *P*=.01; *P* value as reported in the manuscript) were reported. However, reporting was limited to significant correlations only, and no a priori expectation of how performances on the VR and validation tasks were correlated was indicated in the study.

Miskowiak et al [63] assessed executive functions by letting participants complete the TMT-B, One Touch Stockings of Cambridge mean choices to correct, and verbal fluency test versions S and D. The performance on these tests was compared with participants' performance on a cooking task in VR. The authors hypothesized that the number of cooking tasks that were correctly placed on a to-do list and the latency to solve the task would be VR-equivalent measures of EF. The authors found that VR performance was correlated (r_{121}=0.26; *P*=.004) with EF, which consisted of a correlation between the average performance on the VR subtasks and the average performance on the validation tasks. The correlations between the individual performances on the VR and validation tasks were not reported in the manuscript.

Pallavicini et al [64] had participants play the Audioshield dance game, which the authors hypothesized could be closely related to EF constructs such as inhibition and working memory. However, the authors correlated participants' performance on the Audioshield game with their performance on the TMT-A and TMT-B, which measure psychomotor speed (TMT-A) and mental flexibility (TMT-B). Nonetheless, the results showed that TMT performance was negatively correlated with Audioshield performance metrics.

Porffy et al [65] had participants complete VStore, where the 2 tasks measured EF, namely the "Find" task and the "Coffee" task. Specifically, participants had to find 12 items from a list they had previously memorized. In addition, participants had to order a hot drink from the coffee shop after finding, bagging, and paying for the 12 remembered items they had found in the store. Notably, the authors indicated that the 2 VR tasks also tapped into navigation (ie, "Find" task) and processing speed (ie, "Coffee" task). Furthermore, the Groton Maze Learning Test from Cogstate, which the participants completed before the VR task, was used to evaluate general EF. Nonetheless, through their regression analysis, the authors identified that the Groton Maze Learning Test was not a predictor for the "Find" task (*B*=0.024; SE 0.029; *P*=.11; *P* value as reported in the manuscript) or the "Coffee" task (*B*=−0.003; SE 0.051; *P*=.96; *P* value as reported in the manuscript).

Tan et al [66] had 100 participants complete 13 tasks in a virtual environment that were designed to measure 6 cognitive domains, such as EF and complex attention. Although differences in performance on VR tasks related to EF between age groups were found, no comparison was made with a traditional neuropsychological assessment of EF or any subconstructs of EF.

Tsai et al [67] immersed 2 participant groups in a virtual shopping environment: one group with mild cognitive impairment (MCI) and one control group. The VR tasks assessed participants' memory, EF, and calculation by having them memorize a shopping list, search for the listed items in the shop, and subsequently pay for them. The authors trained machine learning models on features extracted from the VR tasks to predict whether participants had MCI or were healthy controls, which was achieved with high accuracy. Nonetheless, no neuropsychological assessment of EF was reported as a validation for the VR tasks.

Targeted Constructs

The following subsections elaborate on the EF constructs and subconstructs addressed in the studies under review. A range of correlation coefficients were reported in these papers; however, because of the lack of uniformity in results reporting, these coefficients were omitted from the current synthesis. Typically, the papers reported only significant correlations between metrics without presenting all potential correlations. Furthermore, only 16% (3/19) of the studies specified an α level (ie, .05), with another 16% (3/19) of the studies indicating statistical significance at a *P* value of ≤.05. A total of 21% (4/19) of the studies did not indicate an α level but mentioned applying corrections for multiple comparisons, yet they did not detail the adjusted α level. In total, 5% (1/19) of the studies adopted Bayesian statistics using a Bayesian factor of >10 for statistical inference. Nonetheless, in the reviewed studies, it was not consistently clarified which VR tasks were validated against traditional tasks, hindering the construct validity of the various EF components. Consequently, drawing consistent conclusions on how EF constructs of subconstructs were evaluated was not feasible without inferring the nature of the tests and assessment paradigms.

Core Executive Functions

Inhibition

Of the 3 "core" executive functions, 37% (7/19) of the studies included in our review investigated inhibitory control, interference control, or impulsivity either singly or combined. Table 2 details the respective validation tasks and target constructs of each of these studies. For example, Chicchi Giglioli et al [68] presented participants with 6 standardized tasks, 3 of which assessed inhibition (Table 2), before administering a serious game in which participants were required to perform tasks in outer space. In total, 10 of the 36 possible correlations between measures for the standardized tasks and the serious game tasks were reported as statistically significant and ranged from weak (0.20<*r*<0.39; relative *P* values indicated in the manuscript, eg, *P*<.05) to strong (0.60<*r*<0.79; relative *P* values indicated in the manuscript). For example, the latency metric of the dot-probe task (DPT) correlated positively (0.35<*r*<0.54; relative *P* values indicated) with the latency metric of the 3 VR tasks aimed at measuring inhibition, whereas no correlations were reported between the correct answer metric of the DPT and the correct answer metric of the 3 VR tasks aimed at measuring inhibition. None of the metrics from the ST correlated with those of the VR task (requiring participants to fight aliens); however, the correct answer and latency metrics of the ST correlated with those of the VR task (requiring participants to repair a valve).

Table 2. The validation tasks, authors, and total number of studies examining each construct.

VR[a] target construct and validation task	Validation	Authors	Studies, n (%)
Inhibition or Inhibitory control			6 (32)
• DPT[b] • GNG[c] • ST[d]	Implicit	Chicchi Giglioli et al [69]	
• DPT • GNG • ST	Explicit	Chicchi Giglioli et al [68]	
• GNG	Implicit	Marín-Morales et al [70]	
• CPT[e]	Implicit	Voinescu et al [71][f]	
• None specifically reported	N/A[g]	Parsons and Carlew [72]	
• ST	Implicit	Parsons and Barnett [73]	
Interference control			3 (16)
• ST	Implicit	Marín-Morales et al [70][h]	
• The CW-IT[i] from the D-KEFS[j] • Automated neuropsychological assessment metrics • ST	Implicit	Parsons and Carlew [72]	
• CW-IT from the D-KEFS	Implicit	Parsons and Barnett [73]	
Impulsivity			1 (5)
• None specifically reported	N/A	Chicchi Giglioli et al [68]	

[a]VR: virtual reality.

[b]DPT: dot-probe task.

[c]GNG: Go/No-Go.

[d]ST: Stroop test.

[e]CPT: continuous performance test.

[f]Some traditional tasks listed were included for divergent validity and, therefore, have been omitted from this table.

[g]N/A: not applicable.

[h]The VR task involved 42 VR mini-games that assessed various cognitive constructs. A total of 4 mini-games and their target constructs were documented and included in this table; however, the comparative assessments were not provided, and an extensive list of all 42 mini-games was not provided.

[i]CW-IT: Color-Word Interference Test.

[j]D-KEFS: Delis-Kaplan Executive Function System.

Similarly, Chicchi Giglioli et al [69] immersed participants in a virtual kitchen in which they had to cook different types of food. The activities were grouped into 4 subtasks of incremental difficulty where, in the third level, inhibition was assessed by determining whether the right dressing was added using a Go/No-Go (GNG)–type paradigm. The authors stated that the DPT, GNG, and ST were used as standard tasks to assess inhibition. The unspecified metric of “correct dressing” was shown to correlate well (*r*=0.527; *P*<.01; relative *P* value indicated in the manuscript) with the correct answer metric of the ST in one group, whereas in the second group, a moderate negative correlation (r=−0.486; P≤.05; relative P value indicated in the manuscript) was found between the execution time of the Tower of London task and the correct dressing metric. However, no other correlations between the VR task metric and those of the traditional assessments of inhibition were reported.

Marín-Morales et al [70] had participants complete neuropsychological assessments, including the GNG task, as well as 42 mini-games in VR. An undisclosed set of variables from the mini-games was used as predictors for measures of neuropsychological batteries. The mini-game predictor variables were fed into different machine learning algorithms. The authors highlighted that games related to inhibition produced worse results compared with other games but did not report any results on inhibition. The authors did find that mini-game features of planning and attention could predict GNG hit proportions and mean time with 80% and 94% accuracy, respectively.

Parsons and Carlew [72] had participants perform the ST in a virtual classroom as well as complete a computerized and paper-and-pencil version of the task. The authors found that participants' performance was lower for color naming and word reading in the VR paradigm than in the paper-and-pencil version but interference performance was better in the VR paradigm than in the paper-and-pencil version. Similarly, Parsons and Barnett [73] had participants perform the ST in a virtual apartment as well as complete a computerized and paper-and-pencil version of the task. Here, the authors found that participants were more accurate in the ST in the paper-and-pencil version than in the VR paradigm.

Voinescu et al [71] immersed participants in a virtual aquarium where they had to perform a variety of tasks. For example, participants had to respond when they saw a fish that was different from a clown fish or heard a fish name different from surgeonfish. After the VR aquarium, participants completed a variety of computerized tasks, among them a continuous performance test (CPT), which was hypothesized to measure sustained attention and inhibition. The authors found weak to moderate (0.22<r<0.49; relative P values indicated, eg, P<.05) correlations between CPT measures and VR measures.

Working Memory

Working memory was investigated in 21% (4/19) of the studies [63,65,70,74]. Table 3 details the respective validation tasks and target constructs of each of these studies. The working memory component from the study by Marín-Morales et al [70] included a mini-game wherein participants had to recall the ingredients of a recipe seen before the mini-game and collect from a range of options only those ingredients found in the recipe. However, no correlations with neuropsychological tasks were presented. Miskowiak et al [63] compared their VR paradigm with a traditional task that assessed working memory. In this study, participants were instructed to plan and cook a meal in a virtual kitchen. Performance metrics, such as the number of drawers opened and the latency until the task was completed, were used to assess working memory and were correlated with metrics from traditional tasks such as the Wechsler Adult Intelligence Scale Letter-Number Sequencing. The authors reported a significant positive correlation (r_{121}=0.31; P=.001) between the VR task metrics and the traditional task metrics that evaluated working memory.

Table 3. The validation tasks, authors, and total number of studies targeting working memory.

VR[a] target construct and validation task	Validation	Authors	Studies, n (%)
Working memory			4 (21)
• WAIS-IV[b] • The Working Memory Index (Digit Span and Arithmetic)	Implicit	Marín-Morales et al [70][c]	
• WAIS-III[d] LNS[e] • SWM[f] CANTAB[g] (error and strategy)	Explicit	Miskowiak et al [63]	
• 1-back and 2-back test (Cogstate)	Implicit	Porffy et al [65]	
• None specifically reported	N/A[h]	Robitaille et al [74][i]	

[a]VR: virtual reality.

[b]WAIS-IV: Wechsler Adult Intelligence Scale–IV.

[c]The VR task involved 42 VR mini-games that assessed various cognitive constructs. In total, 4 mini-games and their target constructs were documented and included in this table; however, the comparative assessments were not provided, and an extensive list of all 42 mini-games was not provided.

[d]WAIS-III: Wechsler Adult Intelligence Scale–III.

[e]LNS: Letter-Number Sequencing.

[f]SWM: Spatial Working Memory.

[g]CANTAB: Cambridge Neuropsychological Test Automated Battery.

[h]N/A: not applicable.

[i]Robitaille et al [74] used a VR paradigm with avatars to trial a dual-task walking protocol.

Porffy et al [65] asked participants to operate a virtual store in which the working memory component was assessed at the "Pay" step, where participants had to select and pay for their items at a self-checkout machine providing the exact amount.

The authors specified that the reaction time on the 1-back task and the accuracy of performance on the 2-back task were metrics from traditional tasks used to assess working memory. Using linear regression, the authors found that performance on the 2-back task was negatively associated (B=−0.085; SE 0.042; P=.047) with participants' performance on the "Pay" step.

Robitaille et al [74] assessed working memory during their simultaneous cognitive tasks, in which participants had to both recognize faces in windows that had been previously declared as "hostile" or "nonhostile" and complete a navigation task. However, no correlations between the traditional and VR tasks were reported.

Cognitive Flexibility

One study by Chicchi Giglioli et al [68] investigated cognitive flexibility (termed "cognitive shifting" in the paper) through 3 VR tasks. The authors specified that the TMT was used as a traditional task to assess cognitive flexibility as a comparator for the first VR task (CF1, cultivating food) and the Wisconsin Card Sorting Test was used as a traditional task to evaluate cognitive flexibility as a comparator for the other 2 VR tasks (CF2, growing plants, and CF3, fueling a turbine). The total time metric of the first VR task correlated positively with the total time of the TMT-B (r=0.396; P<.01; P value as reported in the manuscript), and multiple metrics of VR tasks 2 and 3 correlated with the performance metrics of the Wisconsin Card Sorting Test.

Higher-Order Executive Functions: Planning

In total, 26% (5/19) of the studies [62,68,69,75,76] identified planning as a target construct in their VR paradigms. Table 4 details the respective validation tasks and target constructs of each of these studies. The VR environment created by Chicchi Giglioli et al [69] used a cooking task with 4 levels of difficulty. In the 3 more difficult levels, planning was required to complete the tasks as 2 burners were used. There was no clearly specified metric for the VR task that was used to evaluate planning, but the authors specified that the Tower of London task was used as a traditional assessment to evaluate planning. A variety of VR task metrics, such as total time to complete a difficulty level, were shown to correlate with various Tower of London task metrics.

Table 4. The validation tasks, authors, and total number of studies targeting planning.

VR[a] target construct and validation task	Validation	Authors	Studies, n (%)
Planning			5 (26)
TOL-DX[b]	Implicit	Chicchi Giglioli et al [69]	
TOL[c]	Explicit	Chicchi Giglioli et al [68]	
None specifically reported	N/A[d]	Davison et al [62][e]	
The Key Search task from BADS[f] [78]	Explicit	Kourtesis et al [76]	
None specifically reported	N/A	Kourtesis and MacPherson [75]	

[a]VR: virtual reality.

[b]TOL-DX: Tower of London–Drexel test.

[c]TOL: Tower of London test.

[d]N/A: not applicable.

[e]The VR task was used to assess executive function. The comparative assessments that validated this assessment were detailed under "executive function" broadly as the paper did not specify which components of the VR task the comparative tasks aimed to validate.

[f]BADS: Behavioral Assessment of the Dysexecutive Syndrome.

In another study, Chicchi Giglioli et al [68] used a VR paradigm based on an outer-space environment. The paradigm contained 8 tasks, one of which assessed planning ability (task 7). The authors stated that the Tower of London task was the traditional assessment tool used to evaluate planning and explained that the total score, initial time, and execution time of the VR task were the outcome metrics. Moderate positive correlations were found between the execution time of the VR task and of the Tower of London task (r=0.463; P<.01; P value as reported in the manuscript) and between the initial time of the VR task and the total time of the Tower of London task (r=0.372; P<.05). Furthermore, the VR task correlated with some metrics of other traditional assessments used to assess planning ability, although these were not specified a priori.

Both the studies by Kourtesis et al [76] and Kourtesis and MacPherson [75] used the same VR environment based on a variety of everyday tasks. One task assessing planning ability required participants to draw their route around the city (eg, visiting the bakery, supermarket, and library and returning home) on a 3D board. Kourtesis et al [76] explained that the Key Search Test from the Behavioral Assessment of the Dysexecutive Syndrome was used as a traditional measure to assess planning and found a strong positive correlation between the traditional and VR tasks (r=0.80; Bayes factor=4.65 × 10^8). Furthermore, Kourtesis and MacPherson [75] noted in their results that planning explained a substantial 12% (P=.03) of the variance in time-based prospective memory, which was required in 10 of 17 tasks.

Davison et al [62] assessed planning ability using a task involving the arrangement of a table and a chair. However, they did not explicitly mention the traditional task that was used to evaluate planning. Various correlations between the performance metrics of the VR task and the traditional task were reported.

For example, the performance on the Stroop Color and Word Test was negatively correlated with the time participants took to place a blue chair in the seating arrangement task (Kendall τ=−0.39; *P*=.01; *P* value as reported in the manuscript).

Other Domains

Several studies (14/19, 74%) examined domains of functioning that did not align with the EF definition used in this review. Broadly, these domains fell under the categories of memory, attention, processing, task performance, and a variety of other uncategorized subconstructs. As the literature [1,2,4,6] does not relate these broad domains to EF, they are not discussed further but are presented in Tables 5-6.

Table 5. The validation tasks, authors, and total number of studies targeting constructs classified as uncategorized.

[a]VR: virtual reality.

[b]Williams et al [55] replicated the Wisconsin Card Sorting Test and multitasking task but did not explicitly state the cognitive constructs that the VR task was assessing. For this reason, the paper has not been assigned a target construct.

[c]N/A: not applicable.

[d]The VR task involved 42 VR mini-games that assessed various cognitive constructs. In total, 4 mini-games and their target constructs were documented and included in this table; however, the comparative assessments were not provided, and an extensive list of all 42 mini-games was not provided.

[e]RAVLT: Rey Auditory Verbal Learning Test.

Validity and Reliability

Tables 1-6 show details of the current validated comparator tasks against the novel VR tasks if they were explicitly provided by the authors. Where "None specifically reported" is stated, the authors of each paper did not identify or indicate a direct comparator. All but 2 studies (17/19, 89%) [72,73] set out to assess multiple constructs. In some cases, the subconstructs that were assessed were individually validated against existing validated tasks. In other cases, a suite of existing validated tasks was included in the analysis for correlation against a variety of subconstructs being assessed using the VR battery. In these cases, there was no validation at the construct level identified a priori. In 16% (3/19) of the studies, there was no reported validation of the VR paradigm.

Notably, only one study used real-life validation criteria in addition to construct-driven tests to present a validation of their VR paradigm. Specifically, Miskowiak et al [63] functionally assessed participants using the Functioning Assessment Short Test (FAST) and the brief University of California, San Diego, Performance-Based Skills Assessment (UPSA-B). Participants' scores on these assessments were correlated with their performance on the test domains of the VR paradigm, called cognition assessment in VR (CAVIR). The authors identified that participants' performance on the FAST was negatively associated (−0.17<r<−0.30; no exact or relative P values reported) with CAVIR test domains such as processing speed and working memory, whereas participants' performance on the UPSA-B was positively associated with the CAVIR test working memory (r=0.40; P value not exactly or relatively reported) and cognition composite (r_{68}=0.44; P<.001) domains. Moreover, the authors noted that lower global scores on traditional (ie, construct-led) neuropsychological tests were negatively associated with FAST scores (r_{121}=−0.45; P<.001) and positively associated with UPSA-B scores (r_{68}=0.52; P<.001), highlighting that lower CAVIR scores were associated with more functional disability, as indicated by the functional and traditional assessment tools.

The reliability of the VR paradigm was only assessed in 5% (1/19) of the studies. This was done by Kourtesis et al [76], who reported good internal reliability (Cronbach =.79) of their VR Everyday Assessment Lab (EAL) paradigm. However, this global internal consistency report did not provide a reliability estimate of the unique cognitive functions targeted by their VR EAL paradigm. Nonetheless, none of the reviewed studies included a test-retest analysis to highlight the reliability of their VR paradigm.

Evaluation of User Experience, Cybersickness, Immersion, and Engagement

An overview of the measures used to evaluate participants' experiences and well-being can be found in Multimedia Appendix 1 [53-55,61-76]. Of the 19 studies, 5 (26%) included user experience assessments. To measure participants' virtual presence, experience, and well-being, the studies administered the Igroup Presence Questionnaire [61], Presence Questionnaire [63,71,74], or Slater-Usoh-Steed questionnaire [74]. To measure participants' discomfort, the studies used the Simulator Sickness Questionnaire [61,71,74] or an adaption of it, the Virtual Reality Sickness Questionnaire [63]. To evaluate the usability of the virtual environment, the studies used the System Usability Scale [71]. To measure participants' virtual experience and comfort, 11% (2/19) of the studies used the Virtual Reality Neuroscience Questionnaire [76].

Two studies (2/19, 11%) investigated whether system usability, virtual presence, or cybersickness affected participants' task performance. For example, Porffy et al [65] measured participants' technical familiarity and found that it explained between 10% and 42% of the variability in participants' performance on the VStore outcomes "Recall", "Find", and "Select". Conversely, participants' technical familiarity appeared to influence their performance on VStore. Kourtesis et al [76] used questionnaires to evaluate the quality of the VR paradigm, participants' gaming experience, and the realism (verisimilitude) and pleasantness of the VR paradigm. The authors identified no relationship between VR experience, gaming experience, and performance on the VR EAL tasks.

Some papers (4/19, 21%) reported on cybersickness, presence, or usability scores but did not report an analysis of the relationship between task performance and measures evaluating the VR paradigm. For example, Banville et al [61] recorded participants' sickness and virtual presence but did not report any test evaluating whether sickness or presence affected task performance. Similarly, Voinescu et al [71] obtained system usability ratings from participants; however, no test was reported wherein the effect of usability on task performance was assessed. Finally, Chicchi Giglioli et al [68] recorded participants' use of technology but did not report an analysis between technology use and task performance.

Finally, some studies (2/19, 10%) evaluated participants' experiences post hoc, although it was not disclosed whether any validated scales were used. For example, Davison et al [62] measured participants' enjoyment of the VR tasks and their preference for either the VR tasks or the pencil-and-paper tasks. The authors found that younger participants rather than older ones preferred VR tasks over pencil-and-paper tasks. In addition, 11 out of 40 participants reported having experienced a mild degree of motion sickness. However, 58% (11/19) of the papers did not disclose any information about user experiences.

Discussion

Overview

The purpose of this review was to investigate the development and validation of VR assessment tools for EF. Specifically, we examined the components of EF that were assessed using VR, their validation processes, and whether immersion and cybersickness assessments were used. Although research in this domain is proliferating, the results of this review suggest that the process of development and validation varies considerably between studies.

Components of EF Assessed Using VR Paradigms

Overview

The terminology used in the papers to describe EF constructs was inconsistent. For example, the most popular construct set assessed using VR comprised the inhibition processes. "Inhibitory control" encompasses the inhibition of goal-irrelevant stimuli, cognitions, and behavioral responses [6,84]. In total, two of the key components of inhibitory control are response inhibition and attentional inhibition [85]. Response inhibition was also termed "inhibition control," "prepotent response inhibition," and "motor inhibition," whereas attentional inhibition was also termed "control of interference," "interference control," and "external interference control." Although these terms are used in the literature [85], its readability and synthesis would be improved through agreement on a particular term for the same construct. In the same way, several studies (7/19, 37%) examined "EF" broadly without specifically detailing its components. In these studies, EF was validated using different measurement tools, suggesting that, across studies, EF was defined and used differently in each VR paradigm. As the constructs that these paradigms aimed to assess were not explicitly detailed, this poses a risk of hampering researchers wishing to build upon previous findings.

Furthermore, there was a broad range of constructs that were not commonly considered as EF domains but were reported as components of EF, making it difficult for future research to replicate the findings of undefined target constructs. For example, several papers (14/19, 74%) reported on verbal learning [63], associate learning pattern recognition [65], perceptual motor, social cognition, language [66], and calculation [67]. Although many of these components rely on EF domains or underpin those domains, they exist at various levels of abstraction. Thus, although the reviewed studies investigated components at different levels and used different languages, it is possible that they overlapped. For example, "organization" may be an umbrella term for a range of EF domains, each of which uses different terminology for the same concept, such as "cognitive flexibility," "flexible updating," and "working memory." Although "organization" is not measured as a higher-order version of the subcomponents, it is difficult for the research that has examined cognitive flexibility and working memory to be extended. Thus, 2 studies assessing the same construct are not able to build on each other's progress.

Recommendation: Establish a Coherent and Consistent Framework for EF Terminology

The Research Domain Criteria (RDoC) framework developed by the National Institute of Mental Health could serve as a framework to address this recommendation. The RDoC was originally created to consolidate the research conducted in various fields of mental health [86]. The framework categorizes cognition into 6 domains and encourages the investigation of these domains via different classes of variables, such as behavioral, physiological, and self-report data. This framework encourages a common language and organizes findings in such a way that researchers can identify gaps or discrepancies in the literature and contribute to the ongoing development of the field. This framework indicates the potential benefits of using a common language for research, although it is not necessarily the only option in this field. Alternatively, researchers could engage in a Delphi study to generate expert-informed consensus on the key constructs of EF that merit investigation using VR paradigms (eg, see the study by Yücel et al [87] for a Delphi study on neuropsychological assessment for addiction). Nonetheless, the emerging area of VR development for neuropsychological assessments would benefit from using the RDoC framework to coordinate the research process.

Validation of VR for EF

Overview

Overall, there was limited reporting on the constructs that were assessed using VR paradigms and the associated validation outcome measures. In some papers, there was inadequate reporting of the constructs that the VR paradigm was intended to assess. In others, the same construct was assessed using a variety of traditional tasks. Furthermore, some VR paradigms were intended to replicate real life yet were validated against traditional tasks, none of which assessed ecological validity. In some studies, the correlations between the VR paradigm and the traditional tasks were incomplete. Finally, sample sizes varied considerably between studies, also affecting the evaluation of their psychometrics. These points are expanded upon in this section.

Several studies (5/19, 26%) examined EF as a broad category and then validated the paradigm against a variety of traditional tasks. However, some studies (3/19, 16%) detailed limited (or no) reporting of which aspect of the VR paradigm each traditional task was intended to validate. That is, no details were provided regarding which traditional task outcome measure corresponded to each component of EF within the VR paradigm. Traditional tasks, which often target one construct, were then correlated against seemingly all outcomes of the VR paradigm. Although this practice may be beneficial during the exploratory phase of VR paradigm development, failure to correct for multiple comparisons may provide misleading results whereby a correlation is found between two constructs incidentally. Conversely, some traditional tasks assessed multiple constructs, which poses a slightly different challenge. For example, if the VR paradigm broadly assessed EF but was validated against the ST, it was then unclear whether the VR paradigm aimed to assess processing speed, attention, inhibitory control, or interference control as the ST could be used to measure all four. Similarly, when these studies used multiple traditional assessments, the reader was expected to presume the target constructs of the VR paradigm as this was not clearly outlined. Poorly defined target constructs and failure to specify which traditional task validates which aspect of the VR task produces a literature that is difficult to interpret. Moreover, this general lack of clarity means that future researchers are more likely to invent a new paradigm rather than adopt or extend existing paradigms, creating inefficiency and hampering progress in the field.

Various standardized tasks were used to validate target constructs in the VR paradigm. For example, the study by Chicchi Giglioli et al [69] examined attention and inhibition control using the DPT, GNG, and ST. However, Voinescu et al [71] examined inhibition using the CPT paradigm. In addition, Marín-Morales et al [70] assessed inhibition using one mini-game of their VR paradigm. However, they neither provided details of a specific comparator task for validation purposes nor reported the statistical outcomes. Furthermore, the DPT, which is typically used to assess selective attention [88], was used to assess inhibition, although its own psychometric properties have been the subject of controversy [89,90]. Although several traditional tasks purport to measure the same construct (ie, there is not one task for one construct), the lack of consistency between studies makes it difficult to compare VR platforms. Furthermore, the traditional comparator task used to validate the VR paradigm needs to have sound psychometric properties in its own right to assess the respective construct; when two tasks are compared with one another, it is unclear which task may be responsible for discrepancies in the outcome [91]. These points are especially pertinent for studies that rely solely on traditional measures to validate tasks in the absence of other validation techniques.

Although it is promising to see that VR paradigms are being used for ecologically valid assessments, their validation remains a challenge. In the case of traditional tasks, we assume that a single construct can be assessed using a behavioral task and that the performance on that task is linear with the cognitive construct. In the case of a "function-led" VR task, there is a behavioral task that simulates real-world functioning, which is thought to deteriorate in an EF-declining population. This VR task is not a direct assessment of a target construct—it is a test of a real-world function, such as parking a car. To test convergent validity, the individual would have to park a car in real life and have their performance assessed similarly to that on the VR task and compared. However, when we use traditional measures to validate the "function-led" VR measures, we assume that EF can be reliably measured and the function-led VR task (eg, parking a car) requires the same EF. Thus, those who perform poorly on a traditional EF task are also expected to perform poorly on real-life tasks requiring EF. Critically, if our results do not show this relationship, it could be that the traditional task is a poor test of EF, the function-led assessment is a poor test of EF, or the EF at hand is not related to the functional task (eg, parking a car).

These assumptions place substantial weight on the selection of the traditional task for validating the VR paradigm for predictive validity. Davison et al [62] assessed EF using the ST and TMT. They broadly hypothesized that there would be correlations between the traditional measures and the VR paradigm, which contained tasks that replicated real life, such as car parking, arranging seating, and locating items. In the reported results, the ST and TMT were correlated with all outcome measures of the VR paradigm. For example, performance on the Stroop Color and Word Test was correlated with performance on the second parking simulator task, the number of levels completed on the parking simulator task, and the time taken to place the blue chair in the seating arrangement task. If the ST and TMT are not sufficient validators of the functional task, this may generate misleading results regarding the integrity of the VR paradigm and its ability to sensitively measure EF. Thus, the convergent validity of VR tasks would be better assessed through real-life performance on the same task, such as actually parking in a controlled environment. Although this may seem to be a resource burden to validation, it could provide integral merit to using the paradigm as a proxy for the real-life task thereafter. Alternative options are to assess convergent validity through other forms of real-life functioning (eg, self-care, residence, transportation, and employment) and diagnostic trajectory [49]. Moreover, predictive validators should be carefully chosen to ensure that their target construct aligns with that thought to be required for the function-led assessment.

Nonetheless, for novel task validation, transparent reporting of all results is crucial for advancing future research. Several papers included in this review (4/19, 21%) [61,62,68,69] reported only statistically significant correlations, leaving unanswered questions because of the omission of nonsignificant results. For instance, Chicchi Giglioli et al [69] sought to evaluate inhibition control using the GNG and ST for validation (both are common tasks for assessing inhibition) as well as the DPT yet did not report all correlational data in their results table. Such omissions hinder the comprehensive use or meta-analytic application of these findings. Conversely, Chicchi Giglioli et al [68] provided a detailed comparison between each validation task and its corresponding VR task, including the constructs assessed. However, only significant correlations were reported, some of which were between tasks intended to assess disparate constructs, such as the correlations between the Wisconsin Card Sorting Test (assessing cognitive shifting) and the VR tasks (measuring attention and inhibition control). Although these findings may indicate overlapping constructs in VR tasks, the absence of multiple-comparison correction and a detailed post hoc analysis of these correlations limits the interpretability and applicability of these results.

Finally, it is worth noting that there was significant variation in sample sizes across the studies reviewed. Although it is often accepted that pilot studies or preliminary studies have small sample sizes that often result in underpowered analysis, the utility of the VR paradigms is dependent on sound psychometric properties that require adequate sample sizes and statistical power. As detailed in Multimedia Appendix 1 [53-55,61-76], the sample sizes varied from 12 (6 per group) [74] to 103 (divided into 2 groups) [53]. Although the definition of a "sufficient" sample size may vary between studies and analyses, several of the included VR paradigms would likely require additional validation studies to provide confidence in their psychometric properties.

Recommendations

Our recommendations are as follows:

1. Papers should explicitly detail how their VR paradigms are being validated. If a paradigm has multiple components, it is essential to state how each one is being validated. A good example is the paper by Kourtesis et al [76] in this review.
2. If studies aim to validate a VR paradigm for a specific EF construct, they should identify a priori the precise outcome measures of the VR paradigm that are hypothesized to tap into various EF constructs (eg, time to completion and number of errors) and then validate them against the appropriate traditional tasks that also reliably assess those EF constructs.
3. Where appropriate, the VR paradigm's real-world task should be validated against both traditional task measures and ecologically valid measures. Ecologically valid measures may include carer reports, observation assessments, and activity of daily living assessments.
4. Multiple modes of validation should be used, including measures that provide predictive power [49], and both carer reports of daily functioning and biosensor data should be considered.
5. Papers should report all outcomes of validation data (even those in supplementary materials) to ensure the transparency of the tools' properties. A concerted effort to increase explicit and transparent reporting would greatly benefit this field.
6. To validate the VR paradigm, the psychometric properties of the traditional task must be appropriate.
7. Studies aiming to evaluate the psychometric properties of their VR paradigm should ensure that they have adequate sample sizes for a powered analysis.

Cybersickness

Overview

Although VR offers several key advantages over traditional tasks, these systems can also produce adverse effects such as cybersickness. In our review, only 21% (4/19) of the studies included an assessment of cybersickness. This is concerning as cybersickness presents a substantial confound for valid VR assessment and has been shown to negatively affect task performance [92,93]. Given that the assessment of EF involves ascertaining a participant's cognitive abilities, the recording of cybersickness is key to ensuring that common side effects such as dizziness and vertigo do not affect the participants' ability to perform at their best on the tasks. Without formal evaluation, the degree to which participants' experiences are altered is unclear. Furthermore, it is unknown at this stage whether cybersickness symptoms affect various client populations differently. For example, it is possible that, although a healthy individual may be able to continue the assessment with minor vertigo, an individual with cognitive impairment may be more affected, resulting in severely affected cognitive outcomes. Thus, caution should be exercised when using VR paradigms to ensure that the potential benefits of engagement and ecological validity are not realized at the cost of the potential negative effects of cybersickness.

Recommendations

Our recommendations are as follows:

1. Future papers should include usability data in the form of cybersickness measurements.
2. Correlations between cybersickness and participants' task performance could be included as supplementary material that should be accessible to readers, enabling them to better understand how the VR battery is performing.
3. Even when a paradigm has already assessed cybersickness, we encourage future researchers to use the same paradigm to conduct their own cybersickness assessments. This is because it is still unclear whether cybersickness will have different effects on various populations.
4. Clinical researchers and engineers should continue to investigate and report on techniques and technologies that reduce the incidence or severity of cybersickness.

Textbox 1 provides an overview of the recommendations of this review.

Textbox 1. Recommendations for future research and practice using virtual reality (VR) head-mounted display–based paradigms for executive functioning (EF) assessment.

Validate against multiple forms

- Examples include carer reports, observation assessments, ecological momentary assessments, activity of daily living assessments, physiological sensors, and in vivo studies.
- Consider longitudinal tracking of participants to establish predictive utility to initially validate the novel paradigm.

Report a priori how each assessment in the VR paradigm is being validated

- If there are multiple components to one paradigm, state how each element is being validated (a good example is the study by Kourtesis et al [76] in this review); for example: "Task 2a aims to assess inhibitory control and is validated against the traditional stop signal task and go/no-go task."

Report all validation data

- Report correlations of all aspects of a task that were identified a priori as validating the VR paradigm. In extending the previous example, show all relevant metrics from task 2a, such as errors, proportion of successful stops, reaction time, and stop signal reaction time against the relevant metrics of both the Stop Signal and Go/No-Go tasks.

Include user experience assessment

- Conduct assessments of immersion, cybersickness, usability, and engagement.

Use a common framework for defining target constructs

- The Research Domain Criteria is one option of a framework that can be applied to ensure that terminology used in the field is consistent.

Consider adding biosensors

- These provide additional objective data that may inform the VR-based EF assessment.

Limitations

We searched for articles that used the terms "executive functioning," "higher order cognition," and "functional assessment" to capture tasks that aimed to broadly assess facets of EF. This search strategy may have missed studies that examined a key construct of EF but did not specifically use the aforementioned terms (eg, used VR to assess inhibitory control alone). In addition, we did not contact the authors of the papers included in this review for further information; however, one of the key outcomes of this review was the amount of information contained in the manuscripts for future studies to extend upon.

Future Directions

The authors posit that the integration of biosensors into a VR system has significant potential. Biosensors such as pupillometry, eye gaze, EEG, and language and grammatical characteristic data can be temporally linked to the events occurring in the VR task. For example, pupillometry can offer insights into brain injury prognosis [94] and differentiate between participants with Alzheimer disease and healthy controls [95]. Eye tracking during reading aids Alzheimer disease identification [96], and linguistic attributes (eg, formation and fluency of sentences, syntax, and grammar) distinguish patients with Alzheimer disease from those with MCI [97]. The combination of these biosensor metrics and real-time function-led VR performance could increase the sensitivity of tests, enabling the detection of subtle differences such as between MCI and subjective memory complaints [98]. However, currently, biosignals are rarely evaluated alongside emerging VR paradigms for EF assessment. None of the reviewed studies used biosensors, leaving an untapped potential for VR paradigms to be frontline neuropsychological assessments.

Biosensors could also assist in modulating the cognitive load experienced by participants. Cognitive load is the cumulative working memory resources that an individual requires for a given task [99]. Similar to the gaming industry, VR paradigms could be adaptive and performance driven so that the level of challenge adjusts according to real-time individual responses [100,101]. Modulating the cognitive load adjusts the challenge of a task and enables all participants to encounter similar levels of perceived difficulty for their respective abilities. EEG, pupillometry, and cardiovascular measures are also sensitive to cognitive load capacities [99].

An additional advantage of VR is its ability to facilitate the assessment of spatial navigation. Spatial navigation is a component of cognitive functioning that can be a key factor in detecting early stages of neurodegenerative diseases. However, it cannot be assessed adequately by means of many traditional assessments. Although it is acknowledged that spatial navigation is not a component of EF, the authors of this paper consider it a generally underexamined construct when assessing cognition and general function. For example, spatial navigation is a cognitive marker used to detect early attention deficit [102,103] and offers additional relevant information beyond the traditional neuropsychological tests [103]. The environment could also be systematically manipulated to match the needs of the assessment [104] and tailored to specific populations. However, typically, spatial navigation is assessed using a real-space human analog of the Morris water maze test, which can be difficult to implement under standardized conditions. Computerized versions have been adapted, with findings comparable with those of tests conducted in real space [105], suggesting promise for translating this style of assessment to VR.

Conclusions

VR paradigms assessing EF have great potential to improve upon traditional tests. However, despite their undeniable novelty and potential, their methodological and psychometric properties must be addressed during their development to ensure their validity and reliability. Although there is no shortage of research in this area, the lack of standardized protocols to validate VR-based neuropsychological assessments hinders the progress of this field of research and practice. It is hoped that this study will be the beginning of a larger movement toward systematizing the development and validation of these paradigms.

Abstract

Background: Gamification has been used successfully to promote various desired health behaviors. Previous studies have used gamification to achieve desired health behaviors or facilitate their learning about health.

Objective: In this scoping review, we aimed to describe digital gamified tools that have been implemented or evaluated across various populations to encourage vaccination, as well as any reported effects of identified tools.

Methods: We searched Medline, Embase, CINAHL, the Web of Science Core Collection, the Cochrane Database of Systematic Reviews, the Cochrane Central Register of Controlled Trials, Academic Search Premier, PsycInfo, Global Health, and ERIC for peer-reviewed papers describing digital gamified tools with or without evaluations. We also conducted web searches with Google to identify digital gamified tools lacking associated publications. We consulted 12 experts in the field of gamification and health behavior to identify any papers or tools we might have missed. We extracted data about the target population of the tools, the interventions themselves (eg, type of digital gamified tool platform, type of disease/vaccine, type and design of study), and any effects of evaluated tools, and we synthesized data narratively.

Results: Of 1402 records, we included 28 (2%) peer-reviewed papers and 10 digital gamified tools lacking associated publications. The experts added 1 digital gamified tool that met the inclusion criteria. Our final data set therefore included 28 peer-reviewed papers and 11 digital gamified tools. Of the 28 peer-reviewed papers, 7 (25%) explained the development of the tool, 16 (57%) described evaluation, and 2 (7%) reported both development and evaluation of the tool. The 28 peer-reviewed papers reported on 25 different tools. Of these 25 digital gamified tools, 11 (44%) were web-based tools, 8 (32%) mobile (native mobile or mobile-enabled web) apps, and 6 (24%) virtual reality tools. Overall, tools that were evaluated showed increases in knowledge and intentions to receive vaccines, mixed effects on attitudes, and positive effects on beliefs. We did not observe discernible advantages of one type of digital gamified tool (web based, mobile, virtual reality) over the others. However, a few studies were randomized controlled trials, and publication bias may have led to such positive effects having a higher likelihood of appearing in the peer-reviewed literature.

