Enjoyment has been identified as a key predictor of future exercise participation among young adults [14]. In the present study, *Supernatural* elicited higher enjoyment despite slightly lower wrist-detected MVPA, suggesting that affective response and intensity represent distinct dimensions of the exercise experience. This finding aligns with prior work by Sousa et al [9] and Craig et al [10], who demonstrated that immersive VR exercise platforms can elicit both physiological and affective benefits, and with broader evidence suggesting that immersive VR exercise enhances motivation and enjoyment relative to less immersive conditions at comparable exercise intensities [11,12]. A recent review reported that immersive VR exercise can enhance motivation, engagement, and enjoyment relative to less immersive conditions at comparable intensities [20]. These findings are consistent with prior work demonstrating both psychological and physiological benefits of immersive VR exercise [37].

Cybersickness symptoms did not differ across conditions, indicating that immersive VR exercise was well tolerated during short-duration exposure. This is consistent with prior work by Stanney et al [18] and Kennedy et al [38], who noted that symptom burden during brief, room-scale VR exposure tends to be lower than that during seated or artificially locomoted VR experiences, likely due to reduced visual-vestibular conflict. These findings are consistent with prior work demonstrating low symptom burden during brief VR exercise sessions [34]. Advances in hardware, including improved refresh rates and motion tracking, as well as the use of room-scale movement without artificial locomotion, may reduce sensory conflict and mitigate cybersickness risk [39]. Notably, however, cybersickness scores across all 3 conditions, including the semi-immersive video shadowboxing condition, fell within the ranges classified as significant to problematic on the SSQ [38], suggesting that cybersickness symptom burden is not exclusive to fully immersive VR and warrants monitoring across all boxing-based exercise modalities. However, cybersickness remains influenced by multiple design factors, including movement type and visual feedback, and should continue to be considered in future intervention studies [39].

Limitations

Several limitations should be considered when interpreting these findings. First, this study used an acute, time-matched exercise protocol, which may limit generalizability to longer-term participation. Movement efficiency and intensity regulation may change with repeated exposure due to motor learning and task familiarity [34,39,40]. Second, the sample consisted of healthy young adults, which may limit generalizability to older adults or clinical populations. This is particularly relevant given that exergaming interventions are increasingly applied in older and clinical populations [41]. Participants were also prescreened for cybersickness susceptibility, which may underestimate symptom burden in broader populations. Third, all exercise intensity outcomes were derived from wrist-worn accelerometry [42] without concurrent heart rate monitoring or ratings of perceived exertion. This limits the ability to confirm whether observed differences in wrist-detected MVPA reflect true differences in physiological intensity. Wrist-worn accelerometers demonstrate reduced accuracy for multiplanar and upper extremity–dominant activities, which is particularly relevant in immersive VR exercise contexts [31,32]. Future studies should incorporate multimodal assessments of exercise intensity [38]. Fourth, the SSQ includes items such as sweating, which may reflect exercise-induced responses rather than cybersickness-specific symptoms. This represents a potential source of measurement confounding in exergaming contexts. Finally, only a single standardized session was used for each platform. Variation in content, difficulty, and instructional style may influence both intensity and enjoyment, and the findings may not be generalizable to all available sessions within each platform.

Conclusions

This study is among the first to directly compare 2 commercially available immersive VR boxing platforms alongside a semi-immersive shadowboxing condition within the same participants, providing a more comprehensive evaluation of exercise intensity, enjoyment, and cybersickness than prior platform-specific investigations. Unlike previous studies that have largely examined VR exergaming platforms in isolation, the present findings suggest that platform-specific design characteristics, rather than immersion alone, may influence exercise intensity and user experience.

Although differences in wrist-detected MVPA and enjoyment were modest, the findings highlight that exercise intensity and affective response represent distinct dimensions of the exercise experience, with potentially different implications for long-term physical activity engagement. These results contribute to the growing VR exercise literature by supporting flexible, user-centered approaches to physical activity promotion and exergaming-based exercise prescription. From a real-world perspective, commercially available VR and semi-immersive boxing platforms may represent accessible and engaging tools for promoting physical activity among young adults. Future longitudinal research is needed to determine whether these acute responses translate into sustained exercise adherence and long-term behavioral change across diverse populations.

Multimedia Appendix 1

Participant flow through enrollment, assignment, follow-up, and analysis. Of 33 individuals assessed for eligibility, 31 met inclusion criteria and were enrolled. Using a within-subject, counterbalanced design, all participants completed 3 exercise conditions (video shadowboxing, Supernatural, and FitXR) during a single laboratory session lasting approximately 2 hours. Condition order was randomized and counterbalanced using computer-generated random numbers. No participants were lost to follow-up or excluded from analysis. Abstract

Background: Social participation is a key goal of stroke rehabilitation, yet effective interventions remain limited. Existing approaches focus largely on functional training or general psychological support, rarely targeting resilience as a modifiable mechanism for enhancing social participation. Most interventions are delivered face-to-face, limiting accessibility and scalability. A theory-driven digital intervention that integrates resilience training with contextualized practice may offer a promising pathway to support social reintegration in stroke survivors.

Objective: This study aimed to develop a theory-driven, digital resilience-based course-game sequential intervention for improving social participation in stroke survivors and to evaluate its usability among the target population.

Methods: This was an intervention development and usability study. Following the first 4 steps of intervention mapping, we completed the following steps: (1) conducted a needs assessment based on prior empirical evidence identifying psychological resilience as a key determinant of social participation; (2) defined performance and change objectives grounded in the Kumpfer resilience framework, which delineates 5 protective factors (cognitive, emotional, spiritual, behavioral, and physical); (3) selected theory-based methods and practical applications; and (4) developed an intervention prototype through 4 phases: initial design integrating course learning and gamified experiential modules, expert review and refinement by an 8-member panel, development of the digital system via a WeChat mini-program, and finalization of comprehensive intervention scripts. Participants were recruited using convenience sampling from a rehabilitation hospital in Shanghai, China. Usability was evaluated with 14 stroke survivors through 5 representative tasks, the System Usability Scale (SUS), and semistructured qualitative interviews. Quantitative data were analyzed using descriptive statistics, and qualitative data were analyzed using conventional content analysis.

Results: The intervention comprised 2 sequential modules: a 7-session course learning module targeting 5 resilience factors, delivered weekly via narrative audio and multimodal content, and a gamified experiential module featuring a supermarket shopping scenario that enabled contextualized skill application. Each weekly course session was designed to last approximately 60 minutes. The duration of a single game session was 20 minutes. Participants had a mean age of 65.4 (SD 9.75) years, and 78.6% (11/14) had experienced an ischemic stroke. All participants completed the usability tasks successfully. The mean SUS score was 73.6 (SD 12.2, 95% CI 66.5-80.6; median 77.5, IQR 61.3-80.6), indicating good usability. Qualitative feedback revealed 3 themes: perceived ease of use and accessibility, perceived usefulness and engagement, and suggestions for improvement.

Conclusions: This study systematically developed a theory-driven, digital course-game sequential intervention that is innovative in targeting psychological resilience as a core mechanism for social participation, distinguishing it from conventional function-focused or generic resilience approaches. By integrating systematic course learning with contextualized gamified practice, it offers a scalable, low-burden tool that addresses key gaps in stroke rehabilitation. These findings support progression to feasibility and efficacy testing through randomized controlled trials in real-world settings.

Introduction

Social participation is increasingly recognized as the ultimate goal of stroke rehabilitation, a paradigm reinforced by the ICF (International Classification of Functioning, Disability and Health) [1]. The ICF conceptualizes participation as "involvement in a life situation," though this definition remains broad and its operationalization has been subject to ongoing debate. Building on prior conceptual work, social participation has been further delineated to encompass several key features, such as engagement in social activities, fulfillment of social roles, and interaction with others in community settings [2,3]. However, stroke survivors frequently experience a significant and persistent decline in social participation [4,5], which is associated with elevated risks of low mood, recurrent stroke, diminished quality of life, and mortality [6-8]. Therefore, effective interventions to enhance social participation in this population are urgently needed.

Existing interventions aimed at improving social participation are diverse, including exercise-based programs, complex interventions, self-management strategies, and educational initiatives. Our recent scoping review and network meta-analysis revealed considerable heterogeneity in their effectiveness, with functional training remaining the dominant approach, while systematic interventions targeting psychological determinants are notably scarce [9]. This gap is significant, as negative affective states such as anxiety and depression have been consistently identified as potent barriers to poststroke social reintegration [10,11]. Moreover, the predominant face-to-face delivery mode is resource-intensive and may not be sustainable in settings with limited rehabilitation services, underscoring the need for more scalable digital approaches.

Psychological resilience, defined as the ability to adapt positively and "bounce back" in the face of adversity, offers a promising theoretical target. Based on the Kumpfer resilience framework, the initiation and maintenance of the resilience process are highly dependent on an individual's internal protective traits, specifically cognitive, emotional, spiritual, behavioral, and physical domains [12,13]. Our previous research identified resilience as a crucial protective factor for social participation in stroke survivors, operating through a dual pathway: directly buffering psychological distress and indirectly enhancing participation by improving exercise adherence and subsequent physical function [14]. This finding suggests that the benefits of resilience extend beyond mere psychological well-being; they can catalyze positive behavioral changes, such as consistent exercise, that lead to better adaptive outcomes and, ultimately, greater community involvement.

Digital health interventions have emerged as effective tools for behavioral change in chronic disease management [15,16]. However, traditional mobile health applications in chronic care often focus primarily on the didactic provision of knowledge and skills, which can lead to user disengagement and high attrition rates due to a lack of interactivity [17,18]. Conversely, serious games, which are interactive computer applications designed for purposes beyond pure entertainment, such as training and education, have shown potential in chronic disease management [19-21]. Yet serious games face the inherent challenge of balancing entertainment with educational efficacy; excessive gamification may dilute the therapeutic message, while an overly serious approach can undermine user engagement [22]. To address these limitations, a synergistic approach that integrates the strengths of both conventional digital interventions and gamified components is warranted.

Therefore, grounded in the Kumpfer resilience framework and our prior work establishing psychological resilience as a key lever for improving social participation, this study aimed to develop a theory-driven digital intervention targeting the 5 core resilience factors through a sequential course-game design. The course learning module provides structured, accessible delivery of resilience skills, while the gamified experiential module offers immersive and contextualized practice, enabling participants to rehearse and reinforce these skills in a safe yet authentic environment. This paper describes the development of this digital, course-game sequential intervention using the intervention mapping (IM) approach and presents the results of its initial usability evaluation among stroke survivors.

Methods

Intervention Development Framework

IM is a systematic framework for developing, implementing, and evaluating behavior change interventions [23]. It comprises six consecutive steps: (1) conducting a needs assessment to identify health problems and their underlying determinants; (2) specifying performance objectives and their modifiable determinants; (3) selecting theory-based methods and practical strategies; (4) designing the intervention scope, sequence, and materials; (5) planning implementation; and (6) developing an evaluation plan. This study focused on the first 4 steps of IM, which guide intervention development. The implementation and evaluation of the intervention will be reported separately. This study adheres to the Guidance for Reporting Intervention Development [24].

Step 1: Needs Assessment

A multidisciplinary team comprising physiotherapists, psychologists, nurses, and digital health experts was established to guide the intervention development. Building on our prior research identifying psychological resilience as a critical determinant of social participation in stroke survivors [14], the team adopted the Kumpfer resilience framework [12] as the core theoretical foundation. This framework delineates 5 interconnected protective factors that contribute to an individual's capacity for resilience: cognitive competencies (rational thinking to counteract negative thought patterns); emotional management (identifying and regulating negative emotions); spiritual characteristics (belief in one's ability to improve circumstances and achieve goals); behavioral competencies (problem-solving skills that enhance coping self-efficacy); and physical well-being (sound physiological foundations that facilitate positive psychological states). In this study, these 5 factors from the Kumpfer framework were operationalized as key modifiable determinants to guide the development of a targeted social participation intervention.

XSL•FO
RenderX

Step 2: Behavioral Determinants and Performance Objectives

In this step, we first specified the overarching intervention goal: to enhance both the level and quality of social participation among stroke survivors. This goal was then delineated into five specific performance objectives: (1) formulating a personal social participation plan; (2) developing strategies for meaningful social engagement; (3) participating in self-selected social activities; (4) playing an active role within chosen social activities; and (5) experiencing a sense of fulfillment and positivity derived from social participation. Building on the needs assessment, these 5 determinants were linked to each performance objective through a matrix (Table S1 in Multimedia Appendix 1), specifying the targets for change required to achieve the intervention goal. For example, to address the emotional determinant, the matrix specified that patients need to reduce anxiety related to social participation and feel positive about formulating a participation plan, which directly supports the performance objective of "making plans for social participation." A complete mapping of all 5 determinants to each performance objective is presented in Table S1 in Multimedia Appendix 1.

Step 3: Theory-Based Methods and Practical Applications

Step 3 involved selecting appropriate theory-based and evidence-based methods to bridge the determinants with desired outcomes. Theoretical methods were defined as those derived from theory or research that aimed to modify determinants, while practical applications referred to specific strategies for implementing these methods [25]. The selection of theory-based methods was carried out by the group through three distinct approaches: (1) referencing the IM taxonomy of behavior change methods, (2) consulting the taxonomy of behavior change techniques (BCTs) [26], and (3) considering current empirical evidence. The team then discussed and identified feasible practical strategies to translate these theoretical methods into practice. Table S2 in Multimedia Appendix 1 provides a comprehensive overview of the theories and BCTs used to operationalize each determinant. For instance, to operationalize the emotional determinant, we selected BCTs related to emotion regulation (eg, BCTs-11.2) based on the IM taxonomy and translated them into concrete techniques such as mindfulness and deep breathing exercises.

Step 4: Producing the Prototype Program

Based on the aforementioned steps, a prototype of the digital intervention was developed in 4 distinct phases.

Phase 1: Intervention Conceptualization and Design

The intervention prototype was designed to target both individual psychological characteristics and their precise application within specific social participation contexts. The proposed intervention consisted of 2 sequential components: a course learning module and a gamified experiential module. The course learning module provided contextualized training targeting the 5 resilience determinants. This included fostering positive cognitions regarding social participation, guiding the application of emotion regulation techniques to manage social interaction–related negative emotions, and assisting in the formulation of social participation goals and corresponding behavioral skills. Subsequently, the gamified experiential module simulated commonly encountered real-world barriers to social participation (eg, public skepticism and environmental obstacles). This design enabled individuals to naturally apply the skills acquired during the course learning module when confronted with real social situations, thereby facilitating the formation of efficient situation-response associations. The course learning and gamified experiential modules were thus designed as an integrated sequential system, with the former providing systematic learning and the latter offering a context for practical application. The finalized intervention protocol (Table 1) integrates the determinants, performance objectives, and practical strategies across all sessions, illustrating the complete logic chain from theoretical foundations to practical content. The mapping of determinants to objectives and methods is detailed in Tables S1 and S2 in Multimedia Appendix 1, respectively. A detailed mapping of each course learning session and game level to the corresponding ICF participation domains is provided in Table S3 in Multimedia Appendix 1.

XSL•FO
RenderX

Table . Overview of the digital resilience-based course-game sequential intervention sessions.

Module and week	Topic	Theoretical basis	Objectives	Content
Course learning				
1	Regulate emotions: stabilizing inner state for social participation	Emotional	To master general emotion regulation techniques and apply them to manage specific emotions arising in social participation contexts	General skills: • Introduce changes brought by stroke and normalize poststroke emotional fluctuations • Teach patients to identify negative emotions such as anxiety, frustration, and anger • Teach patients emotion regulation techniques such as mindful breathing and emotional acceptance Contextual application: • Encourage patients to use emotion regulation techniques to cope with anxiety triggered by social participation or fear of others' evaluation • Teach patients to handle frustration or anger arising from the inability to fulfill previous social roles • Teach patients to calm feelings of frustration and impatience due to slow or fluctuating progress in social participation

XSL•FO
RenderX

Module and week	Topic	Theoretical basis	Objectives	Content
2	Building positive cognitions for a new life chapter	Cognitive	To master general cognitive restructuring skills and apply them to establish positive beliefs about social participation	General skills: • Guide patients to learn to identify and challenge negative automatic thoughts (eg, catastrophizing, all-or-nothing thinking, and overgeneralization) • Cultivate patients' ability to find exceptions and remaining strengths in adversity Contextual application: • Encourage patients to reshape cognition regarding self-worth under functional limitations (eg, shifting focus from "instrumental value" to "existential value," such as reframing "I cannot manage household chores for my family" to "I can express care verbally and become the family's emotional pillar") • Encourage patients to reshape cognition regarding others' evaluations • Encourage patients to reshape cognition about social participation: correct erroneous beliefs, such as "Participation is only meaningful if I recover to my former state" or "Such minor participation doesn't count as returning to society"
3	Finding meaning: cultivating motivation for community reintegration	Spiritual (motivational)	To discover inner values and meaning in life within the context of disability and connect them with social participation	

XSL•FO
RenderX

Module and week	Topic	Theoretical basis	Objectives	Content
				General skills: • Guide patients to reflect on core personal values under disability (eg, meaningful connections, helping others, and personal growth) • Encourage patients to assign positive meaning to daily life events (eg, holding a cup steadily and walking 1 step further than yesterday) • Guide patients to establish a personal mission that provides direction and purpose in daily life Contextual application: • Help patients understand the significance of social participation and the consequences of nonparticipation • Encourage patients to explore social activities that align with personal values (eg, "maintaining contact with old friends" fulfills the value of meaningful connection) • Encourage patients to explore social roles they can still perform with their current abilities and provide stories of peers' positive transformations
4	Managing energy: conserving physical and mental resources for engagement	Physical	To adhere to rehabilitation exercises and enhance the physical capacity required for social participation	General skills: • Provide effective strategies for improving physical capacity (methods, timing, and strategies for home-based rehabilitation exercises) • Share functional exercise methods used by other stroke patients Contextual application: • Provide social participation techniques and compensatory strategies used by other patients • Guide patients to establish social participation techniques and strategies suitable for their own abilities
5		Behavioral		

XSL•FO
RenderX

Module and week	Topic	Theoretical basis	Objectives	Content
	Taking initiative: becoming the architect of your social life		To master general methods for goal decomposition and action planning and apply them to plan social participation behaviors	General skills: • Teach goal-setting techniques • Teach plan formulation techniques • Teach problem-solving techniques Contextual application: • Guide patients to set social participation goals based on self-selected activities • Explain potential barriers and facilitators for poststroke social participation, guiding patients to identify factors relevant to themselves • Guide patients to develop a social participation plan
6	Leveraging support: constructing a social network for participation	Behavioral	To develop the general ability to proactively build and use social support and apply it during the social participation process	General skills: • Explain different types of social support (emotional, instrumental, informational, etc) • Provide methods for making clear requests and expressing gratitude • Explain how to proactively seek available resources and opportunities from the external environment Contextual application: • Encourage patients to incorporate necessary social support into their social participation plans • Encourage patients to communicate barriers to social participation with family members/relatives/friends and seek their help when necessary
7	Synthesis: narrating your resilience story in social participation	All elements	To integrate the learning journey into a coherent, positive narrative of personal resilience and growth, thereby consolidating changes	

XSL•FO
RenderX

Module and week	Topic	Theoretical basis	Objectives	Content
				General skills: • Guide patients to review and connect their progress in cognitive, emotional, spiritual, behavioral, and physical aspects • Help patients summarize a resilience toolkit for coping with future social participation challenges Contextual application: • Guide patients to share successful experiences and minor progress in social participation during the intervention period • Help patients reinforce a positive self-identity of being prepared to face more social participation challenges • Encourage patients to develop a flexible long-term plan for the next stage of social participation
Gamified experiential				

XSL•FO
RenderX

Module and week	Topic	Theoretical basis	Objectives	Content
7 (postcourse)	Supermarket mission	All elements	To apply learned skills in a virtual social context and promote their transfer to real life	Within the supermarket shopping scenario, stroke survivors experience various obstacles that they may encounter from leaving home to checkout and use targeted strategies to address them: • Cognitive: when facing psychological barriers like "fear of leaving home" or "negative evaluations from others," guide players to identify and challenge catastrophic thinking, establishing positive beliefs through cognitive restructuring • Emotional: when feeling embarrassed about "asking store staff for help" or "facing impatient others," use emotion regulation techniques to manage social anxiety • Physical: simulate real-world scenarios like "going up/down stairs" and "walking on roads" in the game. Guide patients to use crutches and negotiate steps using the appropriate movement sequence • Spiritual: after completing the ultimate shopping challenge, reinforce the sense of achievement and meaning through system feedback

Phase 2: Expert Review and Protocol Refinement

An expert panel meeting was convened on October 17, 2025, to review and refine the preliminary intervention prototype. Eight experts were purposively selected according to the following criteria: (1) expertise in rehabilitation medicine, nursing, psychology, or cerebrovascular disease; (2) a senior professional title; (3) a master's degree or higher; (4) at least 10 years of professional experience; (5) frequent interaction with stroke survivors; and (6) voluntary participation. The expert authority coefficient (Cr) was calculated as the mean of the familiarity coefficient (Cs) and the judgment coefficient (Ca), with a Cr value greater than 0.70 indicating a reliable opinion. No formal consensus threshold was predefined beyond this criterion, and the panel served as a formative expert review rather than a formal validation. Expert familiarity was assessed using a 5-point Likert scale, with scores assigned as follows: "very familiar" was assigned a score of 1.0, "familiar" a score of 0.8, "moderately familiar" a score of 0.6, "slightly familiar" a score of 0.4, and "not familiar" a score of 0.2. Expert judgment was based on 4 dimensions: practical experience, theoretical analysis, knowledge of current domestic and international evidence, and intuitive judgment. Each dimension was rated as "large," "moderate," or "small," with specific scoring details provided in Table S4 in Multimedia Appendix 1. With the experts' consent, the entire meeting was audio-recorded to capture their evaluations and feedback on the intervention protocol. The recordings were transcribed and analyzed promptly after the meeting. The transcribed feedback was reviewed and categorized thematically by the research team to identify key suggestions for refinement. The intervention protocol was subsequently revised based on the experts' opinions, and disagreements were resolved through discussion and analysis among the research team members.

Phase 3: Digital System Development

Given its widespread use among older adults in China, a WeChat (Tencent Inc) mini-program was developed to deliver the intervention content. The course learning module transformed the content into a standardized, multimedia, interactive

XSL•FO
RenderX

sequence, with users progressing by clicking “next” through text, images, videos, case examples, and interactive questions. To align with the intended “once-weekly” intervention dose, a weekly course unlocking mechanism was implemented, accompanied by scheduled push notifications reminding users to engage with the content. A dedicated “my social participation profile” module generated personalized reports upon course completion, allowing users to view and edit their participation elements and to receive visual progress feedback. The gamified experiential module featured a “supermarket shopping” scenario where users applied resilience skills to overcome simulated obstacles across 5 levels. An auxiliary resource library provided educational materials and self-assessment tools. The backend system enabled researchers to manage content and automatically recorded granular usage data, including course completion, learning duration, game performance, and interactive responses, providing an objective foundation for assessing adherence and informing future evaluations.

Phase 4: Content Finalization

Comprehensive intervention scripts were developed based on the refined intervention, culminating in a complete content repository for the course-game sequential intervention system. The final course learning module comprises approximately 50,000 characters, more than 140 images, 11 videos, more than 20 case examples, and more than 10 interactive questions. The gamified experiential module consists of 5 levels with distinct obstacles and problem-solving mechanisms, supported by approximately 6400 characters of script. This repository encompasses all materials necessary to deliver the theoretically grounded, digitally mediated intervention as designed.

Usability Evaluation

Study Design

This was a formative usability evaluation of a digital intervention prototype.

Setting

Participants were recruited using a convenience sampling approach from a rehabilitation hospital in Shanghai, China, between October and November 2025.

Participants

The inclusion criteria were as follows: (1) diagnosis of stroke confirmed by the Fourth National Conference on Cerebrovascular Disease criteria [27]; (2) aged 18 to 80 years; (3) stable vital signs; (4) at least 1 month poststroke onset; (5) ability to use a smartphone and prior experience with WeChat; and (6) provision of written informed consent. Participants were excluded if they had the following: (1) cognitive impairment (a Montreal Cognitive Assessment score of less than 26; for participants with fewer than 12 years of education, 1 point was added to the raw score); (2) language dysfunction; (3) other serious medical conditions (eg, malignancy or organ failure); or (4) were illiterate.

Sample Size

The sample size of 14 falls within the recommended range for formative usability studies [28].

Measures and Data Collection

Following the ISO 9241‐11 usability framework [29], five representative tasks were designed to evaluate the intervention’s usability: (1) locating and reading the “how to detect stroke early” section; (2) accessing and completing the “building positive cognitions for a new life chapter” learning module; (3) navigating to the game page and completing level 1; (4) viewing personal goals in the “my profile” section; and (5) completing a social participation self-test available in the “my profile” section. For each task, success was defined as reaching the designated interface element and completing the required action without external assistance. Task completion time was measured from the start of the task to its successful conclusion. To enable subsequent analysis, we recorded both the time taken to locate the target interface element and the total time to complete each task. To standardize administration, all tasks were presented to participants in the same fixed sequence.

After task completion, participants completed the System Usability Scale (SUS) [30], a 10-item questionnaire using a 5-point Likert scale (0=strongly disagree to 4=strongly agree). Odd-numbered items are positively worded, and even-numbered items are negatively worded. The SUS scores were calculated using the standard scoring procedure, yielding a total score ranging from 0 to 100, with higher scores indicating better usability. Scores above 60 indicate acceptable usability, with scores above 70 considered good, above 80 very good, and above 90 excellent [30]. The Chinese version of the SUS has demonstrated robust reliability and validity (Cronbach α=0.91) [31,32].

Semistructured individual interviews were subsequently conducted to explore participants’ perceptions and suggestions regarding the digital intervention. The interview guide included questions such as the following: “What was your overall experience with the digital system?”; “What are your thoughts on the font size and page color?”; “Do you find this digital system smooth to use?”; and “What shortcomings did you perceive in the digital system?” All interviews were audio-recorded and transcribed verbatim within 48 hours.

Data Analysis

Quantitative data were analyzed using SPSS (version 27.0; IBM Corp). Descriptive statistics were calculated for all variables. Continuous variables were presented as means with SDs and 95% CIs, or as medians with IQRs, where appropriate. Categorical variables were reported as frequencies and percentages. Item-level SUS responses were also examined descriptively. Task completion times were reported as means with SDs. No missing data were present, so no imputation methods were applied.

Qualitative data from the semistructured interviews were analyzed using conventional content analysis [33]. The first author conducted and transcribed all interviews. The first author was a nursing researcher who was involved in the intervention development, and the second coder was a nursing researcher who was not involved in the intervention development. Two researchers independently coded the transcripts using conventional content analysis. Initial codes were identified from

XSL•FO
RenderX

meaningful text units and then grouped into categories and synthesized into themes. Discrepancies were resolved through discussion, with a third researcher consulted if needed. Given the formative nature of this evaluation, no formal saturation criterion was applied, and member checking was not performed. The analysis was primarily descriptive, focusing on actionable feedback for intervention refinement.

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Shanghai First Rehabilitation Hospital (approval number: YK-2025-03-011). All participants provided written informed consent prior to enrollment. They were informed of the study purpose, procedures, potential risks, and of their right to withdraw at any time without consequence. To protect participant privacy, all data were deidentified and stored securely on password-protected computers accessible only to the research team. No participant compensation was provided for this usability evaluation. All images presented in this manuscript depict the intervention interface only and contain no identifiable information about any participant.

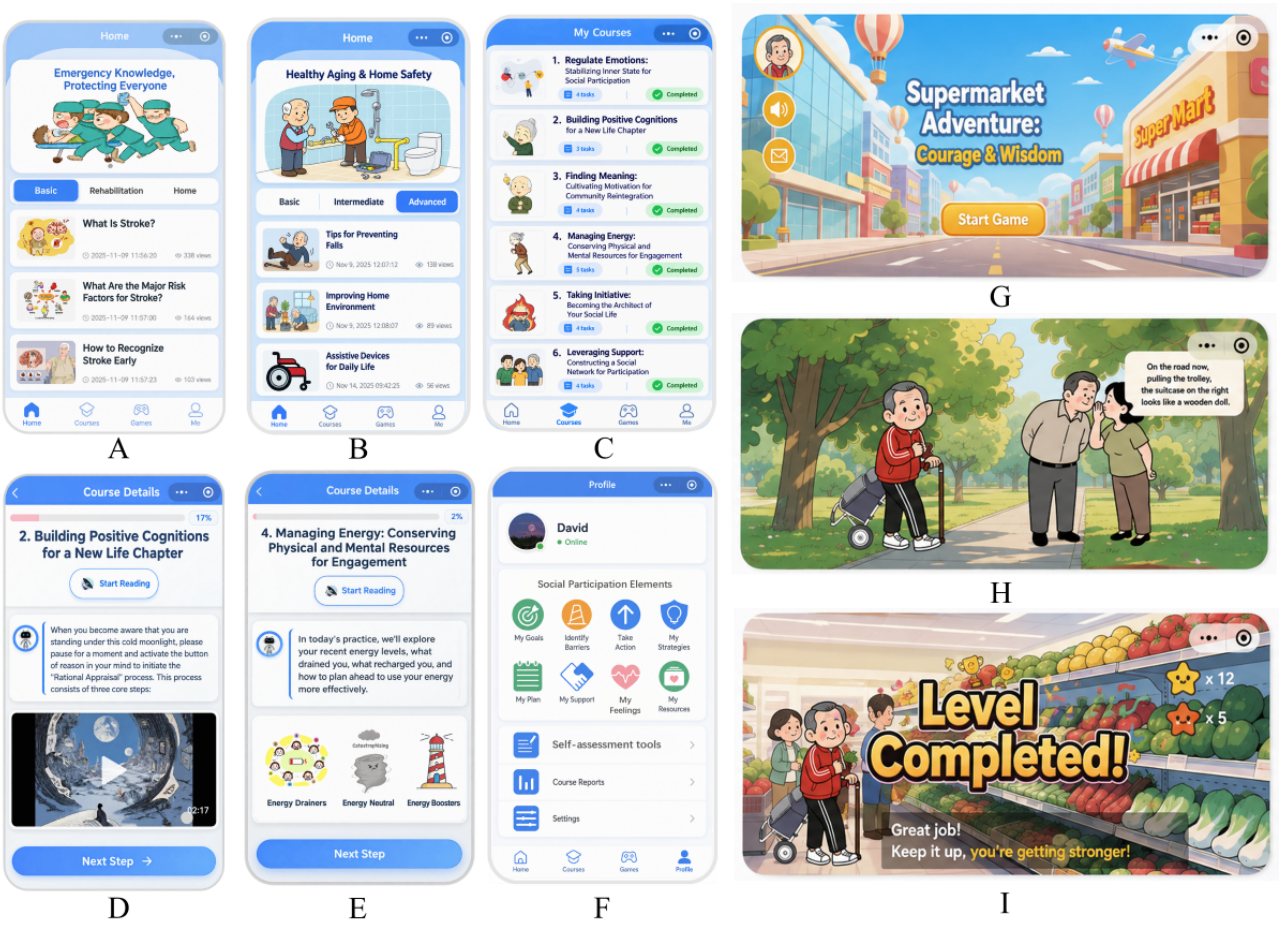
Results

Intervention Prototype Overview

The initial intervention protocol comprised 2 sequential components: a course learning module and a gamified experiential module. The course learning module constituted the core of the intervention system, consisting of 7 weekly thematic sessions. The seven themes were as follows: (1) building positive cognitions for a new life chapter; (2) regulating emotions: stabilizing inner state for social participation; (3) finding meaning: cultivating motivation for community reintegration; (4) managing energy: conserving physical and mental resources for engagement; (5) taking initiative: becoming the architect of your social life; (6) leveraging support: constructing a social network for participation; and (7) synthesis: narrating your resilience story in social participation. The content of the 7 sessions was connected through a coherent storyline and presented in a multimodal format, including integrated text, images, videos, case examples, and interactive questions.

The gamified experiential module was designed as a "supermarket shopping" journey scenario that gamified various obstacles encountered across different situations and guided users to apply resilience skills acquired during the course learning module to address these challenges. The game scenario was centered on a stroke survivor with moderate right-sided functional impairment who was preparing a birthday dinner for their spouse, encompassing 5 core levels: leaving home, the community park, the supermarket entrance, product selection, and supermarket checkout. These 5 levels were deliberately designed to correspond to the five resilience components. Specifically, leaving home addressed cognitive skills by challenging fears of negative evaluations from others. The community park and supermarket entrance targeted emotional and physical skills respectively, requiring emotion regulation for social anxiety and correct movement sequences for environmental navigation. Product selection engaged behavioral skills through goal-oriented decision-making. Supermarket checkout reinforced spiritual skills by providing achievement feedback upon task completion. This alignment is detailed in Table 1. The duration of a single game session was approximately 20 minutes.

Expert Review and Protocol Refinement



A total of 8 experts were included in this study, with their demographic characteristics presented in Table S5 in Multimedia Appendix 1. The mean expert authority coefficient was 0.88 (SD 0.07; Table S6 in Multimedia Appendix 1). Overall, experts expressed broad recognition of the proposed resilience-based course-game sequential intervention for enhancing social participation in stroke survivors, acknowledging its theoretical coherence and integrated design. Nevertheless, specific suggestions for improvement were proposed, including recommendations regarding intervention dose, session order adjustments, content refinement, and increased interactive elements. Based on this expert feedback, the intervention protocol was appropriately modified and refined, as detailed in Table S7 in Multimedia Appendix 1. The finalized intervention protocol is presented in Table 1.

Digital System Development

The intervention was implemented as a WeChat mini-program named "I Love Participating." The name embodies the intervention's core aim: to inspire and support patients in developing a passion for, and actively engaging in, social life. Representative screenshots of the intervention system are presented in Figure 1. To address the reading and cognitive challenges commonly faced by older adults, a narrative, audio-driven course model was developed. Users experience the intervention as if listening to a tailored, serialized radio drama, learning through a warm storyline via "audio guidance+multimodal formats" (texts, images, videos, and authentic interview cases). Furthermore, numerous first-hand cases obtained from our previously published qualitative study [34] were integrated to ensure the content directly addresses patients' core psychological concerns. That study involved in-depth, semistructured interviews with 36 stroke survivors and explored their experiences of social participation, providing rich case materials for intervention script development [34]. Through audio guidance and minimal interaction, users can access practical resilience-building content in a relatively low-burden environment. The intervention is delivered as a self-guided program with a fixed content sequence. Technical support is available through a designated helpline and a WeChat contact for access-related issues; caregiver assistance is permitted but not required; missed sessions can be completed at any time after unlocking; adherence is defined as completion of all 7 course sessions and the game module; and fidelity is supported by the fixed content sequence and automated backend recording. A detailed script of approximately 50,000 characters was developed to ensure content consistency. Full operational details, including procedures for technical assistance, caregiver involvement, missed sessions, and fidelity criteria, are described in the published trial protocol [35].

XSL•FO
RenderX

Figure 1. Representative interfaces of the digital resilience-based course-game sequential intervention. The WeChat mini-program consists of 4 main pages. The first page is the homepage, which presents stroke-related educational information (panels A and B). The second page is the course learning page, providing access to the 7 thematic course sessions (panel C), with each session delivered through a multimedia format integrating text, images, case examples, and videos (panels D and E). The third page is the gamified experiential module entry page, with the corresponding game interface shown in panels G, H, and I. The fourth page is the "my profile" section, which includes social participation elements and self-assessment tools (panel F).

Usability Evaluation

Quantitative Findings

A total of 14 participants were included in the usability evaluation. The mean age of the participants was 65.4 (SD 9.75) years, with an age range of 45 to 80 years, and 71.4% (n=10) of the participants were male. Among the participants, 78.6% (n=11) had experienced an ischemic stroke. The duration from the initial stroke onset to study participation ranged from 1 month to 13 years. Participant characteristics are detailed in Table 2. The completion of representative tasks is documented in Table 3. Task 2 required completing an entire course topic with multimodal content, whereas the other tasks involved brief actions such as locating information, viewing personal goals, or completing a self-test. This difference in scope accounts for the large variation in completion times. All participants completed all 5 tasks successfully (14/14, 100% completion rate). However, because errors, assistance attempts, and first-click accuracy were not systematically recorded, this completion rate should not be interpreted as evidence of uniformly effortless or error-free interaction. The mean SUS score was 73.6 (SD 12.2), with a range of 55 to 95. The median score was 77.5 (IQR 61.3-80.6), and the 95% CI for the mean was 66.5 to 80.6. Item-level results, including the mean, SD, and median with IQR for each of the 10 SUS items, are presented in Table 4.

XSL•FO
RenderX

Table . The characteristics of the participants[a].

ID	Sex	Age	Education	Employment status before stroke	Marriage status	Living status	Self-reported family economic status	Stroke type	Time since stroke onset	Recurrent stroke	Lateralization of motor impairment	Functional dependence level
1	Male	65	University	Retired	Married	Living with family	Very good	Ischemic	8 months	No	Left	Partly self-care
2	Female	45	Senior high school	Employed	Married	Living with family	Good	Ischemic	1 month	No	Left	Cannot take care of themselves
3	Male	67	Junior high school	Retired	Married	Living with family	Very good	Ischemic	2 months	No	Left	Mostly self-care
4	Male	69	Junior college	Retired	Married	Living with family	Average	Hemorrhagic	2 years	No	Right	Completely self-care
5	Male	58	Senior high school	Retired	Married	Living with family	Average	Ischemic	1 month	No	Right	Completely self-care
6	Male	80	Junior high school	Retired	Married	Living with family	Not good	Hemorrhagic	1 month	No	Left	Mostly self-care
7	Female	49	Senior high school	Employed	Married	Living with family	Average	Ischemic	1 month	No	Right	Partly self-care
8	Female	65	Senior high school	Retired	Married	Living with family	Average	Ischemic	1 month	No	Right	Mostly self-care
9	Male	70	Junior high school	Retired	Married	Living with family	Average	Ischemic	1 year	Yes	Both	Mostly self-care
10	Male	75	Junior college	Retired	Married	Living with family	Good	Ischemic	13 years	No	Left	Completely self-care
11	Male	65	Senior high school	Retired	Married	Living with family	Not good	Ischemic	9 years	Yes	Right	Partly self-care
12	Female	70	Primary school	Retired	Unmarried	Living alone	Good	Hemorrhagic	4 years	No	Both	Completely self-care
13	Male	61	University	Retired	Married	Living with family	Good	Ischemic	1 month	No	Left	Completely self-care
14	Male	76	University	Retired	Married	Living with family	Average	Ischemic	2 years	No	Left	Mostly self-care

[a]All variables were based on participant self-report.

Task 5	100	11.51 (3.76)	10.00 (9.00-12.70)	8.73 (1.75)	8.50 (7.73-10.00)

Table . Item-level System Usability Scale (SUS) scores among stroke survivors (N=14).

Item	Description	Mean (SD)	Median (IQR)
1	Would like to use this system frequently	2.71 (1.07)	3.00 (2.00-3.25)
2	Found the system unnecessarily complex	1.00 (1.04)	1.00 (0.00-1.25)
3	Thought the system was easy to use	3.14 (0.54)	3.00 (3.00-3.25)
4	Would need technical support to use the system	1.14 (1.17)	1.00 (0.00-2.25)
5	Found various functions well integrated	2.79 (0.70)	3.00 (2.00-3.00)
6	Thought there was too much inconsistency	0.93 (0.73)	1.00 (0.75-1.00)
7	Most people would learn quickly	3.00 (1.04)	3.00 (2.75-4.00)
8	Found the system cumbersome to use	0.86 (0.86)	1.00 (0.00-2.00)
9	Felt confident using the system	3.07 (0.62)	3.00 (3.00-3.25)
10	Needed to learn a lot before getting started	1.36 (0.75)	1.50 (1.00-2.00)

Qualitative Findings

Theme 1: Perceived Ease of Use and Accessibility

Most participants found the interface intuitive and easy to navigate. Several participants specifically appreciated the audio-guided functionality, which they felt reduced the reading burden. One participant stated:

> *I like the voice function. Since my illness, I have become more attentive to voice, which makes it easier for me to understand words.* [Participant 1]

Another noted:

> *The page color looks comfortable and refreshing.* [Participant 3]

However, some participants expressed concerns about the font size, suggesting that it could be made adjustable to accommodate individual visual preferences.