Conclusions: Digital gamified tools appear to have potential for improving vaccine uptake by fostering positive beliefs and increasing vaccine-related knowledge and intentions. Encouraging comparative studies of different features or different types of digital gamified tools could advance the field by identifying features or types of tools that yield more positive effects across populations and contexts. Further work in this area should seek to inform the implementation of gamification for vaccine acceptance and promote effective health communication, thus yielding meaningful health and social impacts.

Introduction

Vaccination is one of the most cost-effective methods of preventing the spread of vaccine-preventable diseases. If vaccination coverage falls below the thresholds that are safe for the prevention of epidemic transmission, the incidence of vaccine-preventable diseases increases [1,2]. For example, measles returned over the past 2 decades, and the incidence of measles in the European Union increased in 2017-2018 [3].

In 2019, prior to the COVID-19 pandemic, the World Health Organization identified vaccine hesitancy (ie, the reluctance or refusal to be vaccinated despite the availability of vaccination services) as 1 of the top 10 threats to worldwide health [4]. Vaccine hesitancy is one of the several reasons some people are un- or undervaccinated [5-9]. Interventions addressing vaccine hesitancy are therefore necessary to promote vaccine acceptance and uptake. As the contributors of vaccine acceptance are diverse, no single intervention will solve this issue [10]. Multicomponent interventions tailored to local barriers to vaccine acceptance and uptake are known to be the most effective [11,12]. Misinformation and conspiracy theories spread online, where extensive antivaccine content is shared [13-15], potentially negatively influencing views about vaccines [16,17]. Efforts have been made to counter vaccine misinformation and mistrust by targeting various groups, such as parents, non–health care workers [18,19], and adolescents [20], and delivering information about the risks and benefits of different types of vaccines, for instance, human papillomavirus (HPV) vaccination [21] and measles, mumps, and rubella vaccines [22,23]. Along with traditional communication strategies, the use of other strategies to inform and educate about immunizations, for example, with digital gamified tools, may help encourage vaccine uptake.

Gamification is defined as the use of game design elements in nongame contexts [24]. It includes several aspects and features, such as fun interfaces, immediate success or feedback, reward systems (levels, point scores, badges), challenges and competitions, team playing, avatars, and quizzes. Previous studies have used gamification to achieve desired health behaviors [25-27] or facilitate their learning about health [28]. Gamification draws on elements from serious games, meaning fully developed digital games used to train and educate players [29,30]. For example, a serious game “Land of Secret Gardens” facilitates conversations about HPV with preteens. In the game, preteens need to protect their bodies with a “potion,” which offers a metaphor for the HPV vaccine [31]. However, serious games and digital gamified tools are distinct but related concepts. Serious games use gaming as a central and primary medium [32]. In contrast, digital gamified tools (eg, apps) or gamified interventions are not complete game experiences but have gaming features, such as rewards systems, scoring of points, or engaging users in different challenges [33]. In this study, we defined digital gamified tools as digital apps with the aforementioned gaming features. Our definition includes serious games that meet the criteria, that is, they must include such gaming features. This scoping review provides insight into the reported effects of digital gamified tools to increase vaccine uptake. Our review built upon existing reviews in the field by including a comprehensive search of both published literature and online tools, as well as an examination of both the characteristics and the reported effects of these digital tools. This review was distinct in that it focused specifically on digital gamified tools and their effects, rather than simply the effectiveness of gamification in general. In doing so, this review aimed to fill a gap in the literature by providing evidence-based answers to the question of whether gamification “works” to increase vaccine uptake. Therefore, the objectives of this scoping review [34] were, first, to review digital gamified tools that have been implemented or evaluated across various populations to encourage vaccine uptake and, second, to describe any reported effects of the identified tools in terms of influence on users’ knowledge or behavior toward vaccination. Our research questions can therefore be summarized as follows:

- What digital gamified tools intended to encourage vaccination exist and have been described in the literature?
- Do these tools demonstrate any effects on knowledge, attitudes, beliefs, and behaviors about vaccination?

Methods

Search Strategy

For peer-reviewed papers, we searched Medline (Ovid), Embase (Ovid), CINAHL (EBSCO), the Web of Science Core Collection, the Cochrane Database of Systematic Reviews (Ovid), the Cochrane Central Register of Controlled Trials (Ovid), Academic Search Premier (EBSCO), PsycInfo (Ovid), Global Health (Ovid), and ERIC (Ovid) with no language or date restrictions. The proposed search terms were, for example, “vaccine,” “vaccination,” “immunization,” “video games,” “gamification,” “application,” and “virtual reality” (see Multimedia Appendix 1 for the full search strategy). The search was conducted on January 26 and 27, 2022.

We also conducted an online Google search on May 5, 2022, for any digital tools with gamified features that deliver informative or educative messages on vaccination. The search terms we used were “vaccination,” “immunization,” “electronic game,” “computer game,” “mobile game,” “interactive game,” and “digital game” (see Multimedia Appendix 1 for the full search strategy). We reviewed the first 30 results for each search, as it is rare for users to click past the third page of 10 search results per page, and therefore, researchers analyzing medical content available on the web often use 30 as a threshold [35-37]. On May 6, 2022, we conducted the same searches in private browsing mode to ascertain whether our results had been affected by a "filter bubble" [38], that is, the way Google search results are adapted to one's previous browsing activity. Our search strategy was constructed and reviewed by 2 librarians. Following the librarians' advice, we expanded our search strategy to include ERIC and Global Health databases.

Study Selection and Screening Process

We used PICO (Population, Intervention, Comparison, and Outcome) to structure study inclusion and exclusion criteria (Table 1). Our population of interest was the general public or any subgroup, including health care professionals and students. We sought studies describing tools with gamification techniques or gamified elements, including gamified web-based quizzes to deliver informative or educative messages on vaccination. Posters, preprints, editorials, conference proceedings, news bulletins, and paper-based or board games were excluded. Our comparator was any control, including offering no education on vaccination or comparing participants before and after an intervention. Our outcomes of interest included common outcomes associated with vaccine uptake, namely knowledge (comprehension, understanding), attitudes (for or against vaccination), beliefs (perceived benefits, perceived risks), and behaviors toward vaccines (vaccination intention [ie, intention to get vaccinated or not get vaccinated] and vaccine uptake [ie, receiving or not receiving a vaccine]). We excluded papers that did not present the description or evaluation of a concrete digital gamified tool.

Table 1. Inclusion and exclusion criteria.

Component	Inclusion criteria	Exclusion criteria	Question related to the criteria
Type of report	• Original paper • Evaluated intervention or digital gamified tool	• Posters, preprints, and conference proceedings • Modeling or simulation study • Brochures • Editorials • Bulletins	Has the study or research described the development of the tool and evaluated it?
Population	• General public (any subgroup) • Professionals • Students	N/A[a]	Who is the audience for whom the key message was intended?
Intervention	• Tools with gamification technique or gamified elements, including gamified web-based quizzes to deliver informative or educative messages on vaccination	• Any study or gamification tools not intended for vaccination/vaccine uptake • Studies or apps to reduce vaccine pain and fears and to report immunization status or record keeping, surveillance or vaccine coverage apps, contact-tracing or early detection apps • Paper games, board games (not digital) • Videos with no gamified element included	Does the study or tool aim to deliver an informative or educative message on vaccination?
Comparator	• Any control, including offering no education or no digital gamified tool	N/A	N/A
Outcome	• Common outcomes that encourage vaccine uptake: knowledge (comprehension, understanding), attitudes (for or against vaccination, beliefs (risk perception, etc), behaviors toward vaccines (vaccination intention [ie, intention to get vaccinated or not get vaccinated] and vaccine uptake [ie, receiving or not receiving a vaccine])	• Outcomes not related to the encouragement of vaccine uptake	Has the study or tool been evaluated for the outcomes that encourage vaccine uptake?

[a]N/A: not applicable.

For Google-searched digital gamified tools, our inclusion and exclusion criteria used the same specifications regarding population and intervention. We did not apply comparison and outcome criteria to web-based tools because we did not expect these to report evaluation studies.

We reported this review according to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (see the PRISMA checklist in Multimedia Appendix 2) [39]. We registered our protocol on the Open Science Framework [40].

Expert Consultations

After extracting information from peer-reviewed papers and tools identified via a Google search, we contacted experts in the field of digital gamified tools (eg, developers and researchers working on the topic in Canada and worldwide who were already known to the research team) to complement our online searches and ensure completeness. Specifically, we sent emails to 12 experts about the results of our searches and asked them to alert us to any games or papers we might have missed.

Data Charting

We developed a form in Microsoft Excel to guide the charting of data. We pretested and reviewed the form with team members to ensure we were accurately and adequately capturing relevant data. Data charting occurred independently with verification. Specifically, a reviewer (author HH) identified and screened all studies and digital gamified tools for their eligibility. Screening results were verified by a second reviewer (author DG). The data charting was then performed by a reviewer (HH) and again verified by a second reviewer (DG). Any conflicts throughout screening or data charting were resolved by a third reviewer (author ED). From the included papers, we charted data about (1) the type and design of study (developmental or evaluation study, user testing, randomized controlled trial, etc), (2) the vaccine(s) addressed (COVID-19, HPV, etc), (3) the purpose of the study or intervention, (4) the digital gamified tool platform (web based, native mobile app, mobile-enabled web app, virtual reality), and (5) the characteristics of study participants. For the evaluated interventions, we charted data about preselected outcomes that are widely used to predict health-related behaviors and to assess outcomes in studies of interventions about vaccination and immunization [11-14]. Specifically, we extracted data about the tools' effects on knowledge, attitudes, beliefs (perceived benefits, perceived risks), and behavioral intentions. Emotional, cultural, and social factors can also influence a decision about vaccination [29,30]. Therefore, we also extracted data about other outcomes that the studies may have evaluated. Because we sought to understand all possible effects, we did not prespecify any of these as a primary outcome.

We organized the extracted data in tables and synthesized them descriptively.

Quality Assessment

To assess the quality of the studies that evaluated their interventions, we used the Mixed Methods Appraisal Tool (MMAT) developed by Pluye et al [41]. Two reviewers independently conducted the quality assessment, resolving disagreements through discussion until reaching a consensus. A third and a fourth reviewer (authors HH and HW) intervened to settle any remaining conflicts.

Data Synthesis

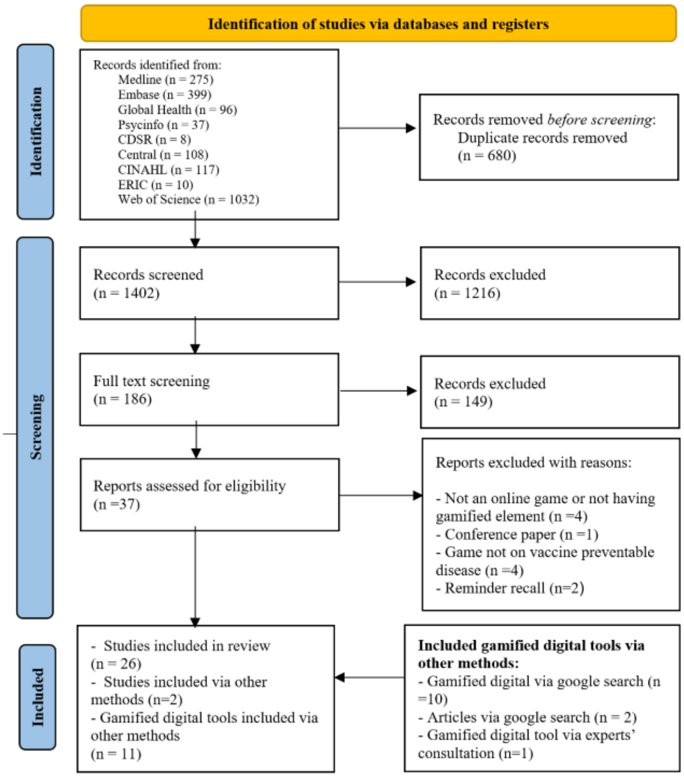
We summarized data using a narrative approach involving framework and content analysis. We classified each digital gamified tool platform using the 4 types of digital gamified tools: web-based tool, native mobile app, mobile-enabled web app, virtual reality tool. For the type of digital gamified tool, we classified web-based tools that explicitly noted their suitability for mobile use (eg, by smartphone or tablet) as mobile-enabled apps. We classified web-based tools without such an explicit statement as web based only, even though they may be functional on mobile devices. For the type and design of study, we grouped randomized designs together, including traditional randomized controlled trials with only 2 study arms and factorial designs with more than 2 study arms. Although these methods are not exactly the same, they all use randomization to minimize potential biases and are therefore functionally equivalent for our purposes of understanding what kinds of evaluations have been undertaken [42]. We summarized the main characteristics of tools, including PICO elements, in a tabular display. We used the PRISMA 2020 flowchart to describe the process of study selection [43].

Results

Papers Identified and Scope of Literature

We identified a total of 2082 records through database searches. After removing duplicates, we screened 1402 (67.3%) database records. Through Google searches, we identified 10 digital gamified tools and 2 papers. In a private browsing mode search, there was no change in search results. Of the 12 experts contacted, 2 (17%) responded and suggested 2 papers and 2 links, of which 1 (50%) digital gamified tool met the inclusion criteria and was included in our review. Through these methods, our final data set included 28 (2%) peer-reviewed papers and 11 digital gamified tools. Figure 1 shows our PRISMA diagram.

Figure 1. PRISMA flow diagram. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.



Of the 28 peer-reviewed papers, 7 (25%) explained the development of the tool, 16 (57%) described evaluation, and 2 (7%) reported both development and evaluation of the tool (Table 2). To report our results, we grouped studies together that reported the same tool, meaning 28 peer-reviewed papers reporting on 25 different tools. Of these 25 digital gamified tools, 11 (44%) were web-based tools, 7 (28%) mobile (native mobile or mobile-enabled web) apps, 6 (24%) virtual reality tools, and 1 (4%) offered in both mobile and web-based versions (for details, see Table 2). The most common single vaccines addressed in the tools were influenza (n=6, 24%, tools) and HPV (n=6, 24%, tools). Other tools addressed COVID-19 (n=2, 8%); measles, mumps, influenza, and smallpox (n=2, 8%); a hypothetical disease (n=2, 8%); other vaccine-preventable diseases (n=6, 24%); and the role vaccines play in preventing the spread of disease with no particular vaccine specified (n=1, 4%). Of the 10 digital gamified tools identified via a Google search and 1 suggested by the expert (a total of 11 digital gamified tools; see Table 3), the largest group (n=5, 45%) addressed COVID-19, and the rest were about other vaccine-preventable diseases. The 11 gamified elements identified in the Google search and expert feedback identified 6 types of gamified elements: reward points, serious games, physical trading cards, certificates, role-playing, and quizzes (see Table 3). The most common type was reward points, which appeared in 5 (45%) cases. Two cases used serious games, one case used physical trading cards and reward points, one case used certificates, one case used role-playing, and one case used quizzes. Additional characteristics of the studies included (eg, country of origin, sample size, participant characteristics) are detailed in Multimedia Appendix 3 [31,44-70]. The expanded versions of Table 2 [31,44-70] and Table 3 [71-81] are provided in Multimedia Appendix 4.

Table 2. General information about the studies.

Type of study and author(s)	Type of digital gamified tool platform	Type of disease/vaccine	Type and design of study (development or evaluation, iterative design, randomized controlled trial, etc)
Evaluation studies			
Betsch and Böhm [44]	Web-based tool	Hypothetical	Evaluation: online experiment
Carolan et al [45]	Web-based tool	Measles, mumps, influenza, and smallpox	Evaluation: pre-post study
Cates et al [31]	Web-based tool	HPV[a]	Evaluation: pilot randomized controlled trial
Dale et al [46]	Native mobile app	Influenza	Evaluation: nonrandomized trial
Darville et al [47]	Web-based tool	HPV	Evaluation: randomized controlled trial
Eley et al [48], McNulty et al [49]	Web-based tool	Bacteria, vaccine-preventable disease	Evaluation: quantitative followed by qualitative research design
Fadda et al [50], Fadda et al [51]	Native mobile app	MMR vaccines	Evaluation: mixed methods research design
Ibuka et al [52]	Web-based tool	Hypothetical disease	Evaluation: experimental design
Kaufman and Flanagan [53]	Web-based tool	Not reported	Evaluation: experimental design
Lee et al [54]	Native mobile app	Influenza	Evaluation: randomized controlled trial
Mitchell et al [55], Laplana [56]	Web-based tool	Influenza	Evaluation: pre-post study
Mottelson et al [57]	Virtual reality tool	COVID-19	Evaluation: randomized controlled trial (2×2 factorial design)
Nowak et al [58]	Virtual reality tool	Influenza	Evaluation: one-way between-subjects design with random assignment
Real et al [59]	Virtual reality tool	Influenza	Evaluation: quasi- randomized controlled trial[b]
Woodall et al [60]	Mobile-enabled web app	HPV	Evaluation: clinic-cluster randomized trial
Vandeweerdt et al [61]	Virtual reality tool	COVID-19	Evaluation: randomized controlled trial
Development studies			
Amresh et al [62]	Web-based tool	HPV	Development: iterative design
Bertozzi et al [63] (data extracted for the game related to vaccines)	Web-based tool	Influenza	Development: iterative design
Carolan et al [64]	Web-based tool	Measles, mumps, influenza, and smallpox	Development: iterative design
de Araujo Lima et al [66]	Native mobile app	Vaccine-preventable diseases	Development: heuristic evaluation by users, content evaluation by experts
Kafai et al [65]	Virtual reality	Dragon swooping cough virus to reflect real-life features of infectious viruses, such as Ebola.	Development: user feedback via surveys (asking users questions) and log files (observing user behaviors)
Real et al [67]	Native mobile app	HPV	Development: usability testing
Streuli et al [68]	Virtual reality	Pediatric vaccines	Development: Community-based participatory research and co-design
Development and evaluation studies			
Davies et al [69]	Mobile or web app (multiple formats available)	Hepatitis B	Development and evaluation: Participatory Action Research
Ruiz-López et al [70]	Native mobile app	HPV	Development and evaluation: Iterative design and evaluation via questionnaire

[a]HPV: human papillomavirus.

[b]Allocation to a study arm was performed according to work schedules, which are often arbitrary. We therefore considered this quasi-randomization.

Table 3. Tools from Google search and expert suggestions.

Digital gamified tool	Type of disease/vaccine	Type of digital gamified tool platform	Gamification elements (eg, rewards, role-playing, leaderboard, serious game)
Antidote COVID-19 [71]	COVID-19	Native mobile app	Reward points
The Vaccination Game [72]	H11N7 and influenza	Web-based tool	Serious game
Help take down COVID-zilla! [73]	COVID-19	Web-based tool	Role-playing
Just the Vax! [74]	Vaccine-preventable disease	Web-based tool	Reward points
COVID Invaders [75]	COVID-19	Web-based tool	Reward points
Vax Pack Hero [76]	Vaccine-preventable disease	Web-based tool	Reward points and physical trading cards
Flu's Clues [77]	Influenza	Web-based tool	Certificate of completion for solving the influenza mystery
Virus Fighter [78]	COVID-19, influenza, Ebola, measles	Web-based tool	Serious game
Immunization411: for preteens and teens' online training [79]	Tdap meningococcal vaccine, varicella, HPV[a], influenza	Web-based tool	Reward points
COVID Chronicles [80]	COVID-19	Web-based tool	Reward points
I Boost[b] [81]	Vaccine-preventable disease	Web-based tool	Quiz

[a]HPV: human papillomavirus.

[b]Suggested by an expert.

The studies were conducted in 26 different countries, with the majority of studies coming from the United States (n=13, 46%, studies) and the United Kingdom (n=5, 18%, studies). Study populations included students at various levels (elementary school to college, specialty programs, eg, nursing and pediatric residency), parents of vaccine-eligible children, adults from the general population, members of particular sociocultural communities (eg, immigrants, Indigenous peoples), and convenience samples, such as players of a game, attendees of a conference, and employees of an organization. Sample sizes ranged from 8 to 50,286. Whenever papers reported study participant characteristics such as age, sex, gender, ethnocultural identity, or socioeconomic levels, we extracted summary data, as shown in Multimedia Appendix 3.

Reported Effects of Evaluated Interventions

In total, 18 (64%) of 28 studies evaluated at least 1 of our outcomes of interest, while 11 (39%) studies reported the effects of the evaluated interventions on more than 1 outcome of interest. Summarized outcomes and their MMAT quality assessments are shown in Table 4. Multimedia Appendix 5 provides full details.

Table 4. Outcomes of evaluation studies included.

Type of digital gamified tool platform and study	Knowledge (comprehension/understanding, etc)	Attitudes (for/against vaccination, etc)	Beliefs (risk perceptions, etc)	Behavioral intentions (getting vaccinated or not, etc)	Others (eg, emotions)	MMAT[a] quality score
Web-based tool						
Betsch and Böhm [44]	—[b]	Negative vaccine attitudes with compulsory vaccination	—	Decreased vaccine uptake with compulsory vaccination	Increased level of anger with compulsory vaccination	60% quality criteria met
Carolan et al [45]	—	No significant effect on attitudes towards vaccination	—	—	Increased confidence in information needs	80% quality criteria met
Cates et al [31]	Increase in knowledge about immunization	—	—	Positive increase in intentions to vaccinate	Increase in vaccination self-efficacy, decisional balance towards vaccination	100% quality criteria met
Darville et al [47]	—	—	Positive effects on beliefs towards vaccination	Increase in intentions to vaccinate	—	60% quality criteria met
Eley et al [48], McNulty et al [49]	Improvements in knowledge about immunization	—	—	—	—	100% quality criteria met
Ibuka et al [52]	—	—	—	—	Free riding in vaccination decisions decreases vaccine acceptance	80% quality criteria met
Kaufman and Flanagan [53]	The digital version of the game was less effective at facilitating learning	The digital version of the game was less effective at attitude change	—	—	The digital version of the game was perceived to be complicated to use	20% quality criteria met
Mitchell et al [55], Laplana [56]	Increase in knowledge	Positive increase in attitudes for vaccination	—	Increase in vaccine uptake after accessing the game	—	80% quality criteria met (Mitchell et al [55])
Mobile app						
Dale et al [46]	—	—	—	Positive increase in intentions to vaccinate	—	80% quality criteria met
Fadda et al [50], Fadda et al [51]	Improvements in knowledge about immunization	—	—	Increase in intentions to vaccinate	Increase in psychological empowerment and confidence in the decision	80% quality criteria met (Fadda et al [50], Fadda et al [51])
Lee et al [54]	—	—	—	Increase in intentions to vaccinate	—	80% quality criteria met
Woodall et al [60]	—	—	Increase in beliefs towards vaccination	Increase in intentions to vaccinate	Increase in vaccine confidence	40% quality criteria met
Ruiz-López et al [70]	Increase in knowledge after playing the game	—	—	—	—	100% quality criteria met
Virtual reality tool						

Type of digital gamified tool platform and study	Knowledge (comprehension/understanding, etc)	Attitudes (for/against vaccination, etc)	Beliefs (risk perceptions, etc)	Behavioral intentions (getting vaccinated or not, etc)	Others (eg, emotions)	MMAT[a] quality score
Mottelson et al [57]	—	—	—	Increase in vaccination intention when both the personal and collective benefit of COVID-19 vaccination was communicated	Increase in COVID-19 empathy, vaccination recommendation, and vaccination readiness	80% quality criteria met
Nowak et al [58]	—	—	Positive effects on beliefs towards vaccination	Increase in intentions to vaccinate	—	100% quality criteria met
Real et al [59]	—	Increase in attitudes in favour of vaccination	—	—	—	60% quality criteria met
Vandeweerdt et al [61]	—	—	—	Increase in intentions to vaccinate	Virtual reality intervention increases a sense of collective responsibility	100% quality criteria met
Mobile or web app (multiple formats available)						
Davies et al [69]	Increase in knowledge about immunization	—	—	—	—	80% quality criteria met

[a]MMAT: Mixed Methods Appraisal Tool.

[b]Not reported.

Effects on Knowledge (Includes Comprehension/Understanding, etc)

Overall, the 28 included studies suggested that digital gamified tools may positively influence knowledge. Of 7 (25%) studies that assessed knowledge, 6 (86%) showed an increase in knowledge about immunization in general [31,48,51,55,69,70]. All these 6 (86%) studies were of high quality (≥80%). One study of low quality (≤25%) reported that a digital game is less effective at increasing knowledge compared to its original board game format [53]. When considering only the high-quality (≥80%) studies, we observed that digital gamified tools are associated with increased knowledge.

Effects on Attitudes (for or Against Vaccination)

Overall, digital gamified tools appeared to have mixed effects on attitudes toward vaccination. Of 5 (18%) of 28 studies that assessed attitudes, 2 (40%), one of high quality (≥80%) and the other of medium quality (60%), showed an increase in positive attitudes toward vaccination [55,59]. In addition, 2 (40%) studies, one of high quality (≥80%) and the other of low quality (20%), reported no or less effect on attitudes toward vaccination [45,53], and 1 (20%) study comparing voluntary and compulsory vaccines in a game context showed negative attitudes regarding compulsory vaccination [44]. When considering only the high-quality (≥80%) studies, we observed inconsistent effects on attitudes.

Effects on Beliefs (Perceived Benefits, Perceived Risks)

Overall, digital gamified tools demonstrated positive effects on beliefs toward vaccination. In total, 3 (11%) of 28 studies, 1 (33%) of high quality (100%) and 2 (67%) of medium quality (60% and 40%), evaluated the effects of digital gamified tools on beliefs toward vaccination. All 3 (100%) studies showed positive effects on beliefs toward vaccination [47,58,60]. When considering only the high-quality (≥80%) studies, we observed that digital gamified tools are associated with positive beliefs about vaccines.

Effects on Behavioral Intentions

Overall, the 28 included studies suggested that digital gamified tools may positively influence intentions to receive vaccines. In total, 11 (39%) studies evaluated the effects of digital gamified tools on behavioral intentions with regard to vaccines. Of these 11 studies, 1 (9%) of medium quality (60%) showed a decrease in vaccination intention when compulsory vaccination was introduced within a game context [44], whereas 10 (91%) studies, 3 (30%) of medium quality (60% and 40%) and 7 (70%) of high quality (≥75%), showed increased intentions to vaccinate [31,46,47,51,54,55,57,58,60,61]. When considering only the high-quality (≥80%) studies, digital gamified tools appeared to be consistently associated with increased vaccination intention.

Other Outcomes

In total, 9 (32%) of 28 studies have also evaluated the effects of digital gamified tools on other outcomes. Of these, 4 (44%) studies reported an increase in confidence in vaccines (medium quality=40%) [60], confidence in information needs (high quality=80%) [45], decisional balance in support of vaccination (high quality=100%) [31], and confidence in vaccine decisions (high quality=80%) [50]. In addition, 1 (11%) study of high quality (80%) reported an increase in empathy toward those vulnerable to COVID-19 and vaccination recommendations [57], and 2 (22%) studies of high quality (100% and 80%) reported an increase in vaccination self-efficacy and readiness [31,57]. An increase in psychological empowerment (high quality=80%) [51] and in emotions such as anger toward compulsory vaccination (medium quality=60%) [44] was also reported by 2 (22%) studies. One study of high quality (80%) reported that the concept of free riding decreases vaccine acceptance [52], whereas another study of high quality (100%) reported that virtual reality intervention increases collective responsibility [61]. When considering only the high-quality (≥80%) studies, we observed a variety of positive effects associated with digital gamified tools, including confidence in vaccines, confidence in decisions about vaccines, empathy toward vulnerable people, collective responsibility, psychological empowerment, and vaccination self-efficacy and readiness.

Effects of the Platform (Web Based, Mobile, Virtual Reality)

The study designs of the 28 included papers did not permit us to formally compare the effects of different platforms in a robust way. Upon inspection, there did not appear to be a strong effect of the platform. In other words, we did not observe evidence in favor of web-based, mobile, or virtual reality apps over the other 2 types of apps.

Discussion

Principal Findings

The broad objective of this scoping review was to map the state of the science regarding digital gamified tools and their effects. In other words, we wished to answer a common question at the intersection of public health and digital health: does gamification encourage vaccination and influence knowledge, attitudes, beliefs, and behaviors related to vaccination? By mapping both published literature and tools currently available online, we observed 2 principal findings.

First, our results suggest that gamification can increase predictors of vaccine uptake, such as knowledge, attitudes, beliefs, behaviors, and vaccination intention. This finding is similar to the findings of a previous review by Montagni et al [82] suggesting that gamification can contribute to changed behaviors and improved knowledge of vaccination. Similarly, other reviews have suggested the potential benefits of gamification for non–vaccination-related behavior change, such as a systematic review suggesting that gamification interventions could be a feasible way to improve health-related outcomes among cancer survivors [83] and another review suggesting their effectiveness in improving physical activity [84]. Such previous work became even more relevant during the COVID-19 pandemic, as many jurisdictions sought to optimize vaccine uptake in the context of an “infodemic” (ie, overabundance of information, true, false, and misleading, about the pandemic and recommended preventive behaviors) [85]. Half of the digital gamified tools identified in our web search addressed COVID-19, suggesting an active interest in using a gamified approach in the pandemic context. Recent research by Plechatá et al [86] published after our data extraction steps were complete suggested that explaining the concept of herd immunity with gamification has a positive impact on the COVID-19 vaccination intention.

Second, our review suggests that although gamification has the potential to enhance the impact of education strategies, gamified tools alone may not wholly address gaps in vaccine acceptance and uptake. Although some of the identified tools did increase vaccination, the increases did not fully close gaps between previous and desired vaccine uptake. This finding aligns with those of Tozzi et al [87], which suggested that promising results could be achieved by combining gamification with educative and informative tools to improve immunization programs. This finding also aligns with previous reviews suggesting the use of digital gamified interventions as a public health tool of interest in enhancing vaccine uptake [82,88]. Further research published by Real et al [89] after our systematic search similarly observed that integrating gamification, such as virtual reality, in training modules enhances uptake of the HPV vaccine. Integrating gamified features may work because they make digital tools acceptable and more fun to use and may reduce the chances of people feeling pushed toward vaccination. In parallel, gamification may be a promising strategy for increasing knowledge, skills, and confidence among health professionals engaging in discussions about vaccines with their patients [90,91].

In addition to these findings drawn directly from our review of the included tools, we offer a broader observation based on the contents of this scoping review, along with the larger landscape of vaccine acceptance research: context is key. Although an engaging approach may work for some groups or in some situations, it may be less well accepted among other groups and in other situations. For instance, a casual and approachable style of communication will work for the younger audience to convey vaccine information but might be deemed insufficient to health care professionals in a more formal setting, such as hospitals. A good understanding of the factors associated with low vaccine acceptance at the local level is needed prior to developing gamified tools [92]. Future research in this area should consider possible contextual factors, such as local culture, social and demographic characteristics of users, and different influences on vaccine hesitancy and acceptance in different regions. To help better match games to the context(s) in which they will be played, when developing games, developers and researchers may wish to consider involving potential players from different contexts early and often. This aligns with previous work [93,94] suggesting that involving users earlier in developing tools may help in designing interventions suitable for a targeted context. One of the examples in our review was an intervention by Cates et al [31] designed to explain HPV vaccines to teenagers using a “secret garden” theme. Involving potential game players early in the development of the game may have contributed toward its positive effects on vaccination intention.

The implications of this research extend beyond the immediate reported effects of gamified tools and delve into the strategic dimensions of public health policy and communication efforts. Considering the insights gleaned from the findings, this study supports a comprehensive and well-informed approach to integrating gamification into strategies for promoting vaccination. As gamification continues to demonstrate its potential in enhancing vaccine uptake, it is crucial to navigate this terrain thoughtfully, considering the various factors that influence its impact. This includes not only the technological and behavioral aspects but also the larger sociocultural context in which vaccination decisions are made. Therefore, our study emphasizes the importance of a comprehensive approach that fosters a mutually beneficial relationship between technological innovation, evidence-based strategies, and an intricate understanding of local contexts. This approach has the potential to make gamification a sustainable and adaptable tool in the arsenal of public health interventions, rather than just a passing trend.

The review does not find a clear advantage for any platform in terms of reported effects. It was challenging to measure the impact of the platforms on behavioral outcomes and calls for more focused research to better understand the specific elements within each platform that drive behavior change. In essence, our study suggests that the reported effects of an app may not be solely determined by its platform but rather by the strategic incorporation of mechanics and elements that facilitate the desired behavior change.

Gamification can influence knowledge, attitudes, and beliefs about vaccines, which can affect vaccine uptake. This is consistent with theories of change proposing that cognitive changes can lead to behavioral outcomes. Although our study mainly examines the immediate effects of gamification on these cognitive aspects, it also offers some implications for using gamification as a potentially viable strategy to improve vaccine acceptance.

Strengths and Limitations

Our study has 5 main limitations. First, because we aimed to capture all relevant evidence and examples, as is typical in a scoping review, we included a broad range of study designs and did not draw conclusions about the relative advantages or disadvantages of different game platforms and features. Given the rapid growth within this field of research, it would be difficult to truly prioritize evidence according to quality criteria at this point. In the future, it may be possible to conduct a systematic review and meta-analysis, restricting included studies to randomized experiments or randomized controlled trials. Such future work may include approaches such as a network meta-analysis to allow for comparison of the effects of different game types or game features. Based on the existing literature, it is difficult to conclude whether certain games are more or less likely to achieve their aims. Second, our results may be influenced by publication bias. It is possible that groups that have developed digital gamified tools that showed disappointing results simply did not publish their studies. This bias could lead to an overestimation of the reported effects of these tools. This highlights the importance of further research to fully understand the real impact of these tools and thus accurately inform policy decisions about the development and use of these tools. Third, and related to the previous 2 points, the rapid growth in this area may mean that we missed more recent evidence in literature published after January 2022 and web searches after May 2022. Fourth, the majority of digital gamified tools on vaccination represented in publications and online were developed in high-income countries. This finding aligns with the findings of previous work by Ohannessian et al [88], who also reported a predominance of high-income countries. This may reflect more widespread internet access and resources for developing digital gamified tools in high-income countries. It may also reflect publication bias in the scientific literature (ie, there may be fewer papers written about digital gamified tools in lower-income countries) and online (ie, tools developed and published in lower-income countries may not be ranked highly by search engines and therefore may not have appeared in our web searches). Tools developed in lower-income countries may also take different forms; for example, they may be text message–based interventions (with or without gamification) rather than web-based tools and therefore would be less likely to be identified in web searches. Analog games from high-income countries were similarly excluded from the scope of our study [95]. Nondigital games, such as board and card games, have demonstrated positive impacts on educational knowledge, cognitive function, and social interactions [96,97]. Such games can support diverse learning across subjects and settings, fostering interactions that develop skills, such as computational thinking and teamwork, and have positive impacts on academic achievement and vocabulary acquisition compared to digital games [97-99]. We restricted our scoping review to digital gamified tools because the review was intended to provide an evidence base for digital game development. Although nondigital games are also potentially useful interventions, the implementation and distribution of such interventions is more challenging, especially in a geographically dispersed country, such as Canada. Fifth, and finally, as we used Google and private browsing in Google, there may be a possibility that different search engines would provide different results.

This study also has 2 main strengths. First, by systematically examining the current literature and currently available tools online, we were able to offer an updated overview of the potential effects of including gamification in digital tools about vaccination. Second, by conducting a scoping review to broadly map the literature, future work can more easily identify and select key outcomes for systematic reviews and meta-analyses in this domain.

Conclusion

Digital gamified tools have the potential to improve vaccine uptake by increasing knowledge and promoting positive attitudes, beliefs, behaviors, and vaccination intention. Further evaluations of these innovative digital tools, including head-to-head comparisons of different features and different platforms, will add more knowledge about what works and what does not in order to achieve public health goals more efficiently. In the wider context of health policy, digital gamified tools may be useful components of multifaceted strategies to improve vaccination rates throughout society.

Acknowledgments

This work was supported by a research grant from the Canadian Institutes of Health Research (GA3177725). The authors gratefully acknowledge the assistance of Frédéric Bergeron (librarian) for reviewing the search strategy. We appreciate the assistance of Charles Racine and Créscence Joëlle Mefou Tasong in conducting the quality appraisal of the studies that evaluated their interventions.

Authors' Contributions

All authors provided substantial contributions to this paper’s conception and edits and approved the final version of the manuscript.

Abstract

Background: Effective health care services that meet the diverse needs of children and adolescents with cancer are required to alleviate their physical, psychological, and social challenges and improve their quality of life. Previous studies showed that serious games help promote people's health. However, the potential for serious games to be used for successful cancer control for children and adolescents has received less attention.

Objective: This scoping review aimed to map the use of serious games in cancer prevention and cancer care for children and adolescents, and provide future directions for serious games' development and implementation within the context of cancer control for children and adolescents.

Methods: This study followed a combination of the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) and the JBI (Joanna Briggs Institute) framework for the conduct of scoping reviews. PubMed, CINAHL Plus Full Text, Scopus, Web of Science Core Collection, and American Psychological Association (APA) PsycINFO databases were used for the search.

Results: From the initial 2750 search results, 63 papers were included in the review, with 28 quantitative, 14 qualitative, and 21 mixed method studies. Most of the studies were cancer care serious game papers (55/63, 87%) and a small number of studies were cancer prevention serious game papers (8/63, 13%). The majority of the included studies were published between 2019 and 2023 (cancer prevention: 5/8, 63%; cancer care: 35/55, 64%). The majority of the studies were conducted in Europe (cancer prevention: 3/8, 38%; cancer care: 24/55, 44%) and North America (cancer prevention: 4/8, 50%; cancer care: 17/55, 31%). Adolescents were the most represented age group in the studies' participants (cancer prevention: 8/8, 100%; cancer care: 46/55, 84%). All (8/8, 100%) cancer prevention serious game papers included healthy people as participants, and 45 out of 55 (82%) cancer care serious game papers included patients with cancer. The majority of cancer prevention serious game papers addressed game preference as a target outcome (4/8, 50%). The majority of cancer care serious game papers addressed symptom management as a target outcome (28/55, 51%). Of the cancer care studies examining serious games for symptom management, the majority of the studies were conducted to treat psychological (13/55, 24%) and physical symptoms (10/55, 18%).

Conclusions: This review shows both the growth of interest in the use of serious games for cancer control among children and adolescents and the potential for bias in the relevant literature. The diverse characteristics of the included papers suggest that serious games can be used in various ways for cancer control among children and adolescents while highlighting the need to develop and implement serious games in underrepresented areas.

Introduction

Cancer Control for Children and Adolescents

The efforts of cancer control to reduce the cancer burden, including interventions in cancer prevention and care, have reduced the prevalence of cancer and ameliorated its impacts on individuals and communities [1,2]. Additionally, with advances in medical technology, the survival rate of children and adolescents who contract cancer has been increasing [3]. However, cancer remains a life-threatening disease for children and adolescents and requires intensive treatment over a long period of time [4]. Practicing cancer prevention is the most efficient approach to avoid the significant physical and psychological burdens experienced during the diagnosis and treatment of cancer [5]. Adolescence, especially, is a critical stage to develop one's cognitive ability and acquire new behavioral factors. Therefore, learning about cancer risks and cancer prevention methods during adolescence may significantly impact one's future health status [6,7]. Nevertheless, cancer prevention knowledge and educational opportunities for children and adolescents are limited [6,8]. Moreover, young patients with cancer easily experience fatigue, pain, sleep disorders, and anxiety and have difficulties in establishing their values and interpersonal relationships while undergoing prolonged and intense treatment [9-11]. Systematic and continuous care that meets patients' needs is crucial to helping them overcome such challenges and improve their quality of life [12-14]. Nonetheless, due to the smaller number of young patients with cancer compared to adult patients with cancer, their needs may not be prioritized in medical policy formulation or service provision [15-17]. More active industrial and research activities supporting the development and implementation of effective cancer control methods for children and adolescents should be undertaken.

The Use of Serious Games

In the significantly growing field of digital health care, based on the rapid development of information and communication technology and computer technology, the potential for serious games to be used as a successful means of cancer control is being recognized [18,19]. Serious games are digital or computerized games used primarily for educational and training purposes rather than entertainment and amusement [20]. With the widespread availability of electronic devices such as computers, gaming consoles, and mobile devices, many users can easily access and enjoy serious games [20]. Additionally, they can experience more interactive, immersive, and engaging game-based learning through various serious game content [21]. By playing serious games, users may not only obtain enjoyable and immersive experiences but also enhance motivation, engagement, and learning outcomes. Users can also develop their skills in critical thinking, decision-making, problem-solving, social interaction, time management, and so on by actively exploring the serious game content in a safe environment without physical constraints [22-25]. Adaptive and personalized functions and immediate feedback offered by the game system also promote users' continuous learning cycles while retaining user engagement [26,27]. Previous literature has shown the effectiveness of serious games designed with diverse objectives, such as improving retention of knowledge [28], pain relief [29], and medication adherence [20] in the context of various diseases.

While several positive outcomes have been associated with the use of serious games, there are a few side effects associated with the use of serious games as a health intervention tool. Previous studies have reported the possibility that the complex features of serious games may increase users' mental workload, which may negatively impact learning [30]. Additionally, some studies have argued that the addictive nature of video games should not be overlooked in the use of serious games [31] (interestingly, though, at least one study has argued the opposite effect, stating that serious games can be used as a solution to game addiction issues [32]). These potential negative effects can be prevented through careful consideration of the user groups, purposes, and appropriate uses of serious games during their development process [33].

Serious Games in the Context of Cancer Control in Children and Adolescents

Past research has also explored the relationship between serious games and young people in the context of cancer [34,35]. Adolescents, especially, tend to have excellent adaptability to new technologies and possess substantial knowledge and experience with games as compared to users of other age groups [36]. Given the research on adolescents' engagement with video games [37] and studies conducted in game-based learning [38] and narrative persuasion [39-41], one may anticipate the positive influence of serious games on adolescents' learning and persuasion outcomes. When it comes to cancer prevention, adolescents can learn about complex cancer concepts and relevant prevention and treatment methods by interacting with engaging characters and objects and actively performing game quests embedded in serious games [34]. Concerning cancer care, serious games can help distract teenage patients with cancer from the pain and anxiety associated with treatment, facilitating successful coping with the challenges of cancer [35]. Serious games can also provide psychological and social support or assist in promoting rehabilitation and physical activity [42]. However, more research is needed relating to the use of serious games in establishing successful strategies for pediatric cancer control. Cancer control for children and adolescents differs from that for adults, from the causes of cancer to the objectives and methods of cancer treatment [43,44]. For example, because children and adolescents are still cared for by caregivers (ie, legal guardians), not only young patients with cancer but also their caregivers should be included in the scope of cancer control

[45]. This is just one of many characteristics indicating the need for different approaches and considerations when providing cancer control services for children and adolescents as compared to adults. Despite these unique needs, there is a relative lack of academic and industrial projects specifically addressing serious games within the context of cancer control in children and adolescents. Systematic and comprehensive consideration of existing studies can inform and direct future research in the use of serious games for cancer control in children and adolescents.

Aim of This Study

This paper assesses the extent to which serious games have been used for cancer control (ie, cancer prevention and care) in children and adolescents. Specifically, this scoping review aimed to understand trends in serious games research in cancer prevention and cancer care for children and adolescents within published, original research papers, and investigate future directions for the application of serious games in successful cancer control for children and adolescents. Due to the importance of introducing cancer prevention and care in children and adolescents, and as the needs in the context of cancer prevention will differ from those of cancer care, this review also sought to compare serious games research focusing on cancer prevention with those focusing on cancer care to identify any key differences in research trends for these subjects.

This study will provide valuable insight and inform successful health intervention strategies relating to the use of serious games within the context of cancer control in children and adolescents. Considering the salience of cancer prevention education in adolescence, we also anticipate this study will encourage future research focusing on the use of serious games within this context.

Methods

Study Design

As the goal of the review was to explore and summarize the literature on our topic, which aligns with one of the primary purposes of a scoping review [46], a scoping review methodology was chosen for this study. Within the context of the population, concept, and context framework, our population was children and adolescents, our concept was serious games, and our context was cancer control. This study followed the JBI (Joanna Briggs Institute) framework for the conduct of scoping reviews, which specifically involved the following steps: "(1) defining and aligning the objectives and questions; (2) developing and aligning the inclusion criteria with the objectives and questions; (3) describing the planned approach to evidence searching selection, data extraction, and presentation of the evidence; (4) searching for the evidence; (5) selecting the evidence; (6) extracting the evidence; (7) analysis of the evidence; (8) presentation of the results; and (9) summarizing the evidence per the purpose of the review, making conclusions and noting any implications of the findings" [46]. This study was reported using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [47]. The PRISMA-ScR checklist can be found in Multimedia Appendix 1. The protocol for this review was registered in the OSF (Open Science Framework) [48].

Search Strategy

The literature search was developed by a health sciences librarian (PW) and included a combination of controlled vocabulary and keywords relating to serious games and cancer. No date, language, age, or geographical filters were applied to the search. The search was translated by PW for use in PubMed, CINAHL Plus Full Text (via EBSCOhost), Scopus, Web of Science Core Collection, and American Psychological Association (APA) PsycINFO (via EBSCOhost) databases. PW executed the search in each database on June 2, 2022, and reran the search using Bramer and Bain's [49] method on December 15, 2023, to retrieve any new results since the date of the first search. The results of the search were imported into EndNote 20 (Clarivate) for the first search run and EndNote 21 (Clarivate) for the search rerun. The results were deduplicated using Bramer et al's [50] method. The deduplicated results were then exported as a Microsoft Excel sheet (version 2402), which was used for screening. The full search strategy used for each database can be found in Multimedia Appendix 2.

Study Selection

To be included in the scoping review, studies needed to meet the inclusion criteria outlined in Textbox 1.

In total, 2 authors (SK and PW) independently screened the titles and abstracts of the records based on the above eligibility criteria (ie, the authors reviewed each of the records in duplicate). Any conflicts were discussed and resolved via consensus. After the completion of the title and abstract screening, the process was repeated for the full-text screening, with the same 2 authors reviewing all records in duplicate based on the previously mentioned eligibility criteria, and all conflicts being discussed and resolved via consensus. In cases where conflicts were challenging to resolve, a third reviewer served as the tiebreaker (OA). All screening (including both title and abstract and full-text screening) was performed in a Microsoft Excel sheet (version 2402).

Textbox 1. Eligibility criteria.

Inclusion criteria

- Language: the paper was written in English.
- Publication type: the paper was a full, original research paper (ie, primary study).
- Age:
  - The study recruited participants who were aged 19 years or younger. The maximum age was based on the World Health Organization (WHO)'s definition of adolescents [51]. We also included studies where data were indirectly collected for this age group, such as when parents were interviewed about their children.
  - If children or adolescents and adults were examined in the same study, the paper separately or predominantly reported on the findings of children or adolescent participants.
- Serious games used for cancer prevention or care:
  - The study examined serious games being used for cancer prevention or care. Within the context of this study, we defined "serious games" as digital or computerized games that were used for education, behavior modification, or therapy. As a note, this definition was inclusive of digital or computerized entertainment games that were used for therapeutic purposes (eg, examining whether playing a commercial video game, such as Frogger, distracted patients from cancer-related symptoms [52]). For cancer prevention, this included studies that used serious games to educate or modify behaviors for cancer prevention. For cancer care, this included studies that used serious games to care for patients or survivors of cancer with cancer-related symptoms, helping them to overcome cancer-related challenges or educating them about their cancer diagnoses or treatments.
  - For studies that examined using serious games in combination with other interventions for cancer prevention or care, the paper separately or predominantly reported on the impact of the serious games on cancer prevention or care.
  - For studies that examined using serious games in the context of cancer and other diseases, the paper separately or predominantly reported on the impact of the serious games on cancer prevention or care.

Exclusion criteria

- Language: the paper was not written in English.
- Publication type: the paper was a literature review, editorial, commentary, essay, white paper, or a type of gray literature.
- Age:
  - The study only recruited participants that were aged 20 years or older, and no data (direct or indirect) were collected on children or adolescents.
  - If children or adolescents and adults were examined in the same study, the study predominantly consisted of adults and reported their findings cumulatively (ie, they did not separately report the findings of children or adolescent participants).
- Serious games used for cancer prevention or care:
  - The study only examined nondigital games, such as board games.
  - The study did not examine serious games being used for cancer prevention or care.
  - For studies that examined using serious games in combination with other interventions for cancer prevention or care, the paper reported their findings cumulatively (ie, they did not separately report on their findings for the serious games).
  - For studies that examined other diseases as well as cancer prevention or care, the study was not predominantly focused on cancer prevention or care and reported their findings cumulatively (ie, they did not separately report their findings for cancer prevention or care).

Data Extraction

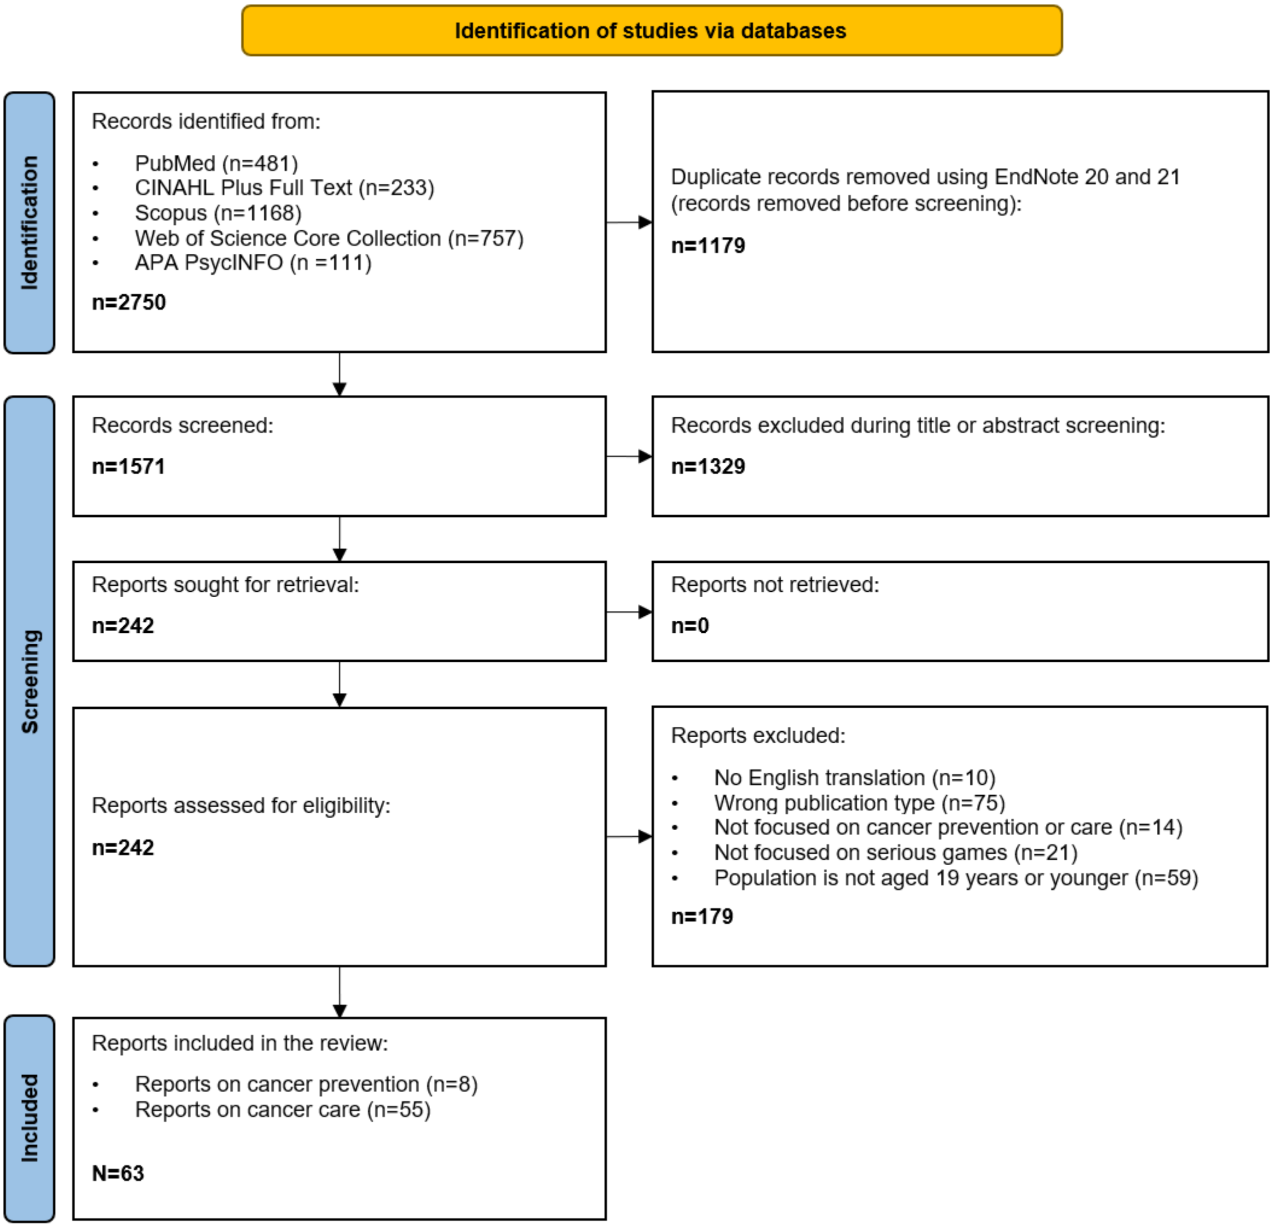
Following a full-text review, 2 authors (SK and PW) created and piloted a standardized extraction chart in Microsoft Excel (version 2402). The pilot entailed the 2 authors independently charting data from the first 10 included reports into the extraction chart, and meeting to identify areas that necessitated clarification or further standardization. After the pilot, information from all included studies was independently charted by the same authors into the extraction chart. The chart included each study's authors, title, publication year, location, participant age (ie, whether participants were children, adolescents, or adults), participant type (ie, whether the participants were patients with cancer, survivors of cancer, health professionals, caregivers, or healthy people; or whether the participant type was unspecified), serious game objective (ie, whether the serious game was being used for cancer prevention or cancer care), serious game name, target outcome (ie, what outcomes were primarily examined for the study), and, for studies that had symptom management as a target outcome, target symptom (ie, what symptoms were primarily examined for the study). Any discrepancies in the data charting were discussed by the 2 authors and resolved via consensus.

Results

Overview

The search retrieved a total of 2750 records. Of those records, 1179 were identified as duplicates and removed. Title and abstract screening was performed on the remaining 1571 records, of which 1329 were excluded. The remaining 242 records underwent full-text screening, with 179 of these records being excluded (resulting in a total of 63 included records for the review; see Figure 1 [53]).

Figure 1. PRISMA flow diagram. Adapted from Page et al. APA: American Psychological Association; PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.



Basic Information

Of the 63 papers included in this study, cancer care was the serious game objective with the most research (55/63, 87%) [35,42,52,54-105], with cancer prevention only having 8 papers (13%) [7,34,106-111]. The majority of the included studies were published between 2019 and 2023. To be specific, 5 out of 8 (63%) cancer prevention serious game papers [7,106,109-111] and 35 out of 55 (64%) cancer care serious game papers [35,42,54,58,59,61-63,65,66,71,72,74,75,78-82,85,91-105] were published between 2019 and 2023. The studies were conducted in Asia, Europe, North America, and Oceania, with the majority of the studies being conducted in Europe and North America. Of the 8 cancer prevention serious game papers, 3 (38%) [107,109,110] and 4 (50%) [7,34,106,108] studies were conducted in Europe and North America, respectively. Of the 55 cancer care serious game papers, 24 (44%) [35,58,61-63,65-67,70,74,75,81-83,85-87,92,93,97-100,103] and 17 (31%) [52,54-57,59,60,63,68,69,73,78,79,84,89,90,102] studies were conducted in Europe and North America, respectively. Of the 8 cancer prevention serious game studies, 3 (38%) were quantitative [34,110,111], 3 (38%) were qualitative [7,107,108], and 2 (25%) were mixed methods studies [106,109]. Of the 55 cancer care serious game studies, 25 (45%) were quantitative

[35,42,52,54-56,58,64,69,71-74,76,77,80,84,87-89,91,96,97,100,105], 11 (20%) were qualitative [57,59,62,63,67,81,82,93,99,102,103], and 19 (35%) were mixed methods studies [60,61,65, 66,68,70,75,78,79,83,85,86,90,92,94,95,98,101,104]. For the distribution of these studies by publication year and location see Table 1.

Table 1. Basic information of included papers.

Characteristics	Serious game objective	
	Cancer prevention (n=8)	Cancer care (n=55)

[a]Note that the frequency numbers may not add up to the total number of studies (N=63), as some studies included more than one category. Percentages may also not add up to 100% due to rounding.

Participant Characteristics

Children and adolescents were the main participants represented in the papers included in this review, which aligned with this study's purpose. The adolescents' age group had the greatest representation in the included studies—all (8/8, 100%) cancer prevention serious game papers [7,34,106-111] and 46 out of 55 (84%) cancer care serious game papers [35,42,52,54-62, 64-66,68-80,83,84,86-93,95-98,100,101,104,105] involved adolescents as participants. Interestingly, many studies included adult participants as well as adolescents or children. As mentioned in our inclusion criteria, studies examining adult populations were included if these also examined and isolated data for our population of interest (ie, children or adolescents) or if adults were interviewed about children or adolescents. Of our included studies, 25 of the 55 (45%) cancer care papers [52,55,56,60-62,66-69,79-82,84,85,92-95,97,99,101,102,104] and 2 of the 8 (25%) cancer prevention papers [34,109] included adults as well as adolescents or children. Further, 2 studies only included adults (being studies where parents were interviewed about their children, but where the children did not participate in the study themselves), with both of these studies being cancer care papers [63,103].

All (8/8, 100%) cancer prevention serious game papers included healthy people as participants [7,34,106-111]. Regarding cancer care serious game papers, 45 out of 55 (82%) studies included patients with cancer [35,42,52,55-57,59-62,64-66,68-79,81-84, 88-90,92-102,104,105]. Surprisingly, several papers also involved health professionals and caregivers as participants, wherein these groups were interviewed to solicit their impressions and opinions of how the serious games affected their young patients or children, respectively [60-63,66,79, 81,82,85,92-95,97,99,101-103]. In these cases, where health professionals' or caregivers' opinions or quotes were associated with our population of interest (ie, children or adolescents) and these opinions or quotes were included in the results section of the studies, our review study included those papers and counted the health professionals and caregivers as the study's participants.

Table 2 presents more details about the distribution of included studies by participant age and participant type.

Table 2. Participant characteristics of included papers.

Characteristics	Serious game objective	
	Cancer prevention (n=8)	Cancer care (n=55)
Participant age (years), n (%)[a]		
Children (0-9) [35,42,52,57-62,64-67,70,72,74,76-79,81-87,91-99,101,102,107,108]	2 (25)	38 (69)
Adolescents (10-19) [7,34,35,42,52,54-62,64-66,68-80,83,84,86-93,95-98,100,101,104-111]	8 (100)	46 (84)
Adults (≥20) [34,52,55,56,60-63,66-69,79-82,84,85,92-95,97,99,101-104,109]	2 (25)	27 (49)
Participant type, n (%)[a]		
Patients with cancer [35,42,52,55-57,59-62,64-66,68-79,81-84,88-90,92-102,104,105]	0 (0)	45 (82)
Survivors of cancer [54,57,58,80,86,87,91]	0 (0)	7 (13)
Health professionals [60,63,66,81,82,85,93,94,97]	0 (0)	9 (16)
Caregivers [60-63,66,79,81,82,92,95,97,99,101-103]	0 (0)	15 (27)
Healthy people [7,34,66,70,75,85,91,106-111]	8 (100)	5 (9)
Unspecified (not disclosed) [67]	0 (0)	1 (2)

[a]Note that the frequency numbers may not add up to the total number of studies (N=63), as some studies included more than one category. Percentages may also not add up to 100% due to rounding.

Role of Serious Games in Cancer Control for Young People

The papers included in this review examined the use of serious games for a variety of target outcomes. For cancer prevention, the target outcome most addressed by the papers was exploring participants' preferences for the content of the serious games (ie, participants' satisfaction with the serious game or likes and dislikes about features within the serious game; 4/8, 50%) [7,108,110,111], followed by educating participants about cancer (3/8, 38%) [34,106,109], and promoting healthy behaviors (1/8, 13%) [107]. For cancer care, the target outcome most addressed by the papers was using serious games for symptom management (28/55, 51%) [35,42,52,58,61,64,65,71-73,76,77,81-84,86-89,91,92,94,97,99,100,104,105], followed closely by exploring participants' preferences for the content of the serious games (24/55, 44%) [55,56,62,63,67,68,70,75,79,84-86,90,92-98,101-104]. Other target outcomes observed for cancer care included promoting healthy behaviors (10/55, 18%) [42,54,57,60,65,74,80,95,96,101], symptom reporting (7/55, 13%) [59,66,75,78,79,90,102], cancer education (6/55, 11%) [55,56,80,95,101,105], and treatment adherence (3/55, 6%) [69,95,101]. Of the cancer care studies examining serious games for symptom management, the majority of the studies were conducted to treat psychological (13/55, 24%) [61,71-73,76,77,81,83,89,92,94,97,100] and physical symptoms (10/55, 18%) [35,42,52,58,65,81,83,86,99,104]. Naturally, none of the cancer prevention serious game papers were conducted with the goal of managing cancer-related symptoms.

Table 3 presents more details about the distribution of included studies by target outcome and target symptom.

Table 3. The role of serious games in included papers.

Characteristics	Serious game objective	
	Cancer prevention (n=8)	Cancer care (n=55)
Target outcome, n (%)[a]		
Serious game preference [7,55,56,62,63,67,68,70,75,79,84-86,90,92-98,101-104,108,110,111]	4 (50)	24 (44)
Treatment adherence [69,95,101]	0 (0)	3 (6)
Cancer education [34,55,56,80,95,101,105,106,109]	3 (38)	6 (11)
Healthy behavior promotion [42,54,57,60,65,74,80,95,96,101,107]	1 (13)	10 (18)
Symptom management [35,42,52,58,61,64,65,71-73,76,77,81-84,86-89,91,92,94,97,99,100,104,105]	0 (0)	28 (51)
Symptom reporting [59,66,75,78,79,90,102]	0 (0)	7 (13)
Target symptom, n (%)[a]		
Psychological symptoms[b] [61,71-73,76,77,81,83,89,92,94,97,100]	0 (0)	13 (24)
Physical symptoms[c] [35,42,52,58,65,81,83,86,99,104]	0 (0)	10 (18)
Cognitive symptoms[d] [42,58,84,87,88,104]	0 (0)	6 (11)
General side effects[e] [73,105]	0 (0)	2 (4)
Other[f] [64,82,87,91,104,105]	0 (0)	6 (11)

[a]Note that the frequency numbers may not add up to the total number of studies (N=63), as some studies included more than one category. Percentages may also not add up to 100% due to rounding.

[b]"Psychological symptoms" includes papers that addressed "anxiety," "depression," "distress," "emotional state," "psychosocial symptoms," or "psychological symptoms" in this study.

[c]"Physical symptoms" includes papers that addressed "endurance," "fatigue," "motor performance," "nausea," "pain," or "physical activity" in this study.

[d]"Cognitive symptoms" includes papers that addressed "cognitive behavioral effects," "cognitive function," "functional capacity," or "reading deficits" in this study.

[e]"General side effects" includes papers that addressed "side effects of chemotherapy" or "symptoms" (nonspecific) in this study.

[f]"Other" includes papers that addressed "activities of daily living," "daily performance," "quality of life," or "sleep" in this study.

Discussion

Overview

This scoping review aimed to examine the extent to which serious games have been used within the context of cancer prevention and care for children and adolescents within published, original research papers, and investigate future directions for the application of serious games in successful cancer control for children and adolescents. In this review, we identified papers that explored the potential of serious games being used for successful cancer control for children and adolescents. When observing the distribution of these papers in a comprehensive map, we also identified several gaps that may introduce bias into the existing literature.

Need for Cancer Prevention Serious Games Research

The results of this study showed that there were considerably fewer cancer prevention serious game papers than cancer care serious game papers. This difference may indicate that cancer prevention serious games are perceived as being less important than cancer care serious games. The necessity of pediatric cancer prevention might also be overlooked because of the relatively insufficient medical infrastructure and interest in pediatric cancer prevention as compared to adult cancer prevention, being in part due to the smaller number of pediatric patients with cancer compared to adult patients with cancer [15-17]. Another explanation could be the complex etiology of pediatric cancer. For adult cancers, there are several studies establishing the associations between cancer occurrence and lifestyle or environmental risk factors [112,113], which may help people take preventive measures. However, it is known that lifestyle or environmental risk factors are unlikely to play a significant role in the occurrence of pediatric cancers [114]. The lack of evidence about lifestyle or environmental risk factors may hinder identifying them and reduce preventive efforts for pediatric cancers. Consequently, the awareness of pediatric cancer prevention may be low. Nevertheless, considering that cancer prevention interventions are the most effective way to reduce cancer-related risks, it is essential to develop and provide cancer prevention services for pediatric cancers. Future research should be conducted to develop serious games that educate young people about cancer so that they can have knowledge about cancer and preemptively engage in healthy behaviors.

Disparities in Cancer Control Serious Games Research Relating to the Publication Year and Location

This study's findings also confirmed that the publication year and location are concentrated in specific years and countries. Both cancer prevention serious game papers and cancer care serious game papers were largely published after the year 2019. This distribution may imply a trend that researchers are recently paying more attention to the application of serious games in digital health care [115]. The impact of serious games will be amplified by systematically delving into the conceptual and theoretical underpinnings of serious games and uncovering strategies to develop and use serious games for constructive and socially beneficial purposes. Future research needs to investigate the positive influence of serious games and accelerate their implementation in cancer prevention and care. Doing so will facilitate the successful use of serious games in pediatric cancer control and spearhead advancements in digital health care. Additionally, research on serious games in both cancer prevention and cancer care has predominantly been conducted in Europe and North America. As the positive effects of serious games in the medical field have been indicated through existing research, future research needs to explore avenues to encourage serious game studies in the medical field for researchers in other geographic regions. Such efforts would be beneficial to mitigate disparities in digital technology and reduce inequalities in access to health care services.

Embracing Various Age Groups in Cancer Control Serious Games Research

Moreover, our study revealed distinct patterns in the distribution of papers based on participant characteristics. Regarding participant age, it was observed that all papers on cancer prevention serious games focused on adolescents. Similarly, the predominant age group featured in papers concerning cancer care serious games was also adolescents. These findings are not unexpected, considering adolescents' familiarity with gaming [36] and the research objective of this review study. However, the observed distribution indirectly suggests a divergence between the child and adolescent groups, while indicating a relative neglect in research focusing on serious games for children. In addition to exploring cancer control serious games tailored for children, future studies could also compare the characteristics and uses of serious games designed for children with those designed for adolescents, and, in doing so, identify salient differences between the 2 groups. An additional finding of note was that, due to the intricate dynamics of pediatric cancer that affect not only young patients but also adults closely associated with them [45], certain studies incorporated adult participants as well as children or adolescents. More research should encompass both child and adult users when developing a serious game for effective pediatric cancer control or when evaluating user experiences, as doing so could furnish more comprehensive and nuanced findings.

Embracing Various Participant Types in Cancer Care Serious Games Research

Regarding participant type, it was observed that all papers on cancer prevention serious games exclusively targeted healthy people. Conversely, the primary participant type featured in papers focusing on cancer care serious games was patients with cancer. Notably, cancer care serious game papers included a diverse array of participant types, with some studies even including multiple participant types. This suggests the potential for serious games to cater to diverse participant types, even those characterized by different interests and attributes. Future research should strive to understand the different needs of multiple participant types to develop effective, and far-reaching cancer care serious games. A comprehensive approach to identify different user needs within the context of serious games should also be encouraged.

The diverse array of participant types also implies the potential for participants to play a variety of roles in developing serious games. Pediatric patients with cancer and survivors can share their opinions and user experiences when using serious games [55,86]. Caregivers can also share their opinions and user experiences when they or their dependents use serious games while also encouraging their dependents to play serious games [60,61]. Health professionals can provide expertise and a nuanced understanding of the needs of their patients and can therefore provide invaluable feedback for the design and content of serious games [60,82]. All these roles can facilitate the evaluation and development of serious games.

Finally, our review found that a small number of papers included survivors of cancer, caregivers, or health professionals as participants when examining the use of serious games for cancer control in children or adolescents. In particular, survivors of cancer and caregivers have difficulties in resolving their unmet needs or draw less emphasis or attention to cancer care services [116,117]. Crafting appropriate serious games for survivors of cancer and caregivers based on an advanced understanding of them may improve both the quantity and quality of cancer care services for young people. As health care providers, health professionals can be overlooked in their potential to play a role in serious game research for cancer control in children or adolescents; however, as stated previously, health professionals can provide invaluable feedback for the development and evaluation of serious games.

Enriching Cancer Control Serious Games Research by Focusing on Underrepresented Target Outcomes

The roles of the serious games differed between cancer prevention and cancer care. Serious game preference was one of the main target outcomes for both cancer prevention serious game papers and cancer care serious game papers. Cancer education emerged as another key target outcome for cancer prevention serious game papers, whereas symptom management took precedence in cancer care serious game papers. Similar to the case with participant types, cancer care serious game papers addressed a diverse range of target outcomes, with some studies addressing multiple target outcomes within a single investigation. This suggests the feasibility of developing and deploying serious games for young people's cancer care with multifaceted purposes. There were, however, some target outcomes that were underrepresented, such as healthy behavior promotion for cancer prevention studies and management of cognitive symptoms for cancer care studies. Future research should delve into effective strategies for serious game development and implementation in these underrepresented target outcomes, thus bridging existing gaps and fostering more comprehensive discussions concerning the use of serious games in cancer prevention and care.

Limitations

This study demonstrated the research state on the use of serious games for cancer control among children and adolescents and suggested the future directions of serious game development and research; however, this study did have limitations. First, only papers written in English were included in the review, so valuable data from relevant papers published in other languages may have been excluded. Second, multiple studies included in this study's data analysis recruited not only children and adolescents but also adults as participants; therefore, careful interpretation of serious games' influence on children and adolescents is necessary. Third, we opted to limit our results to a reputable and manageable selection, with the goal of the review being to provide an overview of original, primary studies on our topic. Due to this, we refrained from including paper types such as reviews, conference proceedings, etc, in our review. Fourth, we did not evaluate the statistical outcomes of the serious games within each study, as this was not within the scope of our review (with the scope of our review being to map the use of serious games within the context of cancer control). Future research, such as a systematic review, could provide valuable insight into the statistical efficacy of serious games within focused areas of cancer control. Future studies could also assess topics such as features and frameworks of serious games, providing more insight into their development.

Conclusions

This review study shows that there has been an increased interest in the use of serious games for cancer control among children and adolescents. At the same time, this study reveals that the number of papers has been skewed in terms of the purpose and context of serious games for cancer control in children and adolescents, with cancer prevention serious games in young people having received considerably less attention than those of cancer care. Additionally, the frequencies of study participants' characteristics and target outcomes differ depending on the serious game objectives. Regarding cancer prevention serious game papers, these studies primarily examined serious game preference. Regarding cancer care serious game papers, these studies primarily examined serious game preference and how serious games help alleviate cancer-related symptoms. These differences suggest that serious games can be used in multiple ways within cancer control in children and adolescents while highlighting the need to develop and implement serious games in underrepresented areas. Further studies are needed to comprehensively examine which features of serious games enhance young people's cancer control and what evidence-based and theory-driven methods are available to develop effective serious games for this purpose. Integrating these future findings into this review study's outcomes may help advance successful serious game development and implementation for young people's cancer control.

Abstract

Background: Children with disabilities face numerous challenges in accessing health services. Mobile health is an emerging field that could significantly reduce health inequities by providing more accessible services. Many mobile apps incorporate gamification elements such as feedback, points, and stories to increase engagement and motivation; however, little is known about how gamification has been incorporated in mobile apps for children with disabilities.

Objective: This scoping review aims to identify and synthesize the existing research evidence on the use of gamification in mobile apps for children with disabilities. Specifically, the objectives were to (1) identify the categories of these mobile apps (eg, treatment and educational) (2), describe the health-related outcomes they target, (3) assess the types and levels of gamification elements used within these apps, and (4) determine the reasons for incorporating gamification elements into mobile apps.

Methods: We searched MEDLINE, PsycINFO, CINAHL, Embase, the ACM Digital Library, and IEEE Xplore databases to identify papers published between 2008 and 2023. Original empirical research studies reporting on gamified mobile apps for children with disabilities that implemented at least 1 gamification strategy or tactic were included. Studies investigating serious games or full-fledged games were excluded.

Results: A total of 38 studies reporting on 32 unique gamified mobile apps were included. Findings showed that gamified apps focus on communication skills and oral health in children with autism spectrum disorder while also addressing self-management and academic skills for other disability groups. Gamified mobile apps have demonstrated potential benefits across different populations and conditions; however, there were mixed results regarding their impact. The gamification strategies included fun and playfulness (23/32, 72%), feedback on performance (17/32, 53%), and reinforcement (17/32, 53%) in more than half of apps, whereas social connectivity was used as a gamification strategy in only 4 (12%) mobile apps. There were 2 main reasons for integrating gamification elements into mobile apps described in 16 (42%) studies: increasing user engagement and motivation and enhancing intervention effects.

Conclusions: This scoping review offers researchers a comprehensive review of the gamification elements currently used in mobile apps for the purposes of treatment, education, symptom management, and assessment for children with disabilities. In addition, it indicates that studies on certain disability groups and examinations of health-related outcomes have been neglected, highlighting the need for further investigations in these areas. Furthermore, research is needed to investigate the effectiveness of mobile-based gamification elements on health and health behavior outcomes, as well as the healthy development of children with disabilities.

(JMIR Serious Games 2024;12:e49029) doi:10.2196/49029

KEYWORDS

mobile health; mHealth; gamification; children with disabilities; mobile phone

Introduction

Background

Worldwide, approximately 93 million children have a moderate to severe disability, and 13 million children have a severe disability [1]. Children with disabilities face numerous barriers to accessing health services and health-promoting activities [2]. Despite the abundance of research investigating different interventions to improve the lives of children with disabilities, the interventions have not been successfully implemented, limiting the impact of research on public health outcomes [3]. To address this issue, innovative technological advances could significantly improve the health and well-being of marginalized groups [4,5], such as children with disabilities, their families, and the systems of care surrounding them.

Mobile apps, as examples of innovative technological tools, are becoming important in improving access to therapeutic interventions and diagnoses for underserved groups [6]. Mobile health (mHealth), a young but rapidly evolving field, enables the delivery of planned interventions and practices via mobile devices and apps, downloaded and installed on mobile devices to perform a particular task [7]. Constant availability, broader access, fairness of service offerings, personalized content, lower cost, and increased service capacity and efficiency are some advantages of mHealth [8]. Therefore, mHealth can be a tool to create more accessible services for children and adolescents with disabilities and their families as applied to various health-related situations.

There is a growing interest in incorporating game-like elements, called "gamification," in mobile apps to promote greater engagement with the technology and motivation to achieve specific personalized goals [9,10]. Gamification is the application of various game strategies and tactics in nongame contexts [11-13]. Gamification aims to change individual behavior through a combination of game elements (often delivered within games but also through mobile apps) [14,15] in contrast to "serious games" that is "any form of interactive computer-based game software for one or multiple players to be used on any platform and that has been developed with the intention to be more than entertainment" [16]. Although gamification is a promising concept [14], the empirical research regarding its applications is still in its early stages.

Gamification is increasingly being applied in mHealth to promote healthy behaviors using a wide range of game elements, including challenges, goal setting, feedback, progress bars, points, and levels [9]. There is an increasing trend toward incorporating gamification in different health domains, such as pediatric rehabilitation, physical activity, and chronic health conditions [5,17,18]. Gamification in rehabilitation can enhance therapeutic adherence and can be used to complement traditional interventions for children with disabilities and promote physical activity and other healthy behaviors [19]. The implementation of gamification has the potential to enhance individuals' adherence to medical protocols and successfully manage their health conditions [20-22]. The inclusion of social support as a gamification component has been recognized as encouraging for enhancing one's social abilities [23-25]. Previous research has also indicated that the use of gamification has the potential to trigger desirable emotional experiences and enhance users' levels of satisfaction and self-esteem [26-30]. Furthermore, game design components have become more accessible, cost-effective, and enticing as video games have gained popularity [10].

Ryan et al [31] introduced an integrative process model that incorporates the fundamental elements of self-determination theory, which is a motivational theory. They argued that actions can support or thwart the satisfaction of basic psychological needs, namely autonomy, competence, and relatedness and consequently influence the quality of motivation. Depending on whether the individual's needs are supported or not, it may then influence mental health outcomes (eg, depression and anxiety) and physical health outcomes (eg, exercise and weight control) [31]. Research has demonstrated that gamification can both facilitate and diminish intrinsic motivation [32]. Therefore, the integration of gamification features in mobile apps entails certain nuances.

Gamification elements such as rewards have the potential to enhance motivation toward continued performance and consequently healthier behaviors; however, numerous research studies indicate that the use of extrinsic motivators or the provision of controlling feedback can significantly diminish intrinsic motivation by impeding individuals' sense of autonomy [33,34]. The presence of increased levels of extrinsic motivation in the context of gamification is not sufficient as the only criterion for evaluating its advantages [35]. Cheating may also escalate as individuals get involved in attempts to attain greater levels of achievement, primarily driven by the rewards [23] Furthermore, there is a prevailing prediction that a significant proportion of gamification implementations will be doomed to failure because of inadequate understanding regarding the effective design principles of gamification [36]. The development of gamified health solutions frequently lacks collaboration with health professionals, potentially compromising their efficacy and diminishing their credibility [23,28]. When gamification to promote health fails to prioritize the user-centered approach and neglects to consider the unique attributes and demographic factors of potential users, their effectiveness may be undermined [23,28,37,38].

As a result, tailoring the gamification features based on the users' profiles is crucial to enhance their engagement [39]. Given the diverse needs of children with disabilities, it is imperative for researchers and mobile developers to possess a comprehensive understanding of gamification principles and strategies. This knowledge will enable them to effectively customize gamification features to cater to the specific requirements of this target population. Although there is a growing interest in using gamification elements in mobile apps, there is still a lack of comprehensive understanding in the field of childhood disability. Currently, there is no literature review investigating gamification in mobile apps designed for children with disabilities.