Theme 2: Perceived Usefulness and Engagement

Participants generally viewed the intervention as potentially helpful for their social reintegration. Several expressed interest in the gamified experiential module, describing it as “novel and interesting” and noting that it enhanced their motivation to learn (Participant 6). The course reminder feature was also positively received, as 1 participant commented:

> *When I get home, I may forget to use this application, and the reminder function is helpful.* [Participant 3]

Theme 3: Suggestions for Improvement

Participants also provided constructive feedback for refinement. Regarding interaction design, some suggested incorporating more video-based content to enrich the learning experience and reduce the perceived monotony of text-heavy materials. Regarding content, a few participants expressed a desire for more concrete guidance on translating psychological resilience into actionable steps and connecting to broader support networks. Regarding intervention dose, while participants affirmed the value of the content and their motivation to learn, some expressed a preference for greater flexibility in the learning schedule rather than being restricted to unlocking one session per week. As one participant noted:

> *I don’t think it’s necessary to limit me to one session per week. If I want to learn, I’m interested. Especially for those of us with hemiplegia, if I want to know more about this, I have the motivation. I don’t think it needs to be once a week.* [Participant 8]

XSL•FO
RenderX

These suggestions indicate that allowing participants greater autonomy in pacing may enhance user experience and accommodate individual learning preferences.

Discussion

Principal Findings

This study systematically developed a theory-driven, digital course-game sequential intervention using the IM approach to support social participation among stroke survivors. Grounded in the Kumpfer resilience framework, the intervention targets 5 resilience-related protective factors through 2 sequential modules: a 7-session course learning component for systematic skill acquisition and a gamified experiential module, which features a "supermarket shopping" scenario for contextualized behavioral practice. The usability evaluation provided initial evidence of good usability among stroke survivors, supporting further efficacy evaluation.

Existing stroke rehabilitation has largely emphasized functional restoration [36,37], while psychological interventions have primarily focused on reducing negative affect, such as anxiety and depression [10,11]. Resilience, in contrast, has not been systematically operationalized as a core intervention target for promoting social participation. The first distinguishing feature of the intervention is its explicit use of psychological resilience as a theoretically specified mechanism for supporting social participation. Resilience is conceptualized as a dynamic process that enables individuals to adapt positively when confronted with adversity [38,39]. Our previous work further suggested that resilience may contribute to social participation through both direct psychological pathways and indirect behavioral pathways involving exercise adherence and physical function [13,14]. This evidence positions resilience as a higher-order determinant that can trigger a cascade of positive adaptive responses, making it a more potent target than addressing isolated psychological or functional deficits [40].

A second contribution is the contextual adaptation of established resilience-building strategies to stroke-specific social participation challenges. Previous resilience interventions may provide limited opportunities for context-specific practice. Although they commonly teach general coping and emotion-regulation strategies, translating these skills into demanding real-world social situations can remain challenging [41,42]. For instance, while these interventions commonly teach generic stress management techniques, they frequently fail to provide specialized training on how to initiate and apply these skills within concrete, demanding social situations [43]. This gap often results in a dilemma where participants understand the underlying principles yet struggle to implement them effectively when confronted with real-world social pressures [44,45]. The present intervention addresses this gap by transitioning from generic resilience education to contextualized resilience training. We focused not only on individuals' intrinsic psychological traits but also anchored the intervention within specific social participation contexts. On the one hand, through the course learning module, we delivered contextualized training targeting the 5 resilience dimensions, including fostering positive cognitions regarding social participation, guiding the application of emotion regulation techniques to manage social interaction-related negative emotions, and assisting in setting social participation goals and formulating action plans. On the other hand, the gamified experiential module realistically simulates real-world barriers to social participation, enabling individuals to rehearse the acquired resilience skills when encountering simulated participation-related challenges [46].

A third contribution concerns the sequencing of structured digital learning and contextual game-based practice. Existing digital health interventions can efficiently provide health information, behavioral strategies, reminders, and self-management support, but predominantly didactic formats may be limited in their capacity to support experiential application and sustained engagement [15-18,47]. Conversely, serious games may promote active participation and motivation but can face tension between educational content and entertainment value [22,48]. The present intervention combines these complementary modalities within a learning-to-practice pathway: the course learning module provides structured acquisition of resilience-related knowledge and skills through narrative audio guidance and multimodal content, while the subsequent game enables contextualized rehearsal in a simulated social-participation scenario. The digital design was also adapted to the target population through delivery via a WeChat mini-program, audio narration, and simplified navigation to reduce reading and operational burden. Participants generally supported the accessibility of these features, particularly the audio-guided content, while suggesting further refinements such as adjustable font size, greater use of video, and more flexible learning schedules [49]. The usability findings, particularly the mean SUS score of 73.6 (SD 12.2), which exceeds the benchmark for digital health apps [50], provide initial evidence that this sequential format is usable in the target population. However, these findings reflect initial usability rather than evidence that the sequential architecture improves clinical outcomes; comparative effectiveness and sustained engagement remain to be evaluated.

This study has several limitations. First, due to resource constraints, the current intervention includes only one comprehensive gamified case rather than providing dedicated scenarios aligned with each of the 7 thematic sessions. Consequently, it cannot offer highly targeted simulation training for each specific resilience dimension, which partially weakens the closed loop of learning, practice, and reinforcement. An ideal model would pair each core thematic session with a corresponding gamified scenario to achieve seamless integration of skill acquisition and application, which is an important direction for future research [51]. Additionally, the game protagonist was designed with a fixed impairment profile, which may not directly reflect the experiences of all stroke survivors. Future iterations could consider incorporating multiple character profiles with varying laterality, severity, and assistive device use to better accommodate the diversity of the target population. Second, the gamified scenario was developed within a Chinese urban context, which may limit its direct transferability to other cultural or geographic settings. Although the supermarket shopping framework was chosen for its cross-cultural familiarity as a common community activity, specific details may require

XSL•FO
RenderX

adaptation for different cultural environments in future implementations. Third, the sample was limited to cognitively intact, smartphone-proficient stroke survivors, limiting generalizability to those with severe conditions, advanced age, or low digital literacy [52]. For these more vulnerable populations, the "digital divide" challenge inherent in digital health interventions may be particularly pronounced. Although our audio-guided design was intended to alleviate the reading burden, the participants in this study were all volunteers with some degree of digital literacy, suggesting that the observed usability may reflect an optimistic bias. Future efforts to extend this intervention to older adults, individuals with low educational attainment, or those with severe disabilities will likely require further adaptation and validation of interface interaction modalities, such as substituting clicking with voice input or incorporating caregiver-assisted delivery models. Fourth, our usability evaluation was conducted through a single, task-based session. The SUS scores thus primarily reflect first-impression usability rather than sustained engagement over time. Participants did not experience the actual weekly, multiweek intervention delivery as intended in the full protocol. Therefore, while the current findings support initial usability, conclusions regarding long-term acceptability or sustained use cannot be drawn from this single exposure. Future studies incorporating repeated measures over the full intervention period are needed to evaluate sustained engagement and acceptance. In addition, errors, assistance attempts, and first-click accuracy were not systematically recorded, and the fixed task sequence may have introduced learning or order effects. Fifth, although the intervention encourages the use of social support, its core remains focused on the individual patient. The family and social environment, as critical determinants of social participation [5], were not systematically addressed within the scope of this individually oriented intervention. Finally, as the primary aim of this study was formative usability evaluation, behavioral or clinical outcome measures were not included.

Conclusions

This study systematically developed and evaluated a theory-driven, digital course-game sequential intervention using the IM approach to support social participation in stroke survivors. Grounded in the Kumpfer resilience framework and informed by prior empirical evidence, the sequential course-game design addresses critical gaps by transitioning from generic resilience education to context-specific training anchored in real-world social scenarios. The usability findings provide initial support for the intervention prototype among stroke survivors. This work offers a scalable, theory-driven tool that has the potential to be integrated into routine stroke rehabilitation to facilitate community reintegration. However, further feasibility and efficacy testing in real-world settings is warranted.

Abstract

Background: Longer life expectancy makes physical exercise crucial for active aging. However, adherence to traditional exercise among community-dwelling older adults is generally low. Virtual reality (VR) and mixed reality (MR) Tai Chi exergames, as novel health promotion tools, show significant potential, particularly for older adults exercising in a home setting.

Objective: This study aimed to evaluate the usability and feasibility of a VR and MR Tai Chi exergame for community-dwelling older adults, focusing on subjective experience, physiological comfort, and objective interaction performance. The study also explored the relationships between key usability factors and sought to quantify links between objective accuracy and subjective experience (the Game Experience Questionnaire or Virtual Reality Sickness Questionnaire [VRSQ]) to inform choices of display mode, feedback strength, and session length.

Methods: Of the 86 community-dwelling older adults recruited for this study, data from 70 participants were considered valid after an initial screening, during which 16 (18.6%) were excluded due to issues with VR adaptation. Participants were sequentially assigned in a rotating order to 1 of 4 variants (VR/MR×soothing/intense) to balance exposure; however, primary analyses were preplanned to be collapsed across variants, focusing on whole-sample usability and feasibility rather than confirmatory between-group hypotheses. The primary outcome measures included the Game Experience Questionnaire, VRSQ, and objective gameplay logs.

Results: The VR/MR Tai Chi game demonstrated good overall usability and acceptability among the screened participants. Subjective experience was highly positive, with median scores for “positive affect” (median 4.0) and “competence” (median 3.8) being significantly high, whereas the median for “Challenge” (median 1.4) was significantly low (P<.001 for all). Physiological comfort in the postscreening sample was acceptable, with the most common mild symptoms being dizziness with eyes closed (20.0%) and vertigo (18.6%), both of low severity; however, the initial exclusion of 18.6% of participants due to VR discomfort is noteworthy. Therefore, generalizability is limited because the analyzed sample overrepresents older adults who tolerate immersive displays. Accuracy showed significant positive correlations with flow (ρ=0.342) and competence (ρ=0.322), whereas the VRSQ total score was significantly negatively correlated with positive affect (ρ=−0.334, P=.005).

Conclusions: Tai Chi exergames based on immersive technologies offer a feasible and attractive pathway for promoting physical exercise among community-dwelling older adults, particularly within the home environment, supporting the goal of aging in place. As a single, laboratory-based session, the reported satisfaction may partly reflect a novelty effect; therefore, longer-term, home-based follow-ups are needed to assess durability. Analysis of the key usability factors provides guidance for specific design choices, while also indicating directions for future research, such as longitudinal evaluations, extension to more diverse populations, and application in real-world home settings.

Introduction

The trend of people getting older around the world is accelerating. By 2050, there will be more than 2 billion people over the age of 60 years, and older adults will make up a larger share of the world’s population, especially in developing areas [1]. This change in the population puts more pressure on the economy and shows how important programs such as “Healthy

XSL•FO
RenderX

Aging" and letting older people "age in place" are. Regular exercise is very important for healthy aging [2]. It helps keep people healthy, helps them stay independent, makes them feel better mentally, and improves their quality of life [3]. These benefits make exercise a good and useful way to help older people all over the world. However, older adults often face numerous barriers that make it hard for them to participate in traditional exercise programs. These problems include not being motivated, being afraid of falling, and not being able to get to the right facilities [4]. These challenges show that conventional exercise models often fail to meet the emotional and experiential needs of older adults. Recent studies suggest that digitally delivered, personalized interventions, such as programs incorporating wearable technology, remote coaching, and motivational messaging, can significantly improve adherence and reduce fear of falling [5,6]. This points to the need for approaches that improve enjoyment and intrinsic motivation in older adults.

To tackle this issue, immersive exergames that combine virtual reality (VR) and mixed reality (MR) technologies are a viable solution. This research concentrates on the integration of Tai Chi with VR/MR technologies. Tai Chi is particularly suitable for older adults due to its proven efficacy in enhancing dynamic balance and substantially decreasing both the frequency of falls and the fear of falling, which is a significant psychological impediment to physical activity engagement in this demographic [7]. These advantages render Tai Chi a pragmatic and psychologically beneficial approach for enhancing mobility and self-assurance in older adults. VR/MR Tai Chi exergames are meant to be a safe, easy, and fun way to work out at home. These exergames can address many limitations of traditional exercise by providing virtual practice environments that are controllable. They may also boost intrinsic motivation by enhancing feelings of autonomy and competence. Although extended reality technologies hold substantial promise for helping older adults, several challenges remain, such as the high cost of equipment, steep learning curves, and cybersickness. Notably, previous research has emphasized that cybersickness is a frequent and underestimated barrier that may lead to user dropout and restrict broader adoption in unsupervised home settings [8,9]. These usability and safety issues should be addressed before extended reality solutions can be widely implemented among older populations.

Although VR and MR exergames show promise for helping older adults avoid falling, there is insufficient systematic research comparing how different display modes and feedback systems affect this group. Some early evidence suggests that augmented reality, a type of MR, may be better for older adults because it gives them a better sense of their body and space, which makes them feel less likely to fall [10]. This points to a research gap in comprehending the preferences and reactions of older users to various immersive environments. Recognizing the distinct interactive experiences of older adults is essential for effective design, particularly in unsupervised home contexts. Hence, distinguishing between VR and MR modes goes beyond being a mere technical matter; it has direct implications for the safety, comfort, and acceptance of these technologies among older adults using them independently at home.

This work provides evidence to guide the development of immersive health care applications to enable older individuals to practice independently at home, a key component within the "aging in place" plan. With professional guidance lacking within home contexts, intrinsic motivational abilities and efficacy and safety of the game within itself become paramount [11]. Thus, this work's investigation into aspects such as cybersickness and "accuracy-competence paradox" remains a key focal point within this work to aid in determining if such technology can be disseminated and leveraged effectively.

Specifically, this study will seek to answer the following core questions:

1. Overall usability and acceptance: How does age affect subjective experience (eg, "empowerment" feelings), physiological comfort (ie, cybersickness symptom occurrence), and objective interaction efficacy (eg, the "accuracy-competence paradox") while playing the VR/MR Tai Chi game?
2. Internal links between fundamental factors: How does objective gameplay performance (eg, pointing precision) influence subjective psychological experiences (eg, flow, competence)? Do users' physiological symptoms of discomfort affect positive emotions? Are positive emotions correlated to users' inherent traits, such as age?

Through systematic investigation of these questions, this study aimed to contribute empirical evidence to be used in designing immersive health applications among older people [12].

Methods

Ethical Considerations

The study received ethics approval and adhered to guidelines for research involving human participants.

Research Ethics Approval

This study received ethics approval from the Institute of Visual Informatics, Universiti Kebangsaan Malaysia. The approval was granted on July 2, 2024, with the reference number UKM.IVI.600-4/6/P130610.

Informed Consent

All participants provided written informed consent before the start of any experimental procedures. The researchers clarified the study's objectives, methods, possible risks (including cybersickness symptoms), and potential benefits. They also made it clear to participants that they could withdraw from the study at any point without facing any consequences.

Privacy and Confidentiality

All personally identifiable information and harvested data were fully anonymized to ensure respondent privacy. Data were stored securely on a password-protected server, and only central research team staff had access.

Compensation

Participants did not receive any monetary or nonmonetary compensation for their participation. Their involvement in this study was entirely voluntary.

XSL•FO
RenderX

Study Design

Overview

This study was designed as a pilot study using a 2×2 factorial design (display mode: VR/MR×feedback: soothing/intense) to effectively explore the feasibility of varying exergame configurations before a large trial. Participants were sequentially assigned to 1 of the 4 conditions using a rotating 1:1:1:1 schedule upon enrollment. The primary goal of this multicondition design was not to conduct formal hypothesis testing between groups, which would require a much larger sample. Instead, its purpose was to ensure that our usability and feasibility assessment covered a range of potential interaction styles. This approach allows us to identify any major negative outcomes (eg, excessive cybersickness or frustration) that might be unique to a specific condition, providing critical insights for optimizing a single, refined protocol for future, larger-scale home-based studies.

Recruitment, Screening, and Final Sample

A research team initially recruited 86 community-dwelling older people who were capable of living independently, via media such as community promotions at community centers and newspaper advertising locally. Such a process was used to maintain the sample's characteristics closely aligned with those of the target end user group for future home-based VR/MR Tai Chi exergames [13].

In this pilot phase of research, screening led to a dropout of 16 participants (16/86, 18.6% of the original sample) who could not accommodate to the virtual environment or who experienced severe dizziness. Notably, this screening process suggests that the final sample was skewed to some degree to VR tolerance, that is, comprised individuals better predisposed to accommodate virtual environment exposures. This characteristic is relevant in estimating the extent to which the findings generalize to a broader community of older individuals.

We performed an analysis of the 16 participants who were excluded due to a failure to adapt to VR. This group comprised 11 (68.8%) women and 5 (31.2%) men, a gender distribution similar to that of the retained sample. However, a systematic difference was evident in age: 43.8% (7/16) of participants excluded were aged older than 75 years, a proportion more than double that of the sample maintained (15/70, 21.4%). This finding suggests that older age could be a determining factor in intolerance to VR in this population.

Inclusion and Exclusion Criteria

The aforementioned recruitment and screening processes adhered to clearly defined criteria. The inclusion criterion was enrollment of participants aged 60 years and older [14,15]. Exclusion criteria encompassed any known adverse reactions to VR experiences and severe cardiorespiratory or musculoskeletal diseases that would significantly impede participation in the experimental procedures, severe vision loss, and other health conditions unsuitable for the use of immersive devices (eg, vertigo and epilepsy).

Self-report alone was considered insufficient; therefore, a brief experiential screening was recommended before unsupervised use.

Demographic Characteristics, Health Status, and Exercise Habits

Data regarding demographic information, health background, and daily exercise habits were collected from the 70 valid participants using a self-developed "basic information questionnaire." The detailed characteristics are presented in Table 1.

The 70 valid participants included in the final analysis exhibited certain demographic tendencies: they were predominantly female (52/70, 74.29%) and largely comprised "younger" older adults aged 60 to 75 years (55/70, collectively 78.56%). In terms of health status, although a considerable proportion (40/70, 57.14%) self-reported chronic conditions such as cardiopulmonary diseases, they were also individuals who actively managed their health, with a high percentage (66/70, 94.29%) undergoing regular physical examinations. This characteristic of "living actively with illness" suggests that the sample group might hold a more open attitude toward health-promoting interventions, but it also necessitates that such interventions ensure safety and appropriateness.

XSL•FO
RenderX

Table . Participant demographic characteristics, health status, and exercise habits (N=70).

Characteristics	Values, n (%)
Sex	
Male	18 (26)
Female	52 (74)
Age distribution (y)	
60 - 65	32 (46)
65 - 70	11 (16)
71 - 75	12 (17)
75 - 80	11 (16)
>80	4 (6)
Height distribution (cm)	
140 - 150	13 (19)
150 - 160	36 (51)
160 - 170	20 (29)
>170	1 (1)
Weight distribution (kg)	
30 - 40	2 (3)
40 - 50	8 (11)
50 - 60	36 (51)
60 - 70	18 (26)
70 - 80	4 (6)
>80	2 (3)
Self-reported illness status	
No reported cardiopulmonary illness	30 (43)
With cardiopulmonary disease	40 (57)
Regular physical examination	
Yes	66 (94)
No	4 (6)
Weekly exercise frequency	
Exercise daily	66 (94)
Exercise 3 - 5 times per week	1 (1)
Rarely exercise	3 (4)

This pilot group reported very high levels of physical activity, such that the vast majority (66/70, 94.29%) used a daily exercise regimen and participated in a broad range of activities, such as walking, square dancing, and Tai Chi. Overall, this sample is a subgroup of predominantly female, aged between 60 and 75 years, who exercise on a regular basis, approach health care management in an active manner, and have good tolerance to VR environment (as a consequence of preliminary screening that eliminated 18.6% (16/86) who reported dizziness while experiencing VR). These characteristics are relevant to explain why this sample reports such a high level of interest and positive response to the VR Tai Chi game. While these same characteristics will limit how widely the investigation can be generalized to broader older groups, such as those who exercise less or who possess poorer VR tolerance.

VR Tai Chi Exergame and Experimental Equipment

Intervention and Equipment

The VR Tai Chi exergame used in this study was designed for older individuals. Its fundamentals can be equally analyzed using the MDA (mechanics, dynamics, and aesthetics) approach [16,17].

Mechanics

It guides users through 16 selected Tai Chi exercises. It is interactive via a head-mounted display (HMD) and hand

XSL•FO
RenderX

controllers reacting to head and hand movements. Users must synchronize their pose to 3 hotspots (head and both hands) provided in the on-screen instruction. A movement only proceeds after a successful success window, and a movement can save up to 3 hotspot holds (left hand, right hand, and HMD) before advancing. If users complete the entire sequence of 16 movements ahead of schedule, they will repeat the sequence immediately, beginning with the first movement. This generous success condition was a conscious design choice intended to provide a sense of accomplishment. It has 2 display modes, VR and MR, and can come equipped with either soothing or upbeat music and vibration feedback. Additionally, players can skip the current move or pause at will during gameplay.

Dynamics

Playing involves players' efforts at mirroring exemplified postures, receiving immediate multisensory feedback, and regulating progression during a trial lasting a maximum of 5 minutes. One key dynamic reveals itself in the gamification mechanics: participants can choose to meet only the bare minimum threshold needed for progress ("single hotspot for 3 s") to progress effortlessly or shoot for immaculate matching across all hotspots to progress to a higher "accuracy" level. This allows participants to balance challenge against victory on a preference and ability level. It is this dynamic that later results regarding user experience build upon.

Aesthetics

The game aims to evoke multidimensional aesthetic experiences, such as a "sense of competence" from successfully completing movements, a "sense of challenge" from improving performance, feelings of "relaxation or motivation" engendered by different musical feedback, and a "sense of immersion" provided by the VR/MR environments. These subjective experiences are intended to encourage physical exercise in older users in an engaging manner, and their achievement was assessed using the Game Experience Questionnaire (GEQ) [18,19]. Design philosophy appears to be interested in desirable affective effects and perceived competence corresponding to self-determination theory principles, such that satisfying the need for competence can improve intrinsic motivation.

Experimental Equipment

This study used the Meta Quest 3 (Meta Platforms, Inc) HMD for presenting both VR and MR conditions [20,21]. The choice of specific, commercially available hardware, such as the Meta Quest 3, enhances the transparency and potential replicability of the study.

Activity Area

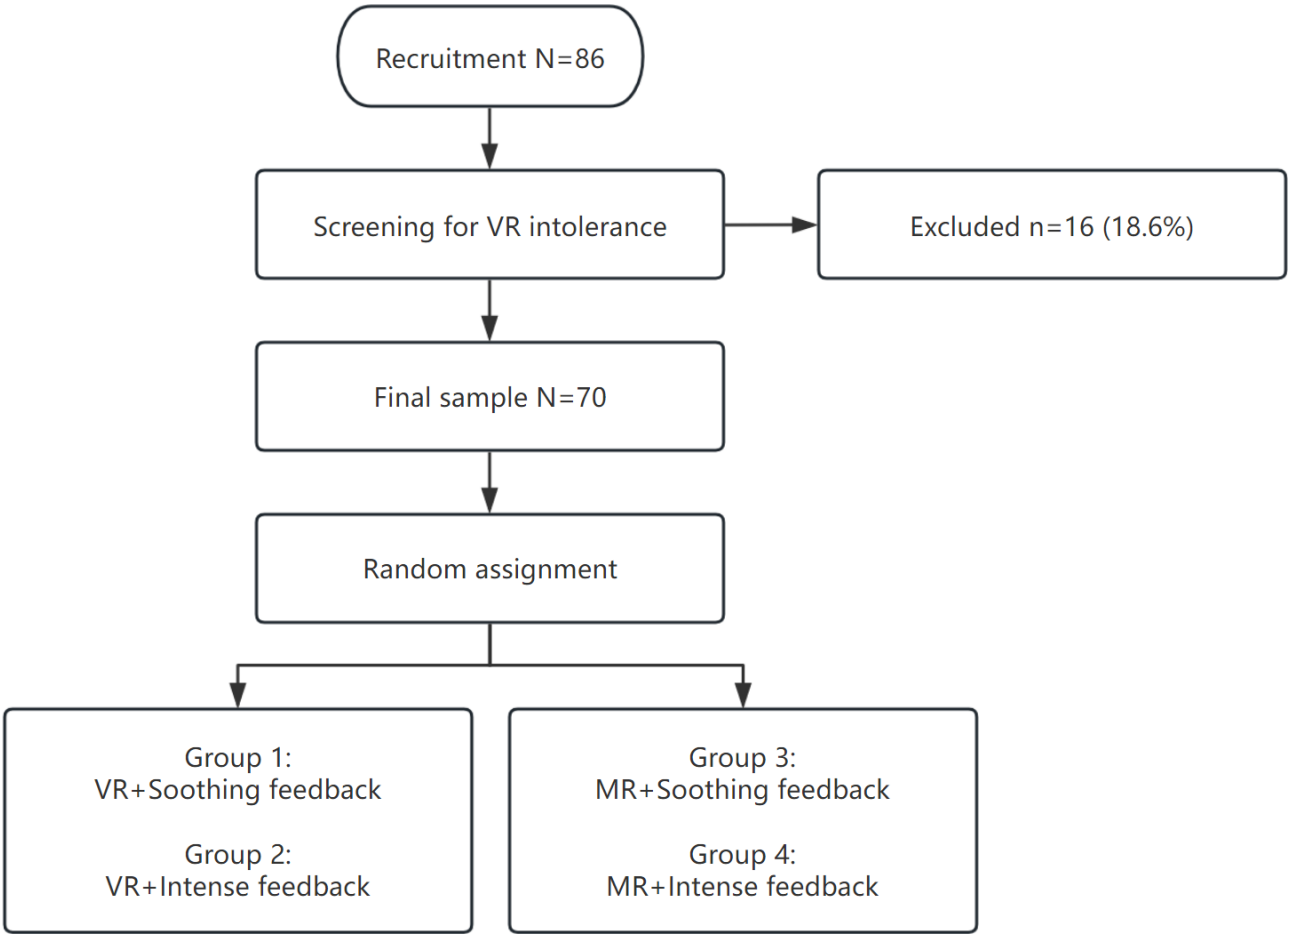
Exercise took place in an area of approximately 5 m^2, comparable to a typical living room, to ensure home feasibility and safety [22,23].

Experimental Procedure

Group allocation followed a prespecified rotating schedule (1:1:1:1) prepared before data collection; participants had no influence on assignment.

Experimental Preparation and Adaptation Training

When participants arrived at the laboratory, they first completed an informed consent process and a general information questionnaire. Next, a short adaptation training session was completed to enable participants (and especially those without any training in VR/MR) to become familiar with both the immersive environment and how to use the equipment. This adaptation step is a valuable step in acclimating older adults to new technology, such as VR, because it can be used to help reduce technology anxiety and achieve a minimum baseline level of comfort and competence in how to use the equipment before beginning the intervention [24,25].



Exergame Intervention

A visual summary of the participant flow and 2×2 design (VR/MR×soothing/intense) appears in Figure 1. This approach ensured that group sizes remained balanced and that potential confounding factors, such as personal preference or prior experience, were minimized. Participants followed a fixed 16-movement sequence; each 5-minute session could end before all movements were finished due to the time limit or restart at the first movement if the sequence was completed early. After this orientation, each participant performed 2 formal 5-minute gameplay sessions under their assigned experimental condition (VR/MR×soothing/intense feedback). The better performance out of the 2 sessions was recorded for analysis. All single-session metrics (eg, posture, accuracy) were computed per session; the higher of the 2 sessions was retained for analysis. This procedure ensured that every participant experienced the complete set of movements while also minimizing the impact of first-trial unfamiliarity on the final outcome [26].

VR provided a fully virtual scene; MR overlaid guidance onto the real room (Figure 2). "Soothing" used gentle cues; "intense" used more salient multimodal cues; task rules were identical [27].

Safety and Supervision

The experimental protocol was observed and supervised in a one-on-one capacity by trained researchers to be able to control and respond to any new sensory stimulus or sensation of disorientation. Subjects were informed they could withdraw from participation at any time if they experienced any type of discomfort or abnormal level of fatigability. Such precautions are particularly relevant in research among older individuals and potentially disorienting technologies such as VR. To regulate fatigue and potential dizziness between sessions, exposure was scheduled in 2 approximately 5-minute sessions, and participants could rest and pause whenever needed.

XSL•FO
RenderX

This was a single-visit, supervised laboratory study, consisting of the 2 gameplay blocks described earlier, with no home-based or longitudinal follow-up. Postsession questionnaires captured immediate responses; repeated exposures to control for novelty were not implemented.

Outcome Measures

Overview

This research took a multidimensional perspective to assess usability and feasibility, where primary data were drawn from:

1. GEQ [18]: An adapted 32-item version of the basic module of the GEQ (skipping item 3 in the original 33-item) was used to measure seven aspects of game experience: flow, competence, positive affect, negative affect, tension/annoyance, challenge, and sensory/imaginative immersion. Item 3 ("I was interested in the game's story") was excluded from the component immersion because our own game did not have a story. Component flow and competence scores were of particular importance to intrinsic motivation. Component scores were calculated as the means of their items on a scale ranging from 0 to 4.
2. The Virtual Reality Sickness Questionnaire (VRSQ) [28]: It was used to detect and quantify physiological symptom indicators of distress that users may experience while controlling VR/MR hardware, such as eye strain, nausea, headache, disorientation, and dizziness. It is a 9-item measure scored on a 0- to 3-point scale, and the VRSQ total score was calculated as the mean of these items, which provided a final score between 0 and 3. It has been shown to be a valid measure in the original investigation of the VRSQ for cybersickness because it was very highly correlated with existing motion sickness indices.
3. Objective game performance logs: Primary objective metrics were derived from automatically collected gameplay data provided by the game's backend system. They were "game score," "movement accuracy," "mean time per round," "task completion rate," "movement level (extracted from hand movement and head movement trajectory)," and "cumulative game time." These data were direct evidence to substantiate the assessment of whether users could use the game in an efficient manner.

We took an integrated approach, triangulating subjective experience (GEQ), physical comfort (VRSQ), and actual performance (game logs) to provide a sound foundation for a unified and rigorous assessment of the game's usability and feasibility.

We adopted a target engineering level of 80% movement precision to be used as an internal and exploration benchmarking.

Psychometric Properties of Outcome Scales

Internal consistency was evaluated on the present sample using Cronbach α and Spearman-Brown split-half coefficients. As several components (tension/annoyance, challenge, and negative affect) exhibited pronounced floor effects with near-zero variance, internal consistency coefficients for these scales were not estimable; for these, we report distributional summaries only. Reliability results for all measures are presented in Table 2. Per the GEQ guidelines, we dropped the story-related immersion item (item 3), leaving 5 items for this component; reliability values in Table 2 reflect this adapted set.

Table . Internal consistency of Game Experience Questionnaire and Virtual Reality Sickness Questionnaire (VRSQ) subscales.

Measure	k (items)	Cronbach α	Split-half (Spearman-Brown)
Sensory and imaginative immersion	5[a]	0.657	0.583
Flow	5	0.546	0.539
Tension/annoyance	3	N/A[b] (floor effect)	N/A[b] (floor effect)
Challenge	5	N/A[b] (floor effect)	N/A[b] (floor effect)
Negative affect	4	N/A[b] (floor effect)	N/A[b] (floor effect)
Positive affect	5	0.86	0.85
VRSQ total	9	0.782	0.689

[a]Game Experience Questionnaire core scored 0 - 4; immersion used items 12, 18, 19, 27, 30 (item 3 removed). Split-half denotes Spearman-Brown.

[b]N/A indicates nonestimable due to floor effect (near-zero variance).

Operational Definitions

The key game performance indicators were defined as follows: score was the system-generated composite points; accuracy (%) was the proportion of frames where hotspots were within tolerance; and posture (count) represented the total number of successful hotspot holds. Per movement, the player aligns the left and right controllers and the HMD with 3 predefined hotspots; holding any hotspot for ≥3 seconds is counted as one successful hotspot hold. The 16-movement sequence loops whenever it is completed before the 5-minute limit; therefore, posture is an open-ended count (no fixed cap) within the time window. For interpretability, 48 holds correspond to one full loop (16 movements×3 hotspots).

Data Preparation and Statistical Analysis

Overview

Consistent with the a priori plan, no confirmatory between-condition hypothesis testing (main effects or interaction) was conducted. To enhance transparency,

XSL•FO
RenderX

per-condition descriptive summaries (medians and IQRs for the 4 cells) are provided in Table 3.

Table . Per-condition descriptive statistics.

Outcome[a]	Group A: VR[b] soothing (n=17), median (IQR)	Group C: VR intense (n=19), median (IQR)	Group B: MR[c] soothing (n=17), median (IQR)	Group D: MR intense (n=17), median (IQR)
Positive affect	4 (3.8 - 4)	4 (3.8 - 4)	4 (3.4 - 4)	4 (3.8 - 4)
Flow	4 (3.2 - 4)	3.8 (3.6 - 4)	4 (3.2 - 4)	4 (3.2 - 4)
Competence	3.6 (3.1 - 4)	3.8 (3.2 - 4)	3.6 (3.4 - 4)	4 (3.3 - 4)
Challenge	1.4 (1.2 - 1.6)	1.4 (1 - 1.8)	1.6 (1.1 - 1.7)	1.6 (0.8 - 1.7)
VRSQ[d] total	0 (0 - 1)	0 (0 - 2)	0 (0 - 1.5)	0 (0 - 2)
Accuracy (%)	75 (56-84)	65 (54-81)	65 (54-77)	79 (54-94)

[a]Per-condition n shown in column headers. No inferential tests were planned; descriptive summaries only.

[b]VR: virtual reality.

[c]MR: mixed reality.

[d]VRSQ: Virtual Reality Sickness Questionnaire.

Data Cleaning

Handled sporadic missingness via median imputation only; no multiple imputation was performed [29].

Analysis Plan

Data normality was examined using the Shapiro-Wilk test [30,31]. Most key variables were found not to be normally distributed (Table 4). Nonparametric methods were consequently unanimously selected across hypothesis testing to yield robust and valid inferences. That is, median dimension scores on the GEQ were compared against a theoretical midpoint score of 2.0 using 1-sample Wilcoxon signed-rank tests. Wilcoxon tests correspondingly compared the median against a theoretical score of 0 on the VRSQ symptom scores (rated 0 - 3) to determine whether symptoms were distinctly present. With the exploratory nature of this item-level analysis, no adjustment for multiple comparisons was made on these 9 tests. Spearman ρ was used to examine associations between key factors. A level of significance was predetermined at an α of .05.

XSL•FO

Movement distance (m)	0.979	70	.29

Overall Usability Analysis

Descriptive statistics summarized the GEQ, the VRSQ, and game log indicators as median (IQR) [19,32].

Results

Participant Flow and Analysis Overview

In total, 86 older adults were recruited; 16 (18.6%) discontinued during acclimation due to intolerance, and data from 70 (81.4%) participants were analyzed. Participant flow and group allocation are shown in Figure 1. Per-condition medians (IQRs) for the 4 cells are available in Table 3.

Scale Reliability

Internal consistency was good for positive affect (α=.860; split-half=0.850) and acceptable for the VRSQ total (α=.782; split-half=0.689). Competence (α=.667; split-half=0.750) and sensory/imaginative immersion (α=.657; split-half=0.583) were in the moderate range, whereas flow was borderline (α=.546; split-half=0.539). Coefficients for tension/annoyance, challenge, and negative affect were not estimable due to floor effects (near-zero variance; Table 2).

Before the main analysis, the assumption of normality for the key-dependent variables was assessed using the Shapiro-Wilk test. The results are detailed in Table 4. While a few indicators did not significantly deviate from normality (eg, *challenge*, *P*=.16; game log *score*, *P*=.06; *posture*, *P*=.06; *movement distance (m)* *P*=.29), the majority of variables substantially deviated (eg, *accuracy*, *P*=.032; most GEQ/VRSQ dimensions, *P*<.001). Therefore, to maintain consistency and ensure robust inference across all analyses, nonparametric procedures were uniformly adopted.

Descriptive Statistics

We reported per-condition descriptive statistics for key outcomes across the 2×2 design (VR/MR×feedback intensity). As planned, no between-condition inferential tests were conducted; values are summarized as median (IQR) for interpretability with nonnormal distributions (see Table 3 for the 4 cells).

XSL•FO
RenderX

Overall Usability and Acceptability of the VR Tai Chi Game

To evaluate the overall usability and acceptability of the VR Tai Chi game for older users, this study collected and analyzed survey data from GEQ, VRSQ, and objective game performance log data.

Subjective Game Experience (GEQ)

As reflected in Table 5, subjective gaming experience as measured using the GEQ was highly positive. The median levels on positive aspects like “positive affect” (median 4.0), “flow” (median 4.0), “competence” (median 3.8), and “sensory/imaginative immersion” (median 3.8) all far surpassed the theoretical midpoint of the scale (P<.001 in all). Medians on negative aspects such as “tension/annoyance” (median 0) and “negative affect” (median 0) were below midpoint to a statistically significant degree (P<.001 in both). The median level on “challenge” was low to a statistically significant degree as well (median 1.4, P<.001).

Table . Descriptive statistics and one-sample Wilcoxon signed-rank test for Game Experience Questionnaire dimensions.

Dimension	Values, median (IQR[a])	*P* value[b]
Competence	3.8 (3.2 - 4)	<.001
Sensory/imaginative immersion	3.8 (3.2 - 4)	<.001
Flow	4 (3.2 - 4)	<.001
Tension/annoyance	0 (0 - 0)	<.001
Challenge	1.4 (1 - 1.6)	<.001
Negative affect	0 (0 - 0.25)	<.001
Positive affect	4 (3.8 - 4)	<.001

[a]Game Experience Questionnaire scores were rated on a 0 - 4 scale.

[b]*P* values reflect a one-sample Wilcoxon signed-rank test comparing the median score against the theoretical midpoint of 2.0.

Physiological Comfort (VRSQ)

The physiological comfort of the screened participants was assessed using the VRSQ. Overall, the incidence and severity of reported symptoms were low. Detailed item-level medians, statistical test results, incidence rates, and severity scores for reporters are presented in Table 6. The *P* values in the table should be interpreted as exploratory signals of which symptoms were most frequently endorsed, rather than as confirmatory hypothesis tests.

Table . Overall Virtual Reality Sickness Questionnaire main symptom statistical analysis.

Symptom item	Median	*P* value	Incidence rate (%)	Mean severity for reporters
General discomfort	0 (0-0)	.08	4.3	1
Fatigue	0 (0-0)	.04	7.1	1.4
Headache	0 (0-0)	.16	2.9	1
Eye fatigue	0 (0-0)	.002	15.7	1.273
Difficulty concentrating	0 (0-0)	.18	2.9	1.5
Head fullness	0 (0-0)	.01	10.0	1.286
Blurred vision	0 (0-0)	.01	10.0	1.143
Dizziness when closing eyes	0 (0-0)	<.001	20.0	1.214
Dizziness/vertigo	0 (0-0)	<.001	18.6	1

Game Performance

A look at the in-game objective performance data listed in Table 7 reveals wide individual variations among older adult participants. Participants demonstrated a fluid interaction rhythm with a median time spent per action of 6.4 seconds. However, large variations across major indicators were apparent due to wide IQRs seen across score and accuracy measurements (Table 7). Median movement accuracy was 68.5% (IQR 54.2% - 82.3%). Scores higher than 48 indicate that participants completed more than a single loop (or accrued numerous hotspot holds within a movement) within a 5-minute period.

XSL•FO
RenderX

Table . Key game performance indicators.

Indicator	Values, median (IQR)
Score	96 (70.25-133.5)
Posture[a] (count; no fixed cap, 48=one loop)	47 (39.75-55)
Accuracy (%)	68.5 (54.2 - 82.3)
Average time spent (s)	6.4 (5.5-7.5)
Movement distance (m)	273.5 (231.5-317.25)

[a]Posture counts the total hotspot holds within the retained 5-min session (best-of-two). The 16-movement sequence loops if completed early.

Correlation Analysis of Key Usability Factors

Correlation between major usability factors was examined using Spearman rank correlation analysis, and the results were presented in Table 8. Flow was significantly positively correlated with accuracy (ρ=.342; *P*=.004), and competence was significantly positively correlated with accuracy (ρ=.322; *P*=.007). VRSQ total score was significantly inversely correlated to positive affect (ρ=−0.334; *P*=.005). Competence was not significantly correlated with age (ρ=−0.179; *P*=.14).

Table . Spearman ρ correlation analysis (n=70).

Hypothesis	Variable 1	Variable 2	Correlation coefficient	*P* value
H1	Flow	Accuracy	0.342[a]	.004

[b]VRSQ: Virtual Reality Sickness Questionnaire.

Discussion

Subjective Experience Profile: High Perceived Competence With Low Perceived Challenge

As presented in Table 5, medians for positive affect, flow, and competence were above the scale midpoint, whereas challenge was markedly below (all *P*<.001). We observe a distinct user experience profile: high perceived competence and low challenge. For older adults who begin using exergames at home, this combination may be most relevant in reducing frustration and promoting first-time engagement [33,34]. At the same time, future research should gradually increase difficulty in an adaptive manner such that motivational support is balanced against accurate skill acquisition in free-living situations [35,36].

The internal consistency profile reveals adequate internal consistency on positive affect and satisfactory consistency on total VRSQ and moderate-to-borderline level in several components of the GEQ. Borderline α on flow is likely owing to constrained variance and the brevity and heterogeneity of item material in this first-stage application involving a single session; such findings on these components should consequently be interpreted correspondingly cautiously.

Physiological Comfort (VRSQ): Acceptability in Screened Sample and Potential Challenges

Regarding physiological comfort, the VR Tai Chi game demonstrated good tolerability within the screened participant sample, but this conclusion must be interpreted with caution [37]. The initial exclusion of a high 18.6% of recruits due to inability to adapt or strong VR-related sickness signifies a considerable bias in the VR tolerance of the final analyzed sample. Consequently, the currently observed low levels of cybersickness might overestimate the game's physiological comfort among the general older adult population. Although within the screened "more tolerant" sample, the average reported levels and perceived severity of various physiological discomfort symptoms (mainly mild "dizziness when closing eyes," "vertigo," and "eye fatigue") were low, 15% to 20% of participants still reported these mild symptoms [38]. This implies that cybersickness continues to be a primary barrier that has to be cleared ahead of VR technology deployment to older age categories. This 18.6% exclusion rate translates directly to current technological or design limitations in making VR universally comfortable among older adults and places a realistic limit on such interventions' immediate impact absent substantive improvements. For plans to promote such VR/MR Tai Chi games to the home environments of community-dwelling older adults, this high initial exclusion rate reveals key practical challenges. In home settings lacking immediate professional guidance, effective user screening, clear adaptation training guidelines, and easy-to-operate personalized comfort settings (eg, mode switching, visual effect adjustments) will be prerequisites for ensuring user safety and continued use [15,39]. To mitigate cybersickness at home, key strategies include starting with MR or low-vection scenes, using brief (≈5 min) sessions, ensuring proper headset fit with stable frame rates, and avoiding artificial locomotion. Furthermore, even mild symptoms, when experienced during unsupervised long-term home use, could affect user experience and adherence, thus

XSL•FO
RenderX

necessitating continuous design optimization to minimize discomfort as much as possible [40].

Accuracy-Competence Paradox

Despite a median movement accuracy of 68.5% (IQR 54.2% - 82.3%), which was below our predefined exploratory benchmark of 80%, participants reported high perceived competence (median 3.8), reflecting a rule set that credits partial hotspot matches (≥1/3 for ≥3 s). This system focuses on older users' positive affective experiences to improve long-term exercise adherence while reducing frustration and elevating confidence but without concomitant increases in stricter movement norms. However, this dilemma positions an additional discussion regarding such a game's effectiveness as a very precise device for training within corresponding trade-offs between motivation and skill fidelity.

The permissive rule (≥1 hotspot for ≥3 s) retains motivation but tends to overcredit partial matches. Future iterations will include adaptive multipoint matching and more informative corrective cues to put verifiable and perceived competence into alignment while retaining engagement [41]. It presents a foundational tension: the probable discrepancy between perceived benefit/competence and verifiable physiological/skill-based benefit [42]. While perceived competence is central to adherence, if it is not adequately correlated to correct movement execution, long-term benefit to health can be undermined and signal a need for "verifiable competence" feedback loops that remain motivating. For a mass market product like this, selling independent home-based exercise to older people, such a motivational design can serve to buffer against users experiencing "anxiety alone" if having trouble and will invite continued participation [35]. It does raise a valuable question, though: without professional instruction in a home environment setup, how can it be ensured that movements/movement effectiveness is appropriate? Therefore, future iterations of the gameplay might involve implementing tiered success criteria or optional stepwise movement guidance and feedback modules such that users can reach a personally optimal balance between enjoying playing the game and checking movement correctness in accordance with their own needs [43].

Insights From Correlation Analysis of Key Usability Factors

The interplay between gameplay performance, user comfort levels, and subjective experience yields direct design recommendations for successful home-based exergames. It was found that "accuracy" was strongly positively correlated with "flow" and "competence." This indicates that more precise movement performance can guide users into a state of deep, immersive focus, forming a positive feedback loop of "successful execution → flow experience → enhanced participation." This also offers a more nuanced interpretation of the "accuracy-competence paradox": the game provides a high baseline of perceived competence for all participants through its lenient judgment, and on top of this, higher accuracy leads to an even stronger sense of competence, cleverly balancing universal motivation with individual rewards. This suggests that users do derive satisfaction from objective mastery; while a safety net of easy success is important, completely removing skill development or clear performance feedback might make the game less engaging long term for some [44,45]. Furthermore, the analysis also highlighted the impact of users' individual states: the degree of physiological discomfort (VRSQ total score) was significantly negatively correlated with "positive affect." This warns that even mild discomfort can negatively affect older users' enjoyment, which is particularly critical in home settings lacking immediate help, thereby re-emphasizing the necessity of minimizing cybersickness risks [46]. Finally, a positive signal was that the study found no significant relationship between "age" and "competence," suggesting that the game possesses good age inclusivity within the 60 to 75 years age group, and users' perceived competence did not systematically diminish with increasing age. This has positive implications for its promotion among diverse community-dwelling older adult groups, although caution is advised when generalizing this conclusion to very old adults [39,47].

Limitations

A number of limitations can be applied to this work. A selection bias in this sample exists since a large number of preliminary participants were lost due to side effects associated with VR, and the resulting group was predominantly female, younger, and physically active. This extremely high level of preexisting physical activity may not be characteristic among this typically sedentary population that such home-based exergames aim to reach but may not serve adequately and hence might limit how much our findings generalize to less active older individuals in this regard. This may inflate physiological comfort but restrict findings' generalizability to a wider range of heterogeneous older people, especially older individuals who may be less technology-savvy or physically constrained. Finally, a single, brief VR intervention cannot eliminate any novelty effects or long-term adherence or long-term effects on health and retention of skill in a naturalistic home environment.

Future Direction

Future research will need to proceed beyond virtual-simulated laboratory settings to home-based settings and use strategies such as Ecological Momentary Assessment to assess long-term use, adherence, skill learning, and actual resultant health effects. It will be important to diversify the samples of participants to include a broader age range, a wider range of health statuses, and a wider range of technology backgrounds to assess the generalizability of such findings. Studies will need to work toward developing adaptive VR systems capable of shifting difficulty and feedback in a dynamic fashion, dependent upon user progress. We will assess fixed versus adaptive thresholds and include per-user calibration routines within a home-based study.

This will aid in connecting, keeping participants motivated, and ensuring appropriate skill acquisition to promote successful unsupervised home-based practice. Although this current system used the Meta Quest 3 headset and hand tracking, future work could include alternative systems (eg, Xbox/Kinect) or outward-facing full-body tracking systems to better assess posture in unsupervised home-based settings. Ecological Momentary Assessment is described as a future longitudinal

XSL•FO
RenderX

assessment methodology to assess adherence and in-the-wild engagement but not a single-session assessment of emotion.

Conclusions

This study demonstrates that well-designed VR/MR Tai Chi exercises can be a realistic and inspiring alternative exercise among community-dwelling older adults, supporting aging in place initiatives. A self-reported profile of high competence but low challenge perception implies early initiation but will need variable difficulty to maintain motivation in alignment with acuity of therapy for long-term use at home. Although physiologically tolerable in this prescreened population, a high entry exclusion rate due to cybersickness is a major barrier to wider use. A future direction to wider use success is a balance between motivational design of content and therapy acuity and modifications to system usability and comfort to provide net health gains in homeowner unsupervised use.

Acknowledgments

The authors are very grateful to the older residents of Chang'an Community in Changde City, Hunan Province, for participating in the experiment.

Abstract

Background: Loneliness has been linked to reduced mental and physical health. The “loneliness epidemic” is recognized as a public health crisis. However, questions remain about the potential of video games, which people play by themselves, to help reduce perceived loneliness.

Objective: This study explored the extent to which open-world games (eg, *The Legend of Zelda: Breath of the Wild*) and fun, accessible games (eg, *Yoshi’s Crafted World*) can help reduce loneliness in adults. We examined how such gameplay can foster a stoic approach to life and how stoicism mediates the reduction of perceived loneliness.

Methods: A cross-sectional survey was conducted using convenience sampling near a video game store. The sample comprised 2252 adults aged 21 years and older (women: n=966, 42.90%; men: n=1281, 56.90%; prefer not to disclose: n=5, 0.20%). Participants completed a questionnaire to measure perceived loneliness and stoicism, as well as their gameplay habits. Data were analyzed using ANOVA and moderated mediation with the PROCESS macro (bootstrapped samples=5000; 95% CI) to examine the effects of video gameplay on stoicism and loneliness, with the α level set at .05.

Results: Zelda players indicated higher stoicism (mean 4.87, SD 0.11; 95% CI 4.66-5.08) than nonplayers (mean 3.23, SD 0.07; 95% CI 3.09-3.37; $F_{1,2252}$=164.95; P<.001). Yoshi players also noted significantly higher stoicism (mean 4.49, SD 0.12; 95% CI 4.27-4.72) than nonplayers (mean 3.61, SD 0.05; 95% CI 3.50-3.71; $F_{1, 2252}$=48.33; P<.001), with a significant interaction effect ($F_{1,2252}$=7.89; P=.005) on stoicism. Furthermore, Zelda players indicated lower loneliness (mean 3.02, SD 0.11; 95% CI 2.81-3.22) than nonplayers (mean 4.28, SD 0.07; 95% CI 4.14-4.42; $F_{1, 2252}$=98.32; P<.001). Yoshi players also noted significantly lower loneliness (mean 3.09, SD 0.12; 95% CI 2.86-3.32) than nonplayers (mean 4.21, SD 0.05; 95% CI 4.10-4.32; $F_{1, 2252}$=76.32; P<.001). Moderated mediation analysis demonstrated that Zelda gameplay was positively associated with stoicism (β=1.28, 95% CI 1.07-1.50; P<.001), and stoicism was negatively associated with perceived loneliness (β=−0.49, 95% CI −0.52 to −0.45; P<.001).

Conclusions: This study is innovative in identifying stoicism as a potential emotional pathway through which video games may reduce loneliness. Moving beyond views of gaming as passive escapism, our findings suggest that specific gameplay experiences may serve as active spaces for cultivating resilience. We introduce a “digital diet” framework, indicating that balancing open-world challenges (eg, Zelda) with low-stakes restoration (Yoshi) produces synergistic psychological support. Practically, thoughtfully curated gaming experiences may serve as scalable and cost-effective digital adjuncts for public mental health interventions addressing the loneliness epidemic.

Introduction

Overview

Addressing perceived loneliness is perhaps one of the most pressing psychosocial challenges of our time [1-7]. Its importance today is magnified by a unique confluence of technological [8,9], societal [10,11], and economic factors [12] that differentiate the modern experience of loneliness from that of any previous generation [13]. Critically, the "loneliness epidemic" is a recognized public health crisis [14-20]. Loneliness is no longer seen as just a fleeting feeling [21]; it is now understood to have severe consequences for both mental health [22,23] and physical health [24], on par with smoking and obesity [25,26].

Chronic loneliness is linked to a 26% increased risk of premature mortality [24,27]. It is associated with higher levels of cortisol (the stress hormone) [28], increased inflammation [29], weakened immune systems [30,31], high blood pressure [32], and heart disease [33]. Furthermore, loneliness is deeply detrimental to mental health [34,35], and is associated with depression, anxiety, and substance abuse [36-40]. It can create a negative feedback loop where loneliness leads to increased social anxiety [21] and negative perceptions of social interactions [24], which, in turn, lead to further isolation [38]. Addressing loneliness is, therefore, a critical public health priority [21,37]; mitigating it can reduce the burden on health care systems and improve overall population well-being.

Despite society existing in the most technologically connected age [21], modern social platforms often promote performative interactions rather than authentic vulnerability, fostering feelings of inadequacy or "FOMO" (Fear of Missing Out) [41] or "FOBO" (Fear of a Better Option Elsewhere). Concurrently, participation in traditional localized communities has declined [42]. Modern, individualized lifestyles [43] and high-stress "hustle" cultures can crowd out the energy required to nurture relationships [42], increasingly leading to a sense of existential isolation [44].

In prior research, the role of video games in relation to loneliness has yielded mixed findings. On one hand, loneliness has been associated with problematic gaming outcomes, such as internet gaming disorder, in some populations [18]. On the other hand, socially oriented gaming interventions have been explored as a possible way to reduce loneliness, particularly among older adults [6]. However, what remains uncertain is the potential for mainstream single-player game genres, specifically open-world and fun, accessible games, to mitigate loneliness internally. While existing work has begun to examine the social potential of multiplayer or socially oriented gaming, the current literature lacks a clear understanding of the internal cognitive and emotional pathways through which specific single-player game environments might alleviate perceived loneliness without relying on digital socializing.

Background on Stoicism and Loneliness

In the context of performative connection and external pressure, stoicism can offer a counterintuitive but powerful solution. Stoicism does not simply advocate to "meet more people." It addresses the root perception of lack [45]. That is, stoicism shifts the source of validation from external to internal [45-47]. If an individual's sense of worth comes from their own character and virtues, they are less vulnerable to the approval and curated feeds of others [45-48]. Critically, stoicism helps reframe solitude, transforming loneliness into purposeful solitude—a time for reflection, self-improvement, and cultivating inner peace [45]. When one is comfortable with oneself, one can attract healthier connections and engage with the world from a place of strength, not lack.

While theoretical frameworks relevant to endurance, self-regulation, and responses to adversity can be found in stoic writings [45-48], direct quantitative evidence examining the association between stoicism and lower levels of loneliness remains limited. However, empirical support exists for some of the psychological mechanisms often linked to stoic practice. For example, cognitive behavioral therapy has frequently been connected to stoic principles, particularly the role of cognition in shaping emotional experience [49,50], and a cognitive behavioral therapy–based intervention has been shown to reduce loneliness in a randomized controlled trial [16]. Furthermore, recent psychometric research conceptualizes philosophical stoicism as a specific, measurable set of attitudes and behaviors rather than a strictly fixed personality trait [51]. While intervention studies explicitly targeting stoicism remain rare, evidence from clinical settings suggests that cognitive processes closely aligned with stoic practice, such as appraisal and reinterpretation, may be malleable [16,49]. Thus, a secondary aim of this study is to address this empirical gap by providing quantitative evidence on whether self-reported stoic attitudes are negatively associated with perceived loneliness.

Stoicism teaches individuals to direct their energy only toward things within their control (their judgments, values, and actions) and to accept what they cannot control (external events, other people's actions). The practice of accepting and embracing everything that happens (*amor fati* or love of fate) is viewed not as a setback but as a necessary part of life's journey [45,47,48]. According to stoicism, true happiness (*eudaimonia*) comes from living a life of virtue (wisdom, courage, justice, and temperance), not from seeking external pleasure or avoiding pain [45]; it is also seen as a path toward mental freedom [52,53]. In addition to this, contemplating potential setbacks (*premeditatio malorum* or the premeditation of evils) can help reduce their emotional impact and prepare individuals for adversity [45,46]. Stoicism aims for a state of *ataraxia* (freedom from distress) [45,46], offering a recalibration of one's emotional baseline to recognize that peace and joy are possible internal states, independent of external circumstances. Finally, a core stoic exercise is *memento mori* ("remember you must die"), not to be morbid, but to appreciate the preciousness of life and to prioritize what truly matters [45-47]. That is, to appreciate the beauty of something precisely because it is fleeting.

Background on Video Gameplay, a Stoic Mindset, and Loneliness

Video Gameplay and Loneliness

Prior empirical research demonstrates that video games can positively impact mental well-being and provide experiences of relaxation and cognitive escapism [54,55]. Furthermore, broader reviews indicate that game-based digital interventions can reduce mental health symptoms in clinical contexts [56,57]. Building on such evidence of gaming's capacity to enhance mastery and overall well-being, we posit that the structured environments of open-world and fun, accessible games could potentially serve as a novel context for cultivating attitudes aligned with stoic philosophy.

By design, open-world games often place players in vast, indifferent environments where survival requires adaptability and resilience. *The Legend of Zelda: Breath of the Wild* serves as a prime, concrete example of this dynamic, as it forces players to embrace a harsh, often unforgiving environment. This is a direct practice of *amor fati*.

In addition, gameplay emphasizes self-reliance and internal resources (virtue as the sole good). Link begins the game with nothing. He is amnesiac, weak, and stripped of all past glory. Progress in the game is not handed to anyone. Players must cook their own meals, forage for ingredients, scavenge for weaker weapons, and slowly learn to conquer challenges through their own wits, courage, and perseverance. The game constantly reinforces the idea that one has the resources within oneself to overcome obstacles. This builds self-sufficiency, a core stoic value. Players learn to rely on their judgment and abilities rather than waiting for rescue or a lucky break.

Moreover, the game's core loop is exploration and observation, not just action. Stoicism begins with the "discipline of perception," which involves judging events clearly and without unnecessary emotional baggage.

Furthermore, accessible, low-stakes games, such as Yoshi, can help strengthen the stoic focus on the present moment through mindfulness and simplicity. The mindfulness is baked into the esthetic and gameplay. *Yoshi's Crafted World* is hand-crafted from cardboard and yarn, encouraging you to appreciate the beauty in simple, everyday objects. The pace is slower, and the goal is often to stop, look around, and find a hidden flower or a shy Poochy pup. This is a practice in appreciating the present moment for its own sake, not just for survival. For someone feeling lonely, this directly counteracts rumination about the past or anxiety about the future, anchoring them in a gentle, pleasant now.

Moreover, games such as *The Legend of Zelda: Breath of the Wild* and *Yoshi's Crafted World* reinforce the idea that purpose is often found in caring for others and contributing to a collective good. They practice the stoic concept of *sympatheia*, the interconnectedness of all people [45]. By engaging in a game that is literally about helping and supporting others (even in a simple, cartoonish way), players can strengthen the neural pathways for empathy and the understanding that we are part of a whole. This directly combats the isolated, ego-centric perception that fuels loneliness.

Loneliness is often less about being physically alone and more about a state of mind characterized by a feeling of lack or neediness, a sense of disconnection from the world and others, as well as anxiety about one's place and ability to cope. The stoic mindset cultivated by *The Legend of Zelda: Breath of the Wild* can help directly address these feelings. That is, the game helps reframe solitude from a state of *loneliness* to one of peaceful aloneness, self-reliance, and agency. The quiet, expansive landscapes are not empty; they are full of possibility that one gets to engage with on one's own terms. This teaches players to enjoy their own company and to see alone time not as a deficiency, but as an opportunity for exploration and self-discovery. One becomes a complete unit unto oneself, less dependent on others for validation or entertainment.

Stoicism teaches that people are part of a larger, rational cosmos. *The Legend of Zelda: Breath of the Wild* mimics this by fostering a connection to something larger and by making players a small part of a vast, open world. One's journey is one's own, but it is woven into the fate of Hyrule. This sense of being part of a larger whole, even when alone, can be profoundly comforting and diminish the feeling of being a lonely, isolated individual.

The Perfect Stoic Diet

Playing *The Legend of Zelda: Breath of the Wild* builds the core, resilient stoic muscles: courage, endurance, acceptance, and self-reliance. Playing a Yoshi game rehabilitates those muscles with stretches of joy, nurtures them with empathy, and keeps them flexible with mindfulness and play. Together, they form a holistic practice. Open-world games such as *The Legend of Zelda: Breath of the Wild* teach players to be strong enough to be alone without being lonely. Fun and accessible games such as Yoshi, on the other hand, can remind one that the world is also a place of softness, connection, and simple joys worth engaging with. Together, these games remind us that light-heartedness and profundity are not opposites but essential partners on the path to a good life. By becoming more stoic, one becomes more resilient, self-contained, and at peace with one's own presence. This inner fortitude is the ultimate cure for loneliness, as it means one is never truly without a stable and capable companion: oneself.

Thus, the aim of this study is to investigate the potential of open-world and fun, accessible video games for reducing loneliness and enhancing stoicism in adults. To achieve this, we address four distinct but interconnected research questions: First, to what extent, if at all, can video gameplay help reduce the risk of loneliness? Second, how does a stoic approach to life, afforded by these games, serve as an emotional pathway to alleviate that isolation? Third, what role do popular open-world video games play in facilitating this resilient stoic mindset? Finally, how does the addition of fun, accessible games (eg, *Yoshi's Crafted World*) interact with open-world gameplay (eg, *The Legend of Zelda: Breath of the Wild*) to further enhance stoicism and ultimately mitigate people's loneliness?

Methods

Research Design

As part of this study, we conducted a cross-sectional survey using a convenience sampling approach. We followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1) to report observational, cross-sectional studies [58] and collected the data in November 2025 and December 2025.

Inclusion and Exclusion

Participants were invited to take part in the study if they were aged 21 years or older. To allow for robust statistical comparisons, prior or current video game experience was not required. Specifically, we compared nonplayer participants with participants who currently or recently played open-world games (eg, *The Legend of Zelda: Breath of the Wild* or *The Legend of Zelda: Tears of the Kingdom*; see Figures 1-3 for visual context of the vast, open-world environments that require a stoic approach) and/or fun, accessible games (eg, *Yoshi's Crafted World* or *Yoshi's Wooly World*; see Figures 4 and 5 for the gentle, nurturing environments).

Sampling Procedures

A total of 3 trained research assistants, who were blind to the study's research questions, approached potential study participants near a video game store in a busy shopping mall. This was done to capture some variance in terms of whether people were playing or had recently played an open-world game such as *The Legend of Zelda: Breath of the Wild* or *The Legend of Zelda: Tears of the Kingdom* and/or fun, accessible games such as *Yoshi's Crafted World* or *Yoshi's Wooly World*. The research assistants informed potential participants that the study, which focused on daily activities, would contribute to current academic research at a university and that participation would not take longer than 7 minutes in total. The research assistants also checked participants' IDs for age in cases where potential participants appeared younger.

Sample Size, Power, and Precision

Over the course of 5 weeks, the research assistants managed to recruit a total of 2300 participants and invited them to complete a brief survey on a tablet. Because 48 participants stopped midway through answering the measurement items and, hence, did not complete the entire questionnaire, their responses were discarded from the study, and the total effective response rate is 2252 (97.90% completion rate).

Participant Characteristics

The final sample consisted of 2252 participants (women: n=966, 42.90%; men: n=1281, 56.90%; prefer not to disclose sex: n=5, 0.20%). Because participants with incomplete responses were excluded during the initial screening phase, there were no missing data in the final analyzed dataset.

Measures and Covariates

Participants answered 3 questions about perceived loneliness that were adapted from previously published and validated scales [59-61]: "How often do you feel a sense of emptiness around you?", "How often do you feel that there is no one you can turn to?", and "How often do you feel that you lack companionship?" (1="never" to 7="always"). Furthermore, participants answered 3 questions about their stoic attitudes and behaviors using items that were adapted from previously published and validated scales designed to measure the core practices of modern stoicism [49-51], "I reflect on the temporary nature of things to help me appreciate them more," "I consciously consider whether things are within my control before deciding how to act," and "When facing a difficulty, I focus on my own virtuous response rather than complaining about the situation itself" (1="very inaccurate" to 7="very accurate"). Participants then indicated whether they are currently playing or have recently played a Yoshi game such as *Yoshi's Crafted World* or *Yoshi's Wooly World* (0="no" and 1="yes"), and an open-world game from the Legend of Zelda series, such as *The Legend of Zelda: Breath of the Wild* or *The Legend of Zelda: Tears of the Kingdom* (0="no" and 1="yes"). As a control, participants indicated their gender (0="female" and 1="male"). To ensure the quality of measurement, all scale items were reviewed by the research team for clarity and consistency.

Statistical Analysis

We followed the recommended procedures for conducting confirmatory factor analyses and examined the factor structure and reliability scores for all the measurement items in our survey study [62,63]. This was done to assess whether the items in the study significantly loaded on their intended factors and had weak cross-loadings. Furthermore, we examined the average variance extracted and composite reliability scores for the measurement scales in our study. Moreover, we tested whether the average variance extracted for each construct was indeed greater than the squared correlations between the construct and other variables in our survey [64]. The hypothesized model was tested using confirmatory factor analysis in IBM SPSS AMOS 29.0 with maximum likelihood estimation.

Next, we conducted an ANOVA to examine the variances across the different groups in our study (ie, open-world game: no vs yes; fun, accessible game: no vs yes). In addition, we conducted a moderated mediation analysis using the PROCESS macro [65] (model 8; bootstrapped samples=5000; 95% CI) to examine the effects of popular open-world gameplay such as *The Legend of Zelda: Breath of the Wild* (independent variable) as well as gameplay of fun, accessible games, such as *Yoshi's Crafted World* (moderator) on stoicism (mediator) and loneliness (dependent variable). To ensure that PROCESS did not treat sex as a continuous variable, sex was coded as a dummy variable (0="female" and 1="male"). Due to the insufficient sample size (n=5), the "prefer not to disclose" category was excluded from the moderated mediation analysis.

Ethical Considerations

Ethical approval for this study was obtained from Kyushu Sangyo University's ethics committee (#2025 - 0019). The procedure ensured compliance with the university's research ethics guidelines and the principles of the Declaration of Helsinki. All data collected were anonymized and kept confidential within the research team. Study participants provided informed consent and were told that they had the right to withdraw from the study at any time without providing a specific reason for withdrawal. Furthermore, we ensured that no identification of individual participants or users in any images included in the paper (eg, in-game screenshots and participant flowchart) or supplementary material was possible. After completing the brief survey, each study participant was thanked for their time and debriefed about the study. Study participants did not receive a financial reward.

Constructs and measurement items	Factor loadings
Loneliness (α=.93; CR[a]=.92; AVE[b]=.81)	
How often do you feel a sense of emptiness around you?	0.89
How often do you feel that there is no one you can turn to?	0.91
How often do you feel that you lack companionship?	0.90
Stoicism (α=.94; CR=.93; AVE=.83)	
I reflect on the temporary nature of things to help me appreciate them more	0.92
I consciously consider whether things are within my control before deciding how to act	0.88
When facing a difficulty, I focus on my own virtuous response rather than complaining about the situation itself	0.93

[a]CR: composite reliability.

[b]AVE: average variance extracted.

Primary Analyses: ANOVA

A set of 2 ($Zelda_{\text{open-world gameplay}}$: no vs yes)×2 ($Yoshi_{\text{fun, accessible gameplay}}$: no vs yes) ANOVA on stoicism showed a significant main effect of open-world gameplay such that participants who played an open-world game like *The Legend of Zelda: Breath of the Wild* indicated higher levels of stoicism (mean 4.87, 95% CI 4.66-5.08) than participants who did not (mean 3.23, 95% CI 3.09-3.37; $F_{1,\ 2252}$=164.95; *P*<.001). Moreover, the results demonstrated a significant main effect of fun, accessible gameplay, such that participants who played a Yoshi game noted significantly higher levels of stoicism (mean 4.49, 95% CI 4.27-4.72) than study participants who did not (mean 3.61, 95% CI 3.50-3.71; $F_{1,\ 2252}$=48.33; *P*<.001). In addition to this, we observed a significant interaction effect of open-world× fun, accessible gameplay ($F_{1,\ 2252}$=7.89; *P*=.005). Gender had no effect on stoicism ($F_{1,\ 2252}$=0.01; *P*=.91; Multimedia Appendix 1).

Furthermore, we conducted a set of 2 ($Zelda_{\text{open-world gameplay}}$: no vs yes)×2 ($Yoshi_{\text{fun, accessible gameplay}}$: no vs yes) ANOVA on loneliness. The results showed a significant main effect of open-world gameplay, such that participants who played an open-world game like *The Legend of Zelda: Breath of the Wild* indicated lower levels of loneliness (mean 3.02, 95% CI 2.81-3.22) than participants who did not (mean 4.28, 95% CI 4.14-4.42; $F_{1,\ 2252}$=98.32; *P*<.001). In addition, the results showed a significant main effect of fun, accessible gameplay such that participants who played a Yoshi game noted significantly lower levels of loneliness (mean 3.09, 95% CI 2.86-3.32) than study participants who did not (mean 4.21, 95% CI 4.10-4.32; $F_{1,\ 2252}$=76.32; *P*<.001). The results also showed a significant interaction effect of open-world× fun, accessible gameplay ($F_{1,\ 2252}$=4.78; *P*=.03), while gender had no effect on loneliness ($F_{1,\ 2252}$=0.34; *P*=.56; Multimedia Appendix 2).

Primary Analyses: Moderated Mediation

We conducted moderated mediation analyses using PROCESS macro [65] (model 8; bootstrapped samples=5000; 95% CI; sample size=2252) with $Zelda_{\text{open-world gameplay}}$ as the independent variable, stoicism as the mediator, $Yoshi_{\text{fun, accessible gameplay}}$ as the moderator, and loneliness as the dependent variable with gender as a potential confound. The results showed that $Zelda_{\text{open-world gameplay}}$ (independent variable) had a significant and positive effect on stoicism (β=1.28, SE=0.11, *t*=11.83; *P*<.001; 95% CI 1.07-1.50; Table 3). Furthermore, $Yoshi_{\text{fun,accessible gameplay}}$ had a positive influence on stoicism (β=0.53, SE=0.14, t=3.70; *P*<.001; 95% CI 0.25-0.81) and the results showed a significant interaction effect of Zelda and Yoshi gameplay on stoicism (β=0.72, SE=0.26, *t*=2.81; *P*=.005; 95% CI 0.22-1.22). Gender had no influence on stoicism (β=0.01, SE=0.08, *t*=0.11; *P*=.91; 95% CI –0.14 to 0.16; Table 3).

XSL•FO
RenderX

Table . Cross-sectional survey moderated mediation regression results: effects of open-world and fun, accessible gameplay on stoicism[a].

Predictor	B	SE	*t* test	*P* value	95% CI
DV: Stoicism					
Constant	2.95	0.13	23.39	<.001	2.70 to 3.20
$Zelda_{open\text{-}world\ gameplay}$	1.28	0.11	11.83	<.001	1.07 to 1.50
$Yoshi_{fun,\ accessible\ gameplay}$	0.53	0.14	3.70	<.001	0.25 to 0.81
Interaction Zelda × Yoshi gameplay	0.72	0.26	2.81	.005	0.22 to 1.22
Gender	0.01	0.08	0.11	.91	–0.14 to 0.16

[a]R=.33; R^2=.11; mean square error=3.19; $F_{4,\ 2247}$=72.37; P<.001.

The conditional effects of the focal predictor (open-world gameplay such as *The Legend of Zelda: Breath of the Wild*) on stoicism at values of the moderator (fun, accessible gameplay such as Yoshi: no vs yes) are shown in Table 4.

Table . Cross-sectional survey conditional effects: effects of the focal predictor ($Zelda_{open\text{-}world\ gameplay}$) on stoicism at values of the moderator ($Yoshi_{fun,\ accessible\ gameplay}$).

	Effect	SE	*t* test	*P* value	95% CI
Zelda -> stoicism					
Yoshi gameplay: no	1.28	0.11	11.83	<.001	1.07-1.50
Yoshi gameplay: yes	2.00	0.23	8.64	<.001	1.55-2.46

The moderated mediation analyses further showed that stoicism was significantly negatively associated with participants' perceived loneliness (β=−0.49; SE=0.02; *t*=−26.46; *P*<.001; 95% CI −0.52 to −0.45; Table 5). In addition, the direct effects of Zelda and Yoshi gameplay on loneliness remained significant such that Zelda (β=-0.36; SE=0.10; *t*=−3.72; *P*<.001; 95% CI −0.56 to −0.17) and Yoshi (β=−0.58; SE=0.13; *t*=−4.62; *P*<.001; 95% CI −0.83 to −0.33) gameplay were significantly negatively associated with loneliness (Table 5). The interaction of Zelda×Yoshi gameplay (β=−0.21; SE=0.22; *t*=−0.93; *P*=.35; 95% CI −0.65 to 0.23) on loneliness was not significant and the results showed no effect of gender on loneliness (β=−0.04; SE=0.07; *t*=−0.60; *P*=.55; 95% CI −0.17 to 0.09; Table 5).

Table . Cross-sectional survey moderated mediation regression results: effects of open-world and fun, accessible gameplay on loneliness[a].

Discussion

Principal Findings

In alignment with our stated objectives, this study investigated the potential of open-world and accessible video games to reduce perceived loneliness and enhance stoicism in adults. Addressing our four core research questions, the findings demonstrated that, first, engagement with these focal games is significantly and negatively associated with perceived loneliness. Second, our theoretical model revealed that stoicism serves as a significant emotional pathway, inversely linking gameplay to feelings of isolation. Third, open-world gameplay (eg, The Legend of Zelda) was strongly associated with a more resilient, stoic mindset. Finally, we observed a significant interaction effect, indicating that the addition of accessible games (eg, Yoshi) positively synergizes with open-world gameplay to further enhance stoicism.

The observed synergy between open-world and accessible gameplay, termed the “Perfect Stoic Diet,” suggests potential as a scalable public health intervention. Traditional mental health services often contend with well-documented barriers, including broad gaps in care availability [66], cost and access challenges [67], and stigma related to mental illness [68]; in contrast, these gaming experiences are widely accessible [54,56]. While the upfront costs of commercial video games and required hardware present a tangible barrier for some vulnerable populations, broader research supports the idea that game-based digital interventions may offer scalable and relatively cost-effective adjuncts to conventional therapy, particularly for individuals from at-risk populations who might otherwise remain underserved [56,57]. Leveraging the immersive nature of these games to foster a stoic mindset provides a novel, decentralized pathway for addressing the loneliness epidemic [21,37].

Comparison With Prior Work

Prior research examined video games and digital environments through the lens of cognitive escapism, relaxation, and mental well-being [54,55], including discussions on bridging gaming and mental health science [69]. Broader digital well-being research further shows that online environments can shape anxiety, stress, and psychological experiences in complex ways, depending on platform features, user goals, privacy concerns, and social dynamics [70-75]. Prior studies also investigated how various digital offerings can help users by offering them hope and making their lives easier [76-78]. However, the specific role of single-player video games as active spaces for cultivating emotional resilience remains underdeveloped. Our findings extend this literature by suggesting that open-world environments, such as *The Legend of Zelda: Breath of the Wild*, may afford more than passive escapism: in our data, they were associated with a stoic mindset that helped players reframe solitude.

Furthermore, while some loneliness-focused gaming interventions have explored social or multiplayer experiences, particularly among older adults [6], this study contributes a novel perspective by suggesting that single-player, mainstream games may mitigate loneliness through internal cognitive processes rather than digital socializing. By linking gameplay to stoic principles [45-48], this study offers quantitative evidence that specific single-player gameplay experiences may serve as an internal emotional pathway for alleviating perceived loneliness.

Finally, while public health research emphasizes the serious physical and mental health consequences of loneliness [14,21,25], game-based digital intervention research has only recently begun to examine how different genres may produce distinct psychological affordances [56,57,79]. Our research introduces the concept of a “digital diet,” suggesting that the psychological benefits of gaming are not monolithic. Specifically, our findings indicate that balancing open-world challenge and autonomy with the low-stakes, calming qualities of accessible games, such as *Yoshi’s Crafted World*, produces a synergistic pattern of psychological support. This extends previous frameworks of digital well-being by suggesting that a thoughtfully curated combination of gameplay experiences may offer a more robust buffer against loneliness than singular game genres alone.

Limitations

As part of this study, we explored the role of open-world and fun, accessible games in facilitating stoicism and reducing loneliness. Future work studying the potential influence of other types of games on adults' loneliness is richly deserving. Moreover, we invite additional work to conduct randomized controlled studies across different participant pools—explicitly accounting for unmeasured confounding variables such as socioeconomic status (eg, income level, educational attainment, and working conditions), marital status, living arrangements, and baseline social contact—to establish causality and help strengthen confidence in the generalizability of the current results. In addition, we did not account for participants' varied lifestyles or capture their social media usage as part of this study. We invite future work to explore how social media usage and individuals' lifestyles (eg, taking regular walks in parks, etc) may influence loneliness in tandem with video gameplay. Additionally, we captured self-reported levels of stoicism. A promising avenue for future research is to investigate objective measures of stoicism and assess its role in the relationship between gaming and loneliness.

Furthermore, it is important to acknowledge potential confounding variables related to our sample composition. Because we did not collect data on the general gaming habits of participants who answered "no" to playing the focal games (ie, The Legend of Zelda or Yoshi), it remains unclear whether this control group consisted of strictly nongamers or players of other video game genres. Similarly, while our sample consisted of adults aged 21 years and older, the differing target demographics and inherent appeal of open-world versus fun and accessible games may introduce subtle confounding factors. Capturing participants' complete digital diets is a necessary step for future research to isolate these variables more effectively.

Finally, it is important to note the limitations regarding our analytical approach. Because we conducted a cross-sectional survey and all variables were measured at the same time, the temporality of the variables cannot be firmly established. Consequently, the mediation analyses may be considered exploratory. Furthermore, the assumptions regarding the absence of confounding among these variables must be interpreted with caution. Since we were not able to collect data on various demographic information of participants and other potential confounding variables, we invite future research to investigate some of these additional variables that may lead to important insights. We strongly encourage future studies to conduct longitudinal observations to better establish the temporality and relational dynamics of these variables.