Our scoping review aimed to bridge the following knowledge gaps:

First, there is a deficiency in the systematic identification and categorization of gamified mobile apps (eg, treatment and educational) that are specifically designed for children with disabilities. Understanding the existing evidence in this niche field is crucial to evaluating the scope and diversity of available gamified mobile apps.

Second, there is a lack of comprehensive documentation on the specific health-related outcomes these apps target. Understanding the existing evidence will help us recognize which health-related outcomes have been targeted in this population and help identify disabilities and health-related outcomes that could have been neglected.

Third, there is a lack of comprehensive documentation on the characteristics of gamification strategies and tactics used in these mobile apps. A comprehensive review of gamification types and levels is required to understand how the game elements address the unique needs of children with disabilities.

Fourth, the underlying justification for incorporating gamification elements into mobile apps for this specific group remains unclear.

Objective

Addressing the abovementioned knowledge gaps is imperative to advance the use of gamification in mobile apps for children with disabilities. Therefore, this review aimed to explore the current use of gamification strategies and tactics in mobile apps for children with disabilities. The four specific objectives are as follows: (1) to identify gamified mobile apps designed for children with disabilities, (2) to identify health-related outcomes that these mobile apps aim to target, (3) to identify the different types and levels of gamification strategies and tactics implemented in these mobile apps (4) to determine the reasons for incorporating gamification elements into mobile apps

Methods

Overview

Scoping reviews help identify the types of current literature in a specific field and key characteristics related to a particular context, and analyze the knowledge gaps, while systematic reviews investigate the conflicting results and address any variation in current practices, or compare new interventions against gold standard, established interventions [40]. As there was no current review exploring the current evidence in gamification for children with disabilities and identifying the types of gamification elements in these mobile apps, we sought a scoping review to answer our research objectives. The methodological frameworks proposed by Arksey and O'Malley [41] and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist [42] (Multimedia Appendix 1) were used to guide this scoping review.

Search Strategy

The database searches were performed in November 2023 in the following web-based databases: MEDLINE, PsycINFO, CINAHL, Embase, the ACM Digital Library, and IEEE Xplore. The selection of databases, keywords, and relevant indexing (eg, Medical Subject Headings and other database-specific search techniques) were finalized in collaboration with the experienced librarian. The full search strategy is presented in Multimedia Appendix 2. In summary, we had 2 main themes: children with disabilities (population) and gamification in mobile apps (exposure). Regarding the full search strategy used on MEDLINE for the first theme, we combined different key disability terms (lines 1-51) with pediatric population terms (lines 53-55) and parent-related terms (lines 57-62). For the second theme, we combined key terms for mobile apps (lines 64-67) and gamification (line 68). The combination of these 2 themes helped us find any papers that studied mobile apps for children with disabilities. The inclusion criteria for the selection of the papers are discussed in Inclusion Criteria section. To ensure the comprehensiveness of the search, the primary author (EM) manually searched the reference lists of the relevant studies and existing reviews. Furthermore, EM searched the JMIR homepage [43], where no new studies were found. All the research results found in the databases were imported to the Rayyan reference manager website [44], where duplicates were identified and removed.

Inclusion Criteria

We included a peer-reviewed research article if the conditions presented in Textbox 1 were met.

Textbox 1. Inclusion criteria for included peer-reviewed research articles.

Inclusion criteria

- Publication language: there were no limits imposed on the language of the studies.
- Type of publication: peer-reviewed journal articles and conference proceedings
- Type of study: qualitative, quantitative, or mixed methods
- Time: published between January 2008 and November 2023. The reason for the selected start date was that the App Store and Google Play were launched in 2008, and almost all mobile apps were developed after 2008. Furthermore, another reason for the start date was that the concept of gamification was first introduced by Deterding et al [13] in 2008
- Population: children (aged up to 18 years) with any of the following disabilities: autism spectrum disorder, developmental delays, cerebral palsy, attention-deficit/hyperactivity disorder, dyslexia, intellectual disabilities, Turner syndrome, deglutition disorders, child behavior disorders, speech disorders, sensory disorder, motor disability, brain injuries (eg, traumatic brain injury), or any other brain-based disabilities
- Exposure: mobile apps on any device (smartphone, tablet, or iPad) and platform (Android or iOS) designed for children with disabilities. The mobile apps were included if they incorporated at least 1 gamification element (gamification strategy or tactics)
- Outcome: any health-related outcome that relates to the child's developmental functioning and general health status

We did not include theses, dissertations, protocols, abstracts, and letters to the editor; however, their references were screened for relevant studies. Nongamified mobile apps were excluded. Furthermore, apps labeled as "serious games" were excluded as they are complete games and fall outside of the scope of this review. Given the unique characteristics of mental health conditions and other disorders such as obesity and cancer in children and adolescents, we excluded these disorders; however, if there was any health-related comorbidity among children with disabilities (eg, if the study was on children with disabilities who are obese), we included them.

Study Selection

First, we tested the selection criteria, with 2 reviewers (EM and PYY) screening titles and abstracts independently until we reached an interrater agreement of 90%. The same process was followed for the full-text review of potentially relevant studies but with 2 dyads of reviewers (EM and PYY and EM and AC). Upon full-text screening, 1 reviewer (EM) manually searched the target journal and the reference lists of the included articles, abstracts, protocols, etc, and no relevant articles were found. Any disagreements were resolved through discussion to reach a consensus on a final decision, or a third adjudicator was implicated (KS and RC).

Data Abstraction and Charting

The data extraction form was developed and calibrated among each dyad of reviewers (EM and PYY and EM and AC) with 3 random articles. As the percent agreement was greater than 90% in each dyad, the data abstraction of the remaining articles began, and the conflicts were resolved through discussion. For each study, we extracted data on the study's first author, country, study design, population (eg, autism), sample characteristics (eg, size and age), mobile app name, device (smartphone, tablet, or iPad), platform (Android or iOS), app purpose, type of gamification strategy and tactics, health-related outcomes, and any reasons for implementing gamification in the mobile apps.

Data Synthesis and Analysis

Both quantitative and qualitative analyses were performed. A frequency analysis was conducted to illustrate the distribution of studies by publication year, country of origin, disability type in studies, gamification strategies and tactics, and the gamification level incorporated by mobile apps.

The gamification framework proposed by Cugelman [12] was used to assess the gamification elements present in these mobile apps. This framework consists of two sections: (1) gamification *strategies*, which are the persuasive principles of gamification and (2) gamification *tactics*, which are the on-screen features of gamification that app users interact with. The concepts of gamification tactics and strategies proposed by Cugelman [12] were used to operationalize gamification in this review. This framework consists of 7 gamification strategies and 10 gamification tactics.

Descriptive statistics were calculated to examine the level of gamification incorporation into mobile apps, as we wanted to understand if the number of gamification features might influence the outcomes. As there is no previous research exploring the level of mobile-based gamification for children with disabilities, we used arbitrary cutoff points to estimate the gamification level used in previous research in a different field [45]. The level of gamification strategies was labeled as none (no gamification strategies), low (1-2 gamification strategies), medium (3-5 gamification strategies), and high (6-7 gamification strategies). Similarly, the level of gamification tactics was classified as none (no gamification tactics), low (1-3 gamification tactics), medium (4-7 gamification tactics), and high (8-10 gamification tactics).

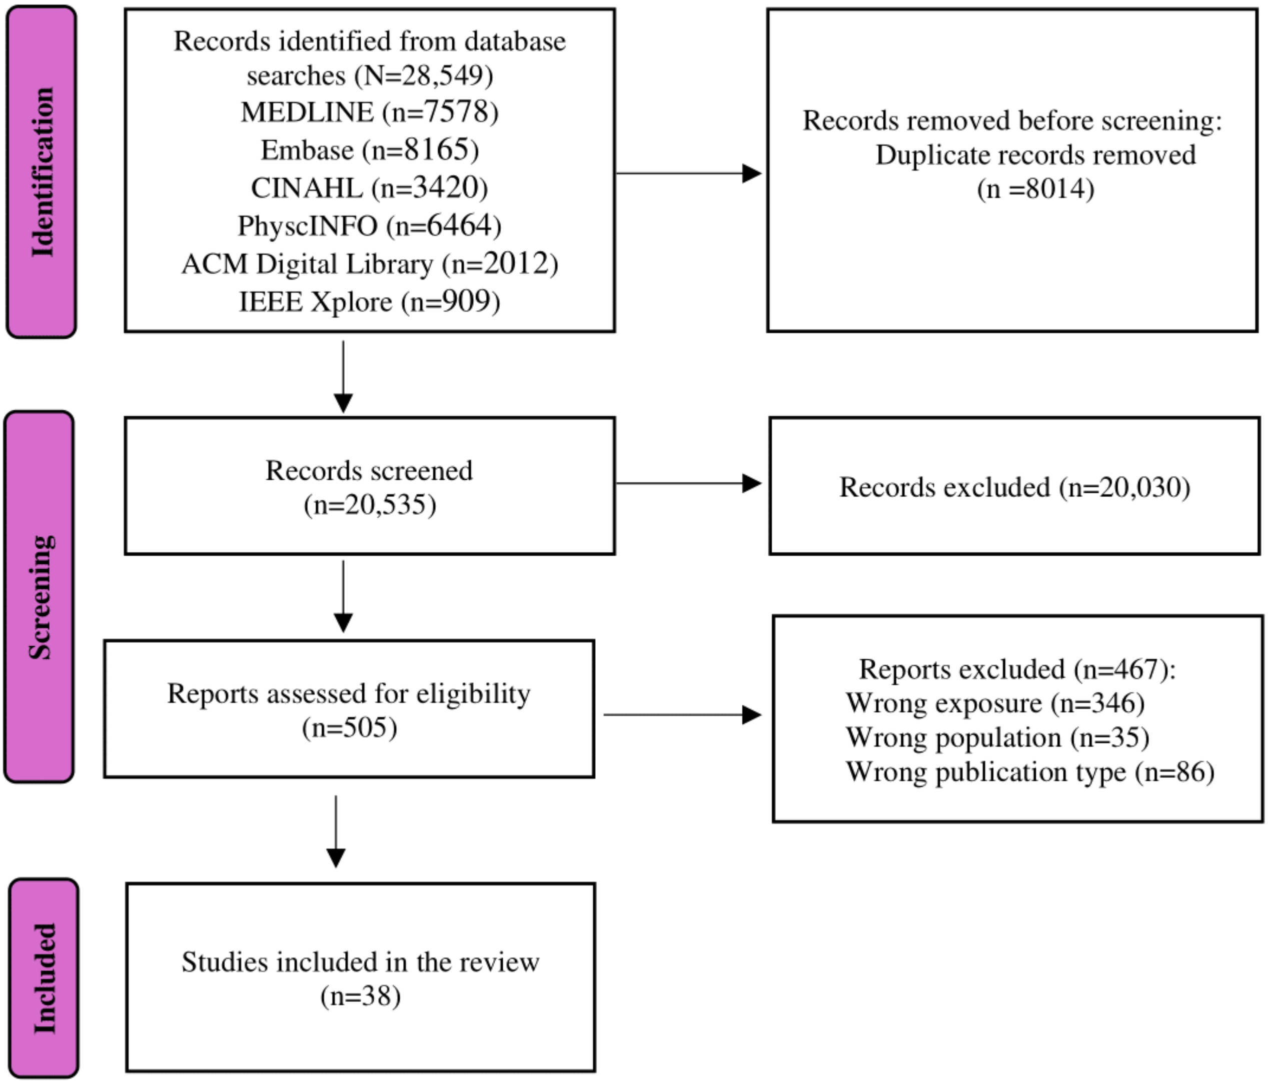
The primary author (EM) performed the content analysis to identify the health-related outcomes targeted by these mobile apps and the rationale for applying gamification in the apps. Further verification was done through discussion and collaboration with another author (RC) with expertise in conducting reviews and data synthesis.

Results

Study Selection

The flowchart of the search strategy and study selection is depicted in Figure 1. The initial database search yielded 28,549 citations; after the removal of duplicates, 20,535 (71.93%) citations remained for the title and abstract screening. The first screening phase led to 505 (2.46%) included and 20,030 (97.54%) excluded documents. The studies were excluded because they did not fit our inclusion criteria (eg, wrong population and wrong exposure). The second screening phase consisted of a full-text review of the 505 (2.46%) included documents, resulting in 38 (7.5%) included studies for this scoping review.

Figure 1. Flowchart of the review process.



Study Characteristics

Table 1 presents an overview of the study characteristics of all 38 articles included in the scoping review. Although we selected 2008 as the beginning year, all studies were published after 2013, demonstrating that gamification is a recently evolving field. The studies were implemented worldwide, with 37% (14/38) of the studies from Asian countries and 24% (9/38) of the studies from the United States. Most studies (29/38, 76%) used a quantitative research approach and were primarily quasi-experimental (9/29, 31%) or randomized clinical trials (RCTs; 6/29, 21%) studies. All 38 articles included in this review were written in English. Autism spectrum disorder (ASD) was the most common condition reported in 18 (47%) of the 38 included studies, followed by vision impairment (4/38, 11%) and dyslexia (4/38, 11%). Multimedia Appendix 3 [46-83] demonstrates details regarding the study and participant characteristics.

Mobile App Characteristics

Table 2 [46-83] demonstrates results regarding the general characteristics of mobile apps and gamification. A total of 32 unique gamified mobile apps were identified in the 38 included studies. Approximately 44% (14/32) of the identified mobile apps fell into the treatment category, designed to help children with disabilities improve their skill competencies, such as story creation and story sharing, and social communication. Educational (n=13, 41%) and assessment (n=3, 9%) apps were the second and third most observed categories. One app was specifically designed for managing symptoms.

Table 2. Summary descriptions of studies included in the scoping review.

Study, year	App name	App category	Health-related outcome	Gamification strategies	Gamification tactics
Kucirkova et al [46], 2014	Our story	Treatment	Social communication and story-telling abilities	Goal setting, capacity to overcome challenges, fun, and playfulness	Provides clear goals and offers a challenge
Moore et al [47], 2015	TOBY	Treatment	Different rehabilitation goals, such as sensory awareness, imitation, and social interaction	Goal setting, feedback on performance, reinforcement, comparing progress, fun, and playfulness	Offers a challenge, levels, points, shows progress, feedback, and gives reward
Parsons et al [48], 2020	TOBY	Treatment	Different rehabilitation goals, such as receptive language, social skills, and pragmatic language	Goal setting, feedback on performance, reinforcement, comparing progress, fun, and playfulness	Offers a challenge, levels, points, shows progress, feedback, gives reward
Parsons et al [49], 2019	TOBY	Treatment	Social communication	Goal setting, feedback on performance, reinforcement, comparing progress, fun, and playfulness	Offers a challenge, levels, points, shows progress, feedback, and gives reward
Penev et al [50], 2021	Guess what	Treatment	Social communication	Goal setting, the capacity to overcome challenges, feedback on performance, reinforcement, fun, and playfulness	Provides clear goals, offers a challenge, points, feedback, gives rewards, and provides badges
Saputra [51], 2016	LexiPal	Educational	Enjoyment and motivation in learning	Goal setting, feedback on performance, reinforcement, fun, and playfulness	Provides clear goals, levels, points, feedback, gives rewards, provides badges, and story or theme
Schmidt et al [52], 2020	SMART	Treatment	Self-management and relaxation	Goal setting, feedback on performance, reinforcement, fun, and playfulness	Provides clear goals, feedback, gives rewards, provides badges, and story or theme
Thida et al [53], 2020	VOIS	Treatment	Language	The capacity to overcome challenge, feedback on performance, reinforcement, fun, and playfulness	Offers a challenge, shows progress, feedback, and give rewards
Urakami [54], 2021	GROWJECTOR	Treatment	Medication adherence	Goal setting, reinforcement, and social connectivity	Provides clear goals, points, and gives rewards
Ying et al [55], 2016	NR[a]	Educational	Learning road safety	Fun and playfulness	Story or theme
Chua et al [56], 2017	NR	Educational	Emotional learning	Feedback on performance, fun, and playfulness	Feedback and story or theme
Doenyas et al [57], 2014	NR	Educational	Sequencing skill	Goal setting, the capacity to overcome challenges, feedback on performance, and reinforcement	Offers a challenge, feedback, and points
Holmes et al [58], 2016	NR	Treatment	Visual acuity	Reinforcement and compare progress	Levels, points, and shows progress
Kelly et al [59], 2016	Dig Rush	Treatment	Visual acuity	Goal setting, fun, and playfulness	Levels and points
Aburukba et al [60], 2017	AutiAid	Treatment or symptoms management	Memory and management of symptoms	Goal setting and social connectivity	Provides clear goals, levels, and points
Alnaghaimshi et al [61], 2020	Autism-World	Assessment and educational	User's literacy on autism	Social connectivity	__[b]
Barta et al [62], 2017	AutiSoft	Symptoms management	Manage daily routines	Feedback on performance and reinforcement	Feedback and gives rewards
Birtwell et al [63], 2019	SideKicks!	Treatment	Social communication	Goal setting, fun, and playfulness	Provides clear goals and story or theme

Study, year	App name	App category	Health-related outcome	Gamification strategies	Gamification tactics
Borhan et al [64], 2018	Mr. Read	Educational	Reading skills	Feedback on performance, reinforcement, fun, and playfulness	Points, feedback, shows progress, and story or theme
Brkic et al [65], 2022	FarmApp	Assessment	No specific behavior	Feedback on performance, reinforcement, fun, and playfulness	Offers a challenge, feedback, points, and story or theme
Daud and Abas [66], 2013	Dyslexia Baca	Educational	Letter recognition	Feedback on performance, reinforcement, fun, and playfulness	Feedback, gives reward, and story or theme
Dehkordi and Rias [67], 2014	GO-Go	Educational	Multiple cues responding	Reinforcement, fun, and playfulness	Offers a challenge, gives rewards, and story or theme
Gómez and Carro [68], 2014	AdaptAD-HD	Treatment	Concentration and impulse control abilities	Goal setting	Provides clear goals and levels
Guzsvinecz et al [69], 2017	Sliders	Educational	Logical thinking and deductive reasoning	Feedback on performance and reinforcement	Points, feedback, and shows game leaders
Hu et al [70], 2019	NeuroCare	Symptoms management	Self-management of pediatric concussion	Goal setting and feedback on performance	Provides clear goals and feedback
Irwin et al [71], 2015	Listening to Faces (L2F)	Educational	Audiovisual speech perception	Feedback on performance, compare progress, fun, and playfulness	Feedback and shows progress
Kalantarian et al [72], 2019	Guess what	Treatment	Social communication	Goal setting, the capacity to overcome challenges, feedback on performance, reinforcement, fun, and playfulness	Provides clear goals, offers a challenge, points, feedback, gives rewards, and provides badges
Macdonald et al [73], 2022	NR	Educational	Reading skills	Feedback on performance, reinforcement, fun, and playfulness	Feedback, gives rewards, and story or theme
Manh et al [74], 2018	NR	Treatment	Visual acuity	Capacity to overcome challenges and reinforcement	Levels and points
Mwamba et al [75], 2019	Paediatric Attention-Deficit/Hyperactivity Disorder Application Software (PANDAS)	Assessment	No specific behavior	Capacity to overcome challenges, reinforcement, fun, and playfulness	Offers a challenge, points, and story or theme
Tang et al [76], 2021	ColourSpot	Assessment	No specific behavior	Feedback on performance, reinforcement, Fun and playfulness	Feedback, gives rewards, and story or theme
Cahyono [77], 2022	LexiPal	Educational	Enjoyment and motivation in learning	Goal setting, feedback on performance, reinforcement, fun, and playfulness	Provides clear goals, levels, points, feedback, gives rewards, provides badges, and story or theme
Chistol et al [78], 2023	Autism Assistant	Treatment	Multiple behavioral skills	Fun and playfulness, goal setting, compare progress, and capacity to overcome challenges	Story or theme, provides clear goals, shows progress, and offers a challenge
Tan et al [79], 2023	NUS care	Educational	Oral health	Fun and playfulness, reinforcement, and social connectivity	Story or theme, points, and rewards
Schmidt et al [80], 2022	Self-Monitoring Activity Regulation and Relaxation Treatment (SMART)	Treatment	Self-management and relaxation	Goal setting, feedback on performance, reinforcement, fun, and playfulness	Provides clear goals, feedback, gives rewards, provides badges, and story or theme
Johnson et al [81], 2022	Zingo	Treatment	Therapy adherence	Fun and playfulness, feedback on performance, reinforcement, goal setting, and compares progress	Feedback, points, story or theme, gives rewards, provides clear goals, and shows progress

[a]NR: not reported.

[b]Not applicable.

A variety of health-related outcomes were identified, including a wide range of developmental, therapeutic, and educational skill competencies. Social communication (5/32, 16%), self-management (4/32, 11%), visual acuity (3/32, 9%), and oral health (2/32, 6%) were the most observed outcomes in the review. Only 2 (6%) studies investigating the LexiPal app targeted psychological outcomes such as motivation and engagement.

Multimedia Appendix 3 demonstrates other details regarding the participant and mobile app characteristics [46-83]. Regarding the 32 platforms, 14 (44%) apps were exclusively designed for iOS and 10 (31%) apps for Android, with 3 (9%) apps available on both platforms. In addition, 3 (9%) studies did not report the platform used. Of the 32 apps, 12 (38%) gamified apps were delivered on smartphones, 10 (31%) exclusively on iPads, 5 (16%) on both smartphones and tablets, 3 (9%) on both smartphones and iPads, and 2 (6%) exclusively on tablets. Most studies (28/32, 88%) did not report on costs related to app development.

Gamification Characteristics

Table 3 outlines the number and percentage of each gamification strategy and tactic adopted by 32 gamified mobile apps in this review. The most popular gamification strategy among 32 mobile apps was fun and playfulness (n=23, 72%), resulting in a higher number of gamification tactics (on-screen features) such as story or theme, avatars, a graphic representation of story characters, fun videos, and sound effects.

Table 3. Number of gamification strategies and tactics (n=32).

	Value, n (%)	Reference
Gamification strategies		
Fun and playfulness	23 (72)	[46-53,55,56,59,63-67,71,73,75,76,78,79,81,82]
Feedback on performance	17 (53)	[47-53,56,57,62,64-66,69-73,76,81,82,83]
Reinforcement	17 (53)	[47-54,57,58,62,64-67,69,72-77,79-82,83]
Goal setting	14 (44)	[46-52,54,57,59,60,63,68,70,72,78,81,82]
The capacity to overcome challenges	7 (22)	[46,50,53,57,72,74,75,78]
Compares progress	5 (16)	[47-49,58,71,78,81,82]
Social connectivity	4 (12)	[54,60,61,79]
Gamification tactics		
Feedback	18 (56)	[47-53,56,57,62,64-66,69-73,76,81,82,83]
Points	14 (44)	[47-51,54,57-60,64,65,69,74,79,81,82]
Story or theme	14 (44)	[51,52,55,56,63-67,73,75,76,78,79,81,82,83]
Gives rewards	13 (41)	[47-54,62,66,67,72,73,76,79,81,82,83]
Provides clear goals	11 (34)	[46,50-52,54,60,63,68,70,72,78,81,82]
Offers a challenge	8 (25)	[46-50,53,57,65,67,72,75,78]
Levels	7 (22)	[47-49,51,58-60,68,74]
Shows progress	7 (22)	[47-49,53,58,64,71,78,81,82]
Provides badges for achievements	3 (9)	[50-52,72]
Shows game leaders	0 (0)	—[a]

[a]Not applicable.

Furthermore, more than half (17/32, 53%) of mobile apps adopted feedback on performance and reinforcement (17/32, 53%). This finding is consistent with the high presence of on-screen features such as visual and verbal feedback, providing points and stars, and giving monetary and nonmonetary rewards upon completing a specified task. Finally, social connectivity was the least common gamification strategy observed in the apps (4/32, 12%), resulting from a low presence of on-screen social connectivity features. Only 12% (4/32) apps provided a social connection like a chat room for users where they can send messages [54,60,61,79]. The most common tactics, meanwhile, were feedback, points, and rewards. None of the apps displayed who the game leaders were.

Table 4 demonstrates the levels of gamification strategies and tactics adopted by 32 gamified mobile apps. Only 1 (3%) app did not adopt any gamification tactics [61]. Although more than half (18/32, 56%) of the mobile apps had adopted a medium level of gamification strategies, only 25% (8/32) of the mobile apps had incorporated a medium level of gamification tactics, known as on-screen features.

Table 4. Level of gamification incorporated in mobile apps (N=32).

	Value, n (%)	Reference
Number of gamification strategies adopted		
0 (none)	0 (0)	—[a]
1-2 (low)	13 (41)	[55,56,58-63,67-70,74]
3-5 (medium)	18 (56)	[46-49,51-54,57,64-66,71-73,75,76,78,79,81,82,83]
6-7 (high)	1 (3)	[50,72]
Number of gamification tactics adopted		
0 (none)	1 (3)	[61]

4-7 (medium)	8 (25)	[47-53,64,72,78,81,82]
8-10 (high)	0 (0)	—

[a]Not applicable.

We identified the rationale for using gamification in apps in 16 (42%) of the 38 included studies. Multimedia Appendix 4 [50-52,56,57,60,62-66,76,77,80-82] presents the complete results. The two most cited reasons were (1) to promote user engagement and motivation and (2) to increase the intervention effects. Some of the underlying reasons for the first theme are as follows: encourage use [52,65] and increase engagement with the intervention [50,81]. For example, the SMART app and FarmApp provided feedback on performance and offered different reinforcement features to keep users more involved with the app content [52,65].

Regarding the second theme, the researchers applied gamification to enhance learning [51,56,63,64] and increase intervention efficacy [66,76,81,82]. As an example, the Zingo app incorporated a digital pet where users, by adhering to the prescribed therapies in the app, receive stars to make changes to avatars. In addition, children and clinicians can monitor their weekly progress in the app.

Discussion

Principal Findings

This scoping review aimed to offer an overview of existing research using gamification in mobile apps for children with disabilities. A total of 38 studies and 32 unique mobile apps were identified, and most incorporated a limited number of gamification strategies and tactics. Of the 32 apps, 18 (56%) were specifically designed for children with ASD, while 14 (44%) were for children with other types of disabilities.

Social communication impairments are a clinical indicator of ASD [84]. Notably, mobile apps designed for children with ASD identified in this scoping review were predominantly focused on enhancing communication and social skills [46,49,63,72]. Our review found that 2 educational apps were designed specifically for children with ASD to acquire knowledge and skills related to oral health [79,83].

This review identified 4 (12%) of the 32 mobile apps that specifically target the self-management of children with disabilities. Previous research indicates that effective self-management behaviors could enhance health-related outcomes in children with complex needs [85]. Self-management interventions for individuals with intellectual disabilities primarily target self-management in the workplace, self-management of medical conditions, and self-management of daily activities [86]. Similar to the previous literature, the 4 (12%) mobile apps identified in this review focused on the management of symptoms in children with ASD [60], traumatic brain injury [52,80], and concussion [70] and on managing the daily routines of children with ASD [62].

Children with developmental delays, including those with learning disabilities, ASD, and attention-deficit/hyperactivity disorder, generally have lower academic achievements than those without developmental delays. The most impacted domains are cognitive, attention and memory, visual-motor skills, and behavioral functioning [87]. Similarly, several mobile apps identified in this review targeted memory [60], reading skills [73], letter recognition [66], multiple cues for responding [67], concentration and impulse control abilities [68], audiovisual speech perception [71], and behavioral skills [78] to help children with disabilities attain a higher level of academic achievement.

The major objective of the 9% (3/32) assessment mobile apps in this review was to assess users' cognitive control and memory [65], visual acuity [76], and screen children with attention-deficit/hyperactivity disorder [75]. These apps did not focus on any specific changes in behavioral, developmental, or other health-related outcomes.

The Gamified Apps and Their Impact

The findings of our scoping review shed light on the relationship between gamified mobile apps and health-related outcomes in children with different disabilities. Multimedia Appendix 5 [46,48-50,54,57-59,64,72-74,77,83] provides a comprehensive overview of 15 studies that have reported the impact of gamified mobile apps as interventions across different populations and conditions. Quantitative studies show mixed results, with significant improvements in targeted health-related outcomes such as social responsiveness, language skills, and visual acuity. However, studies with comparison groups often reveal that traditional methods (eg, patching for amblyopia) may still be more effective in some cases. For example, in 3 studies on children with amblyopia (a type of visual disorder where usually one eye gets poor vision), the 3 mobile apps had treatment goals that aimed to improve the visual acuity of these children. The results of 2 RCT studies showed an improvement in visual acuity using the mobile app [58,59], whereas in 1 RCT, there was no difference in visual acuity level using the mobile app compared to traditional intervention (patching) and even was less effective [74].

Furthermore, gamified systems can intrinsically motivate individuals to start and maintain the execution of healthy behaviors [88]. A meta-analysis by Bai et al [89] showed that gamification can improve student learning outcomes by fostering motivation among learners. In addition, 2 studies using the LexiPal mobile app among children with dyslexia focused on psychological outcomes such as motivation and engagement [51,77]. The study by Cahyono [77] showed that LexiPal has the potential to increase extrinsic motivation through a reward system and intrinsic motivation through activity levels and fun features; however, a longer intervention is necessary to assess the impact of gamification on long-term motivation and engagement of learners.

Moreover, the importance of user preferences and the need for more personalized gamification is highlighted. For example, the variability in the effectiveness of mobile apps in children with different levels of disability in 2 (5%) of the 38 identified studies suggests that personalization is crucial [46,49]. Personalized (or adaptive) gamification is a method for enhancing the design of game-based systems by tailoring tasks, game rules, and features to match each user's preferences or skill level [90]. Personalized gamification can be implemented through (1) customization, where users can select the elements they wish to use, and (2) automatic adaptation, in which the system selects the game design elements for each user, potentially with some user input. Therefore, developers and researchers are encouraged to consider integrating personalized gamification elements into their apps to improve user engagement and, consequently, the effectiveness of mobile apps on health-related outcomes.

Finally, it is noteworthy that most (11/15, 73%) identified studies with an intervention did not have comparison groups, which makes it challenging to draw definitive conclusions regarding the effectiveness of various mobile apps.

Gamification Strategies and Tactics

Following the gamification framework proposed by Cugelman [12], the most common gamification strategies were fun and playfulness, feedback on performance, reinforcement, and goal setting, whereas social connectivity was the least commonly used strategy, followed by comparing progress. Moreover, feedback, points, story or theme, and rewards were the most common on-screen features, while showing game leaders (leaderboards), badges, and showing progress were the least common elements applied to mobile apps.

The fun and playfulness strategy (23/32, 72%) was the gamification principle most applied to mobile apps. There was frequent use of on-screen tactics such as stories, themes, avatars, graphic representations of information, fun videos, and audio effects. Incorporating these features requires a significant amount of computational resources, time, and knowledge [91]. Most (23/32, 72%) of the mobile apps in this review had comparable playfulness elements to enhance children's experience of fun and motivate them to use the app on a regular basis. Previous studies showed that playful and fun experiences in mobile apps will increase positive attitudes toward mobile apps when the users can engage in pleasurable experiences [92,93].

Feedback on performance and reinforcement were among the most frequently used gamification strategies in mobile apps. This finding aligns with the results of previous research identifying successful behavior-change techniques in gamified mobile apps [56]. Previous reviews on gamification in other populations found that 94% and 81% of health apps had incorporated feedback on performance and reinforcement, respectively, and achievement- and progress-oriented elements such as in-app rewards [12,94]. In our scoping review, the most prevalent types of reinforcement were points (14/32, 44%) and tangible rewards (13/32, 41%), aligning with previous reviews, and indicating a positive direction toward promoting health behavior change through these strategies. This finding also emphasizes that easy-to-implement game features, such as points and feedback through messaging are the most widely used gamification features to promote engagement and motivation [94]. Nevertheless, the outcomes were frequently measured only through in-app behavior (eg, completing tasks in the app for rewards).

We found that achievement- and progress-oriented rewards were given to users as a result of their change in specific behaviors, such as completing cognitive assessments [65] or participating in daily language test challenges [66]. For instance, when children with ASD used the TOBY iPad app, an early intervention tool, they had to choose a specific picture from a set of pictures. Upon completing the task, they would gain tokens (points), which could be used to choose a reward [47-49].

Another app, LexiPal, an educational app for children with dyslexia, used various game elements, such as points, feedback, and rewards. Upon successfully completing 1 round of tasks, a pop-up window would appear to illustrate the score and reward. If the child gets a score of 4 to 5, they earn a golden cup reward and receive text and audio feedback [51]. Users were rarely rewarded for behavior changes external to the app. For instance, in the Urakami app, users who completed outpatient therapy sessions could collect points, which could be exchanged to purchase in-app avatars [54].

A growing body of literature has criticized the paucity of use of incentives through points, badges, and leaderboard elements in digital health solutions [95]. Points were among the most frequently applied game elements in our review, whereas badges and leaderboards were incorporated by a minority of apps. Many studies have investigated the effectiveness of a combination of points, leaderboards, and badges to increase outcomes such as engagement in physical activity. Several studies have shown that the application of these game features could significantly enhance individuals' physical activity [20]. In contrast, several studies found that points and leaderboards did not significantly impact walking compared to a nongamified version of the same app [96,97]. In addition, Maher et al [98] found that a combination of rewards and leaderboards led to a short-term increase in physical activity but there was no long-term positive impact on health behavior. Further research is needed to investigate the impact of using game features for short- and long-term impacts in the childhood disability field.

Goal setting is a known intervention strategy for successful health behavior change [99]. In our review, 44% (14/32) of the mobile apps used goal setting to promote user engagement. Previous research has outlined that combining goal setting with showing progress, feedback, and rewards can significantly enhance intrinsic motivation toward behavior [100]. Although feedback and rewards have been extensively applied to the identified apps in our review, comparing progress elements has been underused. There is a vast amount of literature on the possible benefits of rewards and feedback, yet each element's effectiveness still needs to be determined [101]. Another concern is that these features may enhance extrinsic motivation rather than intrinsic motivation, which leads to the weak maintenance impact of gamified apps [102]. Therefore, we recommend further investigating the independent effects of individual mobile-based gamification elements on children with disabilities.

Despite the potential advantages of social connectivity on young people's well-being [103], only 4 (12%) of the 32 apps implemented a social connectivity strategy. They provided the users with access to chat rooms [61], the ability to share the points with parents [60], and the ability to send messages to parents and health professionals [54,79]. The scarcity of social connectivity options found in our review contrasts with previous research indicating that social networks could positively impact health behavior change insofar as app users can interact with other users and share their points and experiences with one another. [103,104]. A recent review identified several social support features where app users could interact with others through sharing posts and sending private messages [105]. However, previous studies highlighted the potential negative aspects of social connectivity in mobile apps. For example, concerns were raised about inappropriate content sharing and messaging between children and information inaccuracy in the technology space [106,107]. Therefore, while much research on the potential effectiveness of social connectivity has been carried out, some critical issues need to be investigated in the childhood disability field. Moreover, no apps provide leaderboards. This may suggest a deliberate decision in the design, as children with disabilities are generally a particularly susceptible group who may experience increased levels of stress when comparing themselves to their peers [108,109]. A meta-analysis of qualitative studies of students shows that gamification can cause anxiety and jealousy among students [89]. For example, Johnson et al [81] did not incorporate some traditional gamification elements, such as badges and leaderboards, considering the needs of children with neurodevelopmental disabilities in their study. Therefore, researchers in this field should investigate the specific needs and potential stressors of children with disabilities when considering the incorporation of gamification elements such as leaderboards.

Level of Gamification and Reasons to Apply Gamification

This review highlights that most (18/32, 56%) identified apps implement a medium level of gamification strategies and a low level of gamification tactics, with few (1/32, 3%) adopting a high level of gamification strategies or tactics. The Guess What app used the greatest number of gamification tactics (6 of 7). All identified apps in our review used at least 1 gamification strategy, which supports previous research findings that gamification is meant to significantly improve psychological outcomes [110,111]. While gamification tactics, also known as on-screen features, are considered to be part of persuasive app design to promote engagement and motivation [12], most identified apps implemented a low (23/32, 72%) number of gamification tactics. Children with disabilities are an underserved group that faces numerous barriers to accessing health services [112]. Designing digital solutions for children with disabilities requires collaboration among childhood disability researchers, mHealth experts, and children and their families. The provision of these solutions such as gamified mobile apps for children with disabilities has the potential to reduce health inequities.

However, the level of incorporated gamification tactics should be interpreted with caution in our review. One vital theoretical issue is that multiple gamification frameworks have different definitions of gamification and categorizations of game elements. For example, Lister et al [11] used "gamification" to define levels, rewards, prizes, and competitions but not avatars; meanwhile, Johnson et al [110] used "gamification" to describe all these game elements. Similarly, multiple studies separate feedback and rewards [11,113], whereas Sardi et al [9] counted them as 1 game mechanic. Although we used the framework proposed by Cugelman [12] to define gamification in our study, it would be difficult to make a definite conclusion regarding the level of gamification, as the number of game elements varies in different frameworks. Therefore, there is a need to have a solid framework for mobile-based gamification for childhood disabilities.

Furthermore, researchers applied gamification to apps for various purposes. We found justification for applying particular game elements in 16 studies. Of the 16 studies, 9 (56%) used gamification elements to promote engagement and motivation. Gamification aims to include playful elements to transform a typically boring activity into one that is enjoyable and engaging [9]. For example, FarmApp, which is a mobile app used to assess cognitive skills among children with neurodevelopmental disabilities, incorporated interactive game-like elements to be more motivating and enjoyable for children to complete the assessments [65]. In addition, the SMART app, which is for the self-management of children with traumatic brain injury, was redesigned and implemented gamified components to encourage youth with mild traumatic brain injury to use the app daily and manage their symptoms [52]. These findings align with the purpose of gamification as a tool to increase engagement and motivation [10,12].

In contrast, gamification was also applied to increase the impact of the intervention. Many mobile apps included game elements to increase the efficacy of the intervention. For instance, gamification was used in the ColourSpot app to encourage users to complete the intervention [76]. In the Dyslexia Baca app, visual graphics were incorporated to assist children with dyslexia in understanding the intervention instructions [66]. In another example, Johnson et al [81] used various gamification tactics, such as avatars, weekly progress monitoring, and earning stars, to engage children in their therapy prescription app. These justifications align with the previous literature showing that engaging apps, such as gamified apps, can enhance the effectiveness of interventions by encouraging users to use them consistently and frequently [114]. Although the capacity of gamification to promote engagement and motivation has been extensively studied [10,12,110], more research is needed to confirm the ability of gamification to increase intervention efficacy.

Limitations and Recommendations

Although this scoping review was guided by the PRISMA-ScR framework [42], it has some limitations. First, the primary aim of our review was to summarize a record of all gamified apps for children with disabilities from 2008 to 2023; however, we did not assemble any information on the effectiveness of gamified apps on any evaluation metric. By including broad search keywords in the search strategy, we had a high volume of document titles and abstracts to screen. Nevertheless, this enhances the risk of accidental exclusion of relevant citations. To minimize this, before both abstract and full-text screening, we performed pilot testing on a random sample of documents, and any discrepancies were resolved by KS. This ensured that the title and abstract screening was appropriate before the full-text screening.

In addition, although our scoping review was inclusive (no restrictions on study design), we excluded studies of children with mental concerns (eg, anxiety and depression) or other health issues (eg, obesity and cancer). Given the unique characteristics of mental health problems in children and adolescents, we recommend an independent review of gamified mobile apps for children with mental health issues.