Future Research

This study has a number of limitations, which also offer promising paths for additional work. Previous research has shown that users may at times feel uneasy about different digital offerings [80-82], while at the same time being able to incorporate digital solutions as part of their concept of self if and when these offerings are seen as enabling their lives and making their lives easier [83]. Future studies that further explore the role of video games in making users' lives easier and helping them through the day by affording emotional reactivity are very promising. In addition to this, we invite work to explore the potential for video games in enhancing individuals' mental health and broader well-being by offering benefits that resemble relaxation, restoration, or meditative forms of psychological recovery [54,55]. Moreover, an increasing number of people may feel overwhelmed by the burden of modern life (24/7 news cycles, an "always on" social media culture, etc) and may lose the ability for childlike wonder and joy [56,57,66-68,79,84], while becoming increasingly detached from nature [85,86]. Yet, people also strive for meaning in their lives [87]. The current findings show how a game can be more than entertainment, how ancient wisdom can be applied to modern problems [45,50], and how interactive experiences may help cultivate a life with less loneliness and more meaning [44,87]. How fun and accessible video gameplay may interact with gameplay of open-world games to help players anchor more strongly in day-to-day life and help them manage daily worries and discomfort is worthy of further investigation [54,79]. Thus, we invite future research to help bridge gaming and mental as well as physical health science to help individuals create a personal, life-affirming way to live such that if a demon told them that they would have to live this exact same life, with all its pain and joy, over and over again for eternity, they would react not with despair but rather with triumphant joy [88].

Conclusions

The findings of this study highlight the potential for video games to help combat loneliness. First, this study is innovative in identifying stoicism as an active emotional pathway through which video games may reduce loneliness. Second, unlike existing studies that view gaming primarily as passive escapism, our findings suggest that video games can serve as active spaces for cultivating mental resilience. Third, it introduces a novel 'digital diet' framework to the field, showing that balancing open-world challenges (eg, The Legend of Zelda) with low-stakes restoration (eg, Yoshi) produces a synergistic pattern of psychological support. Finally, regarding broader real-world implications, these findings position thoughtfully curated video games as scalable and cost-effective digital adjuncts for public mental health interventions addressing the loneliness epidemic [21,37].

Acknowledgments

The authors thank Wendelin Buchinger for his ideation and the insights he shared based on his in-depth gameplay analysis (> 12,700 hours of gameplay of *The Legend of Zelda: Breath of the Wild* – this is not a typo!). Furthermore, the authors thank all the study participants for their time. In addition, the authors would like to thank Nintendo for granting permission to take photos

Abstract

Background: Regular physical activity is critical for healthy aging, yet older adults face persistent barriers to exercise adherence. Exergames, such as video games that require physical movement, have emerged as a promising tool to engage older adults in regular exercise. However, most existing research focuses on physical and cognitive outcomes, with limited understanding of whether exergames are associated with behavioral changes, including sustained exercise habits, healthier lifestyles, and a sense of health ownership, which underpin older adults' environmental mastery and self-management of their health.

Objective: This pilot study investigated how participation in a community-based exergame program was associated with exercise habits, healthy lifestyles, and health ownership and examined the motivational factors driving longer-term adherence.

Methods: This study used a single-group, pre-post pilot design. It involved 33 older adults participating in an exergame program across 2 community centers in Hong Kong. The program was meticulously designed to include 12 supervised training sessions (6 wk), followed by a 4-week free-play period to assess long-term adherence. A package of exergames, covering physical, social, and cognitive health, was selected. Each exergame session lasted 30 minutes. During this time, older adults played 3 different games, with each game taking 10 minutes. Changes in health status, well-being, physical activity level, exercise habits, healthy lifestyles, health ownership, and motivations to play exergames at 4 stages were continuously measured. We applied repeated-measures generalized linear model for health and habit outcomes, Mann-Whitney *U* to examine the relationship between motivational factors and adherence, and Spearman correlation to test links between motivation and play frequency during the free-play period.

Results: The linear mixed model results suggest that participation in the exergame program was positively associated with older adults' healthy lifestyles (mean difference 0.70, 95% CI 0.14 to 1.25, $F_{3,96}$=6.52; P<.001, η^2=0.17), exergame play habits (mean difference 0.50, 95% CI −0.03 to 1.03, $F_{2.77,88.57}$=4.88; P=.004, η^2=0.13), total physical activity metabolic equivalent of task levels (mean difference 2100.83, 95% CI −249.16 to 4450.82, $F_{2.44,78.05}$=3.15; P=.04, η^2=0.09), and health ownership (mean difference 0.24, 95% CI 0 to 0.48, $F_{1.61,51.44}$=4.23; P=.03, η^2=0.12). Posttraining adherence was high at 75.80% (25/33). Further, Spearman rank correlation analysis indicated positive associations between adhered gameplay frequency and social (coefficient=0.41; P=.02) and enjoyment motivations (coefficient=0.39; P=.02).

Conclusions: This pilot study examines exergames as an innovative approach to healthy aging by encouraging sustained behavioral change. Unlike prior research that emphasized health outcomes, these findings suggest potential benefits in formulating physical activity habits, lifestyle adjustment, and health ownership. Enjoyment and social connection emerged as key motivational factors. The study indicates potential for nongovernmental organization–led community programs to foster active aging, lifestyle adjustment, and social cohesion.

Introduction

Exergames: A Digital Health Solution

Participating in exercise is an important strategy for older adults to achieve healthy aging. While the advantages of exercise are well recognized, many older adults struggle to adhere to regular exercise [1]. This could be due to the effort required for exercise and the perception that it can be monotonous. Offering new attractive types of exercise is crucial to encouraging older adults to commit to long-term adherence. With advancements in technology, older adults now have more opportunities for exercise, including exergames. Exergames, a blend of "exercise" and "games," are video games that also serve as a form of physical activity. These games are designed to engage players in physical movement, often simulating activities such as dancing, sports, and fitness exercises [2]. Through gamified activities, routine activities (such as doing exercises) become more attractive and easier to adhere to.

Recent studies have demonstrated the potential of exergames in primary health care, particularly as a preventive approach to support physical and mental well-being. A Korean study reported that older adults aged above 75 years who participated in an 8-week exergame program (playing Ring Fit Adventure for 50 min, 3 times a week) showed a significant improvement in physical function, fall efficacy, depressive symptoms, and health-related quality of life [3]. A San Diego study reported that 36 sessions of training with Nintendo's Wii gaming console (including tennis, bowling, baseball, golf, and boxing) effectively improved older participants' depressive symptoms, mental health–related quality of life, and cognitive functioning [4]. Litz et al [5] found that exergames improve older adults' cognition (such as memory). The intervention group showed significant improvements in dynamic balance and visuospatial memory compared to the control group. In terms of social benefits, a Singaporean study developed an exergame called "New Apple" for 319 participants aged 65 years or older (twice a week for 6 wk), identifying increased positive affect and decreased negative affect on emotional well-being among participants over time [6].

Measurement: From Health Outcomes to Behavioral Intentions

Exergames not only contribute to individuals' health but also support habit formation. A habit is a behavior that repeats regularly and occurs automatically, without requiring scheduling or effort [7,8]. Regular exercise activities performed consistently over time can develop habitual behavior, which becomes "volitional and mindful" as a result of learning [9]. Consequently, when people are exposed to specific contexts, such as designated locations, times, similar objects, and similar people, these contexts could activate an impulse to perform particular behaviors [10]. Exergames have been shown to effectively help people create and sustain robust exercise habits by providing virtual challenges and reward systems [11]. Such habits are often associated with stress relief, mood enhancement, social interaction, and expanded social networks, all of which contribute to the quality of life [12].

Lifestyle refers to a comprehensive pattern of living. A healthy lifestyle includes engaging in physical activity, making good nutritional choices, getting enough sleep, and avoiding harmful behaviors such as smoking and excessive alcohol consumption [13,14]. Developing such a lifestyle reflects competence and coping skills, enabling older adults to manage health conditions and maintain independence [15]. Research has shown that for older adults, developing a healthy lifestyle is linked to reduced mortality, reduced frailty, and decreased risk of chronic diseases [13].

Beyond habit and lifestyle, the study found that exergames are conducive to reinforcing "a sensitivity of the individual responsibility to care for themselves, especially at older age" [16]. This reflects mindset changes in health, from being a passive recipient of health services to proactively managing one's own health conditions. Such reframing is often described as greater health ownership, meaning "taking control of one's health, accepting responsibility for one's health, and being accountable for one's health-related outcomes" [17]. Health ownership indicates a high level of self-efficacy, whereby an individual possesses firm beliefs in their ability to effectively maintain their health by performing specific tasks or goals. This sense of responsibility may empower older adults to take charge of their health conditions and sustain healthy lifestyles.

Motivational Factors

Older adults may recognize the importance of health and prevention, but their awareness does not always lead to behavioral changes or improved exercise habits. Exercise adherence is key, which is driven by motivation [18]. Based on an experiment using wearable equipment with 600 Turkish adults, motivation plays a vital role in stimulating behavioral repetition, which could potentially result in habit formation [7]. A cross-sectional questionnaire survey of 252 adults in the United Kingdom showed that different motivations result in distinct forms, extents, and stages of exercise participation [19]. Within this study, adults who engaged in physical exercise primarily for appearance or weight control tended to report higher external regulation, meaning that their participation was encouraged by external contingencies (eg, social pressure). The authors further noted that such external regulation was linked to lower participation levels and greater introjected regulation, such as exercising to boost self-esteem or relieve guilt [19].

Motivation could be either intrinsic or extrinsic [20]. Intrinsic factors include enjoyment and competence (such as the desire to engage in challenges and to practice skills) [21]. Extrinsic factors involve gaining body-related rewards or outcomes, including fitness and appearance [21]. The findings from 2 studies conducted by Ryan et al [21] highlighted that while extrinsic motivations often serve as the initial reasons for individuals to participate in physical exercise, intrinsic motivations (eg, enjoyment and a sense of competence) play a crucial role in maintaining long-term adherence to exercise.

To trigger intrinsic motivation, it is important to pair less desirable activities, such as conventional exercise, with more enjoyable ones [22]. Exergames provide "joyful activities such as playing a (computer-) game within an enjoyable setting" [16], which act as catalysts for continuous behaviors. A study

XSL•FO
RenderX

developed the "Precious" app to increase adults' daily physical activity and found that adding gamification elements (ie, "use of game elements in non-gaming systems to improve user experience and user engagement" [23]) to the activities could provide adults with experiences of autonomy, competence, and relatedness (eg, the freedom to chase individual goals and obtain customized feedback [24]). Intrinsic motivators, such as challenges and surprises, could lead to spontaneous behavioral change and help adults develop exercise habits. Azman Ong and Ibrahim [25] pointed out that gamified technology could change users' behaviors because it could fulfill users' desire for enjoyment and promote active engagement in the associated environments. Exergames can also influence individuals' habits by promoting the learning process. Orji et al [26] developed a goal-based slow-casual game named "LunchTime" to provide education on healthier meal choices. The findings indicate that the game effectively captures users' interest, promotes learning and reflection, and assists in developing healthy food habits.

From these perspectives, there are good reasons to believe that exergames are conducive to forming exercise habits through intrinsic and extrinsic motivations. Exercise habits contribute to the development of healthy lifestyles, which may further trigger a cognitive reframing process associated with the development of health ownership. However, this conceptual framework lacks empirical evidence, particularly for older adults. Our previous studies showed that not all older adults are familiar with digital devices and their attitudes toward smart technology vary [27]. It is also unclear which motivations play an essential role in adherence.

To address these gaps, our research aims to (1) examine the association of participation in the exergame program with the formation of exercise habits, healthy lifestyle, and health ownership among older adults and (2) to explore which motivational factors are associated with older adults' adherence to playing exergames.

Methods

Inclusion and Exclusion Criteria

Inclusion criteria were being (1) aged 60 years or older, (2) able to perform simple exercises (eg, walk 360 m and move hands and feet), and (3) ambulatory without walking aids at the moment. Older adults with severe mental disorders were excluded to reduce the risk of injury. Social workers at 2 centers assisted in recruiting participants who met these criteria. We organized the introduction and trial sessions to explain the research details and familiarize participants with selected exergames. Ethical clearance was obtained before recruitment.

Participant Characteristics

A convenience sampling strategy was used to recruit participants. Initially, the study recruited 40 older participants from 2 centers. Two participants registered for 2 centers repeatedly, 2 did not attend all training sessions in the first 6 weeks, and 1 withdrew from participation due to health reasons. Finally, 33 participants were included in the data analysis, regardless of whether they adhered to the exergame program during the free-play period. An intention-to-treat analysis was not performed, and this omission is acknowledged as a study limitation. The profiles of the participants are reported in Table 1.

XSL•FO
RenderX

Table . The profile of participants (N=33).

Characteristic	Participants
Age (y), n (%)	
60 - 64	1 (3.03)
65 - 69	6 (18.18)
70 - 74	13 (39.40)
75 - 79	7 (21.21)
80 - 84	5 (15.15)
>85	1 (3.03)
Gender, n (%)	
Female	30 (90.91)
Male	3 (9.09)
Education level, n (%)	
Below primary school	4 (12.12)
Primary school	18 (54.55)
Secondary school	2 (6.06)
Postsecondary	9 (27.27)
Housing, n (%)	
Public housing (rent)	6 (18.18)
Public housing (Home Ownership Scheme)	13 (39.39)
Private housing	14 (42.43)
Motivation to participate in exergame (stage T0), mean (SD)	
Enjoyment	5.94 (1.26)
Social connection	5.60 (1.50)
Fitness	6.36 (1.02)
Competence	5.86 (1.40)
Appearance	5.62 (1.35)
Reasons to continue playing exergame (multiple choices, stage T3), n (%)	
Enjoyment of the activities	22 (66.67)
Improved physical health	19 (57.58)
Social support from friends or group participation	19 (57.58)
Accountability (eg, tracking progress)	14 (42.42)
Setting personal goals	12 (36.36)
Feeling more energetic	16 (48.48)
Stress relief	16 (48.48)
Likes taking up new challenges (ie, becoming better at something)	19 (57.58)
Likes playing new games/learning something new	19 (57.58)

Sampling Procedures

We recruited participants from 2 centers for older adults in Hong Kong, located in urban areas with deteriorating neighborhoods and aged buildings. These areas are characterized by overcrowding, lack of public amenities, and insufficient open space, leading to more sedentary behaviors among older adults. These neighborhoods have a high proportion of older adults, mainly from low-income households with lower health literacy [28]. Poor amenities and housing conditions further hinder access to essential services and physical activities [29].

Sample Size, Power, and Precision

As this study was designed as a single-group pilot study, a priori power analysis was not performed. Sample sizes were determined pragmatically, given feasibility constraints and the

XSL•FO
RenderX

study's exploratory design. Post hoc calculations using G*Power (version 3.1.9.7; Heinrich Heine University Düsseldorf; paired-samples *t* test, α=.05, power=0.80) indicate that the study was able to detect medium-to-large effects (Cohen *d*≈0.50). Smaller effects may not have been detectable. To reflect precision, all outcome estimates are reported with 95% CIs.

Instrumentation

We selected 4 Nintendo Switch games through a panel of interdisciplinary experts in computer science, sport science, geriatric medicine, and urban planning. These games were chosen to target 3 key health domains, namely physical, social, and cognitive. Nintendo Switch Sports and Nintendo Ring Fit Adventure were chosen for physical health. These games leverage the console's motion sensors and controllers to encourage upper-limb movements such as arm raising, swinging, pressing, and pulling. Social health was addressed through Super Mario Party, which fosters social interactions and multiplayer experiences, encouraging cooperation and competition among players. Cognitive health was targeted with Big Brain Academy: Brain vs Brain, which includes puzzle games designed to train cognitive abilities and mental processes across 5 categories, including identifying, memorizing, analyzing, computing, and visualizing.

Procedure

The program consisted of 2 stages: 6 weeks of training (12 sessions) plus 4 weeks of free play. The program required the participants to attend the 12 training sessions at the center to play designated exergames under the supervision of researchers and social workers. In addition, there was a 4-week post–free-play period for older adults to continue playing exergames voluntarily without supervision. During the 12 training sessions, older adults attended 2 sessions per week. Each session lasted 30 minutes to ensure that it would not negatively affect the older adults' health. The schedule of the program was designed to balance between program efficacy and feasibility so that it would be effective in forming habits and producing sufficient benefits [30].

In each session, older adults played 3 selected exergames, with 10 minutes for each game (Figure 1). The social and cognitive games were played in every session, while the 2 physical games were played alternatively. Its goal was to offer a wide range of benefits, encompassing physical, social, and cognitive health improvements. After 12 sessions, participants could voluntarily continue playing exergames at community centers for 4 weeks, with no specific games or order required. The social workers helped collect attendance data during this free-play period.

Figure 1. Older adults playing exergames at centers for older adults in Hong Kong. (A) Physical game; (B) social game; (C) cognitive game.

A B C

Data Collection

We conducted 4 rounds of measurements during the whole program, which were at T0 (before the training session), T1 (after 6 training sessions), T2 (after 12 training sessions), and T3 (after the 4-wk free-play period) stage. The questionnaire consists of 10 parts, including older adults' general health, well-being, cognitive ability, exergame play habits, physical activity level (to reflect exercise habits), lifestyle, health ownership, motivation for exergame play, reasons for continuing exergame play, and their socioeconomic status (age, gender, education level, and housing types).

Measures and Covariates

We measured general health using a 12-item Short Form Health Survey [31]. Well-being was evaluated by using the Chinese version of Keyes's 14-item scale in 3 facets: emotional, social, and psychological well-being [32,33]. The scale has been validated as suitable for Hong Kong's older adults [34]. Older adults' cognitive ability was measured by the Hong Kong version of the Montreal Cognitive Assessment (HK-MoCA) [35], with higher MoCA scores indicating better cognitive ability. We used both HK-MoCA and HK-MoCA Alternate Version 1 interchangeably to minimize the "test-retest" effect. The HK-MoCA was used at T0 (week 0) and T2 (week 6), while the HK-MoCA Alternate Version 1 was used at T1 (week 3) and T3 (week 10).

We measured older adults' health behaviors and perceptions in terms of exercise habits, healthy lifestyle, and health ownership. Older adults' habits of playing exergames were assessed using the Self‐Report Habit Index [36]. It evaluates the extent to which people perceive their behavior as automatic and executed without conscious thought. In this study, all 12 statements were rephrased with regard to exergame play, using a 5-point Likert scale. The physical activity level was calculated based on the International Physical Activity Questionnaire, an internationally recognized scale measuring self-reported physical activity levels [37]. It was used as a proxy for sustained activity patterns and to represent exercise habits, as suggested by previous studies [38,39]. The measurement includes the physical activity levels for work, transport, and leisure. The questions to evaluate older

XSL•FO
RenderX

adults' healthy lifestyles were adapted from the Adams 5-item measurement of smoking, fruits and vegetables, exercise, sleep, and alcohol use [13].

Currently, there is no established scale measuring for health ownership. We adapted measurements from the Workplace Safety and Health Ownership Model [40], which evaluates health citizenship, health climate, and health contract. The scale was validated among 541 older adults in Hong Kong before the exergame program, with the accepted composite reliability values of 0.92 (health citizenship), 0.91 (health climate), and 0.89 (health contract), as well as average variance extracted values of 0.70 (health citizenship), 0.68 (health climate), and 0.67 (health contract).

We measured motivations for exergame play using questions adapted from Ryan et al [21], which included intrinsic factors (namely, enjoyment and competence), extrinsic factors (fitness and appearance), and motivation for social connection. This scale was validated among Chinese older adults in previous studies [41,42]. The questionnaire included 30 items, and each item was measured using a 7-point Likert scale, ranging from 1 ("corresponds not at all") to 7 ("corresponds exactly"). The social network was assessed using the Chinese version of the Lubben Social Network Scale, which has been validated as an appropriate tool for older adults in Hong Kong [43].

Masking

Masking was not applicable to this study, given its single-group pre-experimental design in which all participants received the same exergame intervention, and the outcome assessments were conducted using self-reported questionnaires.

Data Diagnostics

The final dataset contained no missing data. Criteria for excluding participants after data collection included duplicate registration, nonattendance at training sessions, and withdrawal due to health reasons. No data transformations were applied. Statistical outliers were examined using box plots and were retained, given the small sample size of this pilot study.

Quality of Measurements

To ensure the reliability and validity of the measurements, participants at both centers were provided with an introductory briefing and a trial session prior to data collection. During each gameplay period, a research assistant was present to offer assistance in the event of any difficulties. Furthermore, augmentative and alternative communication strategies were employed to enhance the accessibility of the questionnaires.

Analytic Strategy

We performed the general linear model (repeated measures) procedure to determine whether there was a significant improvement in the general health, life satisfaction, well-being, cognitive ability, habits of playing exergames, physical activity, lifestyle, and health ownership of older adults. In addition, the Mann-Whitney *U* test was performed to examine whether and what motivations affect people's adherence to playing exergames during the free-play period. We also conducted the Spearman rank correlation analysis to test whether older adults' motivation for exergame play was related to their frequency of playing exergames during the free-play period. All the statistical analyses were conducted in IBM SPSS Statistics (version 29).

Ethical Considerations

The study protocol was reviewed and approved by the Institutional Review Board of The Hong Kong Polytechnic University (reference number HSEARS20231116003). Written informed consent was obtained from all participants, who were assured that their personal data would be kept strictly confidential. All personal data were kept strictly confidential, and identifying information was removed prior to analysis. Participant records were anonymized by assigning unique codes, with names and contact details stored separately from research data. Only aggregated results were reported, ensuring that no individual could be identified from the findings. As compensation for their participation, each individual received an HK $50 (approximately US $6.40) supermarket voucher upon completion of the study. The paper does not contain any images or materials that could identify individual participants.

Results

The Associations Between Exergame Participation and Changes in Habits, Lifestyle, and Health Ownership

Table 2 presents the linear mixed model results for health improvement and habit formation outcomes. Figure 2 depicts participant recruitment flowchart and Figure 3 illustrates the changes in significant health improvement and habit formation outcomes across 4 time points. The detailed post hoc comparison results are included in Multimedia Appendix 1. The results in Table 2 show that older adults' cognitive ability improved, as indicated by MoCA scores, after participating in the exergame program (mean difference 2.03, 95% CI 0.54 - 3.52, $F_{2.49,79.62}$=7.86; P<.001, η^2=0.20). In addition, older adults' well-being slightly improved after participating in the exergame program (mean difference 2.91, 95% CI −2.21 to 8.03, $F_{3,96}$=4.59; P=.005, η^2=0.13). Moreover, the results did not report significant effects or within-group changes regarding older adults' general health.

[a]The older participants' responses to health ownership were not collected at the end of week 3 (T1 stage). As health ownership indicates a high level of self-efficacy, it may not change quickly after 3 weeks of exergame training (6 sessions). Considering the length of the questionnaire and survey administration, the study did not collect participants' responses to health ownership at the end of week 3.

The results suggested a possible correlation between playing exergames and exercise habits among older adults. Specifically, the results showed a significant improvement in habits of playing exergames (mean difference 0.50, 95% CI −0.03 to 1.03, $F_{2.77,88.57}$=4.88; P=.004, η^2=0.13), physical activity metabolic equivalent of task (MET) level (leisure activity; mean difference 1686.06, 95% CI −219.86 to 3591.99, $F_{2.38,76.04}$=3.72; P=.02, η^2=0.10), and physical activity MET level (total activity; mean difference 2100.83, 95% CI −249.16 to 4450.82, $F_{2.44,78.05}$=3.15; P=.04, η^2=0.09) after participating in the exergame program that covered training and adherence periods. The increase in leisure-time physical activity corresponds to a MET level equivalent to brisk walking for about 1 hour per day. It shows that exergame participation is not only correlated with exergame play habits but also with people's exercise habits (measured by physical activity MET levels). Post hoc comparisons indicated that well-being and exergame play habit scores peaked at T1 and subsequently declined, reflecting a temporal pattern of improvement followed by attenuation.

XSL•FO
RenderX

The results also report a significant improvement regarding healthy lifestyles (mean difference 0.70, 95% CI 0.14 - 1.25, $F_{3,96}$=6.52; P<.001, η^2=0.17) after participating in the exergame program. In addition, older adults' health ownership (mean difference 0.24, 95% CI 0 - 0.48, $F_{1.61,51.44}$=4.23; P=.03, η^2=0.12) was significantly increased after participation in the exergame program. The exergame program not only changes older adults' health behaviors, such as exercise habits and lifestyle, but also helps them gain a sense of mastery over their own health. Post hoc comparisons revealed that improvements in healthy lifestyle and health ownership were most evident at T3 (the end of the free-play period), suggesting that the development of these outcomes may require sustained, long-term adherence.

Association of Motivational Factors With Exergame Adherence

In this study, motivational factors include intrinsic and extrinsic factors [21]. Extrinsic motivations involve pursuing rewards or outcomes that are unrelated to the act of exercising itself, including fitness (eg, keeping physical and mental health and having more energy) and appearance (eg, defining muscles, losing weight, and being attractive to others). Intrinsic motivation refers to fulfilling goals derived from participation in the exercise itself, including enjoyment (eg, enjoying the exergame and making me happy) and competence (eg, keeping up my skill level and obtaining new skills). In addition, the motivation for social connection is considered, such as being with others, meeting new people, and enjoying time with others.

Out of 33 participants, 25 (75.8%) continued using exergames during the free-play period (weeks 7-10). The most commonly selected reason for adherence was enjoyment of the activities (n=22, 66.67%; Table 1). Table 3 illustrates that older adults who played the exergame for social connection reasons, such as playing with friends and meeting new friends, had a higher likelihood of continuing to play the exergame after 6 weeks of training (Mann-Whitney *U*=147.00, mean difference −5.00, 95% CI −8.00 to 0, *P*=.049).

Table . Mann-Whitney *U* test results on differences in older adults' motivation to play exergames (N=33).

Variables	Values, mean (SD)	Independent-samples Hodges-Lehman mean difference (95% CI)	Mann-Whitney *U*	Z	*P* value

Discussion

The Associations of Exergames Training With Habits, Healthy Lifestyles, and Health Ownership

Previous studies have shown that exergames are effective intervention tools to improve the physical and mental health of older adults [3,44]. Gamification could influence people's perceptions by creating a virtual space that can boost their emotions and lived experiences [45]. In this study, we articulate that exergames may also be associated with behavioral and perceptual changes in terms of exercise habits, healthy lifestyle, and health ownership. Consistent, supervised exergame activities could be associated with habitual behaviors: through fixed sessions that take place twice a week, participants are willing to schedule time and devote effort to exercise regularly. This is evidenced by the increasing level of physical activities in daily life, as reported by participants.

Surprisingly, the findings indicated that the proposed exergame program had weak associations with older participants' health status. While improvements in older adults' well-being were observed, scores rose only at stage T1 before declining again. There are good reasons to believe that the emotional boost triggered by exergames could be temporary and nonlasting [46]. This dynamic suggests that initial gains may be driven more by short-term engagement than by the establishment of enduring behavioral routines [47]. It highlights the necessity of structured game rotation and "boost" programs (such as providing positive feedback on training outcomes) as strategies to sustain participation beyond the novelty period. Such approaches may help mitigate attrition, foster long-term adherence, and ultimately support the consolidation of healthier routines and more durable well-being outcomes. In addition, the relationship between exergame participation and older adults' general health was not significant. One possible reason is that the selected exergames may not meet the intensity level of physical activity (ie, moderate intensity [4]). This may limit the effect of playing exergames on health promotion. In addition, the study showed that participation in the program was associated with improvements in cognitive health. Notably, the observed MoCA score improvement may be attributable to "test-retest" effects [48]. Although alternate versions were used at T1 and T3 to mitigate this effect, the absence of a control group precludes ruling out practice effects as a contributing factor to the observed cognitive gains.

Participation in an exergame program reveals a higher likelihood of formulating exercise habits among older adults. Regularly scheduled sessions encouraged participants to engage in routine physical activity, as reflected in their reported exercise patterns at stage T3. Habit formation here can be understood as a learning process that aligns with increased physical activity and psychological engagement [49]. Such exercise habits and increased physical activity levels through routine exercise may improve older adults' physical health and psychological functions [50]. In addition, exercise habits were reported to strengthen individuals' willingness and competence for physical activity through enhanced volition and mindfulness [8]. The latter indicates that older adults explore new life choices beyond their routine activities, leading to new norms and life goals that contribute to a more fulfilling and enriched life [51].

Participation in the program was also associated with the adoption of a healthy lifestyle. Older adults reported positive changes in 5 lifestyle dimensions that may be linked to longer life expectancy and greater adaptive capacity, which can help participants navigate challenges such as declining health status or transitions to new living environments [52]. Participation in the program was associated with a heightened sense of health ownership. The sense of health ownership enhances older adults' personal perception of mastery and self-management of illness, especially chronic disease [53]. Health ownership is an indication of independence and autonomy in old age, which is also an important adaptation strategy [17]. Even if individuals relocate to new neighborhoods or residential care centers, having ownership over their health can help them maintain independence in unfamiliar environments [53]. This ownership fosters their ability and awareness to prioritize healthy targets, and more importantly, encourages them to take proactive measures in health management [54].

Multifaceted Motivations for Gameplay and Adherence

Although older adults may be aware of the importance of exercise and its benefits to health, they may not always be willing to participate in exercise. This is because exercise requires effort and can be boring if there is no fun [1]. Motivation is a key driving factor in encouraging people to exercise or play exergames [55,56]. Previous studies have found that extrinsic motivation is the reason for people to participate

XSL•FO
RenderX

in exercise (eg, for fitness and appearance), and intrinsic motivation (eg, for enjoyment and competence) is the reason for people to adhere to exercise [22]. The findings prove that fitness is the most common reason for older adults to participate in the exergame, which aligns with the previous study [21]. We also identify unique contributions of intrinsic and extrinsic motivation at different stages of gameplay: older adults may initially view the exergame as a playful game. Thus, enjoyment becomes an important trigger for them to participate. While playing exergames, older adults benefit from participating in activities with others, maintaining connections with friends, and meeting new friends, which helps motivate long-term adherence to exergame.

Participants reported that enjoyment and their willingness to gain competence were 2 essential motivations to participate in the 6-week training program, following fitness. This pattern differs from people's motivations for participating in traditional exercise, in which the top 3 are fitness, appearance, and competence [21]. With intrinsic motivation (enjoyment and competence), participants may be willing to invest more resources and effort in gameplay, thereby gradually forming exercise habits [57]. Participants' responses support the effectiveness of gamification technology in encouraging repeated exercise behavior. This is achieved by creating virtual contexts and making the setting enjoyable, which is a crucial component for triggering intrinsic motivation.

Previous studies have reported a general trend whereby adherence to exercise interventions (eg, exergames) may decline soon, even though people may show high enthusiasm at the beginning [58]. The findings suggest that older adults who have developed a strong motivation for social connection may have a higher possibility of adhering to and having a higher frequency of playing exergames in the free-play period. Such a motivation for social connection is noteworthy to mention. Research suggests that motivation for social connection contributes to both intrinsic and extrinsic motivation [59,60]. On the one hand, older adults have the opportunity to engage with others in exergames, which enhances their enjoyment and contributes to their intrinsic motivation. On the other hand, older adults may benefit from maintaining connections with their friends or meeting new ones, which contributes to extrinsic motivation.

The finding is in line with a nationwide Australian study that implemented a community-based walking program [61]. The findings reported that opportunities for social interaction are key motivators for encouraging people's long-term participation in the program. Older adults may benefit from participating in an exercise program to meet new friends or maintain friendships with old ones [62]. Adherence to the exergame program helps expand their social networks and enhance social capital within the community. Since most exergame interventions in the existing literature are solo or competitive [63], it is essential to incorporate more elements of social interaction and engagement into exergame programs in the future.

Limitations and Future Research

First, the findings of this study are constrained by the small sample size. One reason is that the community centers in old urban areas are severely constrained for space (eg, occupying only half a floor in an old building), which limits the potential to recruit more people at the same time. Second, the lack of a control group restricts the ability to draw robust inferences from the results. Future research should aim to recruit a larger sample size encompassing a more diverse range of socioeconomic backgrounds to better assess the impact of exergames on promoting a healthy lifestyle and health ownership among older adults. Third, most study participants were female, due to the higher rate of female engagement in activities organized by centers for older adults in Hong Kong. This imbalance made it challenging to recruit sufficient male participants. Future research should adopt random sampling across diverse community centers to enhance representativeness and generalizability. Fourth, the study relies on self-reported measures (eg, International Physical Activity Questionnaire), which introduce recall and social desirability bias. Future studies should integrate objective measurements to strengthen data validity, such as console-derived play duration or wearable-based MET tracking. In addition, the health ownership scale used in this study is adapted from the Workplace Safety and Health Ownership Model and may require further validation. Moreover, the study does not implement intention-to-treat procedures, which is a limitation, as the estimates may have been influenced by differential loss to follow-up.

Conclusion

This pilot study suggests that exergames show promise for healthy aging, particularly in building exercise habits and fostering a healthier lifestyle. Compared to previous research, our findings indicate that the exergame program was linked only to modest gains in subjective well-being, with no significant changes in general health status. However, the training was associated with higher physical activity levels, a greater willingness to play exergames, adoption of a healthier lifestyle, and increased health ownership. These results should be interpreted with caution, given the limitations of a single-group pre-post design. Motivational factors appeared to play an essential role in sustaining adherence to the exergame program. Among these, motivations related to enjoyment and social connection (eg, companionship) were particularly important. Most participants continued playing exergames even after the supervised training ended, indicating that programs with fun activities and opportunities to connect with other participants are more likely to keep people engaged over time. Furthermore, this motivation for social connection was associated with more frequent program participation during the free-play period.

Taken together, these findings carry implications for both policy and practice. Policymakers may consider allocating resources to nongovernmental organizations for promoting exergame programs, which can be easily installed in community centers to boost participation. Singapore has already included exergames in community centers as part of health promotion. Hong Kong and other regions could consider similar initiatives to align programs with government-established, long-term lifestyle adjustment and capacity-building initiatives. Meanwhile, it is essential to include changes in lifestyle and health ownership as 2 key program outcomes, since these are vital indicators/capabilities that help older adults manage their health

XSL•FO
RenderX

independently and remain proactive later in life. To maximize emotional benefits, nongovernmental organizations could refresh programs with new games and competitions to maintain continuous engagement. Collective play modes may further expand social networks and bring additional social connection benefits.

Acknowledgments

The authors would like to thank all participants, centers, and supporting staff who contributed to the training program and evaluation. The authors declare the use of generative AI (GenAI) in the research and writing processes. According to the GAIDeT taxonomy (2025), grammar checking and correction were delegated to GenAI tools under full human supervision. The GenAI tool used was GPT-5.5 (OpenAI). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. The research team extends its sincere gratitude to the author YLT for her dedication to advancing digital health solutions that enhance the well-being of the aging population. Over the decades, the author YLT has remained deeply committed to translating research findings into practical, real-world applications that drive meaningful societal impact.

Abstract

Background: Sports apps can support physical activity through self-monitoring, feedback, and engagement features; however, evidence regarding their broader health-related outcomes remains mixed. The roles of digitalization and gamification in the association between sports app involvement and core literacy in physical education and health also remain unclear.

Objective: This study aimed to evaluate a multicomponent app-supported physical activity intervention and examine the cross-sectional associations between sports app involvement and core literacy in physical education and health, including indirect statistical associations through digitalization and gamification.

Methods: This study comprised 2 quantitative studies with independent samples. Study 1 used a Solomon 4-group randomized design in which 120 university students were allocated equally to the pretested experimental, pretested control, unpretested experimental, or unpretested control groups. The experimental groups received a 12-week multicomponent app-supported physical activity intervention, and 107 participants completed the postintervention assessment. A 2×2 factorial analysis of variance tested intervention and pretest main effects and their interaction, supplemented by a reference-based attrition sensitivity analysis. Study 2 surveyed 790 students from 8 universities and used latent-variable structural equation modeling to estimate direct and indirect cross-sectional associations, with age and sex included as covariates. The primary model assumed independence between participants; secondary composite-score sensitivity analyses examined additional covariate adjustment and university clustering.

Results: In Study 1, significant intervention main effects were observed for self-reported motor competence ($F_{1,103}$=33.869, P<.001, ηp^2=0.247), health behaviors ($F_{1,103}$=21.548, P<.001, ηp^2=0.173), and sportsmanship ($F_{1,103}$=30.261, P<.001, ηp^2=0.227). Pretesting showed significant main effects on motor competence and health behaviors (both P<.001), but not on sportsmanship (P=.07). The pretest×intervention interactions were not statistically significant for motor competence (P=.92), health behaviors (P=.93), or sportsmanship (P=.79), and the attrition sensitivity analysis produced consistent results under the specified control-reference assumptions. In Study 2, sports app involvement was positively associated with core literacy (β=.135, P=.01). The largest specific indirect association was through digitalization (0.204, bias-corrected 95% CI 0.126 - 0.290), followed by the sequential pathway through digitalization and gamification (0.036, bias-corrected 95% CI 0.005 - 0.081) and gamification alone (0.031, bias-corrected 95% CI 0.004 - 0.077).

Conclusions: The multicomponent app-supported intervention yielded higher self-reported motor competence, health behavior, and sportsmanship scores than the control condition. In the independent cross-sectional sample, sports app involvement was positively associated with core literacy, with specific indirect associations through digitalization, gamification, and digitalization followed by gamification. Digitalization showed the largest specific indirect association. Further studies should assess objective outcomes and examine these associations longitudinally with broader measurement of potential confounders.

Introduction

Background

The integration of mobile health and wearable technologies into sports and exercise has enabled sports apps to support self-monitoring, feedback, and user engagement [1]. Reviews suggest that smartphone apps and activity trackers can increase physical activity, although benefits vary across interventions and outcomes [2-4]. Related research has examined physical activity, intervention engagement, continued app use, and behavioral intentions [5-9]. However, these outcomes do not fully capture broader competencies and dispositions, including motivation, confidence, physical competence, health-related decision-making, and sustained self-regulation [10-12].

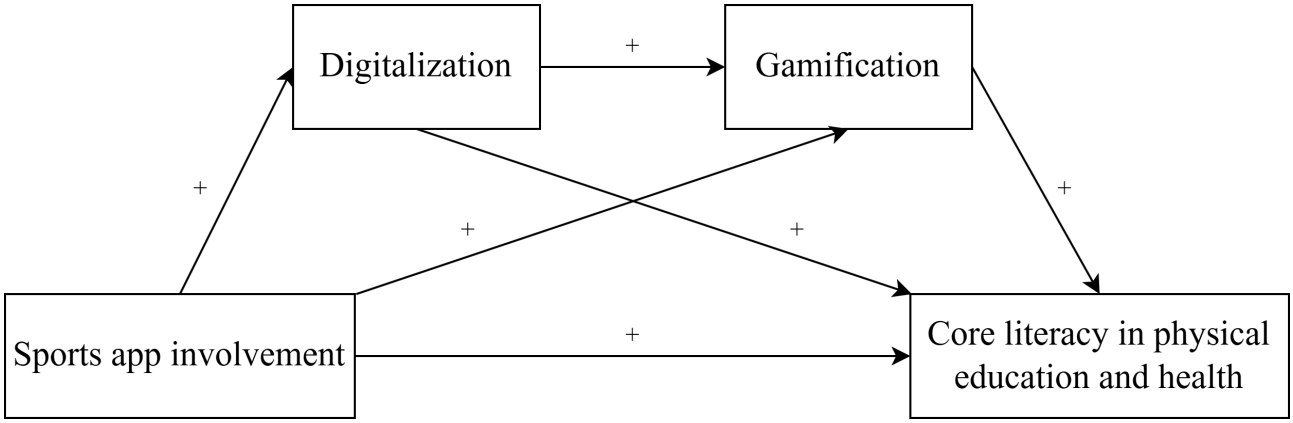
In the Chinese educational context, core literacy in physical education and health is a policy-guided and theory-driven construct that reflects the fundamental competencies that individuals are expected to develop through physical education and health-related learning [13]. This concept emphasizes the integrated development of motor competence, health behaviors, and sportsmanship, highlighting an individual's capacity to engage in physical activity in a sustained, responsible, and health-promoting manner. Although this construct originates from the Chinese educational system, it shares conceptual similarities with internationally discussed constructs such as physical and health literacy, while placing greater emphasis on integrating physical, behavioral, and value-oriented dimensions within physical activity contexts [10-13].

In this regard, previous studies have linked fitness app features to engagement and behavioral intentions and applied technology acceptance frameworks to wearable fitness technologies [8,9]. However, Conroy et al [14] found that behavior change techniques are underrepresented in top-ranked physical activity apps, suggesting that outcomes may depend on specific design features. Consequently, evidence regarding the effectiveness of sports apps remains unclear.

Digitalization of sports apps involves the quantification of activities through real-time monitoring and feedback. The technology acceptance model proposes that adoption is shaped by perceived usefulness and ease of use [15]. Digital monitoring converts physical activity into visible information such as steps, heart rate, and calories [16], while feedback can support progress monitoring, performance evaluation, and behavioral adjustment [17,18]. As these functions may strengthen perceived utility and support health-related self-regulation, digitalization represents a theoretically plausible app-related dimension associated with core literacy in physical education and health. Meanwhile, gamification applies game design elements such as leaderboards, badges, and challenges to nongame contexts [19,20]. Drawing on self-determination theory (SDT), such features may support autonomy, competence, and relatedness through choice, performance feedback, and social interaction [21,22]. Additionally, gamified challenges and achievement cues may encourage continued engagement [20,23,24] and support more autonomous motivation for sustained physical activity and health behavior regulation [25]. Furthermore, digitalization and gamification may be linked because gamified functions often rely on digitally recorded activity data [24].

Objectives and Hypotheses

Therefore, consistent with calls to move beyond technology acceptance toward system features [26], this study examined digitalization and gamification as app-related dimensions associated with health-related outcomes using a 2-study quantitative design to provide complementary evidence on sports app–supported physical activity and core literacy in physical education and health. Study 2 examined a theory-guided cross-sectional association model linking sports app involvement, digitalization, gamification, and core literacy in physical education and health.



The following hypotheses were proposed for Study 1 and Study 2.

- Study 1
  - H1a: Students assigned to the multicomponent app-supported physical activity intervention group will demonstrate significantly higher postintervention levels of core literacy in physical education and health than those assigned to the control group.
  - H1b: Pretest exposure will not modify the intervention-control difference in postintervention core literacy scores.
- Study 2
  - H2: Sports app involvement is positively associated with core literacy in physical education and health.
  - H3: Sports app involvement has a significant positive indirect association with core literacy in physical education and health through digitalization.
  - H4: Involvement in sports apps has a significant positive indirect association with core literacy in physical education and health through gamification.
  - H5: Sports app involvement will show a significant sequential indirect association with core literacy in physical education and health through digitalization and gamification.

The specific hypothesized model diagram is shown in Figure 1.

Methods

Ethical Considerations

The study protocol was reviewed and approved by the Biomedical Ethics Committee of Qufu Normal University (approval number 2023097). All participants were informed about the study purpose, procedures, potential risks and benefits, voluntary nature of participation, and their right to withdraw from the study at any time without penalty. Written informed consent was obtained from all participants prior to participation.

The randomized intervention component of this study was not prospectively registered before participant enrollment. The first participant was enrolled on June 27, 2023, and the intervention began on July 3, 2023. The trial was retrospectively registered in the Chinese Clinical Trial Registry (registration number: ChiCTR2600124527) on May 13, 2026. This delay occurred because the study was initially approved and implemented as a university-based educational and behavioral intervention. The retrospectively registered record is consistent with the ethics-approved protocol, and no post hoc changes were made to the intervention procedures, outcome measures, or main analysis plan. Participant data were deidentified before analysis, kept confidential, and used only for research purposes.

Participants in Study 1 received a commemorative gift valued at approximately RMB 100 (RMB 1=US $0.14 as of September 25, 2023) per participant as a token of appreciation for their participation. Participants in Study 2 received no compensation. No identifiable images of study participants are included in the manuscript or its supplementary materials.

Study Design

Overview of the 2 Studies

This study used a 2-study quantitative design in which the 2 studies addressed complementary but distinct research questions. In Study 1, the theory of planned behavior (TPB) [27] and SDT [21] informed the multicomponent intervention. In educational and behavioral research contexts, baseline pretesting may influence participants' subsequent attitudes or behaviors through familiarity, learning, or recall, thereby threatening internal validity [28]. This phenomenon is commonly referred to as the practice effect, or pretest sensitization. A Solomon 4-group randomized design was used to evaluate the effect of a 12-week multicomponent app-supported physical activity intervention on university students' core literacy in physical education and health, while accounting for potential pretest sensitization. Because the intervention incorporated structured physical activity, app-based monitoring and feedback, health education, gamified activities, peer interaction, goal setting, reminders, and researcher support, the experimental contrast estimated the effect of the intervention package rather than the isolated effect of the sports app.

In Study 2, we used the technology acceptance model [15] and SDT [21], an independent cross-sectional survey sample, and structural equation modeling (SEM) to examine the direct and indirect associations among sports app involvement, digitalization, gamification, and core literacy in physical education and health. In the Study 2 model, digitalization and gamification were specified as functional and experiential app-related dimensions, respectively.

Study 1: Solomon 4-Group Design

Study Design and Sample Size

Given the 4-group Solomon design and anticipated 10% to 20% attrition, 120 participants were recruited, allowing 30 participants each to be assigned to the following groups: pretested experimental (PE), pretested control (PC), unpretested experimental (UE), and unpretested control (UC) groups. Among the included participants, 13 randomized participants did not complete the postintervention assessment. Therefore, the final sample with available postintervention outcome data comprised 107 participants: 28 in the PE group, 25 in the PC group, 25 in the UE group, and 29 in the UC group.

A schematic of the Solomon 4-group experiment is presented in Table 1. The completed CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) reporting checklist for Study 1 is provided in Checklist 1.

PC[c]	O3	—[d]	O4
UE[e]	—[d]	X[b]	O5
UC[f]	—[d]	—[d]	O6

[a]PE: pretested experimental group.

[b]X indicates the multicomponent app-supported physical activity intervention.

[c]PC: pretested control group.

[d]— indicates that the corresponding assessment or intervention was not administered.

[e]UE: unpretested experimental group.

[f]UC: unpretested control group

Randomization and Allocation

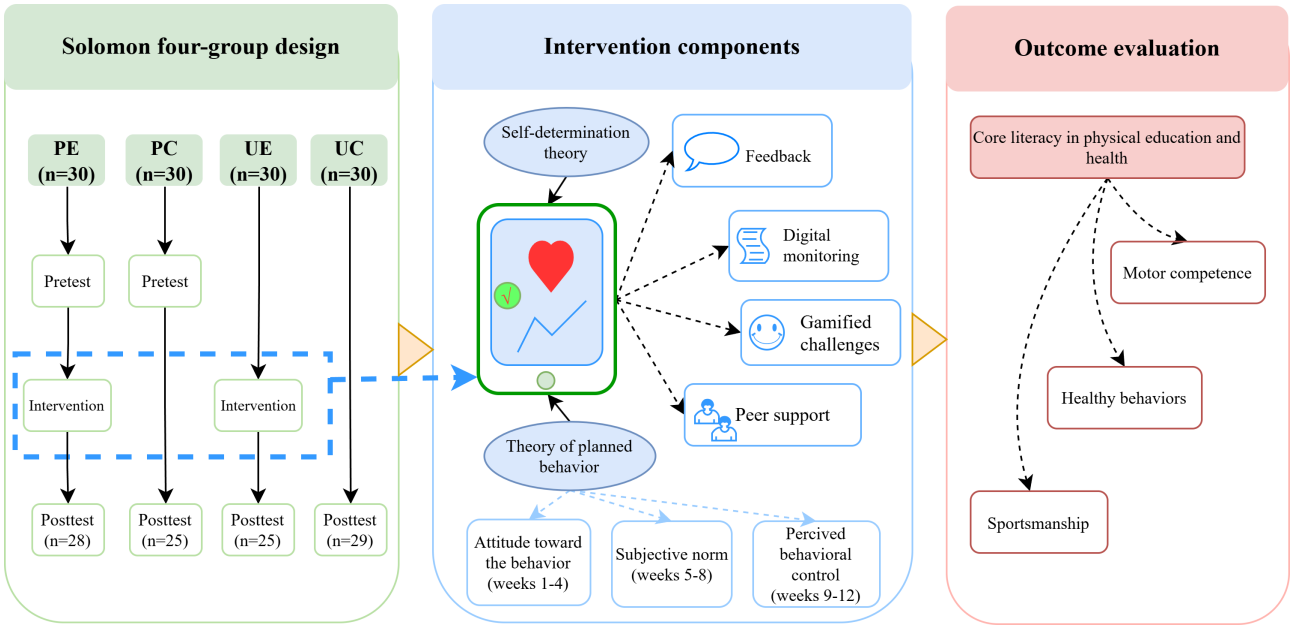
After eligibility screening and written informed consent were obtained from all 120 participants, randomization was performed using a computer-generated random sequence in SPSS (IBM Corp). The participants were randomly assigned to the PE, PC, UE, and UC groups in a 1:1:1:1 ratio, with 30 participants initially allocated to each group. The principal researcher generated a random sequence and assigned groups. Separate allocation concealment procedures were not used.

Participants and Eligibility Criteria

The participants were full-time undergraduate students aged 18 to 25 years recruited in Shandong Province through campus-based and online recruitment. Online recruitment and eligibility prescreening began on June 16, 2023. Eligible participants completed an electronic informed consent form and entered the formal study process between June 27 and 28, 2023, and the intervention was initiated on July 3, 2023. Eligible participants were required to (1) have prior experience using mobile fitness apps, (2) have no professional athletic training background, and (3) safely engage in moderate-intensity physical activity. Students with self-reported medical contraindications to exercise, such as cardiovascular or musculoskeletal conditions, were excluded. The participants received a commemorative gift as a token of appreciation for their time and participation.

Interventions

Intervention Design and Delivery



The 12-week intervention comprised a multicomponent app-supported physical activity program informed by the TPB [27] and SDT [21]. TPB-guided components addressed attitudes, subjective norms, and perceived behavioral control, whereas SDT informed support for autonomy, competence, and relatedness. Participants used the Yodo Run app for activity tracking and were scheduled to complete 3 physical activity sessions per week (36 sessions over 12 wk), with approximately 30 minutes per session and a target rating of perceived exertion of 12 to 14. The activities included aerobic and strength exercises, gamified tasks, team-based activities, goal setting, exercise planning, and participant-selected activities. The intervention progressed from app familiarization and attitude-focused activities in weeks 1 to 4 to peer- and team-based exercise activities in weeks 5 to 8, and then to goal setting, exercise planning, and more participant-directed activity in weeks 9 to 12.

Intervention Content and Human Support

The weekly tasks were posted on WeChat. Participants submitted app-generated screenshots for each scheduled session, which were reviewed by 2 researchers. Missing submissions were followed up on the same day, and procedural or app-related assistance was provided when required. The overall intervention framework is shown in Figure 2, and the complete week-by-week schedule, including the TPB focus and intervention components, is provided in Multimedia Appendix 1 (Table S1).

XSL•FO
RenderX

Figure 2. Solomon 4-group experimental design and intervention framework. PC: pretested control group; PE: pretested experimental group; UC: unpretested control group; UE: unpretested experimental group.

Control Condition and Adherence Monitoring

Participants in the control groups were included in separate WeChat groups, and routine activity records were submitted at the same frequency as the participants in the intervention groups. These records were used to document usual physical activity rather than adherence to a prescribed exercise intervention. The researchers checked the submitted records and provided same-day reminders when scheduled records were missing. The control group did not receive structured weekly exercise tasks, health education, gamified challenges, team-based intervention activities, exercise-planning tasks, or other behavior-change content provided to the intervention groups. Intervention adherence was monitored using the submitted app-generated records. A session was considered complete when the record documented approximately 30 minutes of the scheduled activity on the assigned day or within 24 hours. Participants who missed 3 or more scheduled sessions were classified as noncompliant for adherence monitoring.

Safety Monitoring

Exercise-related adverse events were monitored throughout the 12-week intervention period using participant reports and routine researcher contacts via WeChat.

Study 2: Cross-Sectional Survey Design

Stratified sampling based on university hierarchy, primary specialty, and regional characteristics was used to invite 872 college students from 8 universities in Shandong Province to participate in a cross-sectional survey. Data were collected in November 2023. The participants in Study 2 were independent of those in Study 1. The surveys were conducted online and offline. After logical screening to exclude invalid responses, such as questionnaires completed in less than 120 seconds or containing extreme response patterns, 790 of the 872 (90.6%) questionnaires were retained. A root mean square error of approximation (RMSEA)-based power analysis was used to estimate the sample size required for testing the overall fit of the 11-indicator measurement model [29]. With 38 degrees of freedom, α=.05, a null RMSEA of 0.05, and an alternative RMSEA of 0.08, a sample of 262 would provide 80% power. The final sample size of 790 participants exceeded this benchmark.

Measures

Questionnaire Development and Pilot Validation

The questionnaire drew on published instruments and relevant literature and was contextualized for sports app users and university students. Wording and contextual relevance were reviewed by 5 physical education experts, 3 doctoral students, and 8 master's students, followed by student tryouts and refinements. Items were rated on a 5-point Likert-type scale, with higher scores indicating higher levels of the corresponding construct.

Before the formal Study 2 survey, the 4 instruments were evaluated using a pilot sample of 192 university students. Item screening was performed using the full pilot sample, after which the responses were divided into 2 subsamples comprising 96 university students each. One subsample was used for exploratory factor analysis of the app-related scales, and the other subsample was used for confirmatory factor analysis (CFA) of the retained measurement structures. The prespecified 3-domain core literacy structure was evaluated directly by CFA. Structural hypothesis testing used the subsequent independent 790-participant formal Study 2 sample. The detailed factor loadings, composite reliability (CR), and average variance extracted (AVE) are reported in Multimedia Appendix 1 (Table S2).

Sports App Involvement Scale

The Sports App Involvement Scale was adapted from the leisure involvement framework of McIntyre and Pigram [30] and contextualized for sports app use. The 10-item instrument retained 3 dimensions: attractiveness (4 items), self-expression

XSL•FO
RenderX

(3 items), and life centrality (3 items). In the pilot validation, the 3-factor measurement model showed acceptable fit (χ^2/df=1.479, standardized root mean square residual [SRMR]=0.038, RMSEA=0.071, and comparative fit index [CFI]=0.968).

Digitalization Scale

Digitalization was assessed using an 8-item scale adapted from the monitoring and feedback measures reported by Nelson et al [18], with item wording contextualized from activity trackers to sports apps. The monitoring dimension comprises 4 items addressing the amount, presentation, constructiveness, and frequency of information, whereas the feedback dimension comprises 4 items addressing perceived accuracy, usefulness, effectiveness, and reliability. In the pilot validation, the 2-factor measurement model showed acceptable fit (χ^2/df=1.365, SRMR=0.038, RMSEA=0.062, and CFI=0.977).

Gamification Scale

The Gamification Scale was developed for the sports app context, rather than being directly adopted from a single existing instrument. The dimensional structure of this scale was informed by the SDT and prior research on motivational and game-related experiences [21,22]. Following literature review and expert refinement, gamification was operationalized using 9 items across 3 dimensions: sense of mastery, interaction fluency, and intrinsic motivation. In the pilot validation, the 3-factor measurement model showed acceptable fit (χ^2/df=1.228, SRMR=0.042, RMSEA=0.049, and CFI=0.979).

Physical Education and Health Core Literacy Scale

The Physical Education and Health Core Literacy Scale was developed for this study based on the 3-domain framework specified in the Chinese Physical Education and Health Curriculum Standards and informed by earlier Chinese instruments assessing core literacy among university students. The initial scale included 30 items covering motor competence, health behaviors, and sportsmanship. However, items D9, D14, D29, and D30 were removed during the pilot item analysis. Items D9, D14, and D29 did not meet the prespecified extreme-group discrimination criterion (t≥3.00), whereas item D30 had a corrected item-total correlation of 0.374, which was below the 0.400 criterion. The resulting 26-item scale comprised 8 motor competence items, 11 health behavior items, and 7 sportsmanship items and was used in the formal survey. Item removal was guided by prespecified psychometric criteria while retaining the representation of all 3 theoretically defined domains, thereby preserving the intended 3-domain structure of the scale. The retained 3-factor measurement model showed acceptable fit in the pilot CFA (χ^2/df=1.267, SRMR=0.045, RMSEA=0.053, and CFI=0.948).

In both studies, core literacy in physical education and health and its 3 dimensions were assessed using participant-reported questionnaires. The sources, adaptation procedures, and final structures of the 4 Study 2 instruments are summarized in Multimedia Appendix 1 (Table S3).

Data Analysis

Study 1

Study 1 analyses were conducted using SPSS (version 27.0). The primary analysis was a 2×2 factorial ANOVA of postintervention scores, with pretest exposure and intervention condition as between-participant factors. As a supporting analysis, postintervention scores in the pretested experimental and control groups were compared using analysis of covariance (ANCOVA), adjusting for the corresponding baseline scores. Group-by-baseline interaction terms were examined to assess the homogeneity of regression slopes. These analyses included participants with available postintervention outcomes. Baseline characteristics of completers and noncompleters in the pretested groups were compared using Welch independent-samples t tests and Fisher exact tests, as appropriate.

Sensitivity to the 13 missing postintervention assessments was examined using reference-based resampling with 10,000 replications. Within each pretest stratum, missing outcomes in the intervention groups were sampled with replacement from the observed outcome vectors in the corresponding control group, assuming no intervention benefit among intervention-group noncompleters. Missing control-group outcomes were sampled from the corresponding observed control-group outcomes. The 3 outcomes were sampled jointly to preserve their within-participant correlation structure. The structural absence of pretest measurements in the unpretested groups was not treated as missing data. This sensitivity analysis supplemented the complete-case analyses; it did not constitute a conventional intention-to-treat analysis.

Study 2

Study 2 analyses used SPSS (version 27.0) and Amos (version 29.0). Internal consistency was assessed using Cronbach α and discriminant validity using the heterotrait-monotrait ratio. Common method effects were examined using Harman's single-factor test and a CFA comparison of the hypothesized 4-factor and 1-factor models. Model fit was evaluated using χ^2/df, CFI, Tucker-Lewis index (TLI), RMSEA, and SRMR. Descriptive statistics and Pearson correlations were also calculated.

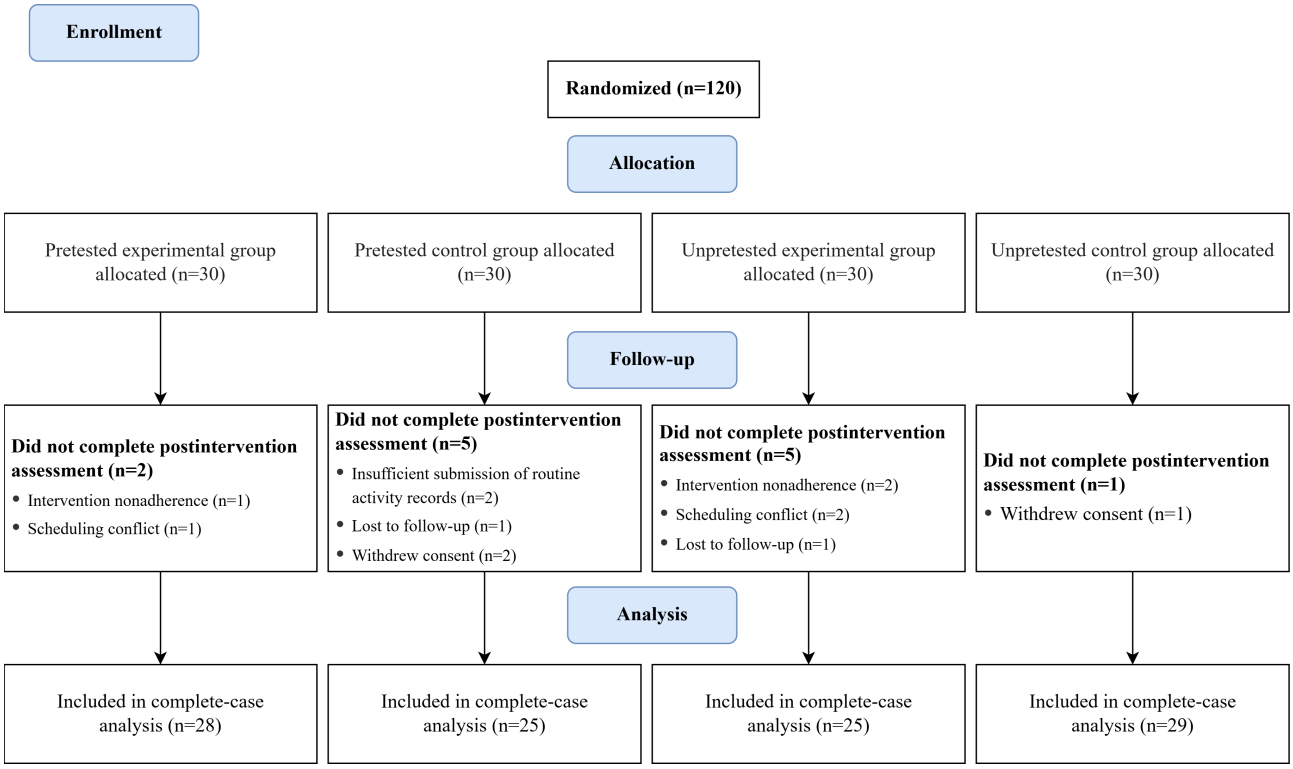
The primary age- and sex-adjusted latent-variable SEM estimated direct and indirect associations, with bias-corrected (BC) CIs obtained from 5000 bootstrap resamples. The latent-variable specification was retained to account for measurement error in the construct indicators. The inclusion of only 8 universities provided limited university-level information for a full multilevel latent model. The primary SEM assumed independence between participants, and its SEs and bootstrap CIs were not adjusted for university-level clustering.

University-level clustering was described using intercept-only random-effects models, intraclass correlation coefficients, and design effects. Two secondary analyses used standardized composite scores. One added BMI and 7 university indicator variables to the age- and sex-adjusted models. The other applied university-clustered robust standard errors to the age- and sex-adjusted composite-score models, with a finite-sample correction and t-based inference using 7 *df*, implemented in

XSL•FO
RenderX

Python (version 3.13.5) with statsmodels (version 0.14.6). These analyses assessed the consistency of the 6 composite-score paths; cluster-adjusted CIs for the primary latent-model indirect associations were not estimated.

Results



Study 1: Randomized Experiment Results

Participant Flow and Attrition

Of the 120 randomized participants, 107 (89.2%) completed the postintervention assessment: 93% (28/30) in the PE group, 83% (25/30) in the PC group, 83% (25/30) in the UE group, and 97% (29/30) in the UC group. In total, 45.8% (49/107) of the participants who completed the postintervention assessment were men; the complete-case sample had a mean age of 20.56 (SD 1.59) years. Detailed participant characteristics are provided in Multimedia Appendix 1, Table S4, and the reasons for 10.8% (13/120) noncompletions are shown in Figure 3.

Among the 60 pretested participants, 53 completed the postintervention assessment and 7 did not. Completers and noncompleters did not differ significantly at baseline in sex, age, anthropometric characteristics, or core literacy measures (Multimedia Appendix 1, Table S5). No exercise-related adverse events were reported.

Figure 3. Participant flow through Study 1.

Primary Factorial Analysis of Intervention and Pretest Effects

The primary analysis in Study 1 was a 2×2 factorial ANOVA of posttest scores, with pretest exposure and intervention conditions as the between-group factors. Significant intervention main effects were observed for self-reported motor competence ($F_{1,103}$=33.869, P<.001, ηp^2=0.247), health behaviors ($F_{1,103}$=21.548, P<.001, ηp^2=0.173), and sportsmanship ($F_{1,103}$=30.261, P<.001, ηp^2=0.227), with higher scores in the intervention condition (Table 2).

XSL•FO
RenderX

Table . Summary of 2×2 factorial ANOVA with posttest scores as dependent variables.

Outcome and source	Type III SS[a]	MS[b]	*F* test (*df*)	*P* value	ηp^{2}[c]
Motor competence					
Pretest (A)	284.170	284.170	22.290 (1, 103)	<.001	0.178
Intervention (B)	431.783	431.783	33.869 (1, 103)	<.001	0.247
A×B	0.144	0.144	0.011 (1, 103)	.92	0.000
Error	1313.119	12.749	—[d]	—	—
Health behaviors					
Pretest (A)	401.367	401.367	19.489 (1, 103)	<.001	0.159
Intervention (B)	443.787	443.787	21.548 (1, 103)	<.001	0.173
A×B	0.161	0.161	0.008 (1, 103)	.93	0.000
Error	2121.284	20.595	—	—	—

A×B	0.473	0.473	0.072 (1, 103)	.79	0.001
Error	672.260	6.527	—	—	—

[a]SS: sum of squares.

[b]MS: mean square.

[c]ηp^2: partial eta squared.

[d]Not applicable.

Pretesting showed significant main effects on motor competence ($F_{1,103}$=22.290, P<.001, ηp^2=0.178) and health behaviors ($F_{1,103}$=19.489, P<.001, ηp^2=0.159), but not on sportsmanship ($F_{1,103}$=3.478, P=.07, ηp^2=0.033). The Pretest×Intervention interaction was not statistically significant for motor competence ($F_{1,103}$=0.011, P=.92, ηp^2=0.000), health behaviors ($F_{1,103}$=0.008, P=.93, ηp^2=0.000), or sportsmanship ($F_{1,103}$=0.072, P=.79, ηp^2=0.001), providing no evidence that the intervention effect differed according to pretest exposure.

Supporting ANCOVA in the Pretested Groups

As a supporting analysis among the pretest groups, posttest outcomes were compared between the PE and PC groups using an ANCOVA while controlling for baseline scores. The group-by-baseline interaction terms were not statistically significant across the three outcomes, supporting the assumption of homogeneity in the regression slopes.

After adjustment for baseline scores, the intervention group had higher self-reported posttest scores than the control group for motor competence ($F_{1,50}$=12.703, P<.001, ηp^2=0.203), health behaviors ($F_{1,50}$=9.481, P=.003, ηp^2=0.159), and sportsmanship ($F_{1,50}$=14.713, P<.001, ηp^2=0.227). These results were consistent with those of the primary factorial analysis (Table 3).

[a]SS: sum of squares.

[b]MS: mean square.

[c]ηp^2: partial eta squared.

[d]Not applicable.

Attrition Sensitivity Analysis

Under the specified control-reference assumptions, the reference-based resampling sensitivity analysis yielded results consistent with those of the complete-case analysis. Across all 10,000 replicates, the main effect of the intervention remained statistically significant for motor competence, health behaviors, and sportsmanship. The median intervention-effect estimates for motor competence, health behaviors, and sportsmanship were $F_{1,116}$=27.60 (ηp^2=0.192), $F_{1,116}$=17.94 (ηp^2=0.134), and $F_{1,116}$=24.52 (ηp^2=0.175), respectively. The detailed simulation summaries are provided in Multimedia Appendix 1 (Table S6).

Exploratory Post Hoc Comparisons

Detailed exploratory Tukey honestly significant difference comparisons are provided in Multimedia Appendix 1 (Table S7). In brief, the corresponding intervention-control contrasts were statistically significant for all 3 outcomes under the pretested and unpretested conditions; exact *P* values are reported in Table S7 in Multimedia Appendix 1. However, as the pretest × intervention interactions were not statistically significant, these pairwise contrasts were interpreted as descriptive rather than primary evidence.

Study 2: Cross-Sectional Survey Results

Participant Characteristics and University Clustering

The final Study 2 sample comprised 790 university students, of whom 409 (51.8%) were men. The mean age of this sample was 20.33 (SD 1.78) years, with an age range of 18 to 25 years. Detailed demographic characteristics and university-specific sample sizes ranging from 61 to 117 per university are presented in Multimedia Appendix 1 (Table S8). The intraclass correlation coefficients for sports app involvement and digitalization were 0.010 and 0.002, respectively, whereas those for gamification and core literacy in physical education and health were approximately 0; the corresponding design effects were 1.99, 1.18, 1.00, and 1.00, respectively (Multimedia Appendix 1, Table S9).

Measurement Reliability, Convergent Validity, and Discriminant Validity

In the pilot CFA subsample (n=96), the standardized factor loadings for the retained items ranged from 0.604 to 0.834. AVE values across the 11 first-order dimensions ranged from 0.508 to 0.617, and CR values ranged from 0.757 to 0.934, supporting convergent validity (Multimedia Appendix 1, Table S2).

The final Study 2 sample had good internal consistency, with Cronbach α values of 0.890 for sports app involvement, 0.848 for digitalization, 0.814 for gamification, and 0.924 for core literacy in physical education and health. In the formal 4-factor measurement model, standardized dimension-level factor loadings ranged from 0.703 to 0.906, CR values ranged from 0.770 to 0.865, and AVE values ranged from 0.527 to 0.683. The heterotrait-monotrait ratios among the four focal constructs ranged from 0.426 to 0.638, with all values below the conservative 0.85 criterion, supporting the empirical distinction among the four constructs (Multimedia Appendix 1, Tables S10 and S11).

Assessment of Common Method Bias

Harman single-factor test identified nine factors with eigenvalues >1, with the first factor accounting for 25.1% of the total variance. The hypothesized 4-factor model showed an acceptable fit (χ^2_{38}=129.39, χ^2/df=3.405, CFI=0.978, TLI=0.968, RMSEA=0.055, SRMR=0.030), whereas the 1-factor model showed a poor fit (χ^2_{44}=1401.80, χ^2/df=31.859, CFI=0.670, TLI=0.587, RMSEA=0.198, SRMR=0.119). These findings argue against a single dominant common factor; however,

XSL•FO
RenderX

common method effects cannot be ruled out because the focal measures were self-reported and collected simultaneously.

Correlation Analysis

Descriptive statistics and correlations are presented in Table 4. Correlations among the 4 focal constructs were positive, ranging from r=0.386 to r=0.538 (all P<.001).

Table . Descriptive statistics and Pearson correlations for Study 2 variables.

Variables	Mean (SD)	1	2	3
Sports app involvement	35.123 (6.831)	—[a]	—	—
Digitalization	30.565 (4.606)	0.538	—	—
Gamification	34.527 (5.085)	0.477	0.529	—
Physical education and health core literacy	103.235 (13.842)	0.388	0.462	0.386

[a]Not applicable.

Structural Model

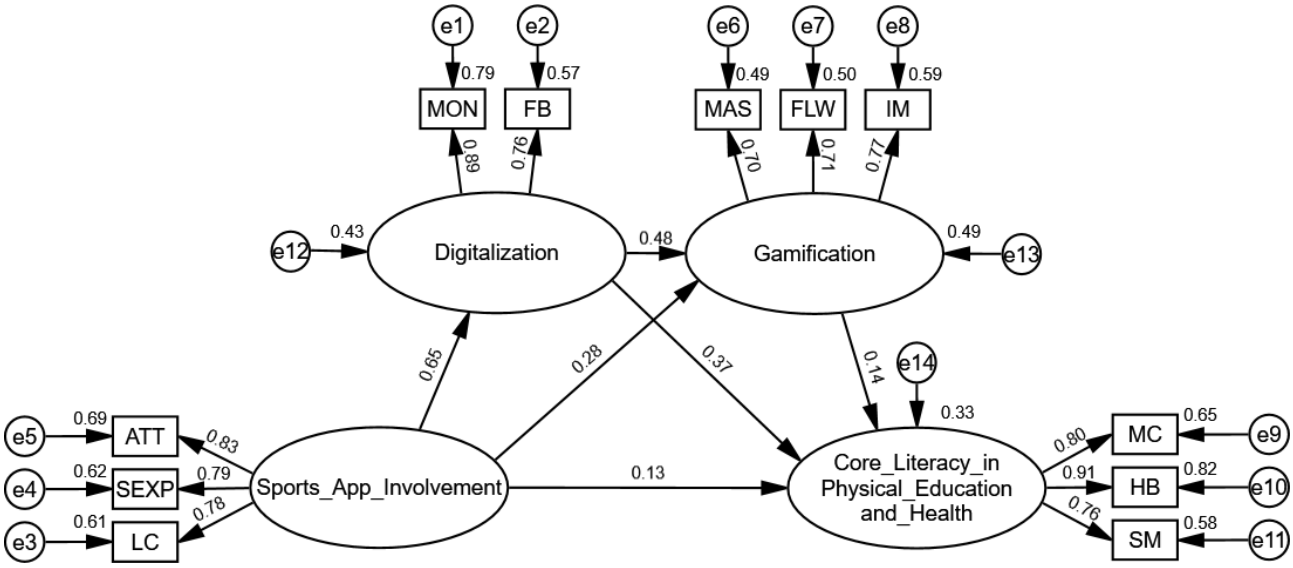
The primary single-level latent-variable model showed an acceptable fit for the cross-sectional data (χ^2_{54}=185.892, χ^2/df=3.442, CFI=0.968, TLI=0.953, RMSEA=0.056, 90% CI 0.047 - 0.064). Sports app involvement was associated with core literacy in physical education and health (β=.135, P=.01), digitalization (β=.653, P<.001), and gamification (β=.279, P<.001). Digitalization was associated with core literacy (β=.374, P<.001) and gamification (β=.486, P<.001), and gamification was associated with core literacy (β=.135, P=.02; Table 5 and Figure 4).

Inference from this primary model was based on the assumption of independence between participants.

The primary latent model was adjusted for age and sex and assumed independence between participants; its SEs were not adjusted for university-level clustering.

Table . Structural path coefficients of the primary latent-variable structural equation model.

Path	B[a] (SE)	z [b]	P value	β[c]
App involvement → Core literacy	0.113 (0.046)	2.470	.01	.135
App involvement → Digitalization	0.578 (0.035)	16.372	<.001	.653
Digitalization → Core literacy	0.353 (0.061)	5.782	<.001	.374
App involvement → Gamification	0.217 (0.043)	5.002	<.001	.279
Gamification → Core literacy	0.145 (0.064)	2.256	.02	.135
Digitalization → Gamification	0.427 (0.053)	7.994	<.001	.486



[a]B: the unstandardized regression coefficient.

[b]z: critical ratio.

[c]β: the standardized regression coefficient.

XSL•FO
RenderX

Figure 4. Latent-variable model of the cross-sectional associations among sports app involvement, digitalization, gamification, and core literacy in physical education and health. Values on paths between latent constructs are standardized regression coefficients; values on paths from latent constructs to their indicators are standardized factor loadings. Circles labeled e1 to e14 represent measurement errors or structural disturbances. Arrows represent statistical associations and do not establish temporal or causal ordering. ATT: attractiveness; FB: feedback; FLW: interaction fluency; HB: health behavior; IM: intrinsic motivation; LC: life centrality; MAS: sense of mastery; MC: motor competence; MON: monitoring; SEXP: self-expression; SM: sportsmanship.

Indirect Associations

Bootstrap analysis showed a model-estimated total association of 0.385 (BC 95% CI 0.296 - 0.478). The direct association was 0.113 (BC 95% CI 0.016 - 0.210), accounting for 29.5% of the model-estimated total association, and the total indirect association was 0.271 (BC 95% CI 0.194 - 0.361), accounting for 70.5%. The specific indirect associations through digitalization (0.204, BC 95% CI 0.126 - 0.290), gamification (0.031, BC 95% CI 0.004 - 0.077), and digitalization followed by gamification (0.036, BC 95% CI 0.005 - 0.081) accounted for 53.1%, 8.2%, and 9.3% of the model-estimated total association, respectively (Table 6).

Table . Model-estimated direct, indirect, and sequential indirect associations between sports app involvement and core literacy in physical education and health[a].

Association	Estimate (BC 95% CI[b])	Proportion of model-estimated total association (%)
Total association	0.385 (0.296-0.478)	100
Direct association	0.113 (0.016-0.210)	29.5
Total indirect association	0.271 (0.194-0.361)	70.5
Sports app involvement → digitalization → core literacy in physical education and health	0.204 (0.126-0.290)	53.1
Sports app involvement → gamification → core literacy in physical education and health	0.031 (0.004-0.077)	8.2
Sports app involvement → digitalization → gamification → core literacy in physical education and health	0.036 (0.005-0.081)	9.3

[a]Estimates are unstandardized cross-sectional associations adjusted for age and sex.

[b]BC 95% CI: bias-corrected 95% CI based on 5000 bootstrap resamples. CIs were obtained from the primary latent model without adjustment for university-level clustering.

Sensitivity Analysis

In the secondary sensitivity path analysis based on standardized composite scores, adding BMI and 7 university indicator variables to the age- and sex-adjusted models resulted in only small changes in the 6 focal coefficients (absolute changes ≤0.010), and all 6 focal paths remained statistically significant (all P<.001; Multimedia Appendix 1, Table S9, panel B). In the university-clustered analysis of the age- and sex-adjusted composite-score models, all 6 focal paths remained positive and statistically significant (all P<.05; Multimedia Appendix 1, Table S9, panel C). These secondary results supported the consistency of the 6 composite-score paths.

XSL•FO
RenderX

Discussion

Principal Findings

Study 1 showed higher participant-reported core literacy scores after the 12-week multicomponent app-supported intervention than under the control condition. In Study 2, sports app involvement, digitalization, gamification, and core literacy showed positive cross-sectional associations, with digitalization showing the largest model-estimated indirect association. These associations warrant further investigation in longitudinal and experimental studies.

App-Supported Intervention and Core Literacy

Study 1 evaluated a multicomponent intervention package combining structured physical activity, app-based monitoring and feedback, health education, goal-setting, peer interaction, gamified challenges, reminders, and researcher support. Recent studies on digital interventions have suggested their selective rather than uniform benefits. A 2024 review of healthy young adults reported limited and inconsistent effects [31], whereas a 2024 JMIR meta-analysis of college students found increased step counts but no significant improvements in light or moderate-to-vigorous physical activity or sedentary time [32]. A 2025 meta-analysis of standalone digital behavior change interventions found modest improvements in physical activity, although the certainty of evidence for physical activity was low [33]. More recently, a 2026 systematic review of digital health interventions among college students reported generally favorable effects on physical activity while emphasizing limited evidence regarding long-term effectiveness [34]. Taken together, these findings suggest that digital interventions can support selected behavioral outcomes, but their effects vary according to the intervention design, population, outcome, and follow-up period.

Testing the Effect of the Pretest

Pretesting showed significant main effects on self-reported motor competence and health behavior scores. Repeated exposure to assessment items may increase familiarity with the questionnaire and prompt reflection on exercise behaviors [28]. The Solomon 4-group design allowed the main effects of pretesting and intervention to be examined separately. The pretest×intervention interactions were not statistically significant for any of the 3 outcomes.

No statistically significant pretest main effect was detected for sportsmanship. Its value-oriented aspects develop gradually through sustained sports participation and social experience [35]. These relatively stable value orientations may be less responsive to a single exposure to assessment items.

Digitalization, Gamification, and Their Indirect Associations

In the cross-sectional model in Study 2, digitalization showed the largest specific indirect association between sports app involvement and core literacy, accounting for 53.1% of the total model-estimated association. From a functional perspective, monitoring and feedback may help users recognize exercise progress, evaluate goal attainment, and adjust exercise plans, providing informational support for physical activity and health self-management. This interpretation aligns with a 2024 meta-analysis showing that self-monitoring interventions with feedback achieved better physical activity outcomes than those without feedback (Cohen *d*=0.29, 95% CI 0.16 - 0.43) [36].