Furthermore, unpublished studies were not included in this scoping review. Because many mHealth apps are privately designed, development or evaluative information for these apps is not available in the public domain, which may result in a substantial knowledge gap. Although private companies have been increasingly transparent in publishing data in recent years [115], this knowledge gap cannot be addressed in this scoping review. Therefore, the results of this review are not generalizable to commercial apps for children with disabilities.

Although the consultation exercise is a vital yet optional component of the scoping review framework proposed by Arksey and O'Malley [41], it was not conducted in this review. Specifically, we are conducting a separate project to seek out stakeholder input to further inform this area of research. The primary author (EM) used the results of this scoping review to inform the interview guide of a qualitative project where different stakeholders, including children and youth with disabilities, parents or caregivers, clinicians, and representatives of community organizations, shared their perspectives about different gamification elements. The findings from this research will not only enhance the results of our scoping review but also make an important contribution to the deeper understanding of best practices in developing gamified mobile apps for children with disabilities.

Scoping reviews aim to rigorously survey the current body of literature and identify crucial concepts, types of evidence, and knowledge gaps. Typically, they are not structured to evaluate the effectiveness of the interventions. In accordance with this methodology, our review did not assess the effectiveness of the identified gamified mobile apps; however, we reported a summary of the mobile app's impact on child outcomes. Indeed, systemically evaluating the effectiveness would be challenging, given the considerable heterogeneity in the types of disabilities, mHealth strategies used, and the wide range of outcomes applied. Recognizing this limitation, there is a need for future research to evaluate the effectiveness of these gamified mobile apps on specific populations and outcomes.

Finally, limited evidence was provided in this review on the extent to which health behaviors "outside the app" were augmented in children with disabilities, and its association with the gamification features proposed. Johnson et al [110] conducted a review to assess the impact of gamified interventions on health and well-being in a broader population indicating that gamification could have a positive impact on healthy behaviors (eg, physical activity). Future research should investigate the association of gamification features in mobile apps with subsequent healthy behaviors "outside the app" for children with disabilities.

Conclusions

This review provides a summary of the current literature on mobile-based gamification used for children with disabilities reported after 2008. A total of 6 databases were comprehensively searched, and 38 studies with 32 unique apps were identified that focused predominantly on treatment goals and were in most cases used in children with ASD. This review demonstrates that gamified mobile apps for children with ASD are mainly designed to enhance communication, social skills, and oral health knowledge. In addition, several mobile apps address self-management in various conditions, academic achievements in learning disabilities, and psychological outcomes such as motivation and engagement, demonstrating their potential in improving diverse health-related outcomes in children with disabilities. The results of this study showed that gamification could provide potential benefits across different populations and conditions; however, there were mixed results regarding its impact and benefits. These results can guide other researchers in the childhood disability field in recognizing disabilities or behavioral outcomes that have been neglected, thus informing future mobile app development and research on those disabilities. Collectively, this information will enable the researchers in this field to understand how gamification can improve intervention effects on relevant outcomes and meet the specific needs of this population.

Acknowledgments

The authors would like to express their gratitude to Ms Jill Boruff, an associate librarian at McGill University, for her valuable support in developing the search strategy.

This project was supported by the CHILD-BRIGHT Strategic Patient Oriented Research Network- Canadian Institutes of Health Research and the TELUS Friendly Future Foundation.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files.

Authors' Contributions

All authors were involved in the design and development of the study protocol, which was undertaken as part of a PhD for EM under the supervision of KS. EM and RC contributed to the database search. EM, PYY, and AC contributed to abstract and full-text screening and data extraction. EM wrote the first draft of the paper, and all authors agreed to be accountable for all aspects of the research project and approved the final manuscript.

Abstract

Background: Among the older population, Parkinson disease (PD) stands out as a leading contributor to disability. Clinically, the foremost objectives in managing PD involve proactively delaying and preventing disability. Understanding the pivotal role of gait and balance in daily functionality holds substantial clinical significance, signaling imminent disability and prompting a reevaluation of management approaches. A key priority lies in identifying novel and effective interventions for symptoms that substantially contribute to disability.

Objective: This paper presents a systematic review that critically examines the existing body of literature on the use of technology in the rehabilitation of older patients with PD. By synthesizing current evidence, we aim to provide insights into the state of the field, identify gaps in knowledge, and offer recommendations for future research and clinical practice.

Methods: A systematic review of the literature was conducted in September 2023 analyzing manuscripts and papers of the last 5 years from the PubMed, Scopus, Embase, Web of Science, and CINAHL databases following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. A total of 14 papers were included. The inclusion criteria are as follows: (1) randomized controlled trial, (2) PD in people aged 65 years and older, and (3) use of technology in the rehabilitation training in the older population.

Results: A large portion of effective interventions relies on the incorporation of technology, particularly through virtual reality exergames. This technology appears to have effects not only on the cognitive aspect but also on the physical domain. The analysis of the results clearly indicates that, in terms of gait and balance performance, the technological intervention outperforms the traditional approach, irrespective of the specific technology employed.

Conclusions: This systematic review seeks to shed light on the evolving landscape of technology-assisted rehabilitation for older individuals with PD. As we delve into the available evidence, we will assess the extent to which technology can serve as a valuable adjunct to conventional therapy, offering new avenues for optimized care and improved outcomes in this growing patient demographic. As we sift through the existing evidence, our goal is to evaluate the potential of technology as a valuable supplement to traditional therapy, presenting fresh opportunities for enhanced care and better outcomes in this expanding patient demographic.

KEYWORDS

technological intervention; Parkinson disease; randomized controlled trail; older adults; efficacy

Introduction

Neurological disorders stand as the primary cause of global disability [1]. Within this category, Parkinson disease (PD) is exhibiting the most rapid increase in disability, fatalities, and prevalence, with an anticipated doubling within the next 2 decades [2]. In Europe, the current PD population exceeds 1.2 million, contributing to an annual economic burden of €13.9

billion (US $15.5 billion) [3]. The annual cost per individual rises with the severity of the condition, while nonmotor symptoms significantly contribute to hospitalizations and institutionalizations. Beyond the challenging aspects of PD itself, individuals with PD grapple with notable comorbidities and a high frequency of falls [4]. Aging is correlated with an accelerated motor progression of the disease; reduced responsiveness to levodopa; heightened severity in gait, posture, and cognitive impairment; and an increased likelihood of developing dementia [5].

With the aging of the global population, the prevalence of PD is on the rise, making it an increasingly significant public health concern. Effective management and rehabilitation strategies are essential to mitigate the debilitating effects of this condition and to enhance the functional independence of older individuals living with PD.

From a clinical perspective, the top priorities in PD management include the delay and prevention of disability [6]. Despite symptomatic relief through medical, surgical, and rehabilitative interventions, older individuals with PD experience a persistent deterioration in disability, marked by a decline in quality of life, diminished functional mobility, decreased performance in daily activities, and worsening neurological impairments. Guidelines suggest early initiation of physical therapy at the onset of the disease for addressing functional decline [7]. However, the evidence regarding its effectiveness in delaying symptom onset or reducing severity is not robust. Recognizing the crucial role of gait and balance in daily function has significant clinical implications, indicating impending disability and necessitating a reassessment of management strategies. The identification of new and effective interventions for symptoms contributing to significant disability is a key priority [8]. In particular, there is a growing body of evidence indicating that exercise and physical activity interventions can slow the rate of functional mobility decline, ultimately improving quality of life, as tertiary prevention solutions [8].

Over the years, advances in technology have revolutionized the field of health care, offering innovative tools and interventions for the diagnosis, monitoring, and treatment of various medical conditions. In recent decades, there has been a growing interest in harnessing the potential of technology to aid in the rehabilitation of patients with PD, particularly in the older population. This shift reflects a broader trend toward incorporating digital solutions into health care, driven by the desire to optimize therapeutic outcomes and improve the overall well-being of patients.

For this reason, recent research [9-11] indicates that balance training delivered through technology leads to performance enhancements that align with noticeable neurobiological changes in the cerebral cortex [9,10]. This underscores the encouraging potential of technological interventions in aiding individuals with PD in managing balance and other motor disorders.

This paper presents a systematic review that critically examines the existing body of literature on the use of technology in the rehabilitation of older patients with PD. By synthesizing current evidence, we aim to provide insights into the state of the field, identify gaps in knowledge, and offer recommendations for future research and clinical practice.

In this comprehensive review, we will explore a wide range of technological applications, including wearable devices, telerehabilitation platforms, virtual reality systems, and robotics, among others. We will evaluate the effectiveness, usability, and safety of these technologies in improving motor function, balance, mobility, and overall quality of life in older patients with PD. Furthermore, we will consider the potential challenges and ethical implications associated with the integration of technology into rehabilitation protocols for this vulnerable population.

Methods

Overview

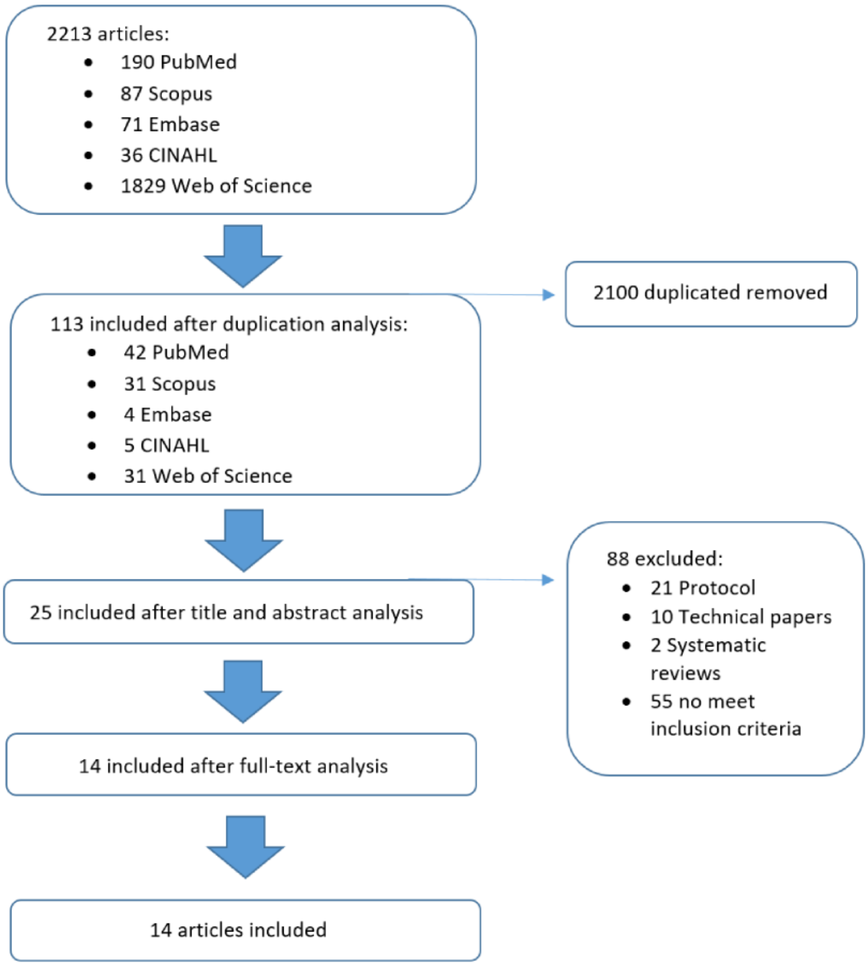
The methodology of this systematic review was based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 1 [12]) [13], with the main aim of analyzing the use of technology in the rehabilitation of older patients with PD.

We used the PICO (Population, Intervention, Comparator, Outcome) framework as follows:

- P: Older patients with PD
- I: Rehabilitation program with technology
- C: Control group that receives a traditional rehabilitation program
- O: The efficacy of the treatment

A systematic review of the literature was conducted in September 2023. The data were collected from PubMed, Embase, Scopus, CINAHL, and Web of Sciences, analyzing manuscripts and papers of the last 5 years (from September 2018 to September 2023) in order to obtain the latest evidence in the field. The inclusion criteria were as follows: (1) randomized controlled trial, (2) PD in people aged 65 years and older, and (3) use of technology in the rehabilitation training in the older population. Systematic and narrative reviews were excluded. Based on consultation with the multidisciplinary research team, technological intervention studies were searched using the following search terms and the combination thereof: Parkinson, rehabilitation, technology, old*, elder*, effectiveness, randomized control trial. The detailed search strategy used in each database is reported in Multimedia Appendix 2. After the preliminary search, 190 papers resulted from PubMed, 71 from Embase, 87 from Scopus, 36 from CINAHL, and 1829 from Web of Sciences. Since the CINAHL database was consulted only after the first round of searches and after the duplicate analysis, a different filtering of the results was chosen. In fact, in order to narrow down the number of results, we looked for papers containing the term “randomized control trial” in the title. The findings were analyzed and screened by 4 experts of the team: a bioengineer, a clinical neurologist, a psychologist, and a physiotherapist. Rayyan software has been used in order to remove duplicates. Identified studies were independently reviewed for eligibility in a 2-step process; a first screening was performed by 4 independent authors (EM, GP, RB, and MB) based on the title and abstract. Then, full texts were retrieved for a second screening by the same 4 authors. At both stages, disagreements among reviewers were resolved by consensus and discussed with the other 2 authors (GA and VDD). After these steps, 25 papers resulted from selected databases. An additional researcher, with a background in biomedical engineering, confirmed the accuracy of the papers' selection and screened for any possible omission. After the screening based on the inclusion or exclusion criteria, conducted on the full-text papers, 14 studies were selected. Figure 1 shows the flowchart search strategy applied. Data extraction, performed by 2 independent raters (EM and MB) included full reference details, sample size, study population details, including gender and mean age, type of technology used, outcomes, and results.

Figure 1. Descriptive analysis of the included clinical studies.



Quality appraisal of included studies was carried out by applying the PEDro scale suggested for evidence-based reviews [14]. The final score was settled when 3 authors reached agreement after repeated review and analysis.

Data Synthesis

A descriptive synthesis of the data was performed. The data were grouped and analyzed based on the types of technological interventions used and their reported outcomes. The main areas of focus included cognitive and physical functioning, specifically gait and balance performance. The synthesis aimed to identify common findings and trends across the studies, highlighting the efficacy of technological interventions compared with traditional rehabilitation methods. No meta-analysis was conducted due to the heterogeneity of the study designs, interventions, and outcome measures.

Results

Study Quality Evaluation

A total of 14 papers were included [15-28]. Findings reported in this section are organized under macroconcept areas of interest.

Table 1 reports the quality evaluation of 14 population-based studies. In particular, the PEDro score ranged from 6 to a maximum of 8. The descriptive analysis of the technological intervention and devices used in the studies selected is shown in Multimedia Appendix 3.

Table 1. Scores of methodological quality assessment of the included studies.

[a]Y: yes.
[b]N: No.

General Characteristics of the Study Population

All the studies were focused on older people with PD with a mean age of 69.8 (SD 14.4) years for the technological intervention group and mean age of 70.3 (SD 7.3) years in the control group. The number of participants involved in all the studies is 578, ranging from a minimum sample of 18 patients to a maximum of 128. There were 297 males and 281 females.

Descriptive Analysis and Outcome Measures

Table 2 shows the characteristics of the included studies. All studies evaluated the impact of technological interventions on physical and cognitive domains. Regarding evaluated domains, cognitive functioning was assessed by 4 studies [16,17,20,22] and physical functioning was assessed by 13 studies [15,17-28], including gait assessment [15,17-20,23-25,27,28] in terms of gait speed or gait performance, falls and fear of falling evaluation [15,18,19,28], and balance estimation [16-18,20,21,24,28]. Examining the technology employed, there is a notable preference for using treadmills coupled with virtual reality and exergames [15,17,18,27]. In addition, numerous studies [16,19,23,24,28] incorporate sensitive pressure platforms, both static and dynamic, often in conjunction with nonimmersive virtual exercises. However, for the specific pathology under consideration, the use of exoskeletons [20] or gait robots [23] appears to be more restricted. It is worth noting that nearly all studies consistently incorporate virtual reality—whether immersive with visors or caves, or nonimmersive through exergames. This technology appears to have effects not only on the cognitive aspect but also on the physical domain. The analysis of the results clearly indicates that, in terms of gait and balance performance, the technological intervention outperforms the traditional approach, irrespective of the specific technology employed. However, from a cognitive perspective, the improvement is limited.

Table 2. Descriptive analysis of the included clinical studies.

	Population		Technology	Outcomes	Results
	Participants in EG[a]	Participants in CG[b]			
Del Din et al [15]	N=66 (older fallers with PD[c]); 81 male/47 female, aged 78.03 (6.21) years (older fallers with PD). HY[d] stage: 2-3	N=62 (older fallers with PD)	Treadmill plus virtual reality	*Primary*: FRA[e] index. *Secondary*: walking activity (total walking time per day, percentage of walking time per day, number of bouts, and steps per day)	*Between*: FRA was higher in PD compared with older fallers and MCI[f] (*P*=.043). Walker activity was lower in MCI and patients with PD compared with older fallers (*P*<.012) *Within*: Walking activity did not change. FRA significantly decreased for all groups following both interventions (treadmill reduced FRA by 26%; treadmill + VR[g] by 39%)
Jäggi et al [16]	N=19 (older people with PD); 12 male/7 female; aged 71.89 (9.09) years. HY stage: 1-4	N=21 (older people with PD); 15 male/6 female; aged 72.86 (10.14) years. HY stage: 1-4	Cognitive-motor training on the exergame device. Dividat Senso, a pressure-sensitive platform	*Primary*: feasibility (adherence rate; attrition rate; occurrence of adverse events; SUS[h], NASA TLX[i] score) *Secondary*: cognitive (Go/no go test; RTT[j]; D-KEFS[k]; TMT[l]); motor (gait speed; SPPB[m]; TUG[n]; 5×StS[o])	*Primary*: Overall adherence rate was 96.5%. EG had an adherence rate of >70%. *Secondary*: no differences between EG and CG. Significant time-group interaction effects for 5×StS, SPPB, RTT, go/no go test, and D-KEFS
Lau et al [17]	N=9 (older people with PD); 6 male/3 female; aged 64 (9) years. HY stage: 1-3	N=9 (older people with PD); 6 male/3 female; aged 71 (5) years. HY stage: 1-3	Treadmill combined with a first-person immersive video game targeting visuospatial skills and working memory.	*Primary*: motor outcomes (6MWT[p], TUG, TUG cognitive) *Secondary*: cognitive outcomes: (MoCA[q], verbal fluency, SDMT[r])	*Primary*: EG improves gait speed and walking distance during 6MWT, TUG cognitive (*P*=.05). EG improves TUG cognitive more that CG (between group: *P*=.04) *Secondary*: EG improves MoCA (*P*=.007) and SDMT (*P*=.01)
Kim et al [18]	N=22 (older people with PD); 6 male/16 female; aged 68.7 (6.9) years. HY stage: 2-3	N=22 (older people with PD); 7 male/15 female; aged 67.5 (9.3) years. HY stage: 2-3	Robot-assisted gait training (treadmill-based exoskeleton robot)	*Primary*: gait speed on the 10mWT[s] *Secondary*: dual task interference on gait speed on the 10mWT, balance (TUG), disability score (BBS[t]), fear of falling (MDS-UPDRS[u]), freezing of gait (KFES-I[v]), brain functional connectivity changes (NFOGQ[w])	*Primary*: no significant difference in gait speed on the 10mWT *Secondary*: EG shows significant improvements in BBS score and in MDS-UPDRS score. *Between*: EG shows significant difference in MDS-UPDRS
Maranesi et al [19]	N=16 (older people with PD); 6 male/10 female; aged 72.7 (6.3) years. HY stage: 2-3	N=14 (older people with PD); 5 male/9 female; aged 75.5 (5.4) years. HY stage: 2-3	Tymo system (wireless platform with nonimmersive virtual reality exergame)	*Primary*: POMA[x] balance, POMA gait, and POMA total *Secondary*: gait speed, fear of falling (FES-I), autonomy in daily living activities (Barthel Index), and physical and psychological state of the patients (12-item Short Form Survey)	*Primary: Between*: POMA balance and POMA gait (EG vs CG) *Secondary*: *Between*: Barthel Index, 12-item Short Form Survey (EG vs CG)
Gryfe et al [20]	N=13 (older people with PD); 4 male/9 female; aged 67.6 (5.9) years. HY stage: 2-3	N=14 (older people with PD); 7 male/7 female; aged 70.7 (7.3) years. HY stage: 2-3	Gait robot (exoskeleton)	*Primary*: cognitive function (SCOPA-COG[y]) and mood *Secondary*: gait speed, 6MWT, freezing of gait, balance, and quality of life	*Primary*: significant improvement in SCOPA-COG in EG than in CG *Secondary*: significant improvement in 6MWT in EG than in CG

	Population		Technology	Outcomes	Results
	Participants in EG[a]	Participants in CG[b]			
Feng et al [21]	N=14 (older people with PD); 7 male/7 female; aged 67.5 (4.8) years. HY stage: 2-4	N=14 (older people with PD); 8 male/6 female; aged 66.9 (4.6) years. HY stage: 2-4	Virtual reality technology	Motor ability (BBS, TUG, UPDRS-III, and FGA[z])	*Within*: BBS, TUG, and FGA improve significantly in EG and CG (*P*<.05). *Between groups*: BBS, TUG, UPDRS-III, and FGA in EG are better than in EG (*P*<.05).
Cikajlo et al [22]	N=10 (older people with PD), 4 male/6 female, aged 71.3 (8.4) years	N=10 (older people with PD), 5 male/5 female, aged 67.6 (7.6) years	Immersive VR using 3D Oculus Rift CV1	*Primary*: effectiveness of treatment (BBT, UPDRS) *Secondary*: motivation effect (Motivation Inventory)	*Primary*: time of manipulation (group × time, *P*=.009), number of successfully placed cubes (group × time, *P*=.028), average tremor (group × time, *P*=.002), and UPDRS for upper limb (U3=0.35). The LCD and 3D groups substantially improved their BBT score with training (U3=0.7, U3=0.6, respectively).
Capecci et al [23]	N=48 (older people with PD), 19 male/29 female, aged 68.1 (9.8) years. HY stage: ≥2	N=48 (older people with PD), 24 male/24 female, aged 67.0 (7.6) years. HY stage: ≥2	GE-O system	*Primary*: motor function (6MWT, TUG, 10MWT, minimal clinically important difference) *Secondary*: Freezing of Gait Questionnaire, UPDRS	Both groups showed significant improvement in all outcomes. As compared with baseline, with robot-assisted gait training and treadmill training, endurance and gait capacity were enhanced by 18% and 12%, respectively, and motor symptoms and quality of life were improved by 17% and 15%, respectively. The maximum advantage was observed with the Freezing of Gait Questionnaire score, which decreased by 20% after either treatment.
Spina et al [24]	N=11 (older people with PD), 5 male/6 female, aged 68 (6.9) years. HY stage: 1-2	N=11 (older people with PD), 4 male/7 female, aged 67.27 (4.85) years. HY stage: 1-2	Hunova (robotic platform)	*Primary*: Quantified balance impairments (mini-BESTest, BBS) *Secondary*: Motor ability (10MWT, 5×StS, PDQ-39[aa], TUG)	*Between*: no significant differences *Within*: primary outcomes improved in EG and CG.
Pazzaglia et al [25]	N=25 (older people with PD), 18 male/7 female, aged 72 (7) years	N=26 (older people with PD), 17 male/9 female, aged 70 (10) years	Nirvana (VR system)	*Primary*: changes in functional standing balance (BBS) *Secondary*: ability to adapt gait to complex walking tasks (DGI[ab]); physical function of the upper limb (DASH[ac]); and physical and emotional scores (SF-36[ad])	*Between*: in EG increases BBS score (*P*=.003), DGI score (*P*=.003), and SF-36 mental composite score (*P*=.037), and a decrease in DASH scale score (*P*=.009). In CG DASH scale score decreases (*P*=.007).
Yuan et al [26]	N=12 (older people with PD), 2 male/10 female, aged 67.8 (5.5) years. HY stage: 1-3	N=12 (older people with PD), 9 male/3 female, aged 66.5 (8.8) years. HY stage: 1-3	Video game–based treatment	*Primary*: Quantified balance impairments (BBS score) *Secondary*: Quality of life and motor/balance ability (SF-36, MFES[ae], MDRT[af], and Maximum Step Length test)	*Between*: changes in MFES and MDRT to the right and left sides were significantly different in the first 6-week period. Changes in BBS, MFES, and MDRT to the right and left sides were significantly different in the second 6-week period.

	Population		Technology	Outcomes	Results
	Participants in EG[a]	Participants in CG[b]			
Calabrò et al [27]	N=25 (older people with PD), 11 male/9 female, aged 70 (8) years. HY stage: 2-3	N=25 (older people with PD), 9 male/3 female, aged 73 (8) years. HY stage: 2-3	Treadmill plus music	*Primary*: gait performance (FGA) *Secondary*: brain oscillation changes related to gait cycle; gait and motor performance: (UPDRS, BBS, FES, 10MWT, TUG, and GQI[ag])	*Between*: improvement in FGA (*P*<.001), FES (*P*<.001), UPDRS (*P*=.001), and overall GQI (*P*<.001) in EG
Alagumoorthi et al [28]	N=96 (with PD), 51 male/45 female, aged 69.7 (10) years. HY stage 2-3-4	N=96 (with PD), 63 male/33 female, aged 68.5 (9.8) years. HY stage: 2-3-4	Nintendo Wii Console	*Primary*: number of fallers *Secondary*: fall rate; risk of falling and quality of life (BBS, TUG, and PDQ-39)	End of treatment: *Between*: number of fallers (*P*=.77), BBS (*P*=.658), TUG (*P*=.967), and PDQ-39 (*P*=.402). Follow-up 36th week: *Between*: number of fallers (*P*=.039), BBS (*P*=.867), TUG (*P*=.959), and PDQ-39 (*P*=.405).

Discussion

Principal Findings

This systematic review seeks to shed light on the evolving landscape of technology-assisted rehabilitation for older people with PD. Delving into the available evidence, we assess how technology can serve as a valuable complement to conventional therapy, offering new ways to optimize care and improve outcomes in this growing patient demographic. In particular, the included studies evaluated the impact of technological interventions on physical and cognitive domains. Cognitive functioning was assessed in 4 studies, while physical functioning, including gait, falls, and balance, was assessed in 13 studies. Technologies used included treadmills with virtual reality, exergames, and sensitive pressure platforms. Exoskeletons and gait robots were less commonly used. Most studies incorporated virtual reality, either immersive or nonimmersive. The results indicate that technological interventions significantly improve gait and balance performance compared with traditional methods, though cognitive improvements were limited.

PD poses a serious burden on patients, carers, families, health care providers, and health authorities globally. Within the relevant unmet need in the management of PD [10], identifying preventive strategies, particularly tertiary, to mitigate severe progression and ensure an adequate quality of life for older patients is one of the most felt needs, with the final aim of slowing disease progression, enhancing the long-term quality of life, and reducing the costs associated with PD, as the majority of expenses occur in advanced stages.

From our analysis, it seems that including technology into a physical intervention can constitute a driver for ensuring the adherence and compliance to rehabilitation trainings. In particular, our analysis reveals an overall improvement in the physical status and outcomes related to disease severity, even if a not clear improvement in cognitive status and quality of life was observed. This result may suggest the need of conducting longer trials to collect evidence on the impact of rehabilitative interventions with technology also in the long term. Moreover, even if the adherence to rehabilitation training is high in hospital facilities, this should be complemented and sustained with training at home to stimulate compliance to physical exercise, considering that patients with PD should remain active as long as possible to counteract the disease progression. Additionally, digital solutions can be a viable option to support the older patients at home by coaching them in an interactive and engaging way, as already demonstrated by numerous evidence in the field [29].

In fact, although in a different context, our analysis has shown that the most engaging interventions involved virtual reality technology, which appears to be the most promising tool for positively impacting cognitive domains due to its highly interactive features. This is in line with recent findings that highlight that virtual reality technology has a particularly promising tool for investigating and rehabilitating gait and balance impairments in people with PD by enabling users to engage in an enriched and highly personalized complex environment [30].

The inclusion of technology and virtual reality into rehabilitative training imposes to stress the attention to assessing the usability and accessibility of such technologies by including the patients-in-the-loop since the design of the solutions in order to be suitable and to not compromise the appropriate use. At this purpose, even if there is a plethora of studies and disciplines that underline the needs of involving older adults and vulnerable user groups in the design process, also with a specific focus on age-related conditions such as dementia [29], there has been limited exploration of how individuals with PD can actively participate in the design process [31], despite the fact that the PD population represents an intriguing user group for design investigation due to the intricate and individual nature of the condition that includes physical and cognitive symptoms, with fluctuations in severity, while dealing with emotional challenges related to social stigma and embarrassment associated with their condition [32].

However, this systematic review has its limitations. The low number of studies and their heterogeneity do not favor valid and generalizable conclusions, but this very limitation shows that, despite the good promises, there is still a need to experiment with technological interventions and, in particular, with virtual reality, in the rehabilitation of people with PD. Moreover, all the studies reported show more or less significantly positive results: this aspect is typical of scientific publications, in which there is a tendency to publish this kind of study to the detriment of those with negative results. For the purposes of research into the implementation of new technologies for the treatment of patients with PD, it is very important to know and take into account even those studies that did not produce the desired results, so that lessons should not be learned again.

The integration of technology into PD rehabilitation holds the promise of enhancing the efficacy and accessibility of interventions, addressing the unique challenges faced by older individuals, and facilitating personalized, patient-centered care. Future challenges of sociotechnical interventions should be focused on unmet needs of the older population with PD by combining a multidisciplinary, multicomponent, and personalized approach and addressing challenges related to health literacy, availability of physical and psychological services, and the stigma associated with PD [10].

Conclusions

In summary, this systematic review seeks to shed light on the evolving landscape of technology-assisted rehabilitation for older individuals with PD. The integration of technology into PD rehabilitation holds the promise of enhancing the efficacy and accessibility of interventions, addressing the unique challenges faced by older individuals, and facilitating personalized patient-centered care.

Abstract

Background: Fatigue is a common and debilitating side effect of chronic diseases, significantly impacting patients' quality of life. While physical exercise and psychological treatments have been shown to reduce fatigue, patients often struggle with adherence to these interventions in clinical practice. Game-based eHealth interventions are believed to address adherence issues by making the intervention more accessible and engaging.

Objective: This study aims to compile empirical evidence on game-based eHealth interventions for fatigue in individuals with chronic diseases and to evaluate their effectiveness in alleviating fatigue.

Methods: A comprehensive literature search was performed across Embase, MEDLINE ALL, PsycINFO, Web of Science Core Collection, Cochrane Central Register of Controlled Trials, and Google Scholar in August 2021. Study characteristics and outcomes from the included studies were extracted, and a random-effects meta-analysis was conducted. Sensitivity and subgroup analyses were performed to identify sources of heterogeneity.

Results: Of 1742 studies identified, 17 were included in the meta-analysis. These studies covered 5 different chronic diseases: multiple sclerosis (n=10), cancer (n=3), renal disease (n=2), stroke (n=1), and Parkinson disease (n=1). All but 1 study used exergaming interventions. The meta-analysis revealed a significant moderate effect size in reducing fatigue favoring the experimental interventions (standardized mean difference [SMD] –0.65, 95% CI –1.09 to –0.21, *P*=.003) compared with control conditions consisting of conventional care and no care. However, heterogeneity was high (I2=85.87%). Subgroup analyses were conducted for the 2 most prevalent diseases. The effect size for the multiple sclerosis subgroup showed a trend in favor of eHealth interventions (SMD –0.47, 95% CI –0.95 to 0.01, *P*=.05, I2=63.10%), but was not significant for the cancer group (SMD 0.61, 95% CI –0.36 to 1.58, *P*=.22). Balance exercises appeared particularly effective in reducing fatigue (SMD –1.19, 95% CI –1.95 to –0.42, *P*=.002).

Conclusions: Game-based eHealth interventions appear effective in reducing fatigue in individuals with chronic diseases. Further research is needed to reinforce these findings and explore their impact on specific diseases. Additionally, there is a lack of investigation into interventions beyond exergaming within the field of game-based learning.

KEYWORDS

fatigue; chronic disease; eHealth; serious games; exergames

Introduction

Chronic diseases are a major cause of morbidity worldwide, with their prevalence steadily increasing due to a growing and aging population, improved disease detection, and advancements in medical treatments, leading to greater longevity [1,2]. Chronic diseases are conditions that persist over a long period or recur frequently, often requiring ongoing medical attention [3,4]. The management of chronic diseases is shifting from cure to care and prevention strategies, with a particular focus on lifestyle management [5]. In addition to the impact of the chronic disease itself, several commonly associated symptoms—such as depression, anxiety, and fatigue—affect quality of life and should be included in routine care [6-8].

Fatigue is one of the most prevalent of these symptoms [8]. It is defined as an overwhelming sense of tiredness and exhaustion that arises without provocation and cannot be relieved by rest [9,10]. Connolly et al [8] found that patients often report fatigue as one of the most debilitating symptoms, significantly impacting daily functioning and quality of life. They report that fatigue occurs across a range of chronic diseases, including multiple sclerosis (MS) and cancer. A recent meta-analysis evaluated the prevalence of severe and chronic fatigue in a cohort of individuals with chronic diseases, finding that 23% experienced severe fatigue and 17% suffered from chronic fatigue [11].

Over the past decades, nonpharmacological treatments for fatigue have been increasingly developed and investigated. Meta-analyses indicate that physical exercise can reduce fatigue severity across various chronic diseases [12-17]. Other successful interventions include psychological therapies—such as cognitive-behavioral therapy, psychoeducation, or mindfulness—whether as standalone treatments or in combination with exercise, as well as relaxation therapies [18,19].

Despite these findings, patients often struggle with adhering to interventions [20,21]. Evidence indicates that the reasons for nonadherence are diverse, including barriers such as time, costs, location, comorbidities, and particularly a lack of motivation [21-25]. To be successful, interventions should be designed to address and overcome these barriers to adherence. This is the goal of game-based interventions, which aim to make treatment easily accessible and highly engaging. This is one reason why such interventions have become increasingly popular in recent years. Games are known to enhance motivation, attention, and learning, among other benefits [26]. Game-based interventions leverage these benefits by embedding therapeutic goals within a game (serious gaming). Evidence indicates that these interventions can significantly improve treatment adherence in chronic conditions compared with standard care [27]. Additionally, from a financial perspective, game-based interventions are attractive to health care providers and insurance companies due to their cost-effectiveness [28-30].

Several studies have investigated the effects of game-based eHealth interventions in individuals with chronic diseases, yielding promising results across a range of outcomes. These interventions include exergames (ie, game-based exercise programs [31]), virtual reality (VR) tools [32], and serious game applications [33]. For example, Kato et al [34] investigated the effect of a serious game designed to improve adherence and other behavioral outcomes in children with cancer, finding that it successfully enhanced medication adherence and self-efficacy in the target group. In a study by Del Corral et al [35], exergaming was found to lead to significantly greater improvements in exercise capacity, muscular strength, and quality of life in children with cystic fibrosis compared with the control group receiving conventional care.

With the accumulation of numerous studies over the past decade, evidence in this field has been synthesized in meta-analyses. Rutkowski et al [36] found that VR interventions appear to be effective in alleviating fatigue in individuals with cancer. Cugusi et al [37] reported small but significant effect sizes for improving health-related quality of life with experimental exergaming interventions in people with various chronic diseases, including Parkinson disease, Alzheimer disease, and stroke. Seiler et al [38] also found promising effects of various types of eHealth interventions in reducing fatigue in individuals with cancer.

However, to date, no meta-analysis has investigated the effects of (1) different game-based eHealth interventions on (2) the reduction of fatigue in (3) individuals with various chronic conditions.

This paper aims to fill this gap by systematically aggregating the findings from these studies to assess the effectiveness of game-based eHealth interventions in alleviating fatigue. The goal is to determine whether these interventions can serve as a suitable alternative to conventional treatments.

Methods

Selection Criteria

We included randomized and nonrandomized controlled trials that reported the effects of video game interventions on fatigue in individuals with chronic diseases. For this study, we defined a video game as a digital or electronic game where players interact with the game by manipulating images on a video screen. A "game" was defined as an engaging, amusing, and structured form of play conducted according to a set of rules with the aim of achieving a specific objective. Chronic diseases are defined as conditions that persist or recur over an extended period and require ongoing medical attention or limit activities of daily living [3,4]. We focused on pathological fatigue, defined as physical, emotional, or mental tiredness/exhaustion related to chronic disease or its treatment [39]. This type of fatigue is characterized by its prolonged, severe, progressive nature or its occurrence without provocation. For practical reasons, we included only journal articles published in English. All studies had to include a T1 measure with a measure of change from the baseline and a control group from the same disease population receiving a different or no intervention.

We excluded trials involving healthy volunteers, individuals with acute diseases, and those with fibromyalgia. The clinical population with fibromyalgia was excluded due to its high heterogeneity, unclear etiology, and purely clinical diagnosis, as there are no specific laboratory abnormalities associated with it [40]. Therefore, fibromyalgia is unsuitable for this meta-analysis due to its heterogeneous nature and unclear etiology, making it difficult to detect the group effects of an intervention. Articles focusing on different types of fatigue, such as fatigue after exertion or transient fatigue, were also excluded. Additionally, we excluded reviews, descriptive and observational studies, study protocols, case studies, uncontrolled studies, conference abstracts, trial registries, posters, and books, as well as studies that used nonstandardized measuring scales for fatigue.

Search Strategy

A medical information specialist from the Erasmus MC Medical Library conducted a comprehensive literature search on August 25, 2021. To ensure the findings were up-to-date, a second search was carried out on March 2, 2023. Both searches utilized the following databases: Embase, MEDLINE ALL, PsycINFO, Web of Science Core Collection, Cochrane Central Register of Controlled Trials, and Google Scholar. For both searches, the coverage years varied by database (Multimedia Appendix 1). Nonetheless, the majority of articles were published within the last 3 decades.

The search terms "game," "video," "fatigue," and related keywords were used. A separate search strategy was developed for each database (Multimedia Appendix 1). We did not include "chronic disease" or specific diseases as search terms, as we deemed the risk of missing relevant studies due to incomplete disease terms to be too high.

Selection Procedure

After removing duplicates, the titles and abstracts were screened by 2 of the authors (LSW and JSL). The full-text papers were then extracted and screened by the same authors along with an additional author (BD). The selection of articles was compared among the authors at all stages of the process. In cases of disagreement, the articles were discussed until a consensus was reached. The authors of the papers were contacted by email when relevant information was missing or inconsistent. Articles were excluded if the authors did not respond.

Assessment of Study Quality

For each study, the risk of bias was assessed by the author LSW using the risk of bias 2 tool (Cochrane Risk of Bias Tool for Randomized Trials) [41]. The assessment covered the following categories: randomization process, deviations from intended interventions, missing outcome data, measurement of the outcome, and selection of reported results. Based on the assessment of the individual categories, each study was classified into 1 of 3 overall risk of bias levels: "low risk of bias," "some concerns," or "high risk of bias." The overall classification was determined by the lowest rating among the individual categories (eg, if 4 of the 5 categories were rated "low risk of bias" but 1 was rated "high risk of bias," the overall classification would be "high risk of bias").

Data Extraction

After the selection process, one author (LSW) performed data extraction for each article. The extracted data included diagnosis, author, year of publication, sample size, mean age, percentage of female participants, interventions in both the experimental and control groups, duration of the interventions in weeks, and key findings. All data were entered into Comprehensive Meta-Analysis (CMA) software version 2 (Biostat, Inc.).