Positive indirect associations were also observed through gamification alone and through the model-estimated sequential pathway involving digitalization and gamification. Gamification may support enjoyment and motivation for participation, complementing the informational support provided by monitoring and feedback [37]. A 2024 meta-analysis reported a small increase in daily steps with gamified compared with nongamified apps [38], while a 2025 meta-analysis in individuals with cardiovascular disease identified feedback as the most important game design element in its meta-regression analysis [39]. From this perspective, feedback may provide a connection between digital functions and gamified experiences, offering a functional interpretation of the sequential association observed in this study. Longitudinal and experimental studies could further examine the integration of these functions and their relationship with changes in core literacy.

Practical Implications

For university physical education, the findings support further evaluation of sports apps as tools within structured physical activity programs. Such programs may combine clear activity feedback and progress monitoring with attainable goals, participant choices, peer interactions, and selectively used gamified challenges. Evaluation should include objectively measured physical activity and performance, adherence, and long-term outcomes alongside self-reported competencies.

Research Limitations and Future Directions

This study has several limitations. First, both studies involved university students, and Study 2 was limited to 1 province, restricting generalizability. The primary latent-variable SEM assumed participant-level independence; its SEs and CIs, including those for indirect associations, were not adjusted for university clustering and may understate uncertainty. Clustering was examined only in secondary composite-score models of the 6 focal paths, with inference limited by the small number of universities (n=8).

Second, Study 1 evaluated a multicomponent app-supported intervention, so the contributions of individual components could not be isolated. The intervention groups also received more structured content and task-related support than the control groups. The absence of allocation concealment posed a risk of selection bias.

Third, the cross-sectional design of Study 2 did not establish temporal ordering, and reverse or reciprocal relationships remain possible. Covariate adjustment did not address unmeasured usual physical activity, health status, or app use patterns, leaving potential residual confounding.

Fourth, 10.8% (13/120) of randomized participants did not complete the postintervention assessment, creating potential attrition bias in the complete-case Study 1 analyses. The reference-based sensitivity analysis yielded consistent findings

XSL•FO
RenderX

under its specified missing-outcome assumptions. Retrospective trial registration also limited prospective verification of planned outcomes and analyses.

Finally, the pilot CFA subsample was not fully independent of item refinement because item screening preceded sample splitting. Structural hypotheses were tested in a separate formal sample. Self-reported outcomes may have been affected by social desirability and residual common method bias; objective physical performance and physical activity were not assessed. Future studies should prioritize multisite longitudinal or experimental designs, attention-matched active controls, independent measurement validation, and objective or multi-informant outcomes.

Conclusions

Study 1 showed higher self-reported motor competence, health behavior, and sportsmanship scores among university students receiving the 12-week multicomponent app-supported physical activity intervention than among controls. The Solomon 4-group design identified pretest effects on motor competence and health behaviors, with no statistically significant pretest-by-intervention interaction for any of the 3 outcomes. In the independent Study 2 cross-sectional sample, sports app involvement was positively associated with core literacy, and digitalization showed the largest specific indirect association, followed by the sequential pathway through digitalization and gamification and the specific pathway through gamification alone. The findings support further evaluation of app-supported university physical activity programs with objective outcomes and attention-matched controls, alongside longitudinal testing of the Study 2 associations.

Acknowledgments

The authors thank all participating students and the universities that supported participant recruitment and data collection.

Generative AI Use

ChatGPT (GPT-5.5 and GPT-6 Astra; OpenAI) and Grammarly were used only for language polishing. The authors take full responsibility for the final content of the manuscript.

Funding

The authors declared no financial support was received for this work.

Data Availability

The datasets generated and analyzed during this study are not publicly available because they contain deidentified participant-level educational and behavioral data collected under institutional ethics approval. Data may be made available from the corresponding author upon reasonable request and with appropriate institutional approval.

Authors' Contributions

RG contributed to conceptualization, methodology, investigation, data curation, formal analysis, visualization, and writing of the original draft. WG contributed to experimental design, intervention implementation, supervision, validation, and critical review of the full manuscript. Both authors reviewed and approved the final manuscript.

Conflicts of Interest

None declared.

Multimedia Appendix 1
This appendix presents the intervention schedule, participant characteristics, measurement validation, attrition analyses, exploratory comparisons, and clustering and sensitivity analyses for Studies 1 and 2.

Abstract

Background: Cognitive impulsivity is a multifaceted construct associated with symptom severity, functional impairment, and poor quality of life in eating disorders (EDs) and mental ill-health. However, objective assessment of cognitive impulsivity is piecemeal and complex, with many assessment tools lacking psychometric evaluation and ecological validity. Furthermore, validated assessment tools are rarely perceived to be engaging or meaningful by individuals who complete them, limiting their utility in research and forming a barrier to clinical translation. Thus, although cognitive impulsivity predicts treatment engagement and outcomes, it is rarely assessed or addressed in a clinical context.

Objective: We aimed to redesign and evaluate the Cognitive Impulsivity Suite (CIS), a validated gamified assessment battery of cognitive impulsivity, through user-centered co-design, agile game development, and user-centered evaluation. This collaborative study partnered researchers with individuals with lived experiences (LEs) of EDs and commonly co-occurring mental ill-health, and game development experts.

Methods: In a sequential mixed methods design, we first defined user requirements through inductive thematic analysis of data from 2 focus groups incorporating 7 individuals with LE of EDs and commonly co-occurring mental health conditions (mean age 27.6, SD 7.03 y; 4 women, 2 men, 1 nonbinary), researchers, clinicians, and technology professionals. Agile game development was achieved through 6-week-long sprints, involving game developers and a play-testing team of researchers. During LE evaluation, we collected and analyzed data from an expanded sample (n=18; mean age 30.5, SD 6.56 y; 12 women, 3 men, 2 nonbinary), using a pragmatic blending of qualitative and quantitative research methods. This included inductive and deductive thematic analysis of “thinking aloud” data, descriptive statistics, and ANOVA tests of the Game User Experience Satisfaction Scale, short version (GUESS-18) surveys.

Results: We co-designed guiding principles and ideas for aesthetics, story concepts, and gameplay features, which closely aligned with leading theories of psychological well-being, clinical evidence concerning ED recovery, and gamification frameworks. Qualitative evaluations of the new tool, CIS *Papillon Park*, showed user engagement and motivation were driven by opportunities for autonomy, personal accomplishment, and simulated interpersonal relationships, aligning with approaches to gamification based on self-determination theory. In quantitative evaluation, a mean GUESS-18 composite score of 45.9 (SD 9.85) showed CIS *Papillon Park* achieved sound overall user satisfaction, with subscale scores revealing strengths in usability, narrative, visual and audio aesthetics, and personal gratification.

Conclusions: The contributions of this study are grounded in its integration of user-centered co-design and evaluation, agile game development, and theory-driven approaches to cognitive assessment and gamification, to redesign and evaluate a validated online task battery. The resulting CIS *Papillon Park* combines appealing aesthetics, gamification elements that address cognitive, emotional, and social needs, and accessible playing experiences, which maximized user satisfaction and engagement while prioritizing psychological safety. Next steps involve psychometric evaluation and dissemination.

Introduction

Cognitive impulsivity is a multifaceted construct that describes rapid, unplanned reactions without sufficient regard for their potential consequences, which arise from alterations in multiple processes, including attentional control, reflection, and feedback monitoring or shifting [1-3]. Distinctive patterns of cognitive impulsivity are well-documented characteristics of eating disorders (EDs) [4-8]. Furthermore, similar patterns are observed in conditions that commonly co-occur with EDs, such as mood and anxiety disorders, obsessive-compulsive disorder, substance and behavioral addictions, and attention-deficit/hyperactivity disorder [9-14]. Although causal pathways remain uncertain, elevated cognitive impulsivity has been shown to predict future onset of these disorders [15], to become more pronounced with illness duration [16], and to predict treatment outcomes [17]. Furthermore, research indicates greater severity of cognitive dysfunction in EDs is associated with symptom severity, functional impairment, and poorer quality of life [18,19]. Importantly, objective assessment of cognitive impulsivity has improved our understanding of shared and unique risk, maintenance, and treatment response mechanisms across EDs and commonly co-occurring conditions [20-24]. Nomothetic assessment of cognitive impulsivity has also facilitated the identification of novel treatment targets and neurocognitive interventions, while idiographic assessment may help identify which individuals will most benefit from those treatments [25-30]. As such, incorporating objective assessment of cognitive functioning in clinical assessment, diagnosis, and treatment planning may offer an opportunity to bridge critical treatment gaps, and help us to better understand and respond to complex clinical phenomena, such as diagnostic crossover, heterogeneity, and comorbidity [31-33]. However, despite persistent calls for this translation, objective assessment of cognitive impulsivity remains absent from routine clinical practice [34,35].

Specific barriers have been identified that limit the research impact and translation of cognitive impulsivity assessments. The first concern is the quality and quantity of existing tools, whereby many measure discrete facets of cognitive impulsivity and fail to predict real-world impulsive behaviors [36], and lack robust psychometric or normative evaluation [24,37-41]. Furthermore, the sheer array of tools, paradigms, and analysis methods creates onerous administration for clinicians and researchers, and limits replicability, comprehensiveness, and comparison [42,43]. Finally, a few of the evidence-based tools are well-accepted or engaging to users, leading to performance invalidity [44-46], limiting research participation and uptake in clinical or self-assessment contexts [47-53]. One approach to address these barriers is gamification—the process of creating opportunities for subjective value [54] through the introduction of game-like elements and mechanics [55]. Central to this approach is that gamification activates intrinsic motivational processes, thus drawing on self-determination theory, which posits human behavior is motivated by needs for competence, autonomy, and relatedness [56]. Gamification also reflects principles from other influential theories and frameworks, including social learning theory, social cognitive theory, behaviorism, and flow [57]. Gamification elements may therefore target a range of mechanisms to strengthen intrinsic motivation—cognitive (eg, achievement, progression, and mastery), emotional (eg, enjoyment, satisfaction, and immersion), or social (eg, collaboration and teamwork) [58,59]. Evidence suggests these can be achieved through various "gameful affordances" [54], for example, decomposing demanding activities into clear, achievable subtasks; creating meaning through narrative, characters, and storytelling; providing feedback, rewards, and visible indicators of progress; enabling exploration and customization; including teammates and social supports; and calibrating difficulty to optimal levels for each player [58-61]. Together with game design elements, such as aesthetic appeal, these in turn foster the desired player behavior or outcome, such as long-term user engagement, satisfaction, and consistent effort [57,62-66]. The Cognitive Impulsivity Suite (CIS) is an online task battery that was designed using these principles [3]. The CIS comprehensively assesses key cognitive processes associated with impulsive behaviors in an integrated environment, featuring a cohesive "Wild West" story and visual design. Multiple mechanisms are assessed in a single session, allowing outcomes to be analyzed and interpreted in a holistic manner, while using gamification to maximize consumer engagement [67-69]. Research has demonstrated this integrated task structure to be valid and reliable in assessing cognitive impulsivity in clinical and community samples, whether administered online or in-person [3,70,71]. However, it has also highlighted opportunities to broaden the reach and enhance the impact of the tool, particularly by advancing its clinical translation, and to improve user satisfaction, including for those with lived experience (LE) of EDs and commonly co-occurring conditions [72,73].

Lack of input from users is a second well-documented barrier limiting the research impact and clinical translation of cognitive assessments and similar technology-enabled tools [74-78]. In response, there is growing acceptance of the need to meaningfully engage users throughout the design, implementation, and evaluation of mental health interventions [79,80], service improvements [81,82], and priorities and processes for research [83-86]. Human- and user-centered design approaches to these health innovations, which prioritize user needs and iterative development processes, have been shown to maximize their usability and satisfaction, and support the translation of evidence-based innovations from research to practice [87-89]. Similarly, co-design approaches, which incorporate multiple stakeholders, including users with LE, can help to maximize the relevance and benefits of health innovations for those users [90,91], promote behavior change [92], support empowerment, uptake, and engagement [93,94], and reduce waste [95,96]. However, although emerging research suggests user-centered and lived-experience informed co-design is well suited to developing and improving cognitive assessment tools, this remains rare [78,97-99]. Additionally, though usability and user satisfaction are recognized as critical to long-term uptake and translation of health innovations, few gamified assessments or interventions are evaluated on this basis [42,88,100].

XSL•FO
RenderX

Our aims for this study were to redesign the CIS and to evaluate user satisfaction, using a collaborative sequential mixed methods co-design framework, informed by both evidence and experience [89,101]. Specifically, our researchers synthesized research evidence and stakeholder feedback to identify the need to reimagine the CIS and to ensure it retained its validated scientific structure (ie, the same cognitive constructs would be assessed in the same manner). Individuals with LEs would co-design guiding principles and ideas for game concepts and features through focus groups, alongside technology experts and researchers (refer to Ideation and Design Phase section), and would leverage their LEs to test and evaluate the new product (refer to Evaluation Phase section). Clinicians would cofacilitate focus groups and provide guidance to researchers to support the psychological well-being of participants. Technology experts would produce the new games through an iterative agile development process in close collaboration with researchers (refer to Production Phase section).

Methods

Overview

We used a sequential mixed methods co-design approach to reimagine the CIS assessment tool [102,103]. We adopted a pragmatic paradigm to achieve our objectives [104], centering users with LE as key informants at critical stages of the design process to maximize usability and satisfaction with the assessment tool [87], integrating researcher perspectives to retain the mechanistic structure of the original CIS games [101], and acknowledging the resource-limited context [89,92]. As such, our methodology adopts a framework that combines user-centered approaches to specifying requirements and evaluating the design, with rapid, low-cost production [105-107]. Here, we define co-design as a participatory process in which stakeholders with various forms of relevant expertise collaborate to address a problem concerning a system or tool [108-110]. This methodology was driven by an ethical commitment to elevate the voices of individuals with LE who will be most impacted by our research [111,112]. Furthermore, the research team values the deep experiential insights and "practical knowing" that can be accessed through participatory inquiry and researcher reflexivity, while also endorsing a critical realist perspective that values quantitative measurement of psychological phenomena [113]. Given this standpoint and our research goals, we adopted a thematic analysis (TA) approach to qualitative data analysis, a family of analytical methods that centers participant perspectives, and that acknowledges the active role of the researcher [114-116].

Details of research designs, participants, data collection, and data analysis for each phase (ideation and design, production, and evaluation) are reported below according to American Psychological Association mixed methods journal article reporting standards [117].

Ideation and Design Phase

Research Design Overview

The qualitative ideation and design phase aimed to specify user requirements and produce a detailed design brief to guide the reproduction of the CIS. This was conducted through 2 focus group co-design sessions, which incorporated individuals with LEs of EDs and general mental health concerns, researchers, clinicians, and technology professionals. Our LE co-design approach in this phase was informed by the Australian Eating Disorder Research and Translation Center, which funded the production and evaluation phases of this project [86,118], and by user-centered design principles for eHealth and serious games [87,107,119].

Ideation and Design Study Participants

Researcher Description

The research team includes a PhD candidate with experience in qualitative and quantitative research, psychological assessment, and software development life-cycle (EC), a clinician-researcher with experience in EDs, addiction, and trauma (AA), a psychologist (LH), and a researcher with experience in qualitative and quantitative research and measurement development (CM). Noting researcher reflexivity and self-reflection as a critical aspect of reflexive TA [120-122], the research team reflected on their positionality and perspectives relevant to the research objectives and aimed to faithfully represent the user requirements and design preferences identified from this phase. Researcher identity and positionality statements are provided in Table S2 in Multimedia Appendix 1.

Participants

A total of 7 individuals participated in the focus groups. Participant characteristics are reported in Table 1. While there is no universally agreed-upon sample size for TA research [123,124], this sample size was deemed practical to manage [125] and sufficient to achieve the research goals based on previous research [78]. Importantly, we aimed to produce one acceptable solution to our identified research problem, rejecting the concepts of a single correct solution or "data saturation," which do not form part of TA approaches to qualitative inquiry [121,126].

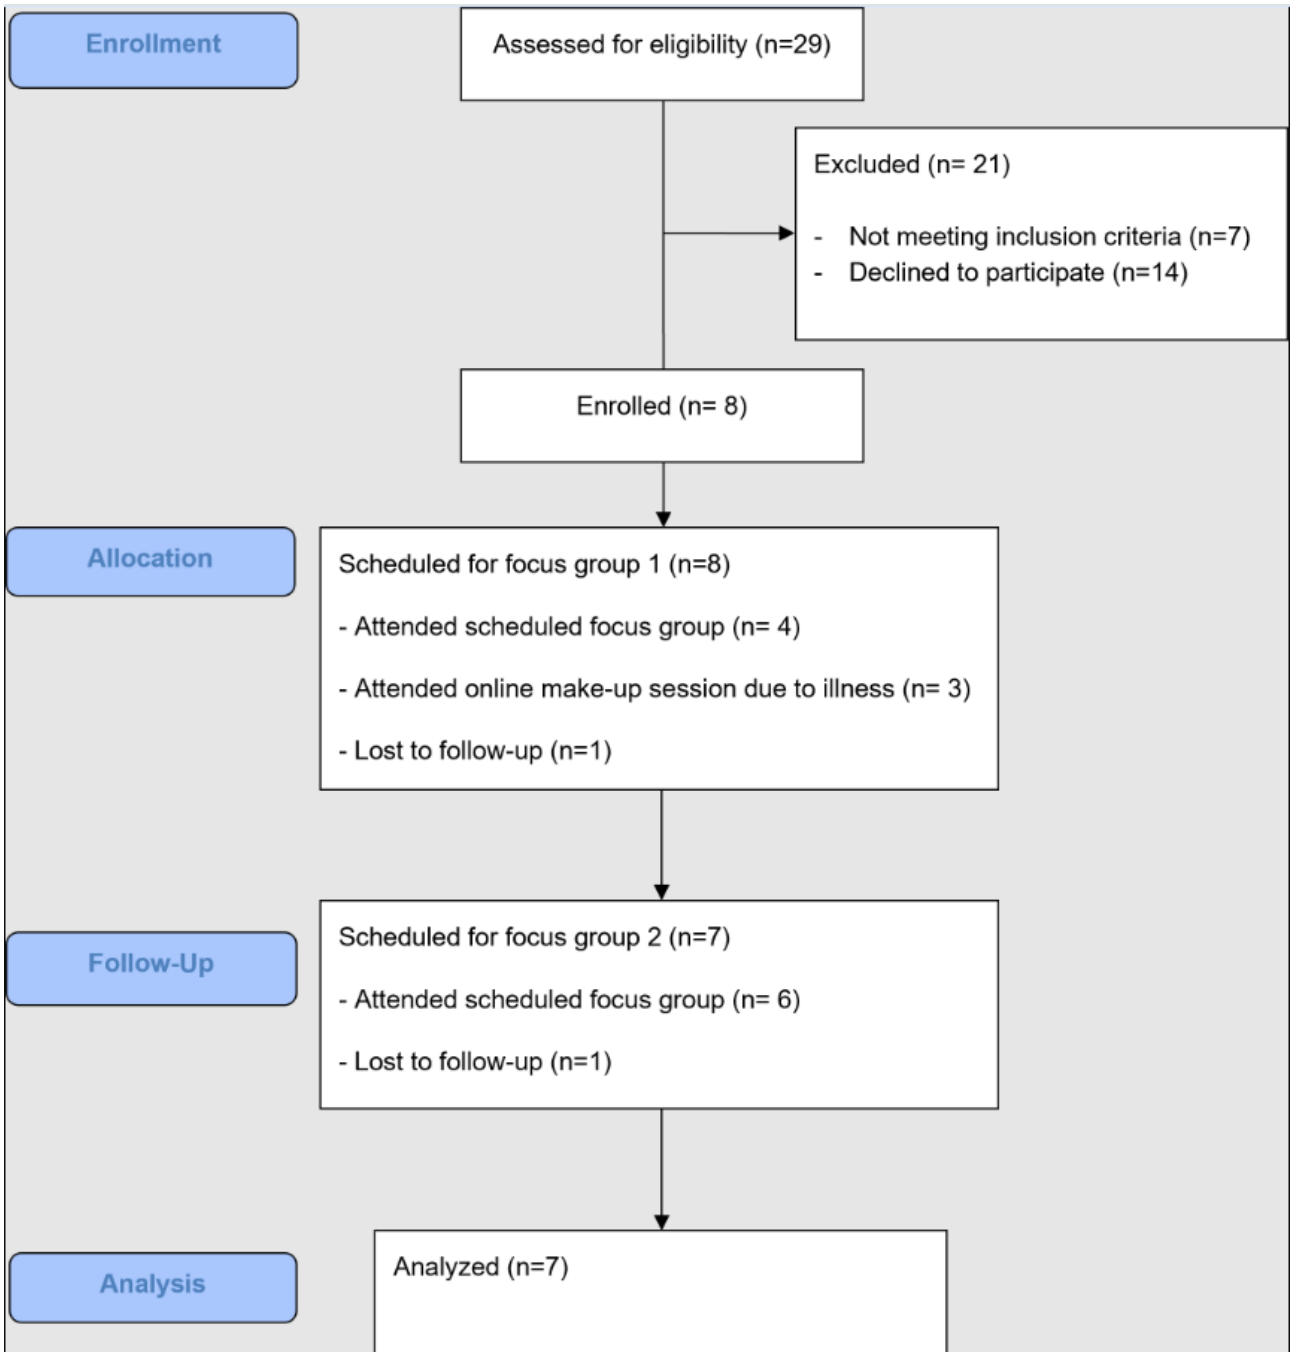
Researcher-Participant Relationship



There was an established relationship between the research team attending the focus groups (AA, EC, and LH) who had collaborated on the development of the original CIS [3]. There were no preexisting relationships between the research team and any of the participants. Ethical concerns relevant to this research context included the unequal power relationship between researchers and participants. In addition to informed consent and ethical review procedures, psychologist, LH, attended the focus groups with the expressed role of supporting participant well-being.

Participant Recruitment and Selection

We recruited participants aged 18 - 40 years who had current or past diagnoses of any ED. For safety and compliance, exclusion criteria were currently experiencing psychotic symptoms, bipolar disorder, and suicidality. Additionally, we excluded individuals who had previously completed the CIS. Participants were recruited using Meta advertisements, existing participant databases, and through local and national ED organizations (eg, InsideOut Institute, Australia & New Zealand Academy of Eating Disorders, and Scientific Work in Anorexia Nervosa & Other Eating Disorders).

Of the 29 who expressed interest in the study, 22 met eligibility criteria. A total of 7 participants were selected and attended the first focus group, with 6 participants returning for the second focus group (Figure 1). Focus groups were held in person at Monash University between June and July 2023. Participant characteristics are reported in Table 1.

Figure 1. Design-phase participant flowchart.

XSL•FO
RenderX

The figure depicts a flowchart of participants who were enrolled, screened, allocated, and completed the ideation and design phase of the CIS redevelopment project from April to July 2023.

Ideation and Design Data Collection

Participants provided informed consent and completed screening and enrollment questionnaires using REDCap (Research Electronic Data Capture) [127,128]. Eligible individuals were contacted to confirm eligibility and be briefed on focus group procedures. Participants attended 2 focus group sessions, scheduled 1 month apart, which were cofacilitated by EC and AA, and attended by a game development professional and a psychologist (LH). Each focus group lasted 3 hours.

Participants were asked open questions to generate ideas for a gamified cognitive assessment tool that should appeal to diverse audiences with EDs and commonly co-occurring conditions (refer to section S4 in Multimedia Appendix 1 for focus group guides). To avoid influencing ideas, participants were not shown visuals depicting the original game. Instead, brief details of the CIS's general purpose, structure, and basic schematics were shared. A brief feedback survey collected their group and research experiences, such that improvements could be made for the second session (section S4.2 in Multimedia Appendix 1) [129-131]. In the second focus group, we honed design concepts and features and clarified key topics of conversation from the first session. Following the second session, participants were again invited to complete a brief survey to evaluate their experiences. Throughout these sessions, the facilitators, psychologist, and technology professional engaged in active discussions and whiteboarding with participants, prompting iterative review, expansion, and refinement of ideas. Sessions were audio recorded using Echo360 or Zoom software, and transcripts were redacted to protect anonymity.

Ideation and Design Data Analysis

Data were analyzed according to the 6 stages of reflexive TA by Braun and Clarke [114]. An inductive approach was used to explore participants' ideas and perspectives, while acknowledging the positivist, cognitive-behavioral perspective inherent in psychological assessments and the constraints imposed by the existing validated task structure. Reflexive TA further acknowledges that themes are actively generated in a subjective process, whereby the researcher interprets meaning from participant statements [126,132]. Final transcripts were coded by EC using NVivo 14 (Lumivero) [133].

In the first stage of reflexive TA, *deep familiarization*, transcripts and recordings were reviewed. The second stage involved *initial coding*, whereby an open coding approach to label segments of text within the data was used. In stage 3, *generating themes*, codes were grouped into categories to generate the main themes. Stage 4 involved *reviewing themes* to ensure a rich understanding of the data, whereby AA, LH, and CM were consulted to provide feedback on the drafted themes and possible interpretations. Themes were further refined in stage 5, *theme finalization*. Finally, stage 6, *interpreting and reporting*, involved the research teams' continued revision of the codes and themes during the write-up phase.

Production Phase

Research Design Overview

The production phase involved implementing the design ideas and guiding principles defined in the Ideation and Design Phase section. Here, we engaged *Noble Steed Games* (NSG) as an expert partner to design and produce the revised CIS. The new CIS was produced in an agile development process, involving 6 week-long iterative and collaborative sprints between NSG and the research team between March and April 2025. This approach was informed by guidelines and case studies concerning the pragmatic integration of user-centered design and LE co-design principles with the challenges of producing highly technical solutions that require expert knowledge, within a context of limited time and resources [88,92,105,106].

Production Participants

The production team involved 4 members of the NSG team, alongside the first author (EC). A play testing team was formed to assess usability and the extent to which the new CIS achieved user requirements and research objectives [119]. This team involved EC, CM, 3 student researchers, and 4 members of the AVG research group. All play testing members were familiar with LE co-design guiding principles and design ideas, and with the original CIS.

Production Procedures

NSG used CIS *Choices in the Wild West*, co-designed guiding principles, and cogenerated design ideas to inform their production of the new version of the CIS, referred to as *Papillon Park* (section S4, Multimedia Appendix 1). For the *Reflection* mini-game, NSG sourced copyright-free images from Unsplashed and Pexels, which were processed by EC to standardize size, color, contrast, and luminance properties using the *magick* package in R (R Core Team) [134]. During each sprint, NSG produced a specific deliverable (eg, wireframes for each mini-game; scene, stimulus, and character art; and scripts and instruction text), which were reviewed and refined in consultation with EC. Once available, playable prototypes were deployed to secure Monash servers, such that game functionality and data capture could be tested. These prototypes were further refined in response to play testing feedback, for example, by modifying stimulus timing and on-screen positioning to ensure target constructs were being effectively assessed. Following completion of the agile production period, ad hoc updates and refinements were defined by EC and implemented by NSG in response to LE play testing and evaluations. No research data were collected or analyzed during this phase.

Evaluation Phase

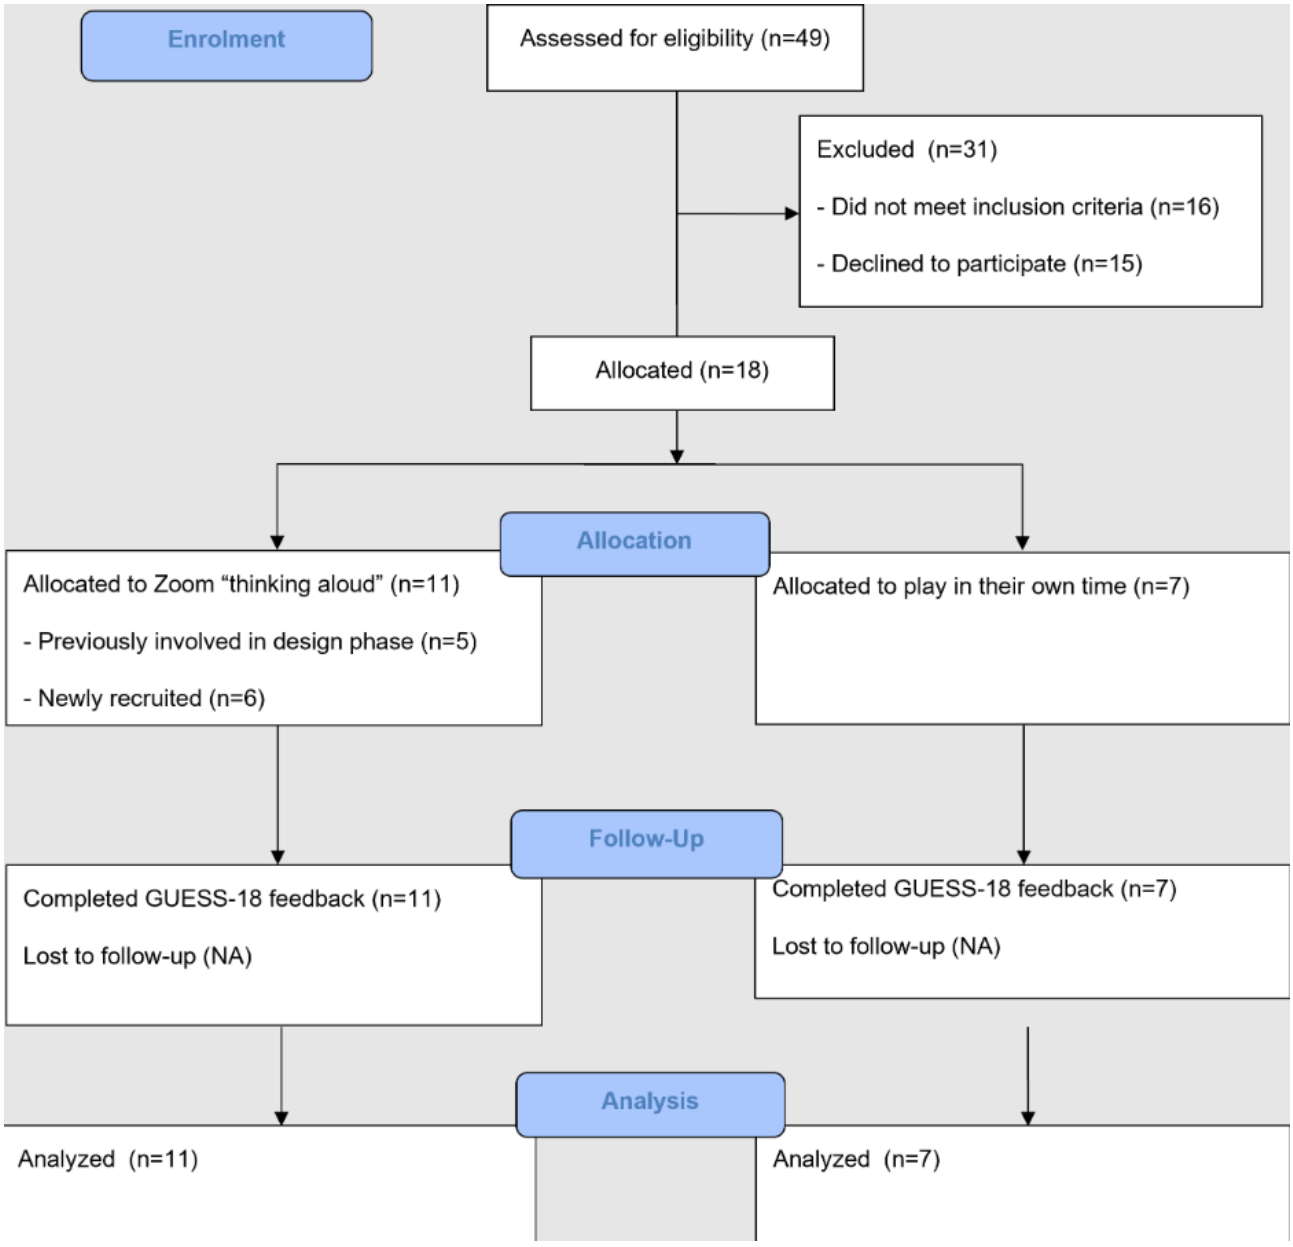
Research Design Overview

The evaluation phase aimed to explore user experience satisfaction and the extent to which the design of CIS *Papillon Park* met user requirements [87,119]. To achieve these goals, we adopted a convergent mixed methods design. The GUESS-18 questionnaire was selected as an effective tool for quantitative data collection [135,136] and analyzed using descriptive and inferential statistics [116,137,138]. "Thinking aloud" was selected as an appropriate method for qualitative data collection,

XSL•FO
RenderX

whereby participants provide a verbal commentary while playing the games [139,140], which was analyzed using deductive and inductive cycles of TA. While this method departs from the "Big Q" paradigm described by Braun and Clarke [115], this approach allowed us to answer our research questions by structuring our analysis according to the user requirements defined during the ideation and design phase, and is well-suited to convergent mixed methods approaches [116].

Evaluation Study Participants



Participants

We sought to retain participants from the ideation and design phase while recruiting additional participants to expand our sample size and composition. We planned to divide this sample into 3 approximately equal groups to examine whether participation in the ideation and design phase, or the process of "thinking aloud" while playing, influenced subsequent quantitative evaluations of user experiences and satisfaction.

Participant Recruitment and Selection

Participants who contributed to the ideation and design phase were invited to the present phase via email. Additional participants were recruited through Meta advertisements and existing participant databases. Identical inclusion and exclusion criteria used in the ideation and design phase were used. Of the total, 5 of the ideation and design phase participants returned for the evaluation phase. Of the 43 additional recruited participants, 27 met eligibility criteria, and 13 completed the study. All 5 participants from the ideation and design phase were invited to attend 1-hour Zoom sessions to play CIS *Papillon Park* while providing "thinking aloud" feedback. Newly recruited participants were split into 2 groups, such that 6 also completed Zoom "thinking aloud" sessions, and 7 played the game in their own time, according to their availability and preferences (Figure 2). Sessions took place in April 2025.

XSL•FO
RenderX

Sample Size, Power, and Precision

We did not perform an a priori power analysis. The target sample size of 21 participants was instead determined by the depth-oriented approach of the qualitative component of the evaluation phase, in accordance with established guidelines for this methodology and previous research [78,123].

Setting

Participants were provided with a link to access the CIS *Papillon Park* online and were instructed to use a computer with a keyboard (ie, not a phone or tablet). Participants were informed that the CIS would take approximately 40 minutes to complete and to complete the games in a single sitting. Participants completing "thinking aloud" sessions were provided with the link during their Zoom session, while those playing in their own time received it via email through REDCap. The 3 mini-games were presented in a randomized order, and server logs were used to confirm completion.

Quantitative Measures

The Game User Experience Satisfaction Scale, short version (GUESS-18) was used to gather quantitative feedback [135,136]. GUESS-18 is a psychometrically validated tool with 9 subscales that assess how various game attributes contribute to user satisfaction (Table S3.1 in Multimedia Appendix 1). Participants rated 18 items (eg, "I think the game is visually appealing") on a 7-point scale from 1 (*strongly disagree*) to 7 (*strongly agree*) with a neutral midpoint of 4 (*neither agree nor disagree*). One item ("I feel bored while playing the game") is reverse-coded. Subscale scores (1-7) are calculated by averaging numeric ratings for component questions, and a composite score (9-63) is obtained by summing subscale scores, with higher scores indicating greater user satisfaction. In this study, internal reliability for the composite scale was excellent (Cronbach α=0.93, Zumbo ordinal α=0.95). For subscales, refer to Table S3.2 in Multimedia Appendix 1.

After critically analyzing the alignment of the GUESS-18 subscale constructs to the co-designed guiding principles in the ideation and design phase (Table S3.3 in Multimedia Appendix 1), 2 items were developed to explore theme, *No Trigger Warnings Needed* ("I feel the games are appropriate for someone with lived experiences like mine," "I feel the games are appropriate for someone with lived experiences like mine," "I feel the games are triggering for someone with lived experiences like mine" [reverse coded]). Space for additional open-text feedback was provided at the end of the instrument.

Evaluation Data Collection

Participants provided informed consent and completed screening and enrollment questionnaires online via REDCap [127,128].

Qualitative Data Collection

Of the 18 participants, 11 confirmed their availability for "thinking aloud" sessions to take place via Zoom [139]. During the session, participants were asked to access CIS *Papillon Park* online and provide a running commentary of their thought process as they proceeded through the game. Participants were advised that the facilitator (EC) would simply observe unless they became quiet, in which case a prompt would be provided. "Thinking aloud" sessions were audio- and video-recorded and transcribed using Zoom.

The remaining 7 participants preferred to complete CIS *Papillon Park* in their own time and were invited to provide qualitative feedback using a free text box in the online feedback questionnaire.

Quantitative Data Collection

After completing the CIS *Papillon Park*, participants were directed to complete the GUESS-18 questionnaire and the additional 2 items concerning the appropriateness of the tool for individuals with lived and living experiences of EDs and general mental health concerns (section S3.1 in Multimedia Appendix 1).

Evaluation Data Analysis

Qualitative Data Analysis

Transcripts were reviewed for accuracy and uploaded to NVivo 15 for analysis [141]. First author, EC, undertook deep familiarization with the data. Data were coded to first identify technical or usability issues that could be rapidly resolved by NSG (eg, statements concerning misunderstandings of game instructions). EC then conducted deductive and inductive cycles of TA [116]. The co-designed guiding principles were used as a coding framework for deductive TA, with statements coded for insights into the extent to which the new tool met these user requirements. Data were then revisited with an inductive lens, seeking further insights into user experiences that had not been captured during deductive analysis. Finally, EC and CM *reviewed* codes, initial themes, and interpretations for clarity and narrative consistency. Themes continued to be *refined* during the *write-up and reporting* phase.

Quantitative Data Analysis

GUESS-18 responses were scored using Microsoft Excel and analyzed and visualized in R Studio [142]. There were no missing data. Means and SDs were calculated for total user satisfaction and for each of the 9 subscales according to published guidelines [135,136]. Exploratory omnibus ANOVA tests were used to examine group differences in GUESS-18 overall and subscale satisfaction between the 3 groups of participants (ie, designers, newly recruited "thinking aloud" participants, and those who completed the games in their own time).

Data Integration

The integration of qualitative and quantitative feedback data was intended to provide greater value than each alone [143]. Qualitative evaluation using a psychometrically sound tool facilitates comparison with other serious games and gamified psychological assessments, which is challenging when using only qualitative data, but lacks depth, and does not distinguish between the 3 component games of the overall tool. Conversely, qualitative data allowed us to understand *why* users felt satisfied or dissatisfied with particular elements of their experiences, and the variability in their experiences between the 3 mini-games. To achieve these goals, we aimed to synthesize and interpret qualitative and quantitative data at individual, group, and sample

XSL•FO
RenderX

levels, and present an integrated narrative of our findings in the results section [137].

Ethical Considerations

Ethical approval for all research procedures was provided by Monash University Human Research Ethics Committee (reference 29393), and all research participants provided informed written consent for the data collection and analysis described herein. Data were deidentified to protect participant privacy and confidentiality. No participants can be identified by the information included within the main paper or supplementary file, where participants are referred to individually (eg, in quotations), pseudonyms have been used. Participants with LE were compensated Aus $60 (approximately US $44) for each focus group (or Aus $20 [approximately US $15] for Zoom make-up sessions) and Aus $40 (approximately US $29) for the evaluation phase.

Results

Ideation and Design Phase Results

Overview

In total, three overarching themes were defined with a total of 9 subthemes that describe guiding principles for redeveloping the CIS: (1) aesthetic appeal and a progressive story create an immersive user experience; (2) achieving individual and collaborative goals fosters player motivation and purpose; and (3) relatedness, variety, and autonomy: fulfilling key psychological needs enhances user engagement. The meanings of these themes and their subthemes are explained below, with illustrative quotes provided in Table 3.

XSL•FO
RenderX

Table . Summary of co-designed guiding principles and illustrative focus group quotes.

Theme and subtheme	Illustrative quotes
Aesthetic appeal and a progressive story create an immersive user experience	
1.1 An interactive journey	• "So, there's a narrative, overarching kind of structure that you have to follow, and the entire story is just the mission." [Ang] • "I like collecting things along the way … or like, just like interacting with objects in a way that doesn't necessarily add anything to your character or development, or anything, but just little interactions that are there." [Erin]
1.2 Whimsical worlds have broad appeal	• "There are a lot of like popular games that take a lot of elements of the real world, but then they adapt it into like their own art style, I guess, like aesthetic. It's just, very NICE to look at. And yeah, I guess the animations and the storyline, it's just very relaxing." [Georgie] • "I guess, I just find them very happy and appealing to look at … whimsical, is kind of the word that comes to mind.…. I guess it's a bit childish, but it's like happy childhood. It's sort of like happy childhood memories. Yeah, it's got that whimsical nature to it, but it still blends in a bit of reality." [Fiona] • "I think when I'm playing games, quite often, I would be doing it to kind of get out of the real world. I think a lot of people who just use games as like a form of escapism." [Chloe]
Achieving individual and collaborative goals fosters player motivation and purpose	
2.1 Growing and "leveling up"	• "I really like being able to level up and acquire certain skills." [Erin] • "With the experience, then you sort of level-up… you can purchase items that help you … or certain sorts of clothing, hairstyle, something like that." [Ang]
2.2 A prosocial purpose	• "For me, that's a quest … you find the person or the clues to save humanity." [Bethany] • "Oh yeah! Rescuing the towns people! That would be so cute!" [Fiona] • "I was thinking of growing something, potentially." [Dylan] • "Yeah, whether it's a garden or a forest. Just … more plant life, the better you do." [Dylan] • "I feel like it's all in a game. You know that this is virtual. It's not real to me. I think others probably feel differently though." [Ang]
2.3 Positive insight	• "I was thinking perhaps keeping it more towards, say, benefit versus less benefit as opposed to danger versus no danger." [Dylan] • "I like that it's not catastrophic, you know? You don't lose entirely." [Ang] • "Interpretation is more helpful. A leader board is a terrible idea." [Bethany] • "Because it just has that social comparison aspect." [Erin] • "Yeah, even though I'm trying, everyone else is doing so much better than I am." [Bethany]
Relatedness, variety, and autonomy: fulfilling key psychological needs enhances user engagement	
3.1 Batman needs his Alfred	• "You're Batman, and you need your Alfred." [Bethany] • "I think belonging to a group does enhance a game, whether it's a community or a gang or whatever. It creates more responsibility. And I really like to be able to get to know the people in your community or team, or whatever, and them all having their own little personalities and stories." [Erin] • "A diverse set of characters is more engaging, and each of the interactions adding to the storyline, adding details to this world. I feel that would make it more engaging." [Georgie]

XSL•FO
RenderX

Theme and subtheme	Illustrative quotes
3.2 Variety is the spice of game-life	• "I think, depending on how often in the game this is going to occur, [it's important] for it to not be the same every time …. I think I'd get a bit annoyed." [Erin] • "I like games with time limits …" [Chloe] • "Whoa, so stressful!" [Ang] • "Yes but keeps it really interesting." [Chloe] • "Where it's not too difficult where it's frustrating, but it's not too straightforward." [Georgie]
3.3 Choose your own adventure	• "I was thinking of a Harry Potter game I used to play when I was a kid, and you could, choose different wands. And that would give you different abilities." [Chloe] • "Yeah, Like different characters, different paths? Yeah. It's like the first game that I ever played was Pokémon. You choose the different sort of Pokémon, right? And then based on the different type, you have different abilities and so on." [Ang] • "I like changing the environment … in terms of customisation." [Bethany]
3.4 No trigger warnings needed	• "The main thing that I was thinking about was in some games you just get a little bit too much freedom with customizing your character. Most of the time people just end up creating, I guess what they wish they looked like. But then it just gets a bit triggering or problematic once you get to adjust heights or body shape and size and stuff. So, yeah, I feel too much customization of characters in games would be triggering." [Georgie] • "I think diversity in size, shape, all that - that's a big one. Size and shape in video games, there's not much diversity. So, I think that's really important." [Erin] • "I think there's going to be a lot less issues around inclusivity and stuff if you're just playing from behind the camera." [Erin] • "I think, if you're the one looking in, you've got less issues, with things like gender representation. If you're representing other people or characters, they need to be diverse." [Bethany]

Theme 1: Aesthetic Appeal and a Progressive Story Create an Immersive User Experience

Subtheme 1.1: An Interactive Journey

Participants described a preference for first-person game-play and a sense of advancement and forward momentum within a cohesive narrative structure. For example, the playing character would proceed through a journey or quest across a series of tasks, completing these as missions toward their overall goal. Participants also agreed that the playing experience would be improved by exploring varied environments as they progressed through the story.

Subtheme 1.2: Whimsical Worlds Have Broad Appeal

Participants described wanting the games to have an appealing art style, with characters and environments that are cartoonish, simple, and colorful, and a playing experience that is gentle and accessible. They consistently drew on examples such as Nintendo's *Super Mario* and *Animal Crossing*, and there was consensus that these features appeal to "gamers" and "nongamers" alike. Participants described a sense of escapism in these whimsical worlds as a key attraction to gaming. They also described the enjoyment of completing relatively simple or familiar tasks that have been rendered funny, quirky, surprising, or novel by the whimsical and cartoonish environment, or by the abilities (or lack thereof) of their playing character.

Theme 2: Achieving Individual and Collaborative Goals Fosters Player Motivation and Purpose

Subtheme 2.1: Growing and Leveling Up

Participants discussed the most meaningful goals and rewards to be gaining knowledge, skills, and expertise. These gains might contribute directly to the overall game goal, achieve personal growth, or be used to augment the character or their environment.

Subtheme 2.2: A Prosocial Purpose

Participants resonated with having an overall objective that helped others, although one participant felt this was less important. Participants agreed, however, that rewards should be nonmonetary, and that in-game "currency" should be instrumental to achieving their prosocial goal, rather than "capitalistic." Examples included rescuing townspeople, growing plant life, or taking care of realistic or mythical animals.

Subtheme 2.3: Positive Insight

Participants discussed that leaderboards and comparisons to other players' performance could be motivating; however, consensus was reached that feedback should avoid social comparison. The participants agreed that poor performance

XSL•FO
RenderX

should be "safe," such that no in-game characters would be harmed or imperiled if the player gained relatively little in-game currency or points. As much as possible, outcomes should be neutral or positive and avoid damage or significant losses, and feedback should be normalizing and supportive.

Theme 3: Relatedness, Variety, and Autonomy: Fulfilling Key Psychological Needs Enhances User Engagement

Subtheme 3.1: Batman Needs His Alfred

Participants felt games played within a mental health context should incorporate positive in-game relationships. One example was through a constant supporting presence of a sidekick, or as one participant stated, "*You're Batman, and you need your Alfred.*" In addition, participants felt the playing character could be part of a virtual team or be depicted engaging positively with nonplayable characters (NPCs) from the broader community. This subtheme, therefore, is closely related to pursuing a prosocial purpose.

Subtheme 3.2: Variety Is the Spice of Game Life

It was emphasized that incorporating as much variety as possible within the constraints of the task structure would be key to maintaining player motivation and would prevent the player experience from becoming monotonous. Participants also felt an appropriate level of difficulty and challenge to be important; while too little can be boring, too much becomes stressful and a barrier to engagement.

Subtheme 3.3: Choose Your Own Adventure

Participants requested the ability to make customizations and to interact with or construct the environment around them. These experiences were felt to create richness and immersion in games, as well as providing a sense of autonomy that fosters active engagement.

Subtheme 3.4: No Trigger-Warnings Needed

To maintain psychological safety, the participants agreed on the importance of avoiding the ability to customize or alter human forms and of diversity in the depiction of human and human-like characters. Avoiding stimuli or gameplay relating to food and eating, body image, alcohol, drugs or gambling, violence or crime, and gendered, racial, or cultural stereotypes was also discussed as critical for individuals who share their lived and living experiences.

In addition to the themes described above, the focus groups generated many specific ideas for each of the component games, which were summarized and communicated to the game developers (section S4 in Multimedia Appendix 1). Importantly, the focus group participants also evaluated their ideation and design phase experience positively (section S4.2 in Multimedia Appendix 1).

Production Phase Results

To achieve the co-designed themes while maintaining the validated structure of the original CIS, our game development partner produced the CIS *Papillon Park* with 3 component mini-games featuring a cohesive community garden theme. Cognitive Impulsivity is assessed as users proceed through *Horticulture Hero* (attentional control), *Fauna Finder* (reflection), and *Verdant Venture* (feedback monitoring or shifting), which can be presented in set or randomized order. Each game occurs within a unique garden environment and begins with a brief practice mode before the scored blocks (Figure 3).

Figure 3. Introductory screens for *CIS Papillon Park* component mini-games: Horticulture Hero (attentional control), Fauna Finder (reflection), and Verdant Venture (feedback monitoring/shifting).

The figure depicts 3 colorful cartoon images of a greenhouse workbench, each overlaid with 3 images from the mini-games, explaining their goals and response keys.

Users are led through the games by 2 virtual helpers—"Grandma Pixie" and "Winston" (Figure 4), and interact with diverse NPCs who reinforce their progress and the positive impact it has on the community. At the conclusion of each mini-game, users receive their total points and are offered a choice between 2 rewards to decorate the community garden. Their progress is visually depicted with their chosen reward and new growth.

The figure depicts an Australian ringtail possum wearing glasses and a yellow bow tie seated on a stool, alongside an older adult woman dressed in pink and leaning on a wooden walking stick. These virtual helpers provide instruction, performance feedback, and companionship to the user throughout *CIS Papillon Park*.

Evaluation Phase Results

Qualitative Outcomes

Qualitative evaluations were consistent with the 3 superordinate themes and subthemes that participants described during phase 1. The meanings of participant evaluations are described below, with illustrative quotations provided in Table 4.

XSL•FO
RenderX

Table . Summary of thematic evaluations and illustrative quotes.

Theme and subtheme	Illustrative quotes
Aesthetic appeal and a progressive story create an immersive user experience	
1.1 An interactive journey	• "Overall, I quite liked the flow of the storyline and the characters that I interacted with…. It's a very well-developed experience." [Liza] • "I like that it's got a little ongoing story to kind of …. I feel like it like with that, and mixing things up, it kind of adds to that gamified element by like giving you something to work towards." [Jay]
1.2 Whimsical worlds have broad appeal	• "I found the graphics and background music/side effects of the game to be very calming and immersive." [Lily] • "I like the way that this is designed. I've done similar things to this before, where, um, I guess they're assessing a similar sort of thing where it's hit the space bar when a particular number comes up on screen. But I think the way that this is … visually it's a lot more ... interesting, which is nice. It's got nice bright colors, which makes it a little bit more fun to look at, versus your kind of black and white numbers on a screen." [Jay]
Achieving individual and collaborative goals fosters player motivation and purpose	
2.1 Growing and "leveling up"	• "You probably get a little better at this game as it goes on … as you get more familiar with it." [Tom] • "The 'practice' rounds of each game helped allay any anxiety I had about learning how to play the game and I found them all quite easy to pick up quickly." [Olivia] • "I would say that overall, it's an interestingly positive experience, because, firstly, it's not a steep learning curve. Not at all. I like and how simple it is, and how easy it is to pick up." [Ang] • "It did make me disheartened to not be able to figure out the pattern for this game and made me question whether I wasn't smart enough." [Millie]
2.2 A prosocial purpose	• "[The NPC's] were great. I think they were all very likable." [Jess] • "Maybe more people will come and visit and bring me [Winston] presents … I want that!" [Grace] • "I'm wondering if these random visitors are gonna come back into the game, - if they like if they play a role, or if they are just … there." [Erin] • "Grandmother's a bit patronizing, isn't she?" [Bethany]
2.3 Positive insight	• "The sound effects when I got answers right/wrong were very cute … and I felt a tinge of sadness when getting an answer wrong, but I didn't inherently feel upset for the rest of the game." [Liza] • "I wouldn't say it's easy not to beat yourself up about it …. but I like how low stakes this is." [Ang] • "I was left wondering how I had performed versus other people playing the game in this study." [Liza]
Relatedness, variety, and autonomy: fulfilling key psychological needs enhances user engagement	
3.1 Batman needs his Alfred	• "I think the art is a really good motivator because you get to see little Winston and Grandma Pixie … Who doesn't like a happy Winston?" [Alex] • "I like his happy sound … if you're happy, I'm happy." [Grace] • "That's three 200's in a row, Winston. I hope you're happy, little buddy." [Ang] • "I'm gonna end up in the negatives. Sorry, Winston." [Lily]

XSL•FO
RenderX

Theme and subtheme	Illustrative quotes
3.2 Variety is the spice of game-life	• "The [horticulture hero] game was interesting and I liked that the plants changed each round." [Liza] • "It's nice to see the variety of points change this time" [Alex] • "I enjoyed the blurry animal guess game most - it wasn't the same choices repeated and it got you to engage cognitively with time urgency." [Millie] • "I feel like the whole design of this game is just to test my patience!" [Jess] • "[There were] too many rounds to make it to the next stage. It became quite tedious, boring and irritating." [Jo] • "If I was playing this game under normal circumstances, like at home, I might just turn it off, because it's really long." [Chloe]
3.3 Choose your own adventure	• "Oooh, there's a bird or a mushroom … I want the bird. (Gasps). It's a bird fountain! Oh my gosh that's so cool. OK, yes, I agree, wonderful choice, I know!" [Grace] • "That's cute … I like how you can customize it." [Erin] • "In the blurry game [Fauna Finder] … I felt I could actually engage and make a difference rather than something allocated/randomized." [Lexi] • "The first game was confusing as it was not clear what made each plant a successful choice [and why there wasn't 100 points, but only − 100, 50 and 200] and made me think the success was randomized like a gambling game rather than anything indicative of your own performance and choices." [Alex]
3.4 No trigger warnings needed	• "I really like the characters around here, because I can see that a lot of thought's gone into their design.... Very interesting gender-neutral choice." [Ang] • "It was nice that there was like a diverse range of different people that came in." [Fiona] • "The choice of animals - since you've got such realistic pictures - gorgeous for animal lovers, and they're not generally one's people get too icked out about - possibly the mice, but, like, if you were showing pictures of snakes, I wouldn't be able to play." [Bethany] • "I wonder what would happen to somebody who had a phobia of frogs." [Ang]

Theme 1: Aesthetic Appeal and a Progressive Story Create an Immersive User Experience

Subtheme 1.1: Interactive Journey

Perspectives concerning the game story, context, and environment were consistently positive. Participants enjoyed the overall story and community garden theme, and that each game took place within a different environment to provide variety and achieve the desired sense of progression.

Subtheme 1.2: Whimsical Worlds

All participants praised the art style and felt the visual and sound designs enhanced their playing experience. Participants described the designs as appealing, calm, and soothing, and as effectively "drawing players in." They felt these designs were key to maintaining their motivation and drew positive comparisons to standard cognitive assessments they had experienced.

Theme 2: Achieving Individual and Collaborative Goals Fosters Player Motivation and Purpose

Subtheme 2.1: Growing and "Leveling Up"

Participants described feeling that they were able to learn and improve their skills in positive terms. However, the degree to which participants endorsed this feeling varied across the 3 mini-games; the most positive statements related to Fauna Finder, which participants felt was more skill-based, and the more negative statements related to Verdant Venture, which participants tended to find frustrating.

Subtheme 2.2: A Prosocial Purpose

The community NPCs were found to be likable and appealing, and participants enjoyed seeing their achievements benefit Winston, their virtual companion. However, while some participants enjoyed interacting with the NPCs and learning that their performance was benefiting the community, others did not connect with this intended feature or found the NPC interactions to be protracted. Grandma Pixie's communication style also inspired some more polarized responses.

XSL•FO
RenderX

Subtheme 2.3: Positive Insight

Participants felt the game created a gentle, low-stakes environment that still engaged them emotionally and cognitively—enough to care about their performance, but not enough to feel stressed—and felt their interactions with Winston effectively supported this. Participants provided more mixed feedback relating to the lack of context for point totals; some participants wanted to understand their performance in comparison to other players or the maximum available, while others appreciated that this was not a feature.

Theme 3: Relatedness, Variety, and Autonomy: Fulfilling Key Psychological Needs Enhances User Engagement

Subtheme 3.1: Batman Needs His Alfred

All participants responded positively to Winston's companionship. Participants commented that they were motivated to perform on behalf of Winston, engaging emotionally with his audio and visual performance feedback.

Subtheme 3.2: Variety Is the Spice of Game-Life

Participants reported high enjoyment, engagement, and motivation when stimuli, responses, and rewards were varied, and when they felt their behavior was consequential. As with *Growing and leveling-up* above, these experiences varied across the mini-games, with participants typically finding Horticulture Hero to be easy but boring, Fauna Finder to be the most purposeful and engaging, and Verdant Venture to be the most difficult, random, and confusing. Moreover, 2 participants felt the game was overall too long.

Subtheme 3.3: Choose Your Own Adventure

Although opportunities for customization were limited, the ability to select from available rewards and to see those rewards depicted as garden decorations was appreciated and enhanced player engagement and fulfillment.

Subtheme 3.4: No Trigger Warnings Needed

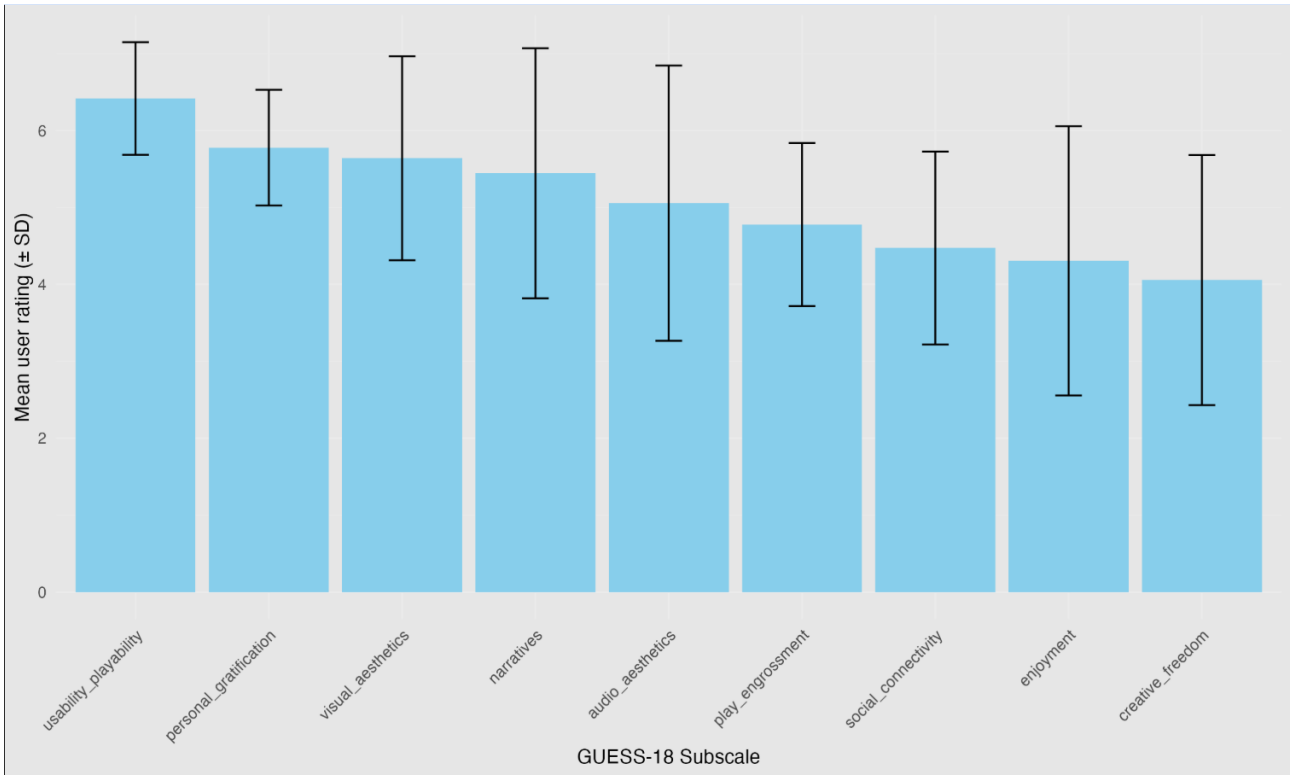
Finally, participants praised the diverse character depictions and "wholesome" gameplay features. They felt the production phase had been attentive to inclusivity and emotional safety, while also highlighting the need to consider individual sensitivities to the animals depicted in *Fauna Finder*.

Quantitative Outcomes

Evaluations of the games were overall positive, with a mean GUESS-18 composite score of 45.9 (SD=9.85; 72.9%, 57.3 - 88.5), and subscale scores ranging from 4.1 (neutral) for "Creative Freedom" to 6.4 (agree-to-strongly agree) for "Usability or Playability" (Table 5; Figure 5). There were no significant differences in mean composite or subscale scores between the groups of participants who were involved in the ideation and design phase, those who completed the "thinking aloud" evaluation over Zoom, and those who evaluated the games independently (Table 5).

Table . Game User Experience Satisfaction Scale, short version user satisfaction survey results.

Measure	All (n=18), mean (SD)	Designers (n=5), mean (SD)	Zoom (n=6), mean (SD)	Own time (n=7), mean (SD)	Group differences (ANOVA)[a]	
					F test (*df*)	*P* value
Composite score[b]	45.9 (9.85)	47.4 (4.98)	42.4 (10.38)	47.9 (12.25)	0.55 (2, 15)	.59
Subscale scores[c]						
Usability or playability	6.4 (0.73)	6.7 (0.27)	6.3 (0.76)	6.4 (0.94)	0.52 (2, 15)	.60
Personal gratification	5.8 (0.75)	5.8 (0.76)	5.7 (0.88)	5.9 (0.75)	0.10 (2, 15)	.91
Visual aesthetics	5.6 (1.33)	5.8 (0.57)	5.3 (1.40)	5.8 (1.73)	0.22 (2, 15)	.81
Narratives	5.4 (1.63)	6.1 (0.82)	5.1 (1.77)	5.3 (1.98)	0.56 (2, 15)	.58
Audio aesthetics	5.1 (1.79)	5.5 (1.70)	4.9 (1.69)	4.9 (2.14)	0.19 (2, 15)	.82
Play engrossment	4.8 (1.06)	5.0 (0.35)	4.3 (1.21)	5.1 (1.21)	1.14 (2, 15)	.35
Social connectivity	4.5 (1.25)	4.6 (0.96)	3.9 (1.46)	4.9 (1.25)	0.94 (2, 15)	.41
Enjoyment	4.3 (1.75)	4.2 (0.76)	3.3 (1.72)	5.3 (1.89)	2.62 (2, 15)	.11
Creative freedom	4.1 (1.63)	3.7 (1.44)	3.8 (1.29)	4.6 (2.05)	0.55 (2, 15)	.59



[a]Achieved power for 1-way omnibus ANOVA tests was calculated as 0.74 using G*Power 3.1 (α=.05, sample n=18, 3 groups, and average effect size of *F*=0.76).

[b]Composite scores range 9 - 63 with neutral midpoint 27.

[c]Subscale scores range 1 - 7 with neutral midpoint 4; higher scores indicate greater user satisfaction.

XSL•FO
RenderX

Figure 5. Game User Experience Satisfaction Scale, short version subscale ratings.

The figure presents a bar graph depicting GUESS-18 subscale ratings for the full evaluation sample (n=18). Bars indicate mean ratings for each subscale, and error bars indicate the SD, arranged from the subscale with the highest user satisfaction (usability or playability) to the lowest (creative freedom).

Ratings for the additional questionnaire items concerning *No Trigger Warnings Needed* produced an overall mean score of 5.72 (SD 1.22). Ratings differed significantly by group ($F_{2,15}$=7.64; P<.01) with significantly higher ratings in the 2 groups providing "thinking aloud" feedback than in the group playing in their own time (scoring and ANOVA outcomes for these items are provided in Table S3.4 in Multimedia Appendix 1).

Integration

Qualitative and quantitative evidence converged to allow us to understand which design features and gamification elements were most effective in facilitating long-term user motivation and engagement. Specifically, both qualitative and quantitative data demonstrated that the "wholesome" environment, cohesive and progressive story, attractive visuals, and appealing audio created a positive emotional user experience, which in turn facilitated immersion and enjoyment.

Qualitative evaluations also complemented quantitative data by allowing users to explain *why* particular subscales were rated higher or lower. For example, the inclusion of virtual helpers, practice rounds, retries, a progress bar, a timer or speed element, and visual depiction of achievements were key to user motivation and underpinned the high levels of usability or playability and personal gratification. Similarly, qualitative feedback explained that perceiving the themes defined during co-design concerning desires for autonomy (*choose your own adventure*) and variety (*variety is the spice of game life*) to be lacking resulted in the lowest GUESS ratings for the "enjoyment" and "creative freedom" subscales. Importantly, qualitative feedback showed users perceived the 3 mini-games that form the CIS *Papillon Park* to vary according to these characteristics, as well as their perceived level of difficulty, such that user motivation and engagement varied significantly between each mini-game. This variability had not been captured in the quantitative user satisfaction ratings.

Qualitative and quantitative evaluations diverged in relation to the GUESS-18 ratings for social connectivity and the overwhelmingly positive appraisals of Winston. Further analysis indicated that lower ratings for social connectivity were associated with qualitative feedback that NPC interactions, and the game overall, were too long.

Discussion

We aimed to redesign and evaluate the CIS, a validated gamified assessment battery of cognitive impulsivity, through a sequential mixed methods approach to user-centered co-design, agile game development, and user-centered evaluation [3,89,106]. We first defined LE user requirements, generating themes and subthemes that described overall guiding principles, and producing specific design ideas. The agile game development process resulted in a functioning suite of gamified assessments, the CIS *Papillon Park*, being deployed to secure Monash University servers. During LE evaluation, our qualitative analysis confirmed that the new tool largely met the co-designed user requirements. Quantitative ratings aligned closely, showing the CIS *Papillon Park* achieved strong overall user satisfaction according to the GUESS-18 composite scale, with strengths in usability, narrative, visual and audio aesthetics, and personal gratification.

XSL•FO
RenderX

Escapism into attractive virtual worlds featuring cohesive narrative storytelling and accessible gameplay, and a sense of personal growth and achievement, were identified as critical themes and key strengths of the gamified assessment tool produced in this study. Aesthetic and narrative characteristics are well-known to increase immersion and pleasure in gaming [144,145]. Furthermore, the gamification mechanisms we incorporated to foster personal accomplishment, including tasks with clear goals and rounds, points and performance feedback, in-game rewards, and visible depiction of achievements, are some of the most commonly used [59,65]. These characteristics were the most strongly endorsed in the qualitative and quantitative evaluations, confirming the new games to be broadly appealing and fulfilling, and reinforcing previous research demonstrating the value of aesthetics and gamification to user engagement and satisfaction with cognitive assessments [63,64,146]. These principles also align closely with the theoretical grounding of gamification [56,57,61], tapping into cognitive and emotional mechanisms to generate intrinsic motivation to engage with CIS *Papillon Park* [58,59]. In the context of cognitive assessments, engagement and intrinsic motivation serve critical instrumental purposes, encouraging uptake and continued, authentic effort, and thus valid assessment outcomes [45,46,62,66].

We also incorporated gamification elements that expand on those most used in mental health interventions, for example, the presence of virtual helpers [65]. Winston, Grandma Pixie, and the community NPCs reflected key ways in which our participants characterized mental health and positive functioning, including affirming interpersonal relationships and the pursuit of prosocial goals. Difficulties in these areas are well-documented features of EDs [147-152]. For example, socializing problems, social isolation, and loneliness have been shown to have a detrimental, bidirectional relationship with ED symptoms [152,153], while social connectedness may protect against ED onset and facilitate recovery [154-156]. As such, re-engaging with interpersonal relationships and meaningful life pursuits form common targets of harm reduction models of care and psychosocial recovery support for individuals living with EDs [157,158]. Within a gaming context, social interaction and collaboration toward mutual, prosocial goals are recognized as key not only to player engagement but also to realizing psychological benefits from gaming [58,59,66,159,160]. While real-time, multiplayer cooperation cannot readily be recreated within the context of cognitive assessment, evaluations suggested we had been successful in modeling meaningful collaboration and prosociality through reinforcing interactions with an endearing “side-kick,” although somewhat less successful in achieving this goal through interactions with members of a broader virtual community [161,162].

A key insight that emerged from the integration of qualitative and quantitative evaluation was the variability in user satisfaction between the 3 mini-games that form the CIS *Papillon Park* [143]. In total, 3 key elements distinguished user satisfaction—perceived autonomy and self-determination, variety, and level of difficulty. Our synthesized evaluation showed that gamification elements, including practice rounds, retries, a progress bar, and timer or speed, were key to achieving a level of difficulty that maximized user satisfaction [59,73]. Perceived lack of variety, autonomy, and creativity received lower quantitative ratings and inconsistent qualitative evaluations. These findings aligned closely with a previous study, where enjoyment helped people keep playing and maintained performance in easy games, while motivation facilitated performance and enjoyment in difficult games [163]. These findings reflect the inherent conflict between the repetition and standardization needed to achieve valid and reliable data in cognitive assessments, and user goals such as novelty and self-directed exploration that make games fun and engrossing, highlighting the difficulty of balancing the constraints of structured assessments with engaging game elements [62,63]. They also indicate that combining multiple gamification strategies, whereby elements enhance or compensate for one another, may be important in determining long-term user engagement [52,164].

User-centered co-design approaches are now commonly used to design mental health services and interventions leveraging web, mobile, and artificial intelligence technologies [48,74,78,99,100,165]. Less commonly, these approaches can be used to design and evaluate valid and reliable psychological assessment measures [42,88]. In developing the CIS *Papillon Park*, we took on board growing impetus to meaningfully incorporate LE perspectives throughout the research process [95,129]. Respectfully collaborating with individuals with lived and living experience in both design and evaluation is therefore a key strength of this study, underpinning its novel contribution to the field. Through evaluation, we were able to confirm user design priorities had been faithfully represented at all stages of the research process and were present in the final product [111,166]. Importantly, in addition to defining what to include in the new product, the co-designed guiding principles defined what *not* to include. It is important to note that some gamification elements might be harmful to certain populations, as exemplified by discussions concerning a leaderboard in this study [59]. Gamification is inherently experiential and subjective [54]; therefore, gamification and user-centered design work most effectively together, such that users define which gamification elements will be most safe and meaningful for them [167]. By following up on user-centered co-design with LE evaluations, we confirmed CIS *Papillon Park* maintained psychological safety for individuals with LEs of EDs and mental ill-health [168].

In terms of limitations, our co-design framework and qualitative methodologies meant we collaborated with relatively small groups of participants, and our quantitative evaluation analysis was somewhat underpowered. However, we nonetheless aimed that they would be representative of the target populations for the resulting assessment tool. We were therefore pleased to engage with groups that comprised varied current and historical experiences with disordered eating, that represented a broad range of experiences of commonly co-occurring mental ill-health, and that encompassed diverse identities and personal characteristics. These sentiments were shared by our participants, who endorsed the co-design groups and research processes as positive experiences, emphasizing their inclusivity [129,130]. This project was undertaken in Australia with

XSL•FO
RenderX

participants of White European, White North American, and Asian ancestry; thus, its findings may be less relevant in other cultures. Our methodology incorporated various forms of expertise to achieve a practical goal of reimagining an existing cognitive assessment tool [101,104,116,169]. As such, we incorporate key principles of qualitative research but depart from certain canonical aspects of "Big Q" approaches [115,122]. Further methodological limitations include the challenges of integrating user-centered co-design and agile development in a resource-limited context [89,92,105,106]. In terms of the quantitative results, our ANOVA analyses were slightly underpowered, such that there is an elevated risk that we failed to detect differences in user satisfaction between groups.

Ultimately, this project intends to enhance the impact and reach of the CIS by facilitating its potential for clinical translation and adoption by end users [170]. Validated tools with streamlined administration and analysis pipelines that are well-accepted by users are urgently needed to support current moves toward transdiagnostic, dimensional, and individualized care, and address the significant treatment gap for individuals living with EDs and mental ill-health [171-174]. Importantly, such individuals who are experiencing cognitive challenges as part of their symptom profile are eager for these issues to be addressed in treatment, yet feel these needs are rarely met [35,175,176], experiences that were highlighted in our focus group discussions. Including objective assessment of cognitive impulsivity in a clinical context may thus allow practitioners to identify individuals who would most benefit from targeted cognitive interventions or augmented treatments, and to achieve data-driven personalization of treatment approaches [177-179]. Next steps will therefore involve a detailed psychometric evaluation of the CIS "Papillon Park," confirming it maintains the properties of the CIS "Choices in the Wild West," before dissemination. Additional qualitative research is also planned, engaging clinicians and LE participants as key stakeholders to co-design feedback reports and implementation strategies.

The unique contributions of this study include effectively blending user-centered co-design, agile game development, and theory-based cognitive assessment and gamification to reimagine a validated assessment tool. By following up on LE co-design with qualitative and quantitative evaluations, we identified a combination of aesthetics, gamification elements, and accessible playing experiences that maximized user satisfaction, engagement, and motivation while prioritizing psychological safety. This underscores the importance of gamified assessments in the mental health field providing opportunities for users to experience satisfaction of psychological needs, including autonomy, personal achievement, and social support. By effectively engaging users, CIS *Papillon Park* therefore holds promise to facilitate valid and reliable assessment of cognitive impulsivity in individuals experiencing EDs and common co-occurring mental health symptoms. Incorporating well-accepted objective cognitive assessment tools in routine clinical care is needed to support the individualization and prioritization of interventions, and thus support treatment engagement and recovery for these underserved conditions.

Acknowledgments

The authors declare that no generative artificial intelligence tools were used during the conduct of this research, nor in the preparation of this manuscript.

The authors wish to thank Noble Steed Games for their expertise and creativity in producing Cognitive Impulsivity Suite "Papillon Park" and acknowledge Torus Games for the original Cognitive Impulsivity Suite "Choices in the Wild West," and for their contributions to the focus group co-design process. EC thanks Assistant Prof Trevor Chong and Dr Justin Mahlberg for their guidance and support, and Kayla Flannagan for her assistance with participant recruitment. Finally, we extend our gratitude to the participants of this study for generously sharing their time and perspectives.

Funding

EC is supported by an Australian Research Training Program scholarship and by a TranslatED scholarship from the Australia Eating Disorders Research and Translation Centre funded by the Commonwealth Department of Health under the National Leadership in Mental Health Program. AVG is funded by an Australian National Health and Medical Research Council Investigators (grant 2009464), and the Australia Eating Disorders Research and Translation Centre funded by the Commonwealth Department of Health.

Abstract

Background: Music education is central to holistic child development; yet, traditional piano instruction in China often emphasizes rote memorization at the expense of meaningful understanding. Elementary school pupils, particularly novices, frequently struggle with rhythm, melody, and music theory. Game-based learning (GBL), which applies game elements to teaching, may address these challenges by enhancing engagement, providing immediate feedback, and fostering long-term learning.

Objective: This study aimed to examine the effects of a GBL module for piano education on elementary school pupils' music knowledge in Anhui Province, China, compared to traditional instruction.

Methods: A quasi-experimental, nonequivalent control group pretest-posttest design was used. Participants were allocated nonrandomly to experimental and control groups based on scheduling feasibility and teacher availability. A total of 60 novice piano learners (mean age 8.8 years, SD 1.16 years; 16 boys and 44 girls) from 3 elementary schools were assigned to either the GBL group (n=30) or the control group (n=30). Music knowledge was measured using the standardized Level 1 Basic Music Written Test before and after an 8-week intervention. Nonparametric analyses were applied, including Mann-Whitney *U*, Wilcoxon signed-rank, and McNemar item-level analyses. Rank-based effect sizes (*r*) and 95% CIs were reported where applicable.

Results: Baseline differences were present, with the control group scoring higher at pretest (median 52, IQR 24-76) than the GBL group (median 28, IQR 16-64; Mann-Whitney U=265.50; r=–0.35; 95% CI –0.39 to –0.32; P=.006). After the intervention, the GBL group significantly outperformed controls (median 100, IQR 88-100 vs median 60, IQR 40-92; Mann-Whitney U=4.0; r=–0.87; 95% CI –0.90 to –0.83; P<.001). Within-group analyses confirmed significant pre-post improvements for both groups (control Z=–3.24; r=–0.59; P=.001; and GBL Z=–4.81; r=–0.88; P<.001). Item-level McNemar tests showed significant improvements (P<.05) in 5 of 25 items for the GBL group. Missing data were negligible (<2%) and handled via listwise deletion after Little's missing completely at random (MCAR) confirmation (P=.08).

Conclusions: The GBL module significantly improved pupils' music knowledge, overcoming baseline disparities and producing posttest score gains with consistent mastery. The innovation of the study lies in the systematic integration of gamification with Orff and Dalcroze pedagogy through the Sidek Module Development Model, which distinguishes it from previous music education studies that examine gamification in isolation. By providing a validated, cost-effective, and scalable instructional module, the study contributes empirical evidence to the field of game-based music education and other practical implications for improving piano instruction in resource-constrained elementary school settings.

KEYWORDS

quality education; gamified learning; piano education; music knowledge; school pupils

Introduction

Music education is a cornerstone of holistic development for elementary school pupils in China, nurturing not only artistic literacy but also cognitive, emotional, and social growth. The piano is highly regarded among musical instruments due to its versatility and extensive skill set. In recent decades, young pupils have taken up piano, a phenomenon known as the "piano heat" [1]. This increase shows a societal commitment to arts education, as piano skills enhance a child's cultural capital and allow for creative self-expression. The setting of this study, Anhui Province, has seen piano education grow along with national trends and demonstrate regional commitment to early artistic development. Despite the excitement for piano learning, it remains difficult to ensure that pupils develop a profound, meaningful understanding of music beyond mechanical proficiency.

Traditional piano teaching methods that emphasize rote memorization and mechanical practice typically fail to interest and comprehend young learners [2,3]. Due to their cognitive and emotional growth, elementary school pupils require pedagogical approaches that match their capacities. Their short attention spans and abstract nature make them struggle to grasp rhythm, melody, and basic music theory [4-6]. The lack of musical knowledge might also prevent pupils from connecting emotionally with the subject, reducing their motivation and interest [7]. These obstacles highlight the need for innovative teaching strategies that improve music knowledge and engagement.

Contemporary research identifies critical shortcomings in traditional piano beginner teaching, including a reliance on single-minded evaluation models, a neglect of process-based instruction, and a teaching focus that often prioritizes technical results over genuine artistic development. A key challenge remains the comprehensive cultivation of musical literacy, which extends far beyond the accurate reproduction of notes and rhythms [8]. To address these pedagogical gaps, game-based learning (GBL) has emerged as a promising intervention. GBL represents a fusion of informal and formal education, leveraging the interactive nature of games to deliver structured content. Scholarly reviews confirm that interactive mechanics of GBL, such as the use of challenges, rewards, and progress tracking, provide learners with a sense of autonomy and competence [9]. Furthermore, well-designed educational games can deepen a pupil's understanding of abstract content, encouraging them to find diverse solutions and train their creative and critical thinking skills. These mechanisms align directly with the goal of developing comprehensive musical literacy that transcends simple rote technique [10].

Gamified learning, which uses game design to boost engagement and learning, is a transformative solution. Reimagining piano exercises as engaging, entertaining experiences makes abstract concepts more approachable and fosters continuous involvement in music instruction [11]. Gamified learning works well in music education with obstacles, rapid feedback, and incentive systems [12]. Gamified learning also fits well with music pedagogy like the Orff and Dalcroze Eurhythmics, which emphasize active participation, rhythm, and movement to meet young learners' developmental needs [13-16].