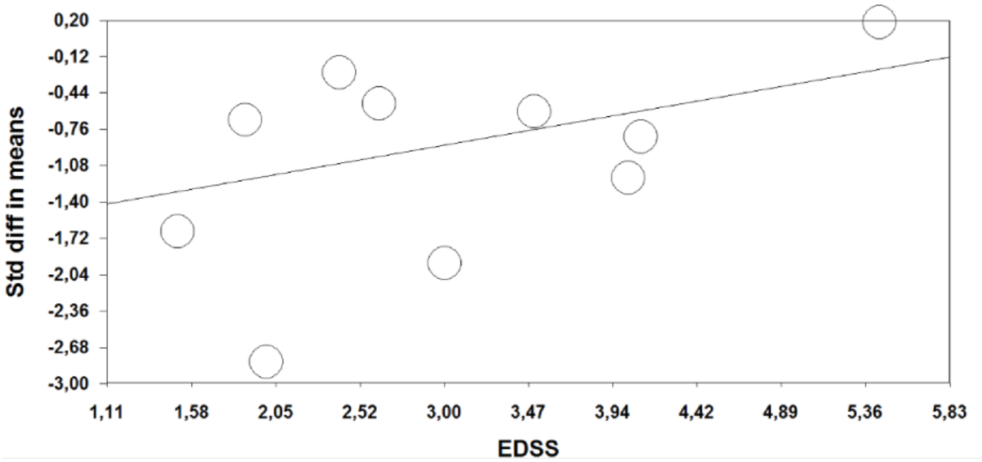
Synthesis of Results

The analyses were conducted using CMA [42]. For our outcome variable, fatigue, the mean scores and SDs for pre- and postintervention (ie, baseline and T1) were either extracted directly from the articles or calculated from median scores and IQRs using the formula described by Wan et al [43]. We followed the guidelines in the Cochrane Handbook for Systematic Reviews of Interventions to calculate the pre-post correlation [44]. It was calculated directly for studies where the SD of change from baseline to T1 was available. For other studies, we imputed the correlation by averaging the calculated pre-post correlations. Additionally, we entered data on sample size per condition, diagnosis, assessment instrument (Visual Analog Scale [VAS] vs questionnaire), mean age, percentage of female participants, modality and type of intervention (nonimmersive, immersive VR, non–VR game; balance, fitness, cognition), intervention duration in weeks, type of control intervention (no care vs conventional care), setting (hospital vs home), supervision, and, where possible, disease severity into the CMA worksheet. Two of the included studies were crossover randomized controlled trials (the remainder were parallel randomized controlled trials). For 1 of the crossover studies, we used only the T1 measure for comparison, which included data only from the period before the crossover [45]. For the other crossover study, we used data from both periods combined (ie, before and after the crossover) because only these combined data were available [46]. In studies measuring different dimensions of fatigue, the dimension reporting the average fatigue measure was used. In studies with 2 control groups—1 receiving a conventional intervention and 1 with no intervention—we chose the inactive control group. In a study comparing 2 interventions using different VR systems with a control group, the aggregated mean of the 2 experimental conditions was used [47]. For studies with 3 measurement points, data from the measures immediately before and after the intervention were utilized.

First, effect sizes were calculated as standardized mean differences (SMDs) to account for possible differences in measurement scales. We conducted a meta-analysis to determine the overall effect sizes for the experimental condition compared with the control condition using a random-effects model. The more conservative random-effects model was chosen over the fixed-effects model due to the expected heterogeneity among studies and because random-effects models are recommended for analyzing data collected in real-world settings rather than controlled laboratory environments [48]. Heterogeneity was estimated using the I^2 index, which describes the percentage of variation attributable to study heterogeneity rather than chance [49], with ≥75% indicating considerable heterogeneity. To explore sources of heterogeneity, we performed sensitivity analyses (by excluding low-quality studies and outliers), moderator analyses, and meta-regressions. Low-quality studies were defined as those with a high risk of bias, as identified by the risk of bias assessment. Outliers were defined as studies where the 95% CI did not overlap with the 95% CI of the pooled effect size. For the moderator analyses, studies were grouped by diagnosis, age, and type of experimental and control interventions, provided there was more than 1 study per group. Additionally, we conducted analyses excluding studies using VAS, exploring the impact of supervision, and distinguishing between studies conducted at home versus those conducted in a hospital setting. A random-effects meta-regression using the method of moments was conducted with gender and disease duration as predictors. For studies on MS, we additionally performed a meta-regression with disease severity, which was measured using the Expanded Disability Status Scale (EDSS) [50], as a predictor. This is shown in Figure 1.

Finally, to check for publication bias, we generated a funnel plot by plotting the SMD against the SE of all studies and assessed it for asymmetry. Additionally, we quantified potential publication bias statistically using the Egger test of the intercept [51].

Figure 1. Scatterplot showing the meta-regression of all multiple sclerosis studies with the Expanded Disability Status Scale (EDSS) as the predictor variable.

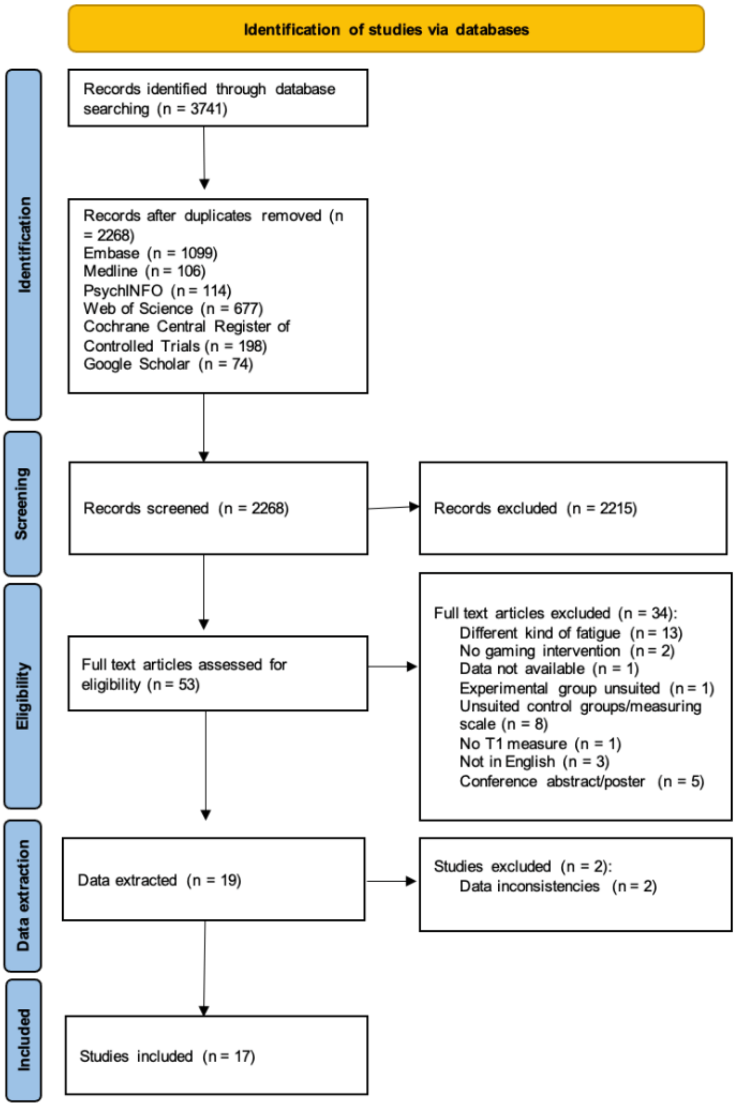


Results

Study Selection

A total of 3741 articles were identified through the literature search, of which 2268 remained after duplicate removal. An overview of the selection process is shown in Figure 2. After screening titles and abstracts, and discussing differences in opinion between the authors (for 14 articles), a total of 53 articles were selected for full-text screening. After independently screening the full text of these studies, the authors discussed discrepancies in study selection for 8 studies until a consensus was reached. Authors were contacted for missing information in 2 cases. We received a reply for 1 article, which led to its exclusion. The other study was excluded due to the lack of a response. In total, 19 articles were excluded after full-text review. Most were excluded because the fatigue measure pertained to exertion from the intervention itself. Relevant data were then extracted from the remaining 19 studies. During this process, 2 additional studies were excluded due to data inconsistencies; we contacted the authors but did not receive a reply. This left us with a total of 17 studies included in the data synthesis for the meta-analysis.

Figure 2. Preferred Reporting Items for Systematic Reviews (PRISMA) flowchart-diagram for study selection.



Characteristics of the Included Studies

Table 1 presents the characteristics of the included studies, organized by participant diagnosis: MS (n=10) [45,47,52-59], cancer (n=3) [46,60,61], renal disease (n=2) [62,63], Parkinson disease (n=1) [64], and poststroke (n=1) [65]. The studies were published between 2013 and 2023 and were all randomized controlled trials, including 2 crossover trials [45,46] and 15 parallel trials [47,52-65]. The number of participants ranged from 20 to 52. The mean age of participants ranged from 7.9 to 68.7 years, with only 1 study [60] including children. For the 16 studies that included adults, the age range was 32.3-68.7 years (median 45 years) [45-47,52-59,61-65]. The mean percentage of female participants ranged from 0% (0/42) to 90% (38/42; median 61.50%). Sixteen studies used VR exergames, which included either balance exercises (n=5) [47,52,55,57,65] or fitness exercises (n=11) [45,46,53,56,58-64]. One study used a serious Nintendo DS game designed to train cognitive functions such as working memory, spatial recognition, processing speed, and mental reasoning in healthy individuals [54]. Thus, the term "game-based eHealth interventions" is technically too broad. Throughout this paper, we used this term to include the serious gaming study as well. The VR technology varied across studies, with most using nonimmersive VR systems (n=14) [45-47,52,53,55,56,58-64]. The control interventions also exhibited some heterogeneity across studies. We categorized the control interventions into 2 groups: the conventional training group (n=7) [46,52,53,55,59,64,65], which involved traditional nonvideo game interventions targeting the same abilities as the experimental intervention, and the no-exercise control group (n=10) [45,47,54,56-58,60-63], which involved no specific intervention beyond the normal level of activity. The duration of the interventions varied significantly between studies, ranging from 2 to 24 weeks (median 8 weeks). Fatigue was measured using various questionnaires, with 1 study using a VAS to assess fatigue severity [62].

Table 1. Study characteristics and key findings of the included studies that reported on the effect of game-based eHealth interventions on the reduction of fatigue in people with chronic diseases. Studies are sorted according to diagnosis.

Diagnosis and study	Participants			Intervention			Key findings
	N	Age (years), mean	Female, n/N (%)	Experimental	Control	Duration (weeks)	
Multiple sclerosis							
Brichetto et al [52]	36	42	22/36 (61)	Balance, nonimmersive VR[a]	Conventional training	12	Significant decrease in fatigue (MFIS[b]) after treatment compared with the baseline and control groups

Risk of Bias of Studies

Study quality was low or moderate in all studies (n=5 and n=12, respectively), with none rated as high quality (Figure 3). The primary reasons for low-quality ratings were issues with the randomization process and handling of missing data.

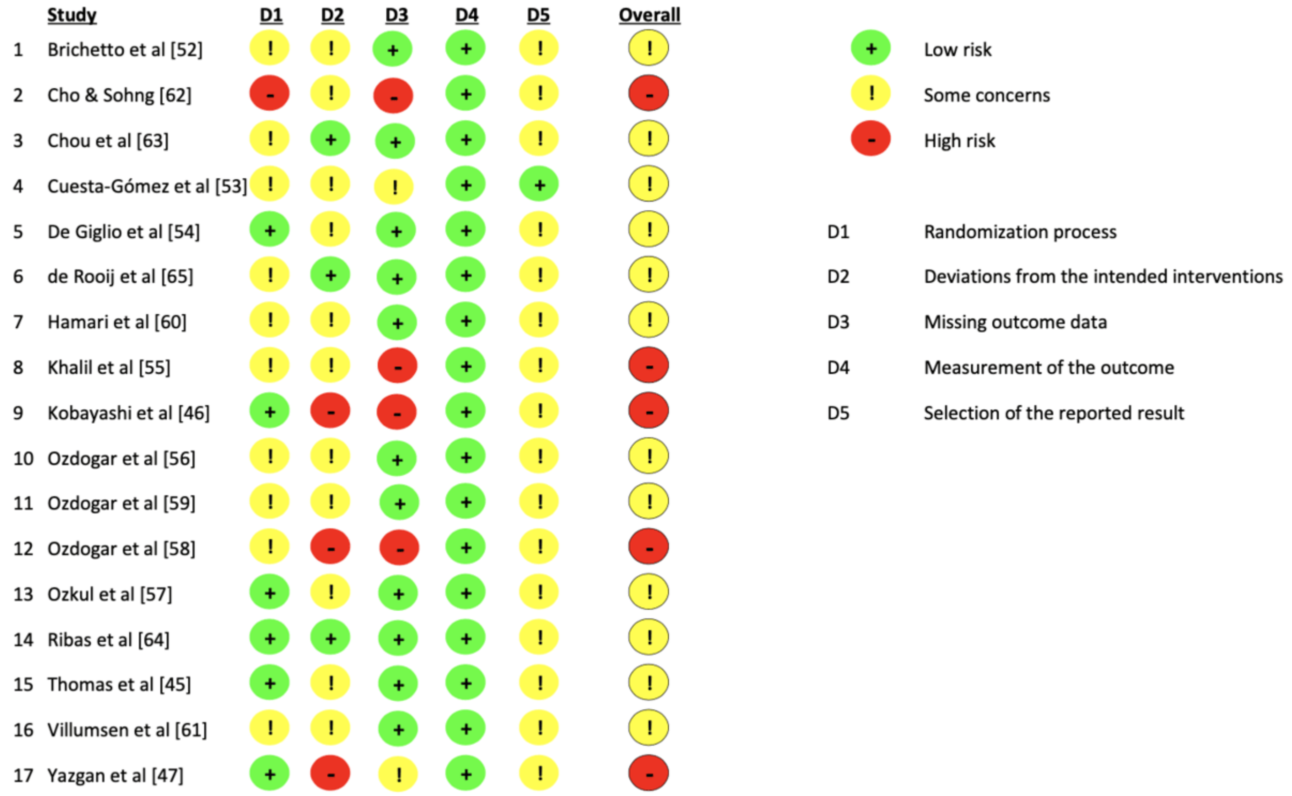
While all studies were randomized, 2 utilized a cluster-randomization procedure, with treatment allocation based on either the days participants visited the hospital [62] or the hospital wards to which they were assigned [63]. For Chou et al [63], we can assume that participant allocation was concealed from the investigator; however, this was not clear for Cho and Sohng [62]. For the other studies, the randomization process was truly random. However, there was some concern about the risk of bias in 9 of the 17 (53%) studies [52,53,55,56,59-61,63,65] due to missing or doubtful information about allocation concealment.

In 10 of the 17 (59%) studies [45-47,53-57,60,62], there was concern about the risk of bias because the authors did not implement an intention-to-treat analysis to account for missing or lost data. However, the missing data were either balanced across studies or not substantial enough to significantly impact the results. By contrast, 2 (12%) studies [46,47] exhibited a high risk of bias due to substantial issues with missing data.

In 8 of the 17 (47%) studies [46,47,53,55,57,58,60,62], it could not be ruled out that the missing data were related to the outcome itself (ie, fatigue), potentially influencing the overall results. Possible reasons related to the outcome were lack of motivation or excessive fatigue preventing participation. Issues related to participants' schedules or travel time were judged as unrelated to the outcome. In 4 of these studies [46,55,58,62], a high risk of bias was concluded as it was likely that the missing data depended on the true value of the outcome. In the other 4 studies [47,53,57,60], there were some concerns about the risk of bias, but the proportion of missing data and reasons for it were balanced across groups.

The risk of bias in the measurement of outcomes was low across all studies. However, there was some concern regarding the selection procedure of reported results in 16 of the 17 (94%) studies [45-47,52-61,63-65]; specifically, 16 (94%) studies did not indicate whether the analysis followed a prespecified plan [45-47,52,54-65]. Additionally, 4 (24%) studies began before the trial had been preregistered.

Figure 3. Risk of bias assessment for all included studies.



Main Analyses

It was possible to calculate effect sizes for fatigue reduction across all studies. Figure 4 presents the SMD and 95% CIs for each study. A negative effect size indicates that the experimental intervention was more effective in reducing fatigue compared with the control intervention. In 4 studies [45,46,53,61], the effect sizes were positive, meaning that the control intervention was more effective in reducing fatigue than the experimental intervention. Three studies were identified as outliers, 2 [46,62] of which were also rated as low quality. The third outlier was the study by Villumsen et al [61], which also reported no reduction in fatigue following the intervention. This lack of effect may be related to the study's population, which consisted entirely of males with a mean age of 68.7 years, the oldest among all the studies. The authors suggest that the lack of supervision over the exercise intensity in the home-based intervention might explain the findings. The overall effect size, calculated using a random-effects model, indicated a significant moderate effect of video game interventions on fatigue reduction compared with control interventions (SMD –0.65, 95% CI –1.09 to –0.21, P=.003). However, there was considerable heterogeneity (I^2=85.87%). To investigate the sources of this heterogeneity, several additional analyses were conducted.

First, we performed sensitivity analyses by excluding the low-quality and outlier studies. This included 4 studies [46,47,55,62] with a high risk of bias and 1 additional outlier [61], leaving us with 10 studies. Despite this more rigorous analysis, the effect size remained significant (SMD –0.42, 95% CI –0.74 to –0.10, P=.01). Although heterogeneity was reduced, it remained substantial (I^2=54.88%). When the study using a VAS was excluded (n=1) [62], the effect size was smaller but still significant (SMD –0.55, 95% CI –0.95 to –0.14, P=.009).

Second, we performed moderator analyses with diagnosis, type of intervention, type of control condition, and age as moderators for all groups where data from more than 1 study were available. Grouping studies according to diagnosis revealed a large and significant effect size for MS (SMD –0.87, 95% CI –1.34 to –0.41, P<.001, n=10). After removing low-quality and outlier studies, the effect size decreased to a trend (SMD –0.47, 95% CI –0.95 to 0.01, P=.05, I^2=63.10%, n=6). For cancer, the pooled effect size was positive, indicating that the control intervention was more effective than the experimental intervention, but this effect size was not statistically significant (SMD 0.61, 95% CI –0.36 to 1.58, P=.22, n=3). For both MS and cancer, heterogeneity was reduced but remained substantial (I^2=77.9% for MS and I^2=72.33% for cancer). For renal disease, with only 2 studies available [62,63], the pooled effect size was –1.13 (95% CI –2.32 to 0.05, P=.06), and heterogeneity was notably high (I^2=96.08%).

Interventions involving balance exercises (n=5) showed a large effect size of –1.19 (95% CI –1.95 to –0.42, P=.002). By contrast, for fitness interventions (n=10), the effect size was nonsignificant (SMD –0.44, 95% CI –1.02 to 0.13, P=.20). Heterogeneity remained substantial for both categories (I^2=62.78% for balance exercises and I^2=87.15% for fitness interventions). We could not pool effects for cognitive interventions, as only 1 study investigated this category [54]. Sensitivity analysis, which excluded low-quality and outlier studies, confirmed these results while substantially reducing heterogeneity (I^2=58.83% with n=3 for the balance group and I^2=23.60% with n=6 for the fitness group). These findings suggest that game-based balance exercises, in particular, are effective interventions for reducing fatigue in individuals with chronic diseases.

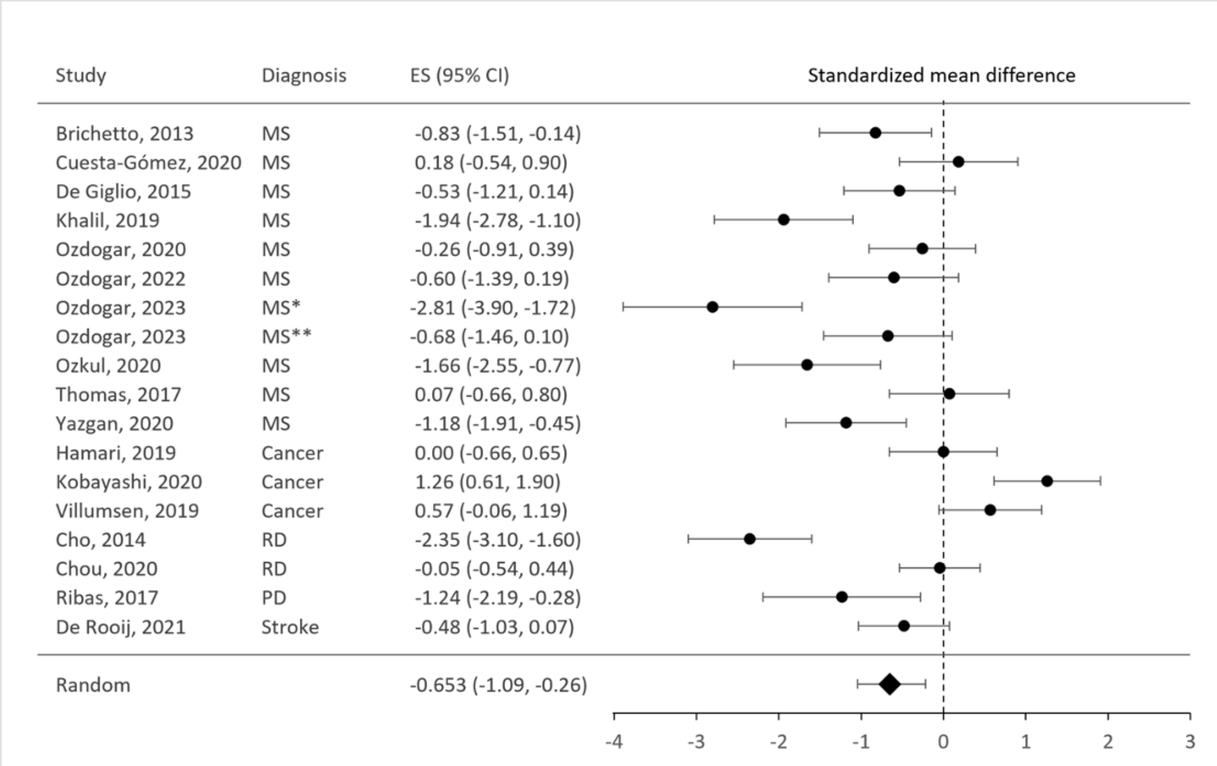
Grouping studies by the type of control group used revealed nonsignificant effect sizes for the conventional training control groups (SMD –0.49, 95% CI –1.12 to 0.15, P=.20, I^2=86.7%, n=7), but significant effect sizes for the no-exercise control groups (SMD –0.75, 95% CI –1.33 to –0.18, P=.01, I^2=85.6%, n=10).

Significant differences were found when comparing participants with a mean age below 55 years (SMD –0.65, 95% CI –1.16 to –0.13, P=.02, I^2=84%, n=12), but no significant difference was observed for those above 55 years (SMD –0.68, 95% CI –1.59 to 0.23, P=.15, I^2=90%, n=5).

Third, we conducted a meta-regression using the method of moments in a random-effects model to estimate the effect of gender and duration of intervention on the impact of game-based interventions. Neither gender nor duration significantly influenced the effect size for fatigue reduction (P=.08 and P=.86, respectively). However, the presence of supervision and the location of the studies have significantly influenced the effect size. For both factors, a meta-regression was conducted using a random-effects model. Supervision significantly affected the effect size, with supervised interventions showing a significant effect (SMD –0.86, 95% CI –1.39 to –0.33, P=.001), whereas interventions without supervision showed no significant effect (SMD 0.04, 95% CI –0.42 to 0.49, P=.88). The meta-regression also revealed a significant effect for studies conducted in a hospital setting (SMD –0.79, 95% CI –1.30 to –0.30, P=.002), contrasting with those conducted at home, which showed no significant effect (SMD 0.04, 95% CI –0.61 to 0.69, P=.90).

We performed an additional meta-regression with disease severity as a predictor for all the MS studies where it was reported (n=9; not reported in n=1) [45,47,52-59]. Increased severity was associated with a smaller effect of the intervention (SMD –0.27, 95% CI 0.06-0.48, P=.01). When high risk of bias studies were excluded, the association remained, although slightly weaker (SMD 0.25, 95% CI 0.02-0.49, P=.04, n=5) [46,47,55,58,62].

Figure 4. Random-effect meta-analysis for the effect of serious gaming on fatigue. ES: effect size; MS: multiple sclerosis; PD: Parkinson disease; RD: renal disease. *With restless leg syndrome; **without restless leg syndrome.



Publication Bias

The funnel plots for all included studies and the MS subgroup displayed asymmetry [45,47,52-59]. The Egger test of the intercept confirmed that this asymmetry was statistically significant, with *P* values of .006 and .004, respectively, indicating evidence of publication bias. This suggests an overrepresentation of studies with positive results, which should be considered when interpreting the findings. However, after excluding studies with a high risk of bias, the observed asymmetry was no longer statistically significant (*P*=.25) [46,47,55,58,62].

Discussion

Principal Findings

In recent years, the digitalization and gamification of interventions have garnered increasing attention as alternatives or complements to conventional treatment approaches. This paper aimed to evaluate the efficacy of game-based eHealth interventions in reducing fatigue among individuals with chronic diseases. We included 17 randomized controlled trials published between 2013 and 2023, encompassing 5 different types of chronic diseases. The relative recency of publications and the small number of studies illustrate that the field of (game-based) eHealth is still in its infancy. The types of interventions were fairly homogeneous, with all but 1 study focusing on exergaming interventions [54]. The remaining studies evaluated a serious game aimed at improving cognition. This trend, although on a smaller scale, mirrors the evidence base for conventional rehabilitation approaches for fatigue, where the majority of studies also focus on physical exercise interventions. However, given the positive findings for psychological interventions, particularly when combined with exercise interventions [18], future eHealth interventions should also explore these approaches.

Findings from this meta-analysis suggest that current game-based eHealth interventions may effectively reduce fatigue in people with chronic diseases. With a moderate effect size, these interventions could potentially be more effective for fatigue compared with other treatment goals, such as knowledge and self-management [66], self-efficacy [67], and health-related quality of life [37], where previous meta-analyses reported smaller effect sizes. Additionally, they appear to be as effective as many conventional (non–game-based) interventions, which typically report moderate effect sizes [18]. Some meta-analyses investigating the effect of exercise therapy on disease-related fatigue (such as in cancer and chronic obstructive pulmonary disease) reported larger effect sizes for physical exercise therapies [13,15], a finding also supported by individual studies in this meta-analysis [47,52,55,57,62,64]. The comparable effectiveness of game-based eHealth interventions is crucial for them to become a viable alternative to conventional interventions. Thus, this result represents an important first step in exploring the potential of game-based eHealth interventions.

With regard to individual chronic diseases, findings from this meta-analysis were less straightforward. Game-based interventions appear effective for MS, but not for cancer. Cancer is a heterogeneous disease with variable cancer-related fatigue. The underlying pathophysiology is relatively well investigated and is likely multifactorial, involving inflammation, disruptions in the hypothalamic–pituitary–adrenal axis, and activation of the autonomic nervous system [68,69]. However, it is influenced by several factors including the type of cancer, the stage of the disease, and the treatment—all of which varied across and within the study populations of the included cancer studies. The considerable heterogeneity of the cancer group, including a wide mean age range from 8 to 69 years, might explain the lack of a treatment effect in this group. By contrast, MS typically presents with a more homogeneous course, commonly consisting of exacerbations and stable phases [70], and all of the MS studies included here focused on patients in a stable phase. As the onset of MS typically occurs between 20 and 40 years of age [71], the study population for MS was more homogeneous in terms of age, ranging from 31 to 49 years. Besides disease-related differences, variations in results might be attributed to statistical power issues due to the limited number of studies [72]. This limitation increases the likelihood of fluctuations due to chance, particularly in the cancer group, where 1 study was an outlier [61] and another was of low quality [46]. Interestingly, 1 of the cancer studies [46] found that the experimental group experienced an increase in fatigue after the intervention. The authors suggested that this might be due to an inappropriate exercise load, as patients were unable to adjust it according to their needs in the experimental condition. Additionally, "fatigue" might have been interpreted as "exercise load," given that the Profile of Mood States—short form (POMS-sf) measuring scale used in the study assesses "general fatigue" nonspecifically.

Another striking finding of this meta-analysis was the clear difference between balance exercises and fitness exercises. The balance exercises showed a markedly larger effect size in reducing fatigue compared with fitness exercises (SMD –1.19 vs SMD –0.17). It is important to note that the balance exercise group was more homogeneous in terms of patient diagnoses, with only 1 study including patients after stroke and the rest consisting of patients with MS [65]. The fitness group included patients with 4 different diagnoses, which might contribute to the observed heterogeneity and complicate the comparison with the balance group. However, a similar observation is evident within the MS studies: all 4 balance studies favored the experimental intervention [47,52,55,57], whereas only 3 [57-59] of the 6 fitness studies did [45,53,56]. These findings contrast with a recent randomized controlled trial by Callesen et al [73], which reported conventional balance training and exercise training as equally effective in reducing fatigue among patients with MS. However, our results align with Hebert and Corboy [74], who demonstrated a significant relationship between fatigue and balance in patients with MS. Additionally, evidence from healthy participants suggests that balance exercises not only improve balance but also muscle strength [74,75]. This dual benefit might make balance exercises more effective than pure strength exercises in reducing fatigue, as they address both balance and strength—factors associated with fatigue. Additionally, balance exercises might be more enjoyable and less demanding than fitness exercises. It is also worth noting that 2 studies in the balance group incorporated additional interventions: 1 included walking alongside balance exercises [57] and another combined Pilates with balance exercises [65]. Given the small number of studies in the balance group (n=5), the effects of these 2 studies significantly influence the overall effect size for this group. Overall, the observation that balance exercises appear particularly effective in reducing fatigue is intriguing and warrants further investigation in future research. It also underscores the importance of developing tailored treatment programs for fatigue, as the underlying mechanisms may vary between different diseases [76].

In this meta-analysis, only 4 studies utilized tailored interventions specifically designed for rehabilitation [53-55,65], while the remaining 13 studies used off-the-shelf commercial games [45-47,52,56-64]. According to serious game design theory, considering the unique interests and needs of the target group leads to the best outcomes [77,78]. Nonetheless, 6 [47,52,60,62-64] out of the 11 studies using commercial games were successful in alleviating fatigue [45-47,52,54,56,60-64]. Gender did not appear to influence the effectiveness of the interventions, which contrasts with the assumption of game design theory. This suggests that the success of commercial games might stem from their broad appeal, as developers aim to meet the needs of diverse target groups to maximize their reach. Yet again, age, particularly a mean age below 55 years, had a significant effect on the effectiveness of the intervention. The literature presents mixed findings regarding the influence of age and gender on treatment outcomes in eHealth interventions. Some studies report differences attributed to these variables [79,80], while others do not [81,82]. From an economic perspective, it is important to determine whether the costly tailoring of games yields better results compared with conventional or commercial interventions. Further research is needed to address this question.

Limitations and Implications for Future Research

The current meta-analysis has several limitations that should be considered when interpreting the findings. First, a notable limitation is the lack of adherence to open science principles, particularly the absence of preregistration before conducting the research.

Second, evidence for publication bias was found among the studies included in this analysis. This suggests that the findings may not fully represent the true effects due to a potential overrepresentation of studies with positive results [83,84]. However, when studies with a high risk of bias were excluded, the asymmetry was no longer significant, indicating that publication bias was not evident in the remaining studies.

Third, the included studies exhibited substantial heterogeneity concerning the target group, interventions, software used, and intervention duration. Although we utilized a random-effects model to account for this variability, considerable heterogeneity remained in the findings. Our sensitivity and moderator analyses managed to reduce, but not entirely resolve, this heterogeneity. Potential sources of heterogeneity that were not examined are the type of software used for the interventions, whether fatigue was a primary or secondary outcome, and intervention intensity and frequency, rather than just duration. We opted to focus on duration because this information was available for all studies.

Fourth, the overall number of studies was rather limited, covering a small variety of chronic diseases and interventions. This limitation was particularly pronounced for studies involving children, which is concerning given that up to 21% of children with chronic disease experience severe fatigue [85]. The need for effective treatment in this population is as urgent as it is for adults. Additionally, no high-quality studies were available for analysis, as determined by the Cochrane risk of bias assessment tool. However, it is worth noting that this tool has been reported to have relatively low reliability [86] and is considered more conservative compared with other risk of bias assessments [87].

Fifth, adherence to the study protocol and treatment satisfaction were not systematically measured nor compared with conventional active intervention groups. This aspect is crucial for determining whether game-based interventions are indeed more motivating than their conventional counterparts and should be a focus of future studies.

Sixth, on a more technical note, different measurement scales for fatigue were used across studies. One study used the VAS to measure fatigue, which is methodologically suboptimal as it is not specifically developed or validated for fatigue assessment and does not differentiate between various aspects of fatigue. To minimize the impact of this on the results, a second analysis was conducted, excluding the study that used VAS. The result remained significant, although the effect size was smaller. This suggests that while the VAS had a substantial influence on the outcome, it was not the sole contributor, as the significant effect appears robust. Although we attempted to mitigate potential discrepancies by standardizing outcome measures using the SMD, variations in psychometric properties may have influenced the results within the studies themselves. Additionally, we had to impute SDs for 1 study [58], means and SDs for 3 studies [53,57,60], and pre-post correlation for 14 studies [45,46,52-55,58-65]. This introduces a degree of uncertainty to our findings, as the reliability of these estimates is uncertain.

Finally, the findings presented here reflect short-term outcomes. As most of the studies did not include follow-up measures, we are unable to draw any conclusions about the long-term efficacy of game-based eHealth interventions.

Overall, more studies are needed across all age groups and various chronic diseases where fatigue is a side effect, to better determine whether these interventions are suited for each disease. These studies should adhere to rigorous design and methodology, including follow-up measures, to assess long-term treatment effects and the use of an intention-to-treat analysis approach for data analysis. We recommend testing not only commercial games but also developing more tailored and personalized games that allow for the investigation of treatments beyond physical activity. In particular, a combination of psychological interventions and physical activity is warranted [18].

Conclusions

Based on the current meta-analysis, we cannot yet make clear recommendations for the use of eHealth interventions in clinical practice. However, we can cautiously conclude that eHealth interventions are effective in reducing fatigue in chronic diseases. As the number of studies in this field is steadily increasing, we hope to soon be able to back up our findings and extend them to other chronic conditions as well.

Acknowledgments

We thank the Stichting Roparun and the Stichting Vrienden van het Sophia for their funding of this research. We also express our gratitude to Sabrina Meertens-Gunput from the Medical Library of the Erasmus Medical Center Rotterdam, the Netherlands, for her invaluable assistance in conducting the systematic literature search.

Abstract

Background: Many studies have shown a direct relationship between physical activity and health. It has also been shown that the average fitness level in Western societies is lower than recommended by the World Health Organization. One tool that can be used to increase physical activity for individual people is exergaming, that is, serious games that motivate players to do physical exercises.

Objective: This scoping review of recent studies regarding exergame efficacy aims to evaluate which sensing modalities are used to assess exergame efficacy as well as motion quality. We also analyze how the collected motion sensing data is being leveraged with respect to exergame efficacy and motion quality assessment.

Methods: We conducted 2 extensive and systematic searches of the ACM Digital Library and the PubMed database, as well as a single search of the IEEE Xplore database, all according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement. Overall, 343 studies were assessed for eligibility by the following criteria: The study should be peer-reviewed; the year of publication should be between 2015 and 2023; the study should be available in English or German; the study evaluates the efficacy of at least 1 exergame; sensor data is recorded during the study and is used for evaluation; and the study is sufficiently described to extract information on the exergames, sensors, metrics, and results.

Results: We found 67 eligible studies, which we analyzed with regard to sensor usage for both efficacy evaluation and motion analysis. Overall, heart rate (HR) was the most commonly used vital sign to evaluate efficacy (n=52), while the Microsoft Kinect was the most commonly used exergame sensor (n=26). The results of the analysis show that the sensors used in the exergames and the sensors used in the evaluation are, in most cases, mutually exclusive, with motion quality rarely being considered as a metric.

Conclusions: The lack of motion quality assessment is identified as a problem both for the studies and the exergames themselves since incorrectly executed motions can reduce an exergame's effectiveness and increase the risk of injury. Here we propose how to use the same sensors both as input for the exergame and to assess motion quality by presenting recent developments in motion recognition and sensing.

exergame efficacy; motion quality assessment; vital signs; body sensors; camera; virtual reality

Introduction

Exergames are interactive games with the additional goal of engaging players in physical activity to promote a healthy lifestyle and increase players' physical fitness [1,2]. Increasing availability of commercial sensing technologies has allowed exergames such as Beat Saber (Beat Games) [3] for various virtual reality (VR) systems and Ring Fit Adventure (Nintendo) for Nintendo Switch [4] to reach a large audience and become highly commercially successful, selling more than 4 million and 14 million copies, respectively [5,6]. Typically, these exergames use sensing technologies as input devices to either control an in-game avatar or detect the execution of specified motions. However, previous studies on motion-based games suggest that exergames should also give feedback on the motion's quality and provide specific guidelines to follow [7,8]. Without these measures, players may not perform the demanded motions correctly, leading to diminished health benefits and risk of injury [9].

A common research question with regards to exergames is that of their efficacy. Efficacy refers to the effectiveness or ability of exergames to achieve their intended goals or their desired effect. This goal can be defined as an increase in the participants' performance, physical activity, or motivation [10]. Previous reviews and meta-analyses on exergames generally confirm the existence of positive effects associated with exergames [10-13]. Nevertheless, the reviews primarily assert that exergames are most effective in facilitating light- to moderate-intensity physical activity, and only a small proportion of exergames have demonstrated the ability to significantly increase physical activity levels among users [14-16]. Furthermore, previous reviewers have primarily focused on assessing the efficacy of exergames in specific populations, such as children and adolescents without [11,12,16] or explicitly with adults with overweight [13] or older adults [15,17-19]. Only a few reviews encompass a broader range of participants and do not specifically focus on any particular population [14].

The evaluation process, particularly sensor technology usage, is typically not the focus of existing reviews. Hence, this paper investigates recent studies on the efficacy of exergames to identify which sensing technologies are used both in the exergames themselves and in their evaluation. We further review whether current exergames and their evaluations include any motion quality assessment. Motion Quality as a term is not clearly defined and is often visually evaluated by a professional physiotherapist or sports scientist. One of the most comprehensive approaches to defining the term is given by Skjaerven et al [20], who found that motion quality has many different aspects, including biomechanical as well as physiological and temporal characteristics. Therefore, motion quality assessment requires evaluating the motion of all relevant body parts at every point in time. Since we want to focus on the study design and methodology, with little regard for results or target group, we opt for a scoping review approach. For each study, we assess how the sensing data is being leveraged with respect to exergame efficacy and motion quality assessment. Based on our findings, we discuss how state-of-the-art methods for assessing motion quality and already used sensing technologies could be used to improve the efficacy of exergames and reduce the risk of injury during play.

Methods

Overview

The goal of this scoping review was to identify sensing modalities in recent studies that evaluate exergame efficacy. For this, 3 systematic searches were conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [21] and PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [22]. A PRISMA-ScR checklist is provided in Multimedia Appendix 1. The database searches were conducted at different points in time by one of the researchers, each without a detailed review protocol.

Search Strategy and Search Terms

Due to the interdisciplinary nature of the research field, 3 different databases were included in the review. To cover both computer science and clinical research, the ACM Digital Library and the subject-specific PubMed database were searched on September 14, 2022, and again on July 14, 2023. A final search on the engineering-focused IEEE Xplore database was conducted on January 15, 2024.

We defined 4 main requirements for studies to be included in our review. First, studies have to feature the evaluation of an exergame. Second, the evaluation has to be conducted quantitatively with sensors with regard to the game's efficacy. Third, the games should focus on general fitness or sports to avoid studies focusing on activities of daily living. Finally, the studies should be recent, which we defined as being published between 2015 and 2023. Based on these requirements, relevant search terms were identified, combined, and generalized as follows:

(exergam* OR "fitness game")

AND (efficacy OR evaluat* OR "heart rate" OR vo2 OR oxygen)

AND (fitness OR sport)

For ACM Digital Library, the search terms were searched for in the categories "Title," "Abstract," and "Author Keyword," each category connected with an OR operator, whereas for PubMed and IEEE Xplore, the search terms were typed "as is" into the "Query Box" and "Command Search," respectively. A detailed search strategy is given in Multimedia Appendix 2.

Study Eligibility Criteria and Selection

Afterward, the following eligibility criteria based on the previously stated requirements were defined. The results were screened and filtered accordingly:

1. Publication type: Peer-reviewed study
2. Publication year: 2015 to 2023
3. Available in English or German
4. The study evaluates the efficacy of at least one exergame

5. Sensor data is recorded during the study and used for evaluation
6. The study is sufficiently described to extract information on the exergames, sensors, metrics, and results

The studies were split among the authors to be screened by abstract and assessed for eligibility. The results of this screening process were then presented and discussed conjointly.

Data Extraction and Data Analysis

Eligible studies were evaluated with regard to their general study design (including participant numbers and focus group), their evaluation methods (including evaluation metrics, vital signs, and sensor usage), and the exergames used (including exergame sensors as well as additional motion sensing). The results were again discussed, assessed for relevance for the review, and generalized conjointly.

Results

Overview

The first search yielded 253 studies of which 30 were removed before the screening process as they were duplicates or not available in English or German. An additional 31 studies were identified through previous work of included authors and citation searching, resulting in a total of 258 studies included in the screening process. 208 studies were excluded in this screening process based on the eligibility criteria stated above, leaving a total of 49 eligible studies. The second search yielded an additional 40 studies, of which 32 were excluded from the screening process. The final search, conducted on the IEEE Xplore database, yielded another 50 studies. After screening by title, abstract, and eligibility criteria, 10 studies were deemed fitting, resulting in a total of 67 studies that were included in our review.

Table 1 gives a brief summary of the vital sign-sensing statistics. Multimedia Appendix 3 [23-89] and Multimedia Appendix 4 [23,24,26-58,60-90] feature additional tables that present details for all 67 studies included in the review. Multimedia Appendix 3 provides an overview of the study design, participants, and how efficacy was assessed. Participation numbers ranged from 6 [23] to 360 [24], with a median of 28. There was a large variety of different focus groups, with the biggest group being healthy adults (n=19 studies). Multimedia Appendix 4 details the exergames and corresponding sensors used in each study and gives information on additional motion sensing if there were any. Not all studies explicitly mention all the exergames evaluated; some feature the evaluation of a multitude of different games, and some tested games they developed themselves. Overall, the 67 studies included in our review feature the evaluation of approximately 49 different exergames. The overall review process with all screening steps is outlined in the PRISMA flow diagram in Figure 1.

Table 1. Summary of vital sign sensing statistics. Detailed statistics for each study can be found in Multimedia Appendix 3.

	Measured vital signs			Evaluated metrics						Evaluation criteria analyzed over time			
	HR[a]	VO_2	Other	mean HR	peak HR or % max HR	peak VO_2 or % max VO_2	MET[b]	EE[c]	Other	Performance	Intensity or PA[d]	Motivation	Other
Number of studies	52	22	18	35	31	21	16	15	45	18	11	6	10

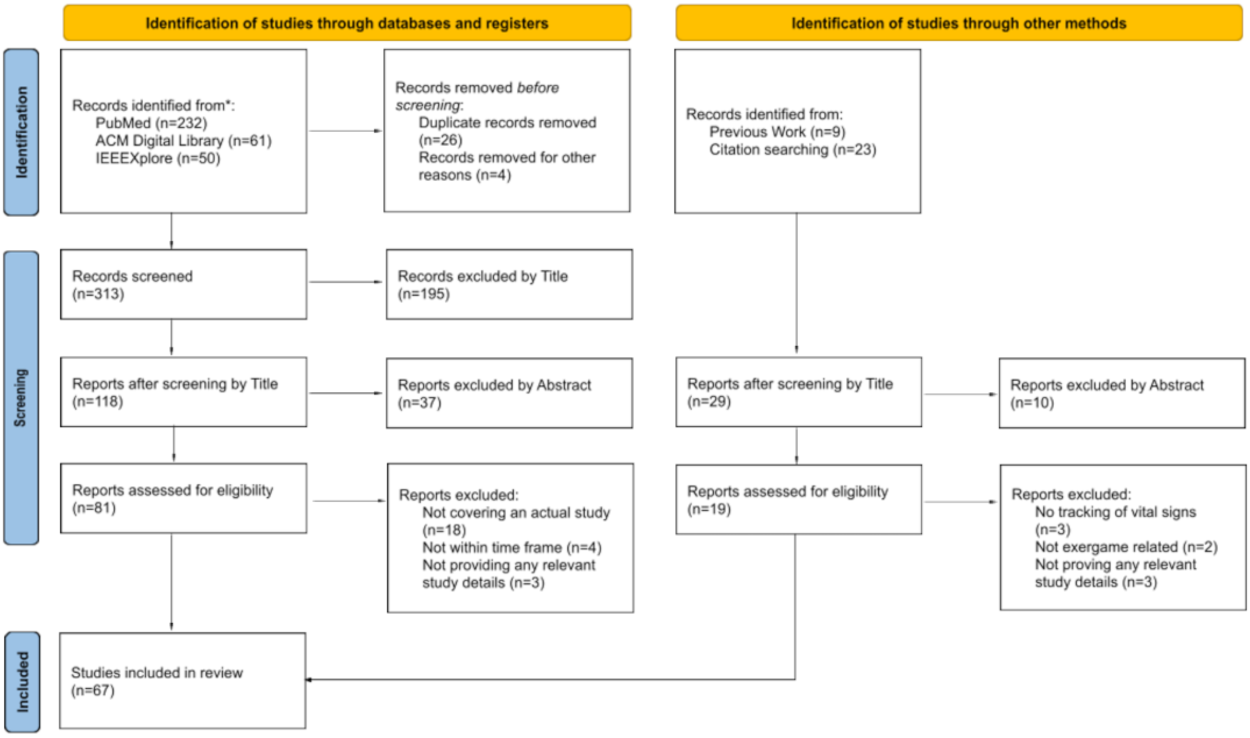
[a]HR: heart rate.

[b]MET: metabolic equivalent of task.

[c]EE: energy expenditure.

[d]PA: physical activity.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [21] flow diagram of the systematic review process.



Vital Sign Sensing Technologies

As per our inclusion criterion, all 67 studies aim to assess efficacy. For that, 54 studies used sensors to measure vital signs, while 11 studies relied only on motion sensing, and 2 studies assessed efficacy without any sensors but with standardized tests only. The majority, that is, 52 of the 54, measured the player's heart rate (HR), and 22 measured the oxygen uptake (VO_2) (more details in Table 1). Furthermore, 18 studies measured other vital signs such as blood pressure, blood lactate concentration, and carbon dioxide production.

Efficacy Assessment

In the context of exergames, efficacy refers to the effectiveness or ability of exergames to achieve their intended goals or their desired effect under optimal or controlled conditions. Efficacy is distinguished from effectiveness, with efficacy focusing on how well an approach works in ideal conditions, while effectiveness considers its performance in real-world or practical situations [91]. However, this distinction is not always clearly made by the researchers [25]. Therefore, in the context of this review, the 2 terms are used interchangeably. Typical goals for exergames can be defined as an increase in the participants' performance, physical activity, or motivation [10,92]. Exergame efficacy is usually evaluated by analyzing these metrics over time or in comparison with conventional physical exercises. Often, they are estimated by measuring vital signs, doing standardized tests, or filling out questionnaires. Efficacy is a highly individual metric and will vary for different activities, different target demographics, and from person to person [10].

When looking at the studies' approaches to assessing exergame efficacy, several different study designs were identified. First of all, a distinction can be made by whether the studies evaluate a single group or compare 2 or more groups. The former is referred to as a within-subject or cross-over study. The latter category is referred to as controlled studies, which again can be split into 2 subcategories. Randomized controlled studies compare randomly split groups, while cross-section studies compare nonrandomized groups based on preexisting conditions. The studies can also be categorized by how many measurements are done. Single-measurement studies use measured metrics and questionnaires to compare the participants' performance, motivation, and general physical activity with nongaming-related exercises. Alternatively, studies with the repeated-measures design, focusing on the long-term effects of exergaming, do the same measurements more than once to observe longitudinal developments. The latter approach was used by 22 studies, while the other 45 studies focused on the first approach. Details on the study design of every included study can be found in Multimedia Appendix 3.

Acute Effects

A total of 53 out of the 67 (79%) studies focus on efficacy evaluation by measuring vital signs in their studies. Out of all analyzed studies (more details in Table 1), 35 reported mean HR, and 31 reported peak HR or proportionate maximum HR (%max HR), with the maximum HR commonly being age-predicted. Ventilation-based evaluation took place in 21 analyzed studies, reporting peak VO_2 or proportionate maximum VO_2 (%max VO_2).

Based on the recorded vital signs, 15 studies processed their participants' data to indicate the recorded energy expenditure (EE) for the exergame activity. In total, 16 studies calculated and reported the metabolic equivalent of task (MET) values for each activity. A total of 8 studies overlapped with studies reporting EE. Furthermore, noteworthy vital-sign-based evaluation metrics are systolic and diastolic blood pressure

[26-29], heart rate reserve [30-33], pulse wave velocity with total peripheral resistance and stroke volume [34], respiratory exchange rate [35,36], lactate concentration [37,38], maximum power output [39], muscle activity [40], concentration through EEG (electroencephalography) [41]. In 3 studies, other derived indicators are used: play intensity and hemodynamic reactivity are calculated based on players' heart rate [37], and the so-called activity counts are based on accelerometer measurements [42,43]. Many studies used subjective questionnaire scales for assessment, which we do not evaluate as they are unrelated to vital sign sensing.

Long-Term Effects

Although many analyzed studies (35 out of 67) comprised more than 1 session of playing exergames, only a minority evaluated changes over time (22 out of 67), and thus qualifies as a longitudinal study in the context of this paper. The evaluation time for longitudinal studies ranged from 4 weeks [44-47] to 6 months [48].

As detailed in Multimedia Appendix 3, most researchers analyzed players' performance. The performance evaluation was predominantly done objectively by tracking changes in anaerobic [46,49,50] or muscular fitness [51,52], functional strength [50], peak VO_2 [28,48], postural control [45], reaction time [24], or cognitive function [53]. The performance was sometimes evaluated subjectively using exercise self-efficacy score [54].

Other evaluation metrics analyzed over time include changes in intensity, usually based on HR or EE [29,45,55,56], whereas further research publications evaluated playtime for different physical activity levels [28,48,51]. In addition to performance and intensity, 6 research publications analyzed changes in motivation, such as play frequency and duration [56] as well as flow [45], player engagement [55] or enjoyment [54], and happiness [57].

Motion Sensing Technologies

The 67 reviewed studies assess various exergames that use different motion sensing technologies, among which the Kinect for Xbox 360 (Microsoft Corp) [93] is the most commonly used (26 out of 67). The Kinect combines a regular RGB (red-green-blue) camera with a depth sensor and can thus be considered a camera-based system. In addition, 1 study each included an exergame using the EyeToy (London Studio) for PlayStation 2 [54] and PS Move (Sony Interactive Entertainment) for PlayStation 3 [44], resulting in 28 out of 67 studies featuring at least one camera-based system. Ergometers, dance mats, balance boards, and other sensing technologies specialized for specific motions are used in 21 out of 67 studies and, thus, make up the second-most common type of motion sensing technology.

VR systems and body-worn inertial measurement units (IMUs) are featured less commonly. Only 5 out of 67 studies feature body-worn IMUs for motion sensing, and only one of them uses IMUs not included in a smartphone or game controller. Furthermore, 7 studies evaluate exergames that use the Nintendo Wii remote controllers held in the player's hands. These controllers are not body-worn and combine an IMU and an infrared sensor with an external emitter for tracking. Together with VR systems, which were used in 16 out of 67 studies as either standalone or within the so-called ExerCube (Sphery AG) [94], they make up the category of hybrid sensing (overall n=22). Finally, one study [58] features a game that does not use any form of motion sensing.

Out of the 67 studies, 21 did additional motion sensing during the exergaming for evaluation purposes. Common motion sensors used for this task are body-worn accelerometers and IMUs (used in 12 studies) and force plates (used in 4 studies). Furthermore, 2 studies used hybrid motion-capture systems, and 2 used camera-based systems. A specialized system to measure reaction times, an exercise bike, surface electromyography, and a handgrip dynamometer were used in 1 study each.

Motion Quality Assessment

Motion quality, as a term, is not clearly defined and is often visually evaluated by a professional physiotherapist or sports scientist. One of the most comprehensive approaches to defining the term is given by Skjaerven et al [20], where they investigated the lived experiences of a group of expert physiotherapists in search of essential characteristics and features of the term. They found that motion quality has many different aspects, including the biomechanical "characteristics of path and form in [motion]" as well as the physiological and temporal "characteristic of flow, elasticity, vitality, and rhythm in [motion]." Therefore, to provide specific feedback on the full motion quality, it would be necessary to assess the whole motion by tracking and evaluating the motion of all relevant body parts at every point in time, independent from the gameplay.

An essential part of exergaming is the game's ability to track and analyze the player's motions to judge the player's gameplay and their exercise quality. Often, exergames focus on the gameplay aspect, only evaluating motions implicitly by requiring players to interact with the virtual environment, for example, slashing, collecting, or avoiding virtual objects [3,39,40,95,96]. Alternatively, some games combine both evaluations by having players fit a predefined shape [59,97,98]. While such an approach might be suitable to verify if players are performing a specific motion at all, it only enables detecting static poses or certain joints without analyzing the holistic motion execution.

None of the 49 games featured in the studies explicitly assess the quality of exercises performed. However, 7 studies use additional motion sensing to do some form of quality assessment during their evaluation. In addition, 4 of these 7 studies focus on specific motion aspects, such as assessing the angular displacement or range of motion of certain joints [41,55], quantifying postural sway [45], and evaluating shoulder flexibility [26]. Only 3 studies [44,51,60] assess the players' motion quality as a whole, using a multitude of sensors and either a standardized test or a professional physiotherapist. However, for 2 of the studies, these assessments do not happen during the exergame but are used to identify general motion quality at times when the subjects are not playing. The final study [44] employs an expert to do an analysis of gross upper body biomechanics based on video recordings of the subjects during the exergames. Therefore, this is the only study in our review that fulfills the condition of holistically evaluating all relevant body parts at every point in time during the exercise, which we consider necessary for motion quality assessment, according to Skjaerven et al [20]. However, this is not an automated process and instead requires manual input from an expert.

Discussion

Overview

To the best of our knowledge, this review represents the first work analyzing sensor usage in studies that examine exergame efficacy. We found 67 eligible studies, which we analyzed with regard to sensor usage for both efficacy evaluation and motion analysis. Overall, HR was the most commonly used vital sign to evaluate efficacy (n=52), while the Microsoft Kinect was the most commonly used exergame sensor (n=26). The results of the analysis show that the sensors used in the exergames and the sensors used in the evaluation are, in most cases, mutually exclusive.

Principal Findings

From the review, 2 main conclusions can be drawn: First, the majority of papers focus on measuring vital signs to infer a physical activity metric. Second, an overall lack of motion quality assessment can be stated among exergame studies. For the studies, this lack of quality assessment can lead to undetected and unwanted influences on the results. For example, it might be hard to differentiate if a lack of efficacy should be attributed to the exergame or to the participants' execution, especially in longitudinal studies. Furthermore, it also poses a problem for the exergames themselves since the players are incentivized to optimize for score, which might lead to optimal gameplay that does not coincide with a correct exercise execution and might lead to injuries instead of increased health [9]. Therefore, in the following outlook, we outline how different types of sensor technologies could be used with existing motion analysis techniques to assess motion quality in exergames.

Outlook

Quality Assessment Based on Cameras

Overview

While the traditional approach of motion analysis by a camera is a hybrid one with visual markers attached to certain body parts, a lot of recent research has focused on markerless methods solely based on single-camera video images [99]. This gives cameras a few advantages over other sensing methods: They are unobtrusive to the players and allow them a full range of motion; they can be easily set up and moved around, and they are comparably cheap and widely available [99]. The recent approaches can be differentiated by their modality: While classic RGB cameras are mostly used when no depth information is needed, so-called RGB-D (red-green-blue-depth) cameras like the Microsoft Kinect [93] are able to also record depth information [100,101].

RGB-D

As stated, 26 of the 28 exergames considered in the review that used cameras for the gaming input relied on the Kinect RGB-D camera. In addition to the advantages of cameras already listed, the Kinect also has its origin in gaming, making it a widespread tool not only for scientists but also for game developers. However, all papers in our review use the Kinect only as input for the games, not for an explicit motion quality assessment. This is surprising as, outside of the exergaming context, RGB-D cameras are used in several motion research areas, such as gait analysis [102-104] and fall detection [105], where they have shown to be a reliable tool to capture and evaluate full-body movements. Sporadically, the Kinect has been used in exergaming-related motion analysis as well, albeit not for quality control in an efficacy assessment study. Examples include motion dissimilarity analysis [106] or interrater reliability evaluation between a Kinect system [107] and a human rater.

RGB

In contrast, classic RGB cameras are not commonly used as motion sensors in exergaming, aside from rare examples [108]. This is also apparent from our review since only 2 exergames used an RGB camera compared to the 26 using the Kinect. However, studies without exergame context have shown that modern RGB-based systems are well-suited to do quantitative motion analysis. Systems like MonoCap (Zhejiang University) [109], OpenPose (Carnegie Mellon University) [110], and MediaPipe Pose (Google) [111] have proven that full-body pose estimation can be done with high accuracy. One of the most well-researched applications of RGB-based motion analysis is gait analysis, which can either be done with a feature-based approach using pose estimation [112-114] or a feature-less approach directly on the images [115,116]. More complex medical applications such as joint load prediction [117] and motion limitation analysis [118] indicate the method's ability to do precise quality assessment of human movements. Furthermore, RGB cameras have already been used in sports analysis [119]. These use cases imply the suitability of RGB cameras as a tool for both gaming input and quality assessment in exergaming.

Quality Assessment Based on Hybrid Sensing Techniques

The release of consumer-grade virtual reality systems contributed to the development of many immersive exergames. An analysis of the 29 top VR exergames from a recent review [120] shows that players prefer games providing a high level of exertion (equivalent to real-world exercise level), whereas a high level of immersion is important for distraction (reducing perceived exertion). Most reviewed exergames using hybrid sensing technology indeed provide a playful fitness experience; nevertheless, existing approaches often fail to analyze motion execution to detect errors or to provide specific feedback on motion quality. For example, approaches letting players fit a predefined shape [59,97,98] might be suitable to verify if players are performing a specific motion at all. However, they only enable the detection of static poses without analyzing motion execution. Furthermore, many VR exergames enabling interaction with VR objects usually depend only on hand-held devices and often lack lower body movement.

To overcome this limitation, other researchers use additional off-the-shelf VR sensors. Previous studies already concluded that VR sensors are feasible for clinical, research, and industry usage [121,122]. For example, Martin-Niedecken et al [90,123] demonstrated how trackers attached to wrists and ankles can be used to recognize different exercises, such as burpees, lunges, and punches. The motion quality, presented by a star ranking, is then assessed according to how well players reached predetermined target points and how quickly they returned to their initial pose. A further study [124] also analyzes the entire motion execution of different yoga poses and thereby identifies execution errors.

Another possibility to assess motion quality is marker-based motion capture systems, for example, OptiTrack (NaturalPoint Inc.) [125] and Vicon Tracker (Vicon Motion Systems Ltd.) [126]. These systems are the gold standard for tracking individual joint positions and angular movements with high accuracy and low latency [127,128]. However, as such systems require several markers and cameras, they can be obtrusive and not suitable for home or clinical environments. Nevertheless, previous research publications have already demonstrated that motion capture suits are reliable for analyzing holistic motion executions during dance [129], identifying exercise execution errors during physical exercise [130], or conducting kinematic trunk motion analysis [60].

Quality Assessment Based on Body-Worn Sensors

IMUs consisting of an accelerometer, a gyroscope, and sometimes a magnetometer are the most common types of body-worn sensors. They are integrated into commercial devices such as smartphones, smartwatches, and fitness trackers. Among other things, they are often used to track fitness activities and activities of daily living. Compared with camera-based or hybrid approaches, they are particularly well suited to track nonstationary activities. In the following, we will not discuss other body-worn sensors, such as EMG sensors, because of their limited availability and applicability.

While regular body-worn IMUs do not provide as extensive motion data as camera-based or hybrid systems, exergames could use them as robust, low-cost sensors to assess specific quality metrics and enable tracking without a stationary setup. An example of this can be seen in the commercially successful exergame Ring Fit Adventure (Nintendo) for the Nintendo Wii, which tracks and assesses performed exercises through IMUs placed at the thigh and the inside of an elastic ring held by the user. Alternatively, commercial IMU-based systems such as Xsens (Movella) [131], Noraxon Ultium Motion (Noraxon) [132], or the Teslasuit (Teslasuit, Deep Divers Ltd) [133] could be used for an extensive motion analysis in a mobile setting [130].

Whereas some exergames in our reviewed papers use controllers that incorporate an IMU, none rely purely on body-worn sensors for tracking. In 7 papers [41,43,51,60-64], body-worn IMUs are used to assess physical activity. Only Ko et al [41] and Mueller et al [60] additionally use body-worn IMU data for quality assessment by determining the users' range of motion and back posture respectively.

In their review, Rana and Mittal [134] show that wearable sensors can be successfully deployed for kinematic analysis in a variety of sports applications. While these included sports applications such as swimming [135,136], which are ill-suited for exergames, most sports applications presented could be integrated into exergames. Particularly noteworthy applications are swing sports such as tennis [137-143] and badminton [140,144], in which IMUs can either be wrist-worn or integrated into the racket to track and assess individual swings, as it can be difficult to track these with stationary setups in a practical setting.

Limitations

This scoping review is prone to the same search-related limitations as other reviews of this type. First, only articles published in international journals and full articles published in conference proceedings written in English or German are considered. Therefore, potentially relevant studies published in other languages may have been missed. Second, some articles were excluded from the analysis because the required information to assess their eligibility based on the inclusion criteria was not provided. Third, we assess a lack of reproducibility for the ACM Digital Library. In general, a very high volatility can be noted in the amount of records ACM's search function returns when changing individual words or operators. Since the current search results in less records than the original search, which were all included in the review, we consider this to be a minor limitation. Finally, out of the 67 studies included in this scoping review, 8 studies were not found firsthand using the search terms but instead through previous work of included authors and citation searching. This may indicate that there would have been even more fitting search terms for the review question. However, due to the author's experience with the topic and the unambiguity of the results, we are confident that we were able to mitigate any possible negative effects and that the included studies present a complete overview of the current state of research.

In addition to limitations related to the search, we can also note 2 limitations related to the scope of evaluation. They are a deliberately chosen result of our research focus, which means to analyze the studies' methodology with regards to sensing instead of their results. First, the definitions for the terms "efficacy" and "motion quality" used in this paper focus on how these 2 metrics are evaluated and do not go into detail on what qualifies as "good" efficacy or motion quality. Instead, we evaluate how well the studies are able to assess efficacy and motion quality with the methodology and especially the sensors they use. Therefore, we do not define what a "high/low quality motion" may look like as this question is highly specific to the individual motion and therefore cannot be answered generally. For the same reason, we also do not go into detail on the cohorts' age, sex, and focus group as they are predominantly relevant to the studies' results.

Conclusions

In this paper, we conduct a scoping review of recent studies that examine exergame efficacy to determine which sensors are being used and how they are being used during gameplay and evaluation. Our results show that most studies evaluate exergame efficacy by measuring vital signs, the most common being heart rate (52 out of 67) and oxygen consumption (22 out of 67). However, motion quality is only assessed in 7 out of 67 studies despite being an important factor in an exergame's effectiveness and risk of injury. Furthermore, out of the 49 exergames evaluated in the reviewed studies, none feature quality assessment during or after gameplay, and only 3 studies feature motion quality assessment beyond the exergame's feedback.

Since exergames already use motion sensing technologies to track the player's motions, they could also be used for external quality assessment. Therefore, we discuss recent advances in the field of motion analysis and potential use cases of different sensors commonly used in exergames. We come to the conclusion that many of the same sensing technologies typically used in exergames and exergame studies are well-suited for additional motion quality assessment to ensure consistent exergame effectiveness and reduce the likelihood of injury while exergaming.

Introduction

Cardiovascular diseases are among the leading causes of death and morbidity worldwide [1,2]. Cardiopulmonary resuscitation (CPR) and early defibrillation increase survival chances [3]. Serious games (SGs) are tools used to enhance the learning process through entertainment. Current strategies focus on teaching CPR to the community and schoolchildren [4].

While other games exist for teaching basic life support (BLS), no studies have validated these for children in low- to middle-income settings. The SG Children Save Hearts teaches the 5 resuscitation steps per International Liaison Committee on Resuscitation (ILCOR) guidelines. Before use in schools, it requires a formal usability assessment by game developers and health care professionals to ensure ease of use, learning, and interaction.

The primary objective was to evaluate the usability of the SG Children Save Hearts among health care and IT professionals using the System Usability Scale (SUS) [5], a validated usability assessment tool.

Methods

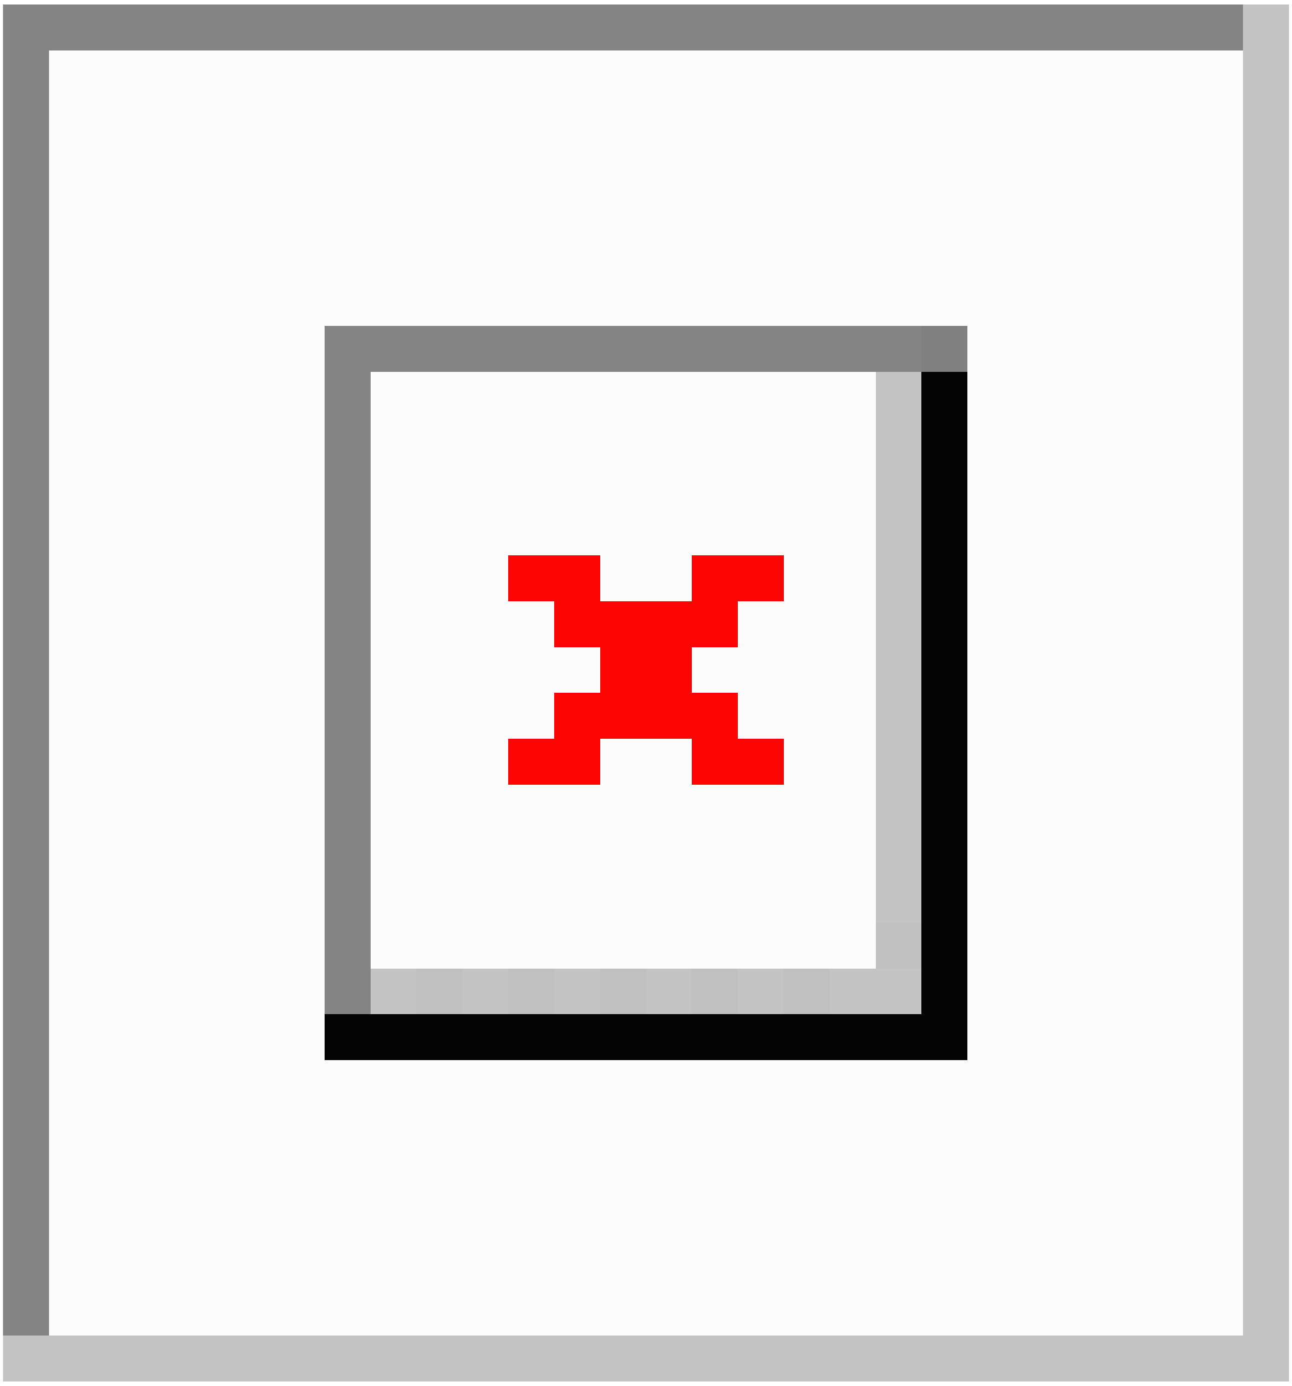
Ethical Considerations

The study protocol was approved by the ethics committee of the University of Marília, Brazil (CAAE: 57160121400005496). All participants signed an informed consent form.

Study Design

We used a nonprobabilistic casual sample to include IT and health care professionals. The usability test was conducted in August 2022 in the university's IT department after a 10-minute lecture on the SG's purpose. Children Save Hearts was developed on the Microsoft Smile Game Builder platform and implemented on Microsoft Windows (versions 7 to 11), targeting schoolchildren aged 7 to 17 years. The script and storytelling are based on the ILCOR 2020 guidelines. The game uses a joystick and simple commands to simplify the user experience (Multimedia Appendix 1). The design and testing process is illustrated in Figure 1.

Figure 1. Design of a serious game for teaching cardiopulmonary resuscitation among schoolchildren. BLS: basic life support; MVP: minimum viable product; SAMU: Serviço de Atendimento Móvel de Urgência; SUS: System Usability Scale.



After completing the SG, participants answered a 10-question survey on its usability using a Likert-type scale. The final grade was converted to a 0 to 100 scale (Multimedia Appendix 2). A grade above 70 was considered acceptable to proceed to a minimum viable product. A sample size of 17 users was required, based on a 10% estimated probability of encountering an interface error, to identify 85% of the problems.

Statistical Analysis

Categorical variables are presented as absolute and relative frequencies. Continuous variables are presented as medians with IQRs. Normality was assessed with the Shapiro-Wilk test. Comparisons were made between IT and health care professionals. Continuous variables were compared using an independent 2-tailed *t* test (for normal distributions) or the Mann-Whitney *U* test (for nonnormal distributions). All analyses were performed using R (version 4.1.0; R Foundation for Statistical Computing).

Results

Children Save Hearts was used by 17 volunteers with a median age of 22 (IQR 20 - 26) years; 8 (47%) were male. Regarding professional training, 8 (47%) held a bachelor's degree in IT and 9 (53%) were health care professionals. All participants played the game and answered the questionnaire. The median SUS score was 75 (IQR 72.5 - 87.5; Table 1). Questions 2 and 4 had the lowest median scores, and questions 7 and 9 had the highest. Health care professionals gave higher grades to all 5 domains when compared to IT professionals. The average time spent in the game was 3.2 (SD 0.4) minutes.

Table . Participant characteristics and System Usability Scale (SUS) scores by profession.

	All (N=17)	IT professionals (n=8)	HCPs[a] (n=9)	*P* value
Participant characteristics				
Age (years), median (IQR)	22.00 (20.00-26.00)	21.00 (18.75-22.75)	24.00 (22.00-27.00)	.07[b]
Male sex, n (%)	8 (47)	4 (50)	4 (44)	>.99[c]
SUS scores, median (IQR)				
Question 1	3.00 (3.00-4.00)	3.00 (2.00-3.25)	4.00 (3.00-4.00)	.08[b]
Question 2	2.00 (2.00-3.00)	2.00 (1.75-3.00)	3.00 (2.00-3.00)	.47[b]
Question 3	3.00 (3.00-4.00)	3.00 (3.00-4.00)	4.00 (3.00-4.00)	.36[b]
Question 4	2.00 (2.00-3.00)	2.00 (1.75-2.25)	2.00 (2.00-3.00)	.61[b]
Question 5	3.00 (3.00-4.00)	3.00 (3.00-3.00)	4.00 (3.00-4.00)	.07[b]
Question 6	4.00 (3.00-4.00)	3.00 (2.00-3.25)	4.00 (4.00-4.00)	.002[b]
Question 7	3.00 (3.00-4.00)	3.00 (3.00-3.00)	4.00 (4.00-4.00)	.009[b]

Discussion

We developed an SG, Children Save Hearts, to teach BLS to schoolchildren. When tested on 17 IT and health care professionals, it achieved an overall mean SUS score of 75, suitable for implementation.

Novel technologies like virtual reality (VR) have been successfully used in Europe to teach CPR to schoolchildren [6]. However, transferring this technology to limited-income countries faces challenges, such as language barriers, VR device acquisition, cultural context, and technical support. Previous SGs for teaching CPR were developed and tested in high-income countries [7]. Educational strategies for teaching CPR in limited-income countries have focused on health care professionals and students [8], not schoolchildren, highlighting a significant gap in the literature. This is the first SG developed in Brazil in Portuguese for schoolchildren.

Our study has some limitations. First, we had a small sample size due to insufficient data to calculate sample size in usability tests and financial constraints in contracting a software house. Continuous usability monitoring with larger sample sizes is needed to maintain external validation. Further studies should target schoolchildren to assess the effectiveness of teaching BLS in schools and explore user experiences to gain insights into how users feel about SGs.

Active teaching methods are crucial to improving survival rates and translating accessible knowledge into practice. Programs like Kids Save Lives [9] and World Restart a Heart Day [10] are teaching schoolchildren that CPR is vital. Despite some usability issues, the game is adequate for testing in schoolchildren.

Acknowledgments

We would like to thank the University of Marília for the use of their facilities and resources. We also thank the participants for their time and dedication to our study.

Data Availability

Due to the nature and design of this study, the raw data supporting our findings cannot be made publicly available. The data set contains detailed information that could compromise the privacy and confidentiality of the participants involved. Protecting participant confidentiality is a priority for us, and thus, in adherence to ethical considerations and participant consent agreements, we are unable to deposit our data in publicly accessible repositories or present it within the manuscript or supplementary files.

Abstract

This research letter presents the co-design process for RG4Face, a mime therapy–based serious game that uses computer vision for human facial movement recognition and estimation to help health care professionals and patients in the facial rehabilitation process.

(JMIR Serious Games 2024;12:e52661) doi:10.2196/52661

Introduction

Facial paralysis is a consequence of damage or injury to the facial nerve, resulting in functional impairments. A challenge of rehabilitation through exercise repetition is maintaining patients' engagement and motivation in the intensive and repetitive execution of the exercises necessary for successful rehabilitation [1]. Repetitive and intensive movements are recommended for progress in treatment [2], and the variety of movements has significant effects on patient recovery [3].

In motor rehabilitation, exergames—serious games that require physical exercise to play—add fun to exercises and allow patients to forget about their condition and focus on the game [4]. Studies conducted with games for motor rehabilitation have achieved promising results [5] on patient motivation and engagement [4]. This study aimed to co-design *RG4Face*—an exergame for facial rehabilitation.

Methods

Ethical Considerations

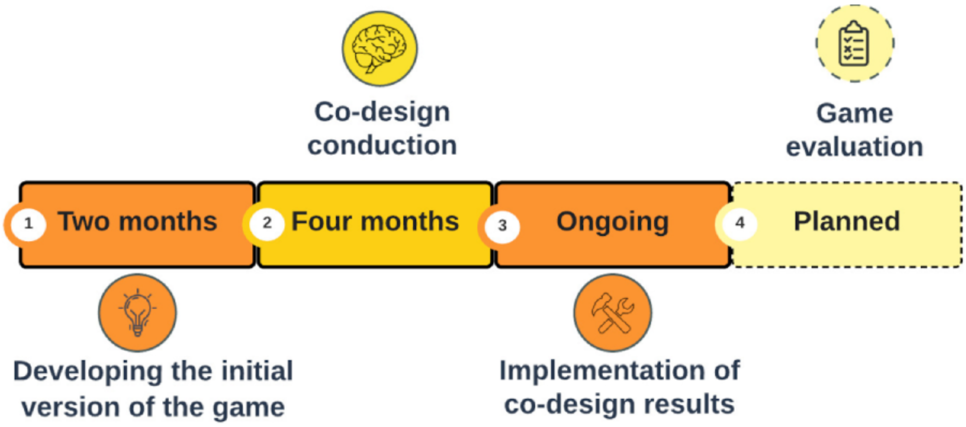
This study was approved by the Research Ethics Committee of Universidade Federal do Delta do Parnaíba (5.632.311). The first author (DLS) provided explicit consent for use of his image in Multimedia Appendices 1 and 2.

Study Design

To develop *RG4Face*, a co-design procedure (Figure 1) was conducted with physiotherapists (n=16) and psychologists (n=5; Multimedia Appendix 3) to obtain the necessary knowledge on the game requirements.

In the first stage, a version of the game was developed with an initial idea (Multimedia Appendix 1). In the second, we recruited physiotherapists and psychologists to participate in co-design meetings (August to November 2022) and answer a questionnaire. We then presented the game to the participants and allowed them to make suggestions. The prototype was essential to encouraging participation during meetings. In total, 5 meetings were held—4 with physiotherapists and 1 with psychologists. The main activities of the meetings were brainstorming sessions, in which the generation of game requirements was encouraged for their incorporation into visual elements, gamification, and game mechanics. Meeting results allowed for the creation of a list of requirements. As a third stage, we are concluding the implementation of *RG4Face* based on the produced requirements. The game code was implemented in JavaScript to provide new features for facial rehabilitation via the Rehabilite Game platform [6].

Figure 1. Co-design timeline.



Results

Per its initial conception, *RG4Face* uses computer vision (via a camera) for capturing, recognizing, and estimating human facial movements. The game prototype was implemented via the MediaPipe face mesh [7] to enable the recognition and use of 1 movement (eg, raising eyebrows; ie, frontal muscle) to control game elements. The game involves a spaceship moving horizontally across the bottom of the captured video window and firing a projectile when face movement is detected. The main objective is to hit triangles that randomly appear on the player's face.

Table 1 presents participants' suggestions during co-design, game requirements, and rationales.

RG4Face is in the testing phase and, prior to evaluations, can recognize 6 movements used in mime therapy to improve facial muscle strength and mobility (Multimedia Appendix 2). To implement the recognition of these movements, MediaPipe was used [7]. The face mesh model allows for the real-time tracking of 468 3D landmarks on the human face that represent important facial features (eg, eyes, eyebrows, nose, and mouth). Distances between landmarks are calculated to recognize movements.

RG4Face provides a mirror therapy feature [8], which can mirror the healthy side of the face to create a visual illusion that can help reduce pain and improve function. *RG4Face* allows for parameter adjustment on the Rehabilite Game platform. Health care professionals can choose specific game mechanics for each rehabilitation case, thereby customizing the game according to patients' needs and difficulties.

Table 1. Functional and nonfunctional game requirements from the co-design procedure.

Participants' suggestions	Refined requirement	Rationale
• Improve the game scenario • Improve the representation of the ship and projectiles • Choose attractive colors and contrasts	• Improve game colors and elements: border, ship, projectiles, and collision	• Enable the game to become more attractive and stimulating
• Include levels with difficulty levels	• Provide difficulty levels	• Gamification for each level, depending on the patient's condition
• Provide an option of mirror therapy for the game	• Implement a mirror therapy simulation	• Patients with Bell palsy can benefit from it
• Implement better game mechanics for rewards • Promote progression in the game	• Create a scoring and bonus system	• Increase patients' adherence to and engagement with treatment
• Movement sensitivity must be customized according to the patient's degree of disability	• Implementation of sensitivity levels for motion recognition	• The level of sensitivity respects the movement capacity of each patient
• Create metrics on the game platform to monitor the rehabilitation process	• Provide in-game metrics	• They are interesting for the health care professional to follow the patient's progress
• To avoid causing botheration to some types of patients, the sound should be optional	• Allow game sound to be optional (ie, turn off the sound)	• The sound may be unnecessary for some patients
• Consider visual acuity of the players • The game scenario should be full screen	• Make game screen full, automatically adjusting to the aspect ratio	• Game elements should be clearly visible
• Head movement should not influence the game • Calibration is essential to avoid false positives and false negatives of movements	• Perform a prior calibration of the player's face	• Adjustment of the distance between player's face and screen, in addition to improving movement recognition

Discussion

We co-designed a serious game for facial rehabilitation that represents a potential new approach to improving patients' adherence to facial rehabilitation. The co-design procedure allowed stakeholders to participate in defining game requirements, thereby empowering the tool to meet the needs and expectations of patients and be more engaging and motivating.

Although there are studies that focus on games for rehabilitating specific parts of the face (eg, eyes [9] and mouth [10]), to our knowledge, no serious game for facial rehabilitation has been proposed that can recognize the face movements used in mime therapy. This study proposes the first such exergame.

Our results demonstrate that the co-design approach was effective for creating a serious game with the potential to meet patients' needs. We plan to evaluate the game with health care professionals, healthy participants, and patients with facial paralysis.

Abstract

Virtual reality (VR) is an immersive technology in which delivery of psychological therapy techniques can be automated. Techniques can be implemented similarly to real-world delivery or in ways that are not possible in the real world to enhance efficacy. The potential is for greater access for patients to effective therapy. Despite an increase in the use of VR for mental health, there are few descriptions of how to build and design automated VR therapies. We describe the development of Phoenix VR Self-Confidence Therapy, designed to increase positive self-beliefs in young patients diagnosed with psychosis in order to improve psychological well-being. A double-diamond, user-centered design process conducted over the course of 18 months was used, involving stakeholders from multiple areas: individuals with lived experience of psychosis, clinical psychologists, treatment designers, and VR software developers. Thirteen meetings were held with young patients diagnosed with psychosis to increase the understanding and improve the assessment of positive self-beliefs, help design the scenarios for implementing therapeutic techniques, and conduct user testing. The resulting Phoenix therapy is a class I United Kingdom Conformity Assessed (UKCA)–certified medical device designed to be used on the standalone Meta Quest 2 (Meta Platforms) headset. Phoenix aims to build up 3 types of positive self-beliefs that are connected to psychological well-being. In a community farm area, tasks are designed to increase a sense of mastery and achievement ("I can make a difference"); in a TV studio, users complete an activity with graded levels of difficulty to promote success in the face of a challenge ("I can do this"); and in a forest by a lake, activities are designed to encourage feelings of pleasure and enjoyment ("I can enjoy things"). Phoenix is delivered over the course of approximately 6 weekly sessions supported by a mental health provider. Patients can take the headsets home to use in between sessions. Usability testing with individuals with lived experience of psychosis, as well as patients in the National Health Service (aged 16‑26 years), demonstrated that Phoenix is engaging, easy to use, and has high levels of satisfaction.

KEYWORDS

virtual reality; VR; psychosis; cognitive behavioural therapy; psychological well-being; design process; self-beliefs; psychological therapy; real-world; efficacy; well-being; mental health; participant; stakeholder; user; Phoenix VR Self-Confidence Therapy

Introduction

Virtual reality (VR) has the potential to automate the delivery of powerful psychological therapy techniques. This includes direct translation of evidence-based techniques that are used in traditional face-to-face therapies as well as techniques that are not possible or difficult in the real world, potentially enhancing efficacy. The automation of such techniques means therapies can be more widely available in clinical services. However, automation of psychological therapy in VR requires careful execution to ensure there is precise translation of effective techniques that link to clear clinical targets. In order for an automated VR therapy to be effective, the design process must be methodically and rigorously conducted.

We previously published 2 papers on the design process of gameChange [1,2], a VR therapy targeting agoraphobic avoidance in patients with psychosis. Most VR therapies have been used to target avoidance of feared situations and reduce anxiety [3]. We describe in this paper the development of a new VR therapy with a different clinical target: the improvement of positive self-beliefs and psychological well-being. Phoenix VR Self-Confidence Therapy uniquely combines techniques derived from existing therapies with techniques that differ from those used in the real world to target key processes that impact psychological well-being. Additionally, since the development of gameChange, there have been improvements in VR hardware and programming capabilities. Primarily, this has included the use of standalone headsets (ie, a gaming laptop is not required to run the program, nor external cameras) such as the Meta Quest 2 (Meta Platforms). Standalone headsets are more affordable and accessible for patients and do not require a staff member to set them up and be present throughout use.

VR for Psychosis

VR allows for the creation of 3D computer simulations of environments that can be interacted with in a similar way to the real world. Virtual environments elicit similar responses to their real-world counterparts [4]. This makes it possible for people to enter environments in the virtual world and learn new things that can then apply to real-world situations. VR has a number of advantages. It allows for full control over the environment, including specific stimuli. Scenarios can be repeated and entered gradually. People are more willing to enter virtual scenarios precisely because they know the situations are not real; indeed, one study indicated that three-quarters of people would rather participate in VR-based exposures than real-world exposures [5]. Lastly, VR therapies can be highly engaging; therefore, they are more appealing for patients [6].

The use of VR among patients with psychosis has included aided therapies (ie, using VR alongside traditional face-to-face therapy). For example, Pot-Kolder and colleagues [7] compared participants who received VR-based cognitive behavioral therapy (VR-CBT) to those in a wait-list control group and found that those who received VR-CBT had reductions in paranoid ideation and anxiety. Patients received 16 sessions with a psychologist, and VR was used together with face-to-face therapy: psychologists provided in-the-moment feedback and guidance on how to respond to situations differently while the patient was in the headset. Another study examined the initial feasibility and efficacy of VR therapy to target the impact of negative symptoms (eg, poor motivation, blunted affect, and difficulties experiencing pleasure). Patients received 12 sessions of VR therapy using principles based on existing evidence-based therapies (CBT and cognitive remediation). Environments were simulated real-world scenes (eg a factory, pub, and rooms that may be found in one’s house, such as a TV room). The VR therapy was found to be acceptable and engaging, with patients indicating increased levels of goal attainment [8]. As with the Pot-Kolder et al [7] study, all sessions were completed with a graduate-level psychologist, and tasks in VR were discussed directly with the therapist in each session.

A significant advantage of VR is that therapy can be automated and psychological principles embedded within the VR program, including through the use of a virtual coach. This allows the therapy to be supported by a range of staff members, including peer support workers and graduate mental health workers, thereby making it accessible to many more people. An automated VR therapy developed by our team was shown to significantly reduce fear of heights over the course of 2 weeks [9]. In the largest trial of VR with patients to date, an automated treatment developed by our team (gameChange) was found to be effective at reducing agoraphobic avoidance in patients with psychosis, particularly for people with severe levels of avoidance [10,11]. VR scenarios were simulated everyday situations, such as a physician’s clinic, bus, and café. Both gameChange and Fear of Heights include a virtual coach who describes the treatment principles and guides patients through the program. Another study conducted by our team compared an automated VR cognitive intervention with automated VR mental relaxation to reduce paranoia and persecutory beliefs in patients with psychosis. Both therapies included 4 sessions including anxiety reduction techniques. The cognitive intervention was delivered directly in VR by a virtual coach while the mental relaxation intervention included audio files of relaxation techniques. Both interventions were supported by a clinical or assistant psychologist and produced large reductions in paranoia [12].

The studies mentioned above all use exposure-based techniques to target anxiety, social avoidance, and paranoia, which are typical treatment targets in traditional face-to-face therapies for psychosis. They focus on encouraging patients to enter simulations of real-world scenes such as a café, shopping center, or pub in order to learn that they are safe and capable of coping with anxiety. However, there are other important treatment targets for patients with psychosis that may benefit from interventions that encourage users to enter situations they may not encounter in everyday life.

Positive Self-Beliefs and Psychological Well-Being

Our new treatment focused on a different clinical issue in psychosis: low self-confidence and psychological well-being. Patients with psychosis can be self-critical, see themselves as inferior to others, and feel a sense of failure [13]. Psychological well-being is often low [14]. Negative self-beliefs exacerbate the experience of other psychotic symptoms, including paranoia, voice-hearing, and lack of motivation. The result is often a withdrawal from everyday activities. Withdrawal further increases the sense of defeat and means there are fewer opportunities for people to have positive experiences, thereby lowering self-confidence even more. A survey of 1800 patients with schizophrenia found that increasing self-confidence is 1 of the top 3 treatment goals [14].

Psychosis often first presents in late adolescence or the early twenties [15,16]. This is an age at which many people are in school or university, beginning employment, and experiencing other significant life events (eg, moving out of the family home, entering into a significant romantic relationship, and making new friends). Such changes can affect one’s self-beliefs and psychological well-being and have a lasting impact. Therefore, this is a key time to intervene as there are greater connections on which to build (ie, colleagues and friends, hobbies and interests, a sense of purpose through employment or study, and family relationships). Indeed, intervening early during the experience of psychosis has been shown to improve clinical outcomes [17,18].

Effective face-to-face interventions, drawing on CBT and positive psychology techniques, can improve self-confidence

[19-22]. Some of these techniques involve helping patients learn to increase positive self-beliefs—a mechanism for improving psychological well-being—through direct experience (ie, being in situations in which these positive self-beliefs can be activated and maintained). It is these techniques that lend themselves particularly well to implementation in VR therapies.

Design Process

Overview

An automated VR program with embedded therapeutic principles requires a design process that ensures these principles are correctly targeted and implemented. This means input from end users is imperative. The overall aim is to create a program that is easy to use, meaningful, accessible, and highly satisfactory. The design process for Phoenix specifically used a double diamond approach to achieve this aim. Similar to gameChange [1], we used a person-centered design process within the double diamond approach. This is an iterative approach that ensures that the end user's perspective and needs are incorporated into all stages (in this case, the end users are patients with psychosis).

The double-diamond design approach, developed by the Design Council [23], involves exploring an issue widely then taking focused action. It is organized into 4 phases: discover (understanding lived experience of the clinical problem and enhancing understanding and assessment of the key target), define (set out the design brief), develop (refine storyboards, program the application, and perform user testing), and deliver (finalize implementation, perform debugging, and conduct final usability testing). The design process for Phoenix will therefore be described within each of these phases. The double diamond approach was used for the overall look, feel, and design of Phoenix, as well as for individual elements within the program itself (eg, the virtual coach). Prior to beginning the design process, a young person's advisory group (YPAG) was formed, facilitated by the McPin Foundation (a foundation that aims to include people with lived experience of mental health difficulties in mental health research). The YPAG included 14 members aged 16 - 30 years with lived experience of the clinical problem (ie, low levels of positive self-beliefs in the context of the experience of psychosis).

The research team at Oxford included clinical psychologists, a treatment designer, and the software development team (3 VR programmers, a 3D artist, and a lead computer scientist). As with gameChange, the overall responsibility for final design decisions was held by the chief investigator at Oxford.

Discover

Before the first meetings with the YPAG, clinical psychologists and the treatment designer met weekly over the course of 2 months (January and February 2021) to develop a basic design brief that would form the basis for initial discussions with the YPAG. This design brief set the boundaries for the treatment and how techniques could be implemented in VR. The initial aim of the discover phase was therefore to further elaborate this design brief. Using clinical expertise and findings from previous face-to-face studies [19,24], we set the key mechanisms to be targeted as well as the psychological techniques used to target these mechanisms. The resulting design brief outlined the clinical problem (low self confidence and psychological well-being), the target audience (young people with a diagnosis of psychosis), the clinical target (positive self-beliefs), the key function of VR (provide experiences of positive beliefs in VR to stimulate engagement in real-world activities), essential elements (eg, a virtual coach who would guide users through the program), and how it might fit in existing services (a discrete form of standalone therapy that patients could take home and use with the support of a mental health provider and supplementary materials). The script for the program needed to effectively communicate psychological principles using accessible language and ensure that the content was appropriate for the users. Additionally, the program needed to be certified as a medical device and therefore developed with regulatory and safety procedures in mind.

The first meetings with the YPAG primarily centered around clarifying the terminology used to describe self-confidence, as well as specific activities and situations in everyday life that increase self-confidence and psychological well-being. At least one member of the software development team, as well as all members of the research team, attended these meetings. Given the clinical target (positive self-beliefs), an important aspect of these initial meetings with the YPAG therefore included the identification of specific positive self-beliefs associated with increased self-confidence and psychological well-being. It became clear that existing measures did not provide a wide enough range of positive self-beliefs, did not use clear and precise wording, and would not select those in greatest need of interventions to improve such beliefs. It was agreed that a well-validated measure of positive self-beliefs—informed by people with lived experience—should include key beliefs highly connected to psychological well-being that can be targeted by psychological approaches.

Therefore, as part of this discovery phase, we developed such a measure: the Oxford Positive Self Scale (OxPos) [25]. Through discussions with the YPAG, it was agreed this measure should assess the key types of positive self-beliefs to be targeted in VR. Three key types were identified: those relating to mastery and achievement ("I have a purpose," "I am capable," and "I can achieve things"); those relating to strength and resilience in the face of a challenge ("I am strong," "I am resilient," and "I don't give up"), and those relating to enjoyment ("I can relax," "I can have fun," and "I can switch off"). These beliefs fed into all aspects of programming. The validation study for the OxPos began during this phase and resulted in a 24-item, easy to use, and psychometrically robust assessment of positive self-beliefs linked to psychological well-being.

The YPAG also discussed their views on the virtual coach who would guide users through Phoenix. Different ideas about the coach were shared, including the possibility of a coach that was nonhuman (ie, a robot or creature). Ultimately, it was agreed that a human coach that was friendly, kind, and was ethnically ambiguous and relatively gender neutral in appearance would be maximally relatable and therefore most effective for guiding patients through Phoenix. Emotional attributes such as the warmth of facial expressions and animations such as head nodding were highlighted as particularly important for therapeutic alliance [26]. Furthermore, following discussions on the importance of terminology used to describe self-confidence and positive self-beliefs, initial ideas on the script for the coach were developed during meetings among the research team. During this phase, how the coach would describe the rationale behind Phoenix was discussed: that often, feelings of vulnerability and difficult experiences can allow negative self-beliefs to flourish and make it difficult to access positive self-beliefs. Therefore, Phoenix is about redressing this balance.

Given that any suggestions for activities and environments in VR needed to be programmable, weekly meetings among the clinical psychologists, treatment designer, and software development team at the University of Oxford were held in parallel to meetings with the YPAG. Additionally, at least one member of the software development team attended meetings with the YPAG to provide input on what was programmable. Due to the COVID-19 pandemic, meetings were conducted remotely over Zoom (Zoom Video Communications Inc).

Define

The design brief was used as a living document that, in the define phase, was elaborated in greater detail to set the framework for the software development team. This included identifying the broad virtual environments linked to the 3 key types of positive self-beliefs and the activities within these environments. For mastery and achievement, YPAG members particularly identified activities that would tap into a sense of responsibility, such as caring for animals. They also highlighted the importance of simply completing tasks (ie, via a to-do list). For strength and resilience, it was agreed that patients should enter a challenging situation that would allow them to learn that they could complete a task despite feeling anxious and therefore feel a sense of accomplishment. Finally, for enjoyment, members described wanting a situation that was relaxing, where patients could immerse themselves in their surroundings and enjoy the experience in the moment. It was agreed that this situation should include an outdoor space.

Three environments were chosen: a community farm for mastery and achievement, a TV studio for strength and succeeding in the face of a challenge, and a forest by a lake for pleasure and enjoyment. Initial sketches were drawn by the 3D artist and provided to YPAG members in both 2D and 3D format for feedback. When discussing activities to include in each environment, the importance of multiple types of positive feedback was emphasized (eg, animals' facial expressions or behavior, comments from the coach, and positive sounds when tasks were completed). Therefore, these were incorporated in all activities. In addition to the 3 environments where users would complete activities, a fourth area was highlighted as important: the welcome room where users were initially greeted by the virtual coach. It was decided that this room should be a calming, indoor space with elements of nature (ie, plants, a room overlooking mountains). Similar to the other environments, sketches were drawn by the 3D artist and provided to the YPAG members for feedback. We also discussed having uplifting music playing in the background; the music chosen was also provided to the YPAG for feedback.

In this phase, the features and appearance of the coach were also finalized with feedback provided by the YPAG on the look and feel (ie, hair color, body shape, and clothing) as well as the voice (eg, male vs female and young vs old). The YPAG indicated that they would prefer a female coach. They wanted a body shape that was tending more to gender neutral (eg, not too feminine or masculine) and average in terms of size and height (eg, not too thin). Her name (Farah) and voice were therefore also finalized. Several voice actors were identified from the Royal Academy of Dramatic Art in London, United Kingdom, and clips were sent to the YPAG for feedback. A voice actor was chosen and recording sessions for the script took place in later phases of the design process. This occurred concurrently with the development of the script.

The 3D artist also created an overall visual design manual detailing the general look and feel of each element of the program (including textures, lighting, color, animation, and stylization) to ensure consistency across the environments. The name of the therapy (Phoenix) and logo were also designed during this phase, and feedback was provided by the YPAG. Phoenix was suggested by the research team given that, in Greek mythology, a phoenix is associated with the sun and a sense of renewal. This fitted with the aim of the therapy—to encourage patients to build up positive self-beliefs and rediscover themselves. The logo was drawn by a consultant graphic designer and included suggestions of color schemes, images of the phoenix bird, and different fonts for the name.

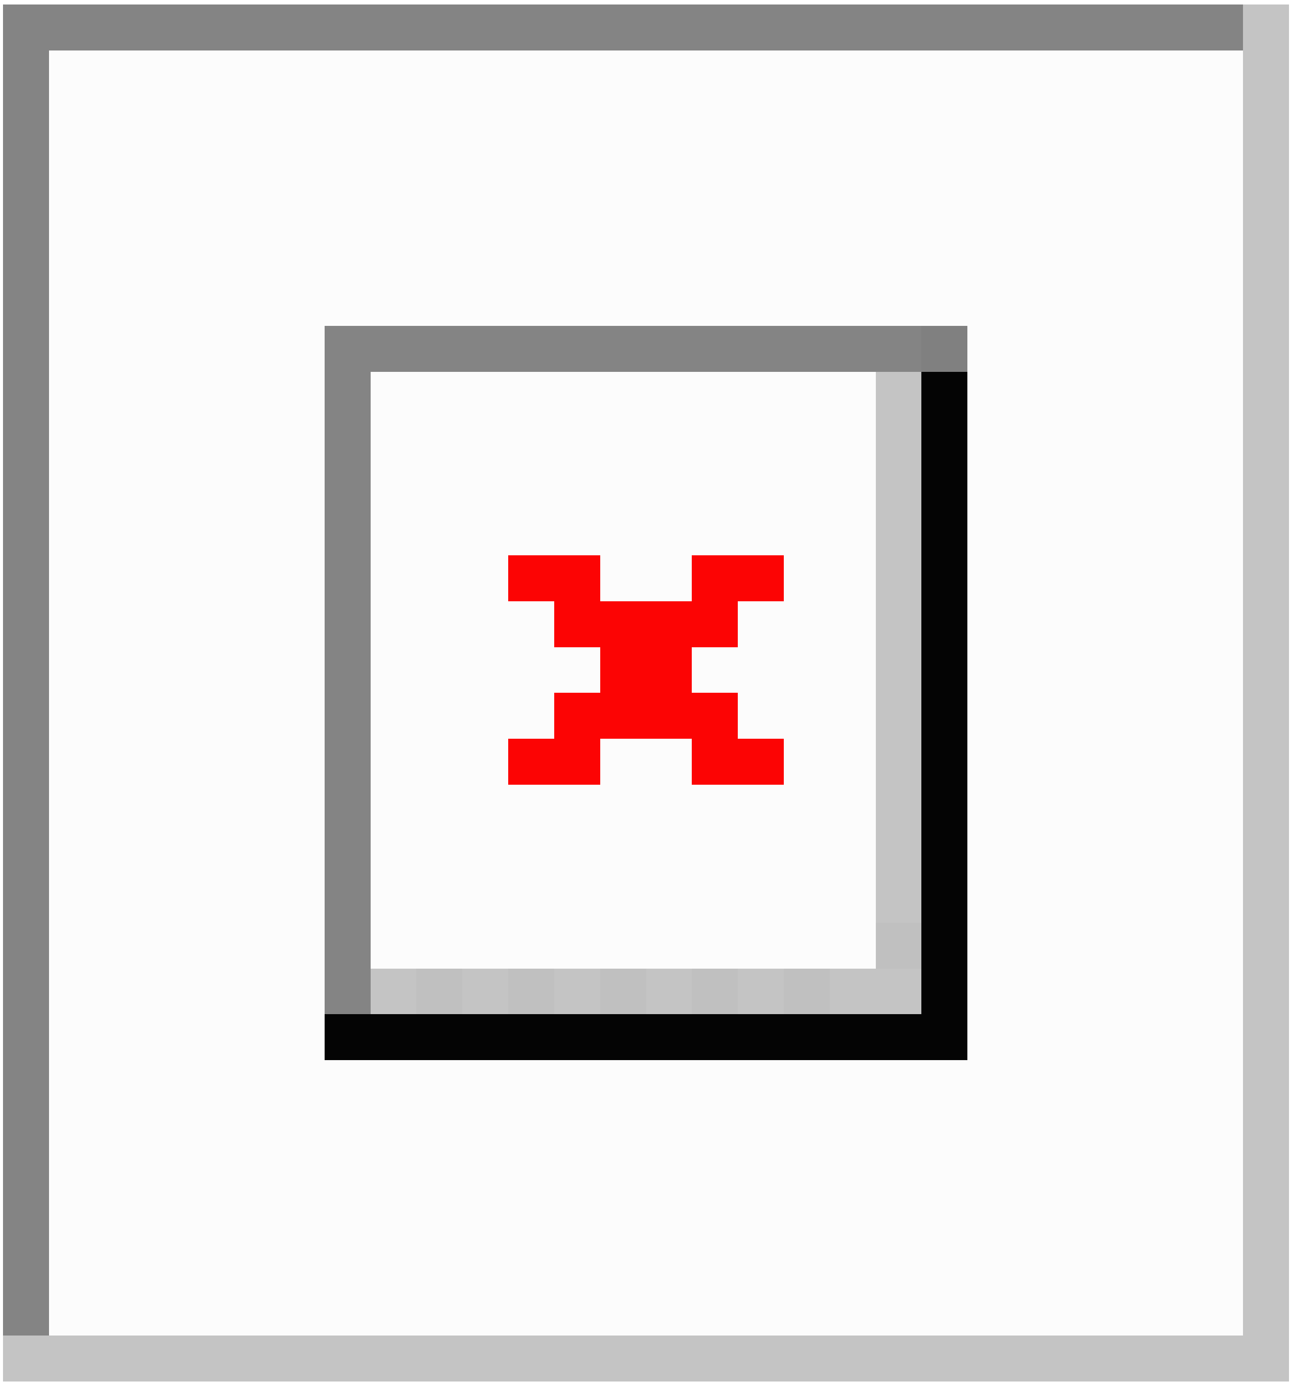
Altogether, across both the discover and define phases, 7 virtual meetings were held with the YPAG over the course of 3 months (February-May 2021), totaling 76.5 YPAG person-hours. Email consultations on the final version of the OxPos questionnaire, logo, and project and coach names totaled an additional 19.75 YPAG person-hours.

Develop

Overview

The develop phase (June 2021-August 2022) included finalizing and programming the specific activities within each of the 3 main environments, as well as the welcome room (Figure 1 provides screenshots). The welcome room includes large glass-fronted windows looking out onto waterfalls, a lake, and mountains, with the room itself containing plants and a fireplace. Users can hear the sounds of birds and water splashing and uplifting music. The coach greets users in front of the window while describing the purpose of Phoenix and providing a tutorial on how to use the equipment to navigate through the program.

Figure 1. Pictures of the areas within the Phoenix VR Self-Confidence Therapy program.



In the mastery and achievement scenario (the community farm), 3 key activities were chosen, comprising 10 steps: caring for animals (feeding one animal, building a hutch, and then feeding multiple animals), growing plants (preparing the bed, planting the seeds, watering the seeds, and picking crops), and redecorating a house (hanging and populating items on shelves, hanging pictures on the wall, and building a bird feeder). Rabbits were chosen as the animals due to patient preference and design complexity (ie, rabbits are relatively easy to design, animate, and program in VR compared to other animals).

In the scenario designed to promote success in the face of a challenge (the TV studio), the key element was being the center of attention and having to perform a specific task, where an audience would gradually increase in size and provide positive feedback. The resulting activity requires users to read out preexisting text from a teleprompter, with the scene being gradually populated by an increasing number of characters (eg, crew and audience). The audience (when present) claps at the end of each reading. Other elements to increase difficulty include the addition of cameras (being both off and on), spotlights, and "on air" signs. The resulting scenario includes 10 levels of difficulty, with the final 2 levels requiring users to make up a weather report rather than read a preexisting one from the teleprompter.

For the pleasurable scenario (the forest), the main programming focus was to ensure the scene was rich in terms of audio (eg, birds singing, owls hooting, water splashing) and visual detail in order to ensure full immersion. Four activities were ultimately chosen: 2 exercises to promote relaxation (a savoring exercise, whereby users are encouraged to focus on different elements of the environment, and a progressive muscle relaxation exercise, both delivered by the coach) and 2 games purely for fun (a game whereby users throw pinecones into holes in trees for points and a drumming game with different modes). The YPAG also suggested giving users choice about whether they complete activities in daylight or at night—therefore, this is built into each exercise and each mode has different sounds and sights.

The script for the dialogue of the virtual coach evolved as activities were programmed. Preferences for wording were elicited through feedback from the YPAG at all stages of the design process. As the scenarios in Phoenix do not include social interaction with other virtual characters, the script only includes lines delivered by the virtual coach. Initial voice recording for the script took place at a recording studio in Oxford over 2 sessions in June and August 2022.

Software Development

The development of the Phoenix software was carried out by the software development team (3 VR programmers, a 3D artist, and a lead computer scientist) within the research team at the University of Oxford. A key requirement was for Phoenix to run on a standalone headset to allow for greater accessibility and portability (ie, ensuring that participants could take the headsets home and run Phoenix themselves, without the need for additional hardware such as a laptop and link cable). Therefore, Phoenix was developed to run on a Meta Quest 2 headset.

The 3D model for the virtual coach was created by the 3D artist using Character Creator (Reallusion)and ZBrush (Maxon). This model was then animated using iClone (Reallusion) software, including blinking and lip-sync. The coach was programmed to look at the user when speaking to them (or at other objects in the scene at relevant moments). Virtual environments and interactive objects were modeled using 3ds Max and Maya (both Autodesk) and textured using Substance Painter (Adobe).

The 3D models were imported into a project in the Unity game engine (Unity) where they were assembled into individual scenes. The programmers added behaviors to create the various activities and other scripts to control positioning and navigation. The player rig and object interactions were based on Oculus Unity Integration (Meta Platforms), with enhancements provided by HurricaneVR (CloudWalkin Games).

A database was created in the cloud using Azure (Microsoft) to facilitate identification of users, store their progress, and receive a log of each session generated in real time by the application. The session logs contained a chronological list of details of significant events occurring during the session to facilitate future analyses. This system allowed for offline use, with data generated while the headset was not connected to the internet being stored on the headset so that it could be synced with the server later when an internet connection was available.

For efficiency of development, an iterative approach was used whereby initial prototypes of environments and activities were checked by the research team at the University of Oxford for usability and effectiveness. Thus, the initial design and script were continuously honed as each build of the application was distributed and reviewed. Some decisions regarding scoping and descoping of design elements became clearer only once a prototype containing the whole experience in some form was available. Once elements and activities were more fully programmed, we ran usability testing sessions with members of the YPAG.

Usability Testing

Usability sessions were completed in person with members of the YPAG as well as 2 members of another project's patient involvement group to ensure a diversity of users. Testing sessions took place at the Warneford Hospital site at the University of Oxford in Oxford, United Kingdom, and the McPin Foundation offices in London, United Kingdom. At least one member of the research team (clinical psychologist or treatment designer) and one member of the software development team were present for all sessions. Sessions lasted approximately 2 hours, with the first 1 - 1.5 hours spent using Phoenix (with breaks) and approximately 30 minutes for debriefing. A usability questionnaire, created by our team, was given to all users during the final user testing session. Users were offered the choice to complete the questionnaire on their own or with help from the research team. Additional feedback was elicited during the debrief using specific questions about what they had done in VR (ie, how they found interacting with the objects, what they thought of the activities, and whether the coach was helpful).

The first usability session was held with 4 users in May 2022 to provide feedback on the farm activities, welcome room, TV environment, and forest environment (particularly the pine cone game). The second usability session was held with one user in June 2022 and the third and final usability session was held in August 2022 with 7 users (3 of whom had attended the earlier user testing sessions and 4 of whom had not) to review all activities and provide feedback on Farah, the virtual coach. At this point (August 2022), only 50% of the coach's lines had been animated. Table 1 and Table 2 show the results from the usability questionnaire given during the final user testing session. These results indicated that all users found it easy to understand the coach's instructions, carry out actions, and move through the program. All users except one found it easy to remember how to do things a second time. Four users found it easy to know what to do in any given situation while 3 found it difficult. This was likely because the coach's lines had not been fully programmed and a textbox with instructions was used in its place. All users felt immersed in VR, were satisfied with the experience, and enjoyed using the therapy. Two users felt mildly nauseous while using VR while 5 did not.

Table . First part of usability questionnaire completed by members of the young person's advisory group (n=7) during Phoenix VR Self-Confidence Therapy testing in August 2022.

Questions	Very easy, n	Easy, n	Difficult, n	Very difficult, n
Knowing what to do in any given VR[a] situation was…	0	4	3	0
Understanding the coach's instructions was…	2	5	0	0
Carrying out an action (for example, planting the seeds, throwing the pinecones) was…	2	5	0	0
Moving through the program was…	2	5	0	0
Learning what to do and how to do it was…	1	4	1	1
Remember how to do things a second time was…	4	2	1	0

Deliver

This phase of the design process (August 2022-May 2023) included finalizing all activities, debugging, and conducting final usability testing (as part of a cohort study with patients in clinical services). As in the develop phase, an iterative approach was used whereby finalized activities were checked by the research team at the University of Oxford for usability and effectiveness. The script was also finalized during this phase after feedback from users in the cohort study and a last recording with the voice actor for the coach took place in February 2023. The final script is approximately 500 lines. When the design and script were locked in, there was a pure bug-testing phase involving the whole team (clinical psychologists and software developers), during which the application was polished to remove glitches and add final enhancements.

The cohort study for Phoenix examined usability, satisfaction, and initial effectiveness of Phoenix in 12 young people with a diagnosis of psychosis across 3 different mental health trusts in the south of England. Patients were recruited over a 4-month period (December 2022-March 2023). All patients were being seen in National Health Service (NHS) services. The primary outcome was usability (Table 3 and Table 4) and satisfaction with the Phoenix program, with secondary outcomes of positive self-beliefs (measured by the OxPos) and psychological well-being (a full description of this cohort study was provided by Freeman et al [27]). The same usability questionnaire administered during user testing in the develop phase was also used with patients in the case series. Compared with the first usability testing session conducted in the develop phase, all users found it easy to move through the program, understand the coach's instructions, carry out an action, learn what to do, and remember how to do things a second time. Only one person found it difficult to know what to do in any given situation. This improvement in user experience is likely due to the coach's lines being fully programmed. Similarly, all users enjoyed the treatment, all but one user were satisfied with the overall VR experience, and all but one user felt immersed in VR when they were using it. Only one user reported that the VR made them feel sick.

Table . First part of usability questionnaire completed by patients (n=11) in the case series for Phoenix VR Self-Confidence Therapy.

	Very easy, n	Easy,n	Difficult, n	Very difficult, n
Knowing what to do in any given VR[a] situation was…	7	3	1	0
Understanding the coach's instructions was…	10	1	0	0
Carrying out an action (for example, planting the seeds, throwing the pinecones) was…	7	4	0	0
Moving through the program was…	7	4	0	0
Learning what to do and how to do it was…	7	4	0	0
Remember how to do things a second time was…	8	3	0	0

Regulatory Process

As described in the original design brief, Phoenix is certified as a class I medical device in conformity with the essential requirements of Directive 93/42/EEC. The certification process was run in parallel with the design process for Phoenix and involved evaluating risks, software, usability, clinical safety, and efficacy of the application. A medical device consultant provided feedback on how to document the software development to ensure it complied with requirements. This was done via online project management and bug tracking software (Jira/Confluence; Atlassian Corporation). The research team, along with the consultant, developed and completed documentation regarding potential hazards of use and embedded mitigating factors, instructions for use, a data processing impact assessment, software specifications, and a clinical evaluation report (which included data on usability testing, described in the Design Process section).

Phoenix VR Self-Confidence Therapy

The resulting Phoenix VR Self-Confidence Therapy program is designed to be delivered over the course of approximately 6 weekly sessions. The activities within Phoenix spark positive self-beliefs that are consolidated through real-world activities. Although key positive self-beliefs are embedded within each broad area and explicitly named by the coach, patients are also encouraged to identify additional positive self-beliefs on which to focus. Key techniques, aided by the mental health provider, include helping patients identify their strengths and the activities linked to those strengths, develop the ability to fully immerse themselves in and therefore savor positive activities, and increase engagement in meaningful activities.

Users start out in the welcome room and, after an introduction to Phoenix and tutorial on how to use the program, choose from the 3 environments. They can repeat activities and return to the welcome room at any time. Prior to each activity, they are provided with a description of the purpose and what steps need to be taken to complete it. After completion, Farah provides positive feedback and encouragement. Farah directs users to pay attention to the feelings of enjoyment and achievement elicited by the activities in Phoenix and encourages them to elicit these same feelings in their daily life. Handouts with positive psychology techniques supplement the delivery of Phoenix.

Users also have the option to take the headset home with them to use in between sessions. This means that in-person sessions may or may not involve the use of VR depending on patient preference. The mental health provider helps users set practices to complete between sessions aimed at continuing to build positive self-beliefs, with sessions focused on reviewing these practices and consolidating the learning made from using Phoenix.

Clinical Evaluation

Ethical Considerations

Ethical approval for the cohort study and the randomized controlled trial (described below) was obtained from an NHS research ethics committee (22/LO/0273). The study abided by the Ethical Principles of Psychologists and Code of Conduct. The McPin Foundation followed all appropriate safeguarding policies and ethical considerations during the design process.

Next Steps

Twelve patients completed Phoenix as part of the cohort study and 11 provided outcome data [27]. Uptake of Phoenix was high: 9 users had 6 sessions and 8 patients consistently used Phoenix on their own in between sessions. Satisfaction was high and there were few side effects. All users rated the quality of the VR therapy as good or excellent. An initial evaluation of positive self-beliefs and psychological well-being showed large improvements. Therefore, the cohort study is now being followed up with a randomized controlled trial in 4 mental health trusts in the south of England.

Eighty patients will take part [28]. Half of the participants will receive Phoenix in addition to their usual treatment and half will continue with their usual treatment only. There will be 2 follow-up assessments: one at 6 weeks (after treatment completion) and one at 12 weeks. Assessments will be completed by research assistants who are blind to the treatment allocation. The primary outcome is positive self-beliefs (measured by the OxPos), with secondary outcomes of well-being, everyday confidence, depression, anxiety, hopelessness, activity levels, and quality of life. Service use will also be measured for an analysis of health economics. For those who receive Phoenix, satisfaction and side effects will also be assessed.

Acknowledgments

Phoenix VR Self-Confidence Therapy is funded by an award to DF from the International Foundation, an independent and not-for-profit foundation. The project is also supported by the National Institute for Health and Care Research (NIHR) Oxford Health Biomedical Research Centre. DF is an NIHR senior investigator. FW is funded by a Wellcome Trust Clinical Doctoral Fellowship (102176/B/13/Z).

The project is sponsored by the University of Oxford. The views expressed are those of the authors and not necessarily those of the National Health Service, the NIHR, the Department of Health, the University of Oxford, or the International Foundation. We wish to thank all the members of the young person’s advisory group.

Conflicts of Interest

DF is the scientific founder of Oxford VR, a University of Oxford spin-out company. DF and JF hold equity in Oxford VR. Oxford VR was not involved in the development of Phoenix VR Self-Confidence Therapy. L Rosebrock, RW, MB, AR, ALM, L Riffiod, RK, TK, and FW have no conflicts of interest.