In Anhui, elementary school pupils' piano music knowledge is still lacking despite research showing the benefits of gamified learning in other educational settings and music contexts. Regional specificity is essential for meaningful research since local teaching practices and resource availability may affect gamified intervention efficacy [17]. Gamified music education literature emphasizes short-term outcomes, like skill acquisition, but lacks data on long-term knowledge retention and conceptual understanding [10]. Few studies have examined how gamified learning can be integrated with traditional piano teaching methods or tailored to individual learner differences.

This study examines how a tailored GBL module affects elementary school pupils' music knowledge in Anhui. Innovative, evidence-based strategies to meet these learners' unique issues are used to promote music instruction. The design of the GBL module was grounded in established pedagogical principles of Orff-Schulwerk and Dalcroze Eurhythmics, which provided the theoretical foundation for integrating movement, rhythm, and embodied cognition into game tasks. These theories collectively informed the development of a multimodal, developmentally appropriate, and musically grounded GBL intervention for elementary pupils.

The findings should make theoretical and practical contributions to the field. The study expanded on Orff and Dalcroze frameworks to better understand how GBL can promote cognitive, emotional, and creative development in piano teaching. It will provide a validated GBL module for educators to enhance teaching, particularly in resource-constrained or outdated curriculum situations. The findings may also inform policymakers about how gamified learning might improve music education and offer a scalable approach. Accordingly, this study aims to examine the effects of a GBL module on piano music knowledge among elementary school pupils in Anhui province, China, and hypothesizes that pupils receiving the GBL intervention demonstrate greater improvements than those receiving traditional instruction.

Methods

Study Design

This study used a quasi-experimental, nonequivalent control group pretest-posttest design to examine the effects of a GBL module for piano education on elementary school pupils' music knowledge in Anhui Province, China. This design allowed comparisons between an intervention group receiving gamified piano instruction and a control group receiving traditional

XSL•FO
RenderX

instruction. The report follows the Transparent Reporting of Evaluations with Nonrandomized Designs (TREND) statement to enhance transparency and reproducibility [18].

Setting

The study was conducted at a private piano training center located in Anhui Province, China. Three elementary schools partnered with the training center to provide access to novice piano learners. Data collection took place between February and April 2025, with 8 consecutive weekly sessions delivered during this period. Teacher workshops to standardize instructional methods were conducted in January 2025 before the intervention.

Participants

A total of 60 elementary school pupils aged 7 to 12 years were recruited through a series of briefing sessions held at the training center and affiliated schools. Eligibility criteria included (1) no previous formal piano training, (2) enrollment in the first year of piano lessons at the training center, and (3) parental consent and child assent for participation. Pupils with known hearing impairments or learning disabilities that could substantially affect music learning were excluded. Participants were systematically assigned to an experimental or a control group using a quasi-random sampling procedure: the first 60 pupils whose parents or guardians signed consent forms were enrolled, and every alternate consenting child was assigned to one of the two groups. This resulted in 30 participants in the gamified learning group and 30 in the control group. The final sample comprised 16 boys and 44 girls, consistent with broader trends in higher female participation in music education. Table 1 summarizes demographic characteristics. Although participants were alternately allocated, the procedure did not constitute true randomization. To minimize allocation bias, baseline demographics and pretest scores were compared across groups to assess equivalence.

Table 1. Demographic characteristics of elementary school pupils participating in a quasi-experimental study of game-based piano learning in Anhui, China.

Demographic variable	Experimental group, n	Control group, n	Total, n
Age (years)			60
7	2	4	6
8	6	17	23
9	7	6	13
10	11	3	14
11	3	0	3
12	1	0	1
Sex			60
Male	11	5	16
Female	19	25	44
Year in school			60
Year 1	3	9	12
Year 2	3	12	15
Year 3	13	9	22
Year 4	7	0	7
Year 5	3	0	3
Year 6	1	0	1

Intervention

The experimental group received an 8-week GBL module for piano education designed using the Sidek Module Development Model (SMDM). The module consisted of eight 45-minute sessions incorporating music games, including the “Central C Knocking Game,” “Rhythm Clapping Game,” and “Music Notation Song Game.” Content followed a progressive trajectory from basic note recognition to more complex rhythm and score interpretation, guided by Orff and Dalcroze pedagogical principles. All lessons were delivered on an individual basis, with hands-on keyboard practice embedded within structured teacher-led activities. Attendance was recorded weekly, and teachers completed session-by-session fidelity checklists to ensure consistent adherence to the intended instructional sequence for both the gamified and traditional teaching conditions.

The control group received traditional piano instruction over the same period. Both groups were taught by the same 5 piano teachers, who attended a 3-day workshop to ensure standardized delivery of both instructional methods. Teachers applied gamified methods for the intervention group and conventional techniques for the control group. Neither participants nor teachers were blinded due to the nature of the educational intervention; however, outcome assessors scoring the written test were blinded to group allocation.

GBL Module Development

Overview

The SMDM, proposed by Sidek and Jamaludin [19], emphasizes systemic structure and the operational feasibility of instructional activities, making it particularly suitable for developing educational modules. In the context of a GBL module for piano education for elementary school pupils, the SMDM iterative and user-centered approach aligns seamlessly with GBL principles, fostering an engaging and effective learning experience tailored to young learners' needs. The structured yet flexible model of SMDM supports the creation of a GBL module for piano education by prioritizing user engagement and iterative refinement. The SMDM was used to create the GBL module to enhance elementary school pupils' piano music knowledge in Anhui [20]. The SMDM is a user-centered instructional design framework that emphasizes comprehensive needs analysis and iterative feedback to create effective multimedia learning tools. The model prioritizes user involvement and adaptability, which are essential for addressing the dynamic challenges in piano education, such as motivation, posture, and skill progression. While the original SMDM framework consists of 2 main stages, the study adapted it into 5 phases (design, development, assembly, validation, and evaluation) to provide a more granular and systematic approach tailored to the development of a GBL module for piano education. This expansion was necessary to accommodate the complexities of integrating technology, gamification, and pedagogical scaffolding in piano learning for elementary school pupils. The needs analysis stage was refined into the design phase for thorough user requirement gathering, while the multimedia development stage was subdivided into development, assembly, and validation phases to ensure iterative refinement and quality assurance. The evaluation phase was added as a distinct step to assess the effectiveness of the module after its implementation, aligning with empirical validation of SMDM. This 5-phase adaptation mirrors the scaffolding process in one-to-one piano lessons, where instruction progresses systematically from foundational to advanced skills, and supports targeted interventions. This systematic approach made the module pedagogically robust, engaging, and customized to young learners. Design, development, assembly, validation, and evaluation built on each other to create a cohesive educational tool.

Design Phase

The main goal of the module was to develop a dynamic GBL approach that elevates piano music knowledge for 7- to 12-year-olds. The aim was to craft a challenging but fun learning experience that deepened musical understanding. A game-based piano learning experience for elementary school pupils should be engaging and appealing [21]. The module emphasizes engaging experiences, clear goals, immediate feedback, diverse gaming techniques, and adaptive difficulty levels. Games that reinforce piano music knowledge use these principles. A comprehensive needs analysis identified learning challenges and ensured the module addressed them through targeted gamification. The 4Keys2Fun framework [22] was used to keep pupils engaged by incorporating social interaction, challenge, exploration, and purposeful learning to improve musical knowledge retention.

Development Phase

Content and instructional strategies were carefully selected during development to support a progressive learning trajectory. Music was used to teach specific knowledge outcomes, starting with note recognition and rhythm in "Please Play" and advancing to complex structures in "Church Organ" and "Yankee Doodle." Teacher demonstration, GBL, guided practice, rhythmic chanting, and formative feedback were used to teach piano. "Rhythm Clapping Game" (pupils competed to replicate rhythmic patterns in pairs, turning practice into a lively and collaborative challenge that reinforced knowledge while fostering peer learning), "Musical Notation Song Game," and "Central C Knocking Game" were embedded to improve rhythm, note positions, and key identification. A piano and copies of John Thomson's Easiest Piano Course 1 were needed for 45-minute sessions, ensuring the module is accessible. The teacher demonstrated real-time modeling to explain music.

Assembly and Draft Completion

A backward design model prioritized piano music knowledge outcomes before aligning assessments, content, and activities [23]. This concentrated and unified the framework. A total of 8 successive lessons with objectives, assessment tools, and resources guided pupils from basic note recognition to sophisticated musical interpretation in the final edition. This systematic assembly ensured that every part improved musical comprehension.

Validation and Pilot Testing

Validation was essential for module reliability and suitability. Three music pedagogy specialists critically assessed its content and design, followed by semistructured interviews with 2 piano teachers. Their suggestions improved content alignment and game dynamics. After expert approval, a pilot test with 17 students over 8 weeks (November 19, 2024, to January 14, 2025) provided practical input and revisions to ensure the readiness of the module for broader use. The 17 participants were novice learners aged 7 to 11 (mean age 8.8, SD 1.16) years, with 11 girls and 6 boys, mostly in Year 2 and Year 3 of elementary school.

Piano Education GBL Module

This basic school package has 8 lessons that establish musical principles through individual works. It uses games like "Central C Knocking Game," "Five-Line Speech Practice," and "Right-Hand Shooting Game" (students aimed to strike correct notes under time pressure, and their excitement translated into improved recognition and accuracy) to enhance learning. The curriculum systematically teaches piano key identification, note values, rests, and specific notes (C, D, B, E, A, G, and F). It emphasizes practical exercises to improve finger independence, rhythmic precision, and technical fluency on the piano. It also promotes curiosity, self-confidence, and music appreciation through interactive games and collaborative activities. Rhythm accuracy, hand coordination, and note and rest recognition are used to assess student progress, ensuring evidence-based musical progression. This structured technique improves musical

XSL•FO
RenderX

proficiency and makes learning fun, supporting game-based music education.

Assessments and Outcomes

The primary outcome was music knowledge, assessed using the Level 1 Basic Music Written Test developed by the Chinese Music Academy. This 25-item multiple-choice test evaluates aural recognition (tones, melodic contours, dynamics, tempo, and rhythmic structures) and theoretical knowledge (pitch, solfège, intervals, meter, and musical symbols). The test was administered at baseline (pretest) and at the end of the intervention (posttest). Exposures included the gamified learning intervention, while potential confounders such as age, grade level, and baseline knowledge were recorded.

Study Size

The study included 60 participants (30 per group). The sample size was determined pragmatically based on the capacity of the training center and the number of eligible consenting pupils during the recruitment window. Although no formal power calculation was conducted, a sample of 30 per group has been shown in previous quasi-experimental studies to detect medium-to-large effects in educational outcomes.

Recruitment Procedures

Recruitment was conducted in collaboration with school administrators and the piano training center. Parents and guardians were provided with written study information, and informed consent was obtained prior to enrollment. Children also provided verbal assent. Recruitment was based on voluntary self-selection following briefing sessions conducted at the partner schools and training center. All eligible pupils whose parents provided consent during the 2-week recruitment window were included, and no incentives were offered.

A total of 86 pupils were screened for eligibility; 60 met the inclusion criteria and consented to participate. All 60 pupils were allocated to one of the two study conditions (30 experimental and 30 control). All participants received the assigned intervention, completed the 8 sessions, and completed both pretest and posttest assessments. No participants were lost to follow-up, and no protocol deviations occurred.

Data Analysis

All analyses were conducted using SPSS (version 29.0; IBM Corp). The normality of the pretest was assessed using the Shapiro-Wilk test, which indicated nonnormal distributions; hence, nonparametric statistical tests were chosen. Mann-Whitney *U* tests were carried out to compare the control and experimental groups in every pretest and posttest. Rank-based effect sizes (*r*) and 95% CIs were measured where applicable. Wilcoxon signed-rank tests examined changes from pretest to posttest within each group. McNemar tests assessed changes in correct responses for individual items on the 25-item test [24]. Data completeness was assessed, in which only less than 2% of responses were missing, and Little's missing completely at random (MCAR) test indicated data were missing completely at random (P=.078). As the proportion was small, listwise deletion was applied. No imputations were performed. Interpretations emphasized both statistical significance and precision of effect estimates, with CI reporting throughout.

Ethical Considerations

This study was approved by the Institutional Ethics Committee, UCSI University, under approval number IEC-2024-FOSSLA-0167, dated November 19, 2024. Written informed consent was obtained from all legal guardians, and verbal assent was provided by children before participation.

Confidentiality was ensured by anonymizing all datasets and storing them securely with restricted access. No personal identifiers were included in analyses or publications. Participants were not given financial incentives, but small educational gifts (eg, notebooks and stationery) were provided as tokens of appreciation. No identifiable photographs were taken; all supplementary materials were free of personal identifiers. Where identifiable images were unavoidable, written consent was obtained from both pupils and guardians.

Results

The pretest results showed a baseline piano music knowledge difference between groups (Table 2). The control and experimental groups had considerable piano music knowledge gaps before the intervention. The control group recorded a median pretest score of 52 (range 24-76) and a mean of 47.73 (SD 14.59), while the experimental group had 28 (range 16-64) and 36.13 (SD 12.92). In Table 3, a Mann-Whitney *U* test revealed a statistically significant difference (Mann-Whitney U=265.50; P=.006), indicating that the control group began with a higher level of knowledge.

Table 2. Pretest and posttest piano music knowledge scores among elementary school pupils receiving an 8-week game-based learning module versus traditional piano instruction in Anhui, China.

	Pretest scores			Posttest scores		
	Control[a]	Experimental[b]	Both	Control[a]	Experimental[b]	Both
n	30	30	60	30	30	60
Median (IQR)	52 (32-60)	32 (28-45)	40 (28-56)[c]	60 (51-65)	100 (95-100)	90 (60-100)[d]
Mode	60	28	28	60	100	100
Mean (SD)	47.73 (14.59)	36.13 (12.92)	41.93 (14.86)	58.67 (11.71)	97.33 (3.68)	78 (21.31)
Minimum	24	16	16	40	88	40
Maximum	76	64	76	92	100	100

[a]Control group (n=30).

[b]Experimental group (n=30).

[c]*P*=.006.

[d]*P*<.001.

Table 3. Between-group comparison of piano music knowledge at pretest and posttest using Mann-Whitney U tests in a quasi-experimental study of elementary school pupils in Anhui, China.

	Mann-Whitney *U*	*Z*	*r* (95% CI)	*P* value
Pretest	265.50	–2.75	0.35 (–0.39 to –0.32)	.006
Posttest	4.00	–6.71	0.87 (–0.90 to –0.83)	<.001

To evaluate the effectiveness of an 8-week GBL intervention on piano music knowledge, Mann-Whitney *U* tests were conducted to compare pretest and posttest scores between the experimental group (n=30) and the control group (n=30). Descriptive statistics and test results are presented in Table 3. No adverse events or unintended effects were observed in either study condition throughout the 8-week intervention.

In the pretest, a significant difference was observed between the experimental and control groups (Mann-Whitney *U*=265.50; *Z*=–2.75; *P*=.006), with the experimental group demonstrating higher scores compared to the control group. The effect size was medium (*r*=0.35, 95% CI –0.39 to –0.32), indicating a moderate baseline advantage for the experimental group.

In the posttest, the experimental group significantly outperformed the control group (Mann-Whitney *U*=4.00; *Z*=–6.71; *P*<.001). The experimental group achieved a median score of 100 (range 88-100; mean 97.33, SD 3.69), while the control group had a median score of 60 (range 40-92; mean 58.67, SD 11.71). The effect size was large (*r*=0.87; 95% CI –0.90 to –0.83), reflecting a substantial improvement in the performance of the experimental group. These results suggest that the 8-week GBL module effectively reversed the baseline performance patterns, closing the initial knowledge gap and significantly enhancing piano music knowledge in the experimental group compared to the control group.

The posttest scores achieved by the experimental group indicate a high degree of knowledge mastery, with reduced variability, in contrast to the more varied outcomes observed in the control group. The decreased SD (SD 3.69) in the experimental group suggests more consistent learning gains, reinforcing the ability of the GBL module to achieve uniform learning outcomes. Table 4 shows pretest and posttest score disparities demonstrating the effect of the intervention. The experimental group experienced a median gain of 64 points (range 36-84) with a mean improvement of 61.20 (SD 12.61). The pronounced disparity in knowledge gains shows that the GBL module promotes significant learning progress.

Table 4. Differences in piano music knowledge scores between pretest and posttest among elementary school pupils receiving game-based versus traditional piano instruction in Anhui, China

	Score difference between pretest and posttest		
	Control group	Experimental group	Control group and experimental group
n	30	30	60
Median (IQR)	8 (4-16)	64 (55-68)	36 (8-64)
Mode	4	64	64
Mean (SD)	10.93 (11.64)	61.20 (12.61)	36.07 (28.05)
Minimum	–4	36	–4
Maximum	64	84	84

XSL•FO
RenderX

To assess the effect of an 8-week GBL intervention on piano music knowledge, the Wilcoxon Signed Ranks test was conducted to compare pretest and posttest scores within the experimental group (n=30) and the control group (n=30). Results are presented in Table 5.

Table 5. Within-group comparison of pretest and posttest piano music knowledge using Wilcoxon signed-rank tests among elementary school pupils in Anhui, China.

Group	*Z*	*r* (95% CI)	*P* value
Control group	–3.24	–0.59 (–0.66 to –0.53)	.001
Experimental group	–4.81	–0.88 (–0.94 to –0.82)	<.001

Both groups demonstrated significant improvements in piano music knowledge from pretest to posttest. For the control group (Z=–3.24; P=.001), a substantial increase was observed (Z=–3.24; P=.001), with a large effect size (r=–0.59, 95% CI –0.66 to –0.53). The experimental group exhibited a more robust improvement (Z=–4.81; P<.001), with a larger effect size (r=–0.88, 95% CI –0.94 to –0.81). The higher Z value and lower P value in the experimental group with a larger effect size indicate that the GBL intervention led to greater knowledge growth compared to the control group. These findings, combined with the between-group comparison (see Table 3), suggest that the GBL module significantly enhanced learning outcomes, effectively closing the baseline knowledge gap in the experimental group.

McNemar tests were conducted on pretest and posttest scores for 25 test items to assess significant changes in performance. The item-level McNemar tests were exploratory ancillary analyses intended to examine differential item difficulty and the distributional impact of the intervention across 25 outcomes.

For the experimental group, McNemar tests were applied to each of the 25 piano knowledge items (Table 6). The analysis revealed statistically significant improvements (P<.05) in 5 items, highlighting the targeted effectiveness of the GBL module [25]. The remaining 20 items showed no statistically significant changes (P>.05).

For the control group, McNemar tests were similarly conducted on the 25 items. Five items (#1, #4, #5, #18, and #19) showed statistically significant improvements ($P<.05$), though the gains were less pronounced than in the experimental group. Both groups improved significantly in aural recognition (#1, #4, and #5) and rhythmic analysis (#18 and #19). However, the experimental group showed greater gains in complex tasks like beat identification (#18) and score interpretation (#19), suggesting the GBL module excels at engaging pupils in challenging musical concepts. The improvements in the control group were more stable in simpler tasks (eg, #1 and #4), indicating retention rather than new learning, consistent with the limited scope of traditional approaches. The item-level analysis underscores that the GBL module improves piano music knowledge, particularly in rhythm and score analysis, where the experimental group outperformed the control group. Both groups mastered several things, but the larger and more substantial gains of the experimental group show that the GBL module can enhance music education outcomes.

Discussion

Summary of the Main Study

This study examined whether a GBL module for piano education could improve music knowledge among elementary school pupils in Anhui, China, compared with traditional piano instruction. The findings demonstrated that pupils in the gamified learning group significantly outperformed their peers in the control group after the 8-week intervention, achieving near-perfect posttest scores with reduced variability. This suggests that gamification not only facilitated mastery of theoretical and aural skills but also promoted more consistent learning outcomes across participants. The between-group Mann-Whitney *U* test showed a large effect size, while the within-group Wilcoxon analysis confirmed significant pre-post improvements in both groups, with stronger gains in the gamified condition. These results validate the hypothesis of the study that gamified learning would yield superior knowledge acquisition compared to conventional methods, addressing the gap identified in the Introduction. In summary, the evidence confirms that gamification is an effective and scalable pedagogical approach for strengthening music knowledge in early piano education.

A tailored GBL module improved elementary school pupils' piano music knowledge in Anhui, compared to the control group. Postintervention, GBL module students outperformed the control group by a significant margin. Gamified approaches improve music knowledge, supporting previous research on GBL for music education engagement [11,12]. The near-perfect scores of the experimental group and low variability indicate that the module boosted knowledge acquisition and ensured consistent mastery, a challenge in traditional piano pedagogy.

A comprehensive needs analysis indicated that Anhui elementary pupils struggle with motivation and foundational skills when learning piano. A dynamic, entertaining GBL approach was used to improve piano knowledge, skills, and attitudes. The module promoted musical competency and positive learning habits through gamification principles, including fun, clear objectives, immediate feedback, and adaptability [26]. Addressing these challenges created an engaging experience targeted to young learners' interests, establishing the groundwork for the research findings.

Starting with "Please Play" to build foundational skills and on to "Church Organ" to refine expressive techniques, the module material was progressive. Structured repetition improved cognitive and motor skills in this sequencing. The instructional design integrated traditional piano pedagogy with gamified activities like the "Right-Hand Shooting Game" and "Five-Line Speech Practice" to improve retention and motivation [27]. These entertaining activities improved rhythm, note recognition, and expression, directly benefiting the understanding of the experimental group.

The lesson design required only a piano and basic multimedia tools, ensuring accessibility across schools in Anhui. Teacher-led demonstrations emphasized real-time feedback and interpersonal connection, which young learners need, above digital media. Tailored feedback allowed pupils to correct errors and refine performance immediately [4], boosting motivation and addressing individual needs [27]. While technology provided aural and visual signals, research suggests that interleaving teacher demonstrations with student imitation is better than audio-only or blocked observation [28]. Thus, the module balanced traditional and technological approaches in a practical, learner-centered environment [28].

XSL•FO
RenderX

Comparisons to Existing Literature

Quasi-experimental assessments confirmed the efficacy of the module. The pupils improved their piano knowledge and skills from a poor baseline to mastery by the end of the study, outperforming peers in traditional settings. Item-level analysis demonstrated targeted gains in aural recognition (pitch differentiation) and rhythmic skills (beat identification), aligning with the gamified focus [29]. Game-based elements, including challenges, real-time feedback, and rewards, increased the median score of the experimental group much more than the control group. Similar to Molloy et al [21], gamified piano instruction enhanced note accuracy and technical performance compared to traditional techniques, possibly due to greater engagement and skill mastery. Fadhli et al [30] found in a meta-analysis that gamified instruction improves children's musical knowledge and technical proficiency. These findings support the idea that GBL approaches can significantly improve musical learning outcomes.

Both groups started with similar baselines, but the experimental group improved by posttest. Traditional teaching methods yielded marginal, inconsistent gains in the control group. GBL improves engagement and retention, according to Robert et al [31] and Qian and Jiang [32], who linked it to piano performance. The interactive design of the module addressed the focus of traditional pedagogy on mechanical execution over holistic understanding, resulting in limited development in the control group [33,34].

The success of the experimental group reflects the affective and cognitive benefits of GBL. Gamification increases motivation and self-efficacy, while narrative-driven GBL deepens emotional connections to information [35]. These mechanisms likely drove the experimental group to engage and master. Molero et al [36] observed that gamified systems simplify challenging concepts, which promotes integration of Orff and Dalcroze approaches [15,37]. The focus of the module on aural and rhythmic skills addressed music education gaps, where an outdated curriculum hinders creativity [32]. Beyond immediate outcomes, the performance of the experimental group in analytical tasks (eg, interval comparison) implies GBL fosters higher-order thinking and skill transferability, areas understudied [17,38].

Implementation fidelity was generally high, as teachers followed the structured lesson plans and completed weekly fidelity checklists. However, minor barriers were observed, particularly in maintaining pupil focus during transitions from game activities to reflective discussions. These challenges suggest that future iterations of the module should incorporate more structured debriefing routines to support smoother transitions and deepen conceptual understanding. This study builds on the Orff approach, Dalcroze Eurhythmics, and the SMDM to better understand how gamified learning improves music knowledge in elementary school pupils. The interactive, rhythm-focused exercises of the game-based module increased engagement and musical comprehension, following the Orff approach [13]. The kinesthetic features of the module follow Dalcroze Eurhythmics, which integrates movement and music to improve rhythmic and expressive skills [14], improving pupils' competency and sensitivity.

Practically, the validated game-based module offers Anhui educators a scalable, resource-efficient tool to modernize piano teaching in often underresourced settings. The experimental group outperformed the control group significantly in knowledge and skills underscores the efficacy of integrating game elements, such as points, levels, and immediate feedback, into instruction [4]. By fostering enjoyment and reducing anxiety, the module also sustains long-term engagement, addressing dropout risks and challenging traditional methods' focus on technical drills over emotional connection [39,40]. Curriculum designers should thus prioritize holistic, learner-centered approaches.

Limitations

Despite the promising outcomes of this study, several limitations warrant consideration to contextualize the findings and guide future research. First, the quasi-experimental design used a nonequivalent control group without true random assignment, which may have introduced selection bias, as evidenced by initial differences in pretest scores [24]. Future studies should use true random assignment to enhance internal validity and ensure baseline equivalence between groups. Additionally, the sample size of 60 participants, while sufficient for detecting significant effects, limits the generalizability of findings. The study focused on novice piano learners in a private training center in Anhui, which may not fully represent the diverse educational contexts across China or other regions. Expanding the sample size and including public school settings could strengthen the applicability of the GBL module.

The 8-week intervention period provided valuable insights into short-term knowledge gains but was insufficient to assess long-term retention or the sustained impact of GBL on musical development. Previous research highlights the need for longitudinal data to evaluate deep conceptual understanding and skill retention [10]. Future studies should extend the intervention duration and incorporate follow-up assessments to examine whether the observed gains persist over time. While gamification enhanced engagement, teachers occasionally reported difficulty redirecting pupils' attention from gameplay to reflective discussion. To mitigate this, future iterations may include structured debrief sessions after each activity.

Another limitation lies in the assessment tool, the Level 1 Basic Music Written Test, which exhibited ceiling effects in the experimental group through their posttest scores. These effects suggest that the test may not have been sufficiently challenging to fully capture knowledge gains, potentially underestimating the impact of the intervention. Moreover, the study primarily measures aural and theoretical knowledge. This focus may overlook other critical aspects of piano learning, such as technical proficiency, emotional expression, or creativity, which are integral to holistic music education [7]. Incorporating multifaceted assessment tools, such as performance evaluations or qualitative measures of student engagement, would provide a more comprehensive understanding of the impact of GBL. Future studies may supplement written tests with recorded piano performances assessed using standardized rubrics, teacher observations, and student portfolios, enabling a more holistic evaluation of musical skill development.

XSL•FO
RenderX

The study did not account for individual learner differences, such as cognitive abilities, learning styles, or previous musical exposure, which may influence the efficacy of GBL [41,42]. The GBL module's one-size-fits-all approach, while effective overall, may not equally benefit all pupils. For instance, item-level analysis revealed variability in performance on complex tasks like interval comparison, suggesting potential confusion for some learners. Future research should explore adaptive GBL designs that tailor content to individual needs. Additionally, the reliance on teacher-led instruction, while resource-efficient, may have introduced variability in implementation fidelity. Although teachers underwent training, differences in their delivery styles could have influenced outcomes.

Finally, this study focuses on a specific context of Anhui, while a strength for regional relevance, but limits its generalizability to other cultural or educational settings. Local teaching practices and resource constraints in Anhui shaped the design of the module, but these may differ elsewhere. Comparative studies across diverse regions could elucidate how contextual factors influence the effectiveness of the GBL module. Furthermore, its integration with traditional pedagogy like Orff and Dalcroze was effective, but its compatibility with other music education frameworks remains underexplored. Investigating hybrid models that combine GBL with varied pedagogical approaches could broaden its applicability.

To address these limitations, researchers should prioritize longitudinal studies with larger, more diverse samples to validate and extend the findings. Randomizing group assignments and incorporating varied assessment methods will enhance the robustness of future investigations. Educators in Anhui and similar regions are encouraged to adopt the validated GBL module, adapting it to local needs while ensuring teacher training emphasizes consistent implementation. Policymakers should consider investing in scalable GBL frameworks, potentially integrating digital tools to enhance accessibility and personalization in resource-constrained settings. By addressing these limitations and implementing these recommendations, the field can further harness the potential of GBL to transform piano education, fostering both musical proficiency and lifelong engagement among young learners.

Conclusion

The design and validation of the module underscore key implications for music education. Gamification enhanced engagement and knowledge acquisition, suggesting its potential for broader application. Multimodal instruction catered to diverse learning styles, while collaborative practices extended learning beyond the classroom. In conclusion, this GBL module provides a robust, validated approach to early music education for Anhui pupils. By integrating structured content, playful activities, and reflective teaching, it strengthens musical competencies and fosters a positive learning ecosystem, contributing to the evidence base for innovative pedagogy.

This study highlights that integrating gamification into piano pedagogy is both innovative and impactful for early music education. By embedding elements of play, challenge, feedback, and progression into traditional piano lessons, the GBL module transformed abstract musical concepts into engaging learning experiences that fostered consistent mastery among elementary school pupils. This approach is particularly valuable in resource-constrained environments, as the module was designed to be cost-effective, requiring minimal technology beyond a piano and simple teaching aids, while still producing large and meaningful learning gains. The innovation lies in bridging established pedagogical traditions, such as Orff and Dalcroze, with systematic gamification through the SMDM, thereby creating a hybrid framework that supports motivation, knowledge retention, and skill transfer. While traditional methods often emphasize technical drills at the expense of holistic understanding, this study shows that gamification sustains engagement and cultivates deeper conceptual knowledge. Practically, the validated GBL module can be adopted widely by music educators and curriculum designers to modernize piano teaching, reduce dropout risks, and increase accessibility of music learning across diverse school settings. Ultimately, the study demonstrates that gamified learning is not only a pedagogical enhancement but also a scalable and sustainable solution for advancing children’s cultural capital, creativity, and long-term musical engagement.

In conclusion, this study demonstrates that integrating gamification into elementary piano education represents both an innovative and effective pedagogical advancement. The study differs from existing research by systematically embedding GBL within established music education frameworks, namely Orff-Schulwerk and Dalcroze Eurhythmics, and operationalizing this integration through the SMDM. This approach moves beyond previous studies that primarily focus on engagement or short-term skill gains by providing robust empirical evidence of consistent knowledge mastery and reduced performance variability among young learners. The contribution of this study lies in offering a validated, theoretically grounded, and developmentally appropriate GBL module that advances understanding of how gamification can support foundational music knowledge acquisition. From a real-world perspective, the module provides educators and curriculum designers with a scalable, low-cost, and practical solution for modernizing piano instruction, particularly in underresourced educational contexts, while fostering sustained engagement, reducing learner attrition, and strengthening long-term musical development.

Data Availability

Abstract

Background: Nonpharmacological interventions for cognitive problems play a critical role in dementia care, yet maintaining engagement and adherence remains challenging. Immersive virtual reality (VR) provides a promising platform for cognitive training, particularly when integrated with personally meaningful leisure activities that may enhance therapeutic resonance.

Objective: This study aimed to examine the feasibility of gardening-based immersive VR cognitive training and to explore pre-post changes in clinical outcomes among older adults with dementia.

Methods: This study reports an analysis of intervention-phase data from an ongoing registered randomized crossover clinical trial (ClinicalTrials.gov NCT07033468). For this report, the available data were analyzed using a single-group pretest-posttest approach; data from the waitlist-control period were not included. Between September 2024 and December 2025, 16 older adults with mild-to-moderate dementia were recruited through referral-based convenience sampling from a hospital and a dementia day care center in Taiwan. Participants completed a 15-session VR intervention over 5 weeks, involving gardening-based activities targeting multiple cognitive domains. Feasibility outcomes included VR acceptance, simulator sickness, and observed emotional responses during the first VR session. Cognitive outcomes included global cognition assessed using the Montreal Cognitive Assessment (MoCA) and domain-specific cognitive measures. Secondary outcomes included activities of daily living, depressive symptoms, behavioral and psychological symptoms of dementia, quality of life, and well-being. Paired *t* tests were used to examine pre-post differences, and the Holm-Bonferroni procedure was applied to adjust for multiple comparisons.

Results: Sixteen participants (5 men and 11 women; mean age 78.12, SD 6.61 years) completed feasibility assessments, 15 participants (4 men, 11 women; mean age 78.57, SD 6.58 years) completed the intervention, and 5 occupational therapists evaluated the usability of the VR system. VR acceptance significantly increased after the first session (t_{15}=−5.40, 95% CI −0.61 to −0.26; P<.001), while simulator sickness significantly decreased (t_{15}=2.42; 95% CI 0.34-5.27; P=.009). Emotional responses indicated high levels of pleasure (mean 3.38, SD 1.63) and alertness (mean 4.63, SD 0.89) with minimal negative affect. Usability was rated as acceptable (system usability scale: mean 70.5, SD 12.17). Global cognitive performance was higher at postintervention than at baseline (MoCA: Cohen d=1.03; 95% CI −3.28 to −0.99; P=.001). No statistically significant pre-post differences were observed in domain-specific cognitive measures, activities of daily living, quality of life, or psychosocial outcomes.

Conclusions: Gardening-based immersive VR cognitive training appears feasible, acceptable, and well tolerated among older adults with dementia. The program extends existing VR approaches by embedding familiar, goal-directed gardening activities within an interactive cognitive training environment. By combining participant-centered feasibility outcomes with occupational therapist–rated usability, this study provides preliminary evidence relevant to the development and implementation of person-centered VR cognitive training in clinical and community dementia care. The favorable pre-post change in global cognition further supports investigation of this approach in larger controlled studies.

KEYWORDS

cognitive training; leisure activities; feasibility; usability; immersive virtual reality; dementia

Introduction

The rapid growth of the aging population worldwide has led to a substantial increase in the prevalence of dementia. According to recent estimates [1], more than 60 million people are currently living with dementia globally, and this number is projected to rise steadily in the coming decades. Dementia is characterized by a progressive decline across multiple cognitive domains, including memory, executive function, language, and visuospatial abilities [2,3]. As the disease progresses, these impairments interfere with independence in activities of daily living (ADL) and contribute to increased long-term care needs. In addition to cognitive decline, behavioral and psychological symptoms of dementia (BPSD) are highly prevalent and are associated with poorer quality of life and increased caregiver burden [4]. Given the absence of curative treatments, interventions that aim to preserve cognitive function and maintain daily functioning remain central to dementia care.

Nonpharmacological interventions are widely recommended due to their safety and applicability for individuals with dementia. Various approaches, including physical exercise, cognitive training (CT), music therapy, art-based interventions, and animal-assisted therapy, have been investigated [5-9]. Among these, CT has received particular attention as a targeted intervention, given that cognitive impairment is the defining feature of dementia and is closely linked to functional decline [10]. Guided by the principles of neuroplasticity, CT uses systematic, task-oriented exercises to bolster neural resilience across diverse domains [11]. However, the overall effectiveness of traditional CT remains constrained, particularly in terms of long-term adherence and generalization to daily life [3,11]. A primary bottleneck for conventional CT is the "motivation gap": traditional tasks are often repetitive and decontextualized, which may reduce engagement in individuals with cognitive impairment [5].

Engaging in leisure activities has been identified as a modifiable lifestyle factor that may enhance cognitive reserve [12,13]. Integrating leisure-based elements into CT may improve motivation and ecological validity [14]. Gardening serves as a multimodal intervention that harmonizes affective well-being with cognitive stimulation [15]. From a neurobiological perspective, this approach is particularly promising as it correlates with increased concentrations of neurotrophic factors such as brain-derived neurotrophic factor, which are essential for neuroplasticity and hippocampal-dependent memory [12]. Consequently, the synthesis of horticultural elements within standardized CT protocols represents a strategic shift toward more ecologically valid interventions. Such a strategy not only addresses the biological requirements for cognitive health but also ensures that the intervention remains contextually meaningful for users, potentially bridging the gap between clinical exercises and daily lives [11,14,15].

To operationalize such contextually rich interventions, virtual reality (VR) has emerged as a promising tool for CT in older adults. Fully immersive VR provides a highly interactive and ecologically valid environment, allowing users to engage in realistic simulations of everyday or meaningful activities [16]. Compared with traditional approaches, VR offers several advantages, including enhanced sensory stimulation, real-time feedback, and the ability to tailor task difficulty to individual performance [17]. Previous studies have demonstrated that VR-based interventions can improve cognitive function, including global cognition, executive function, and visuospatial abilities, in older adults with and without cognitive impairment [17-19]. Moreover, immersive VR may enhance user engagement and motivation, which are critical factors for intervention success [20]. A recent systematic review of immersive and semi-immersive VR interventions for older adults with mild cognitive impairment, dementia, or cognitive frailty also found that supervised VR delivery was generally feasible and well tolerated, with promising findings across cognitive, mobility, and emotional or behavioral outcomes [21]. However, the review also identified considerable heterogeneity in intervention content, dosage, outcome measures, and methodological quality [21]. Beyond cognitive outcomes, a longitudinal observational study conducted in dementia day care centers in Taiwan found that culturally familiar immersive VR reminiscence was associated with improvements in BPSD after the intervention and at follow-up [22]. These findings support the potential relevance of immersive VR across cognitive, emotional, and behavioral domains of dementia care.

Despite these promising findings, several critical gaps persist. First, the evidence for immersive VR among people with established dementia remains limited by small samples, heterogeneous intervention protocols, and methodological concerns [21]. Second, many VR-based CT programs focus on simulated daily activities or use commercially available games that may not be tailored to the preferences and life experiences of older adults [23]. Although culturally familiar reminiscence content has been investigated [22], relatively few studies have incorporated meaningful, goal-directed leisure activities, such as gardening, into immersive VR CT for people with dementia. Integrating such activities may enhance the contextual relevance of CT and support participant engagement. Third, although previous studies have examined feasibility and acceptability, evaluations combining multiple dimensions of participant experience with health professionals' perspectives on system usability remain limited.

To address these gaps, this study developed a gardening-based CT program delivered through a fully immersive VR system. The program incorporated familiar, goal-directed gardening

XSL•FO
RenderX

activities intended to promote engagement among older adults. The primary objective was to examine the feasibility of the intervention among older adults with dementia, including participant acceptance, simulator sickness, and emotional responses during VR use. System usability was also evaluated from the perspective of occupational therapists. The secondary objective was to explore pre-post changes in global and domain-specific cognitive function, ADL, quality of life, depressive symptoms, behavioral symptoms, and mental well-being. The feasibility evaluation may also provide useful information regarding intervention delivery, usability, and safety monitoring to support the ongoing randomized crossover trial. We hypothesized that (1) the program would demonstrate favorable feasibility and professional usability, reflected by increased VR acceptance, limited simulator sickness, predominantly positive emotional responses during the first VR session, and acceptable usability ratings from occupational therapists; and (2) participants would show favorable pre-post changes in global and domain-specific cognitive function, daily functioning, quality of life, and psychosocial outcomes.

Methods

Study Design

This study reports a feasibility-focused analysis of currently available intervention-phase data from an ongoing, registered randomized crossover trial (ClinicalTrials.gov: NCT07033468). This report used a single-group pretest-posttest design to evaluate the feasibility of gardening-based immersive VR CT, obtain supplementary professional usability ratings, and explore pre-post changes in clinical outcomes among older adults with dementia. Participant recruitment for the registered trial remains ongoing; therefore, the findings reported here should be considered preliminary.

Inclusion and Exclusion Criteria

Individuals were eligible for enrollment if they met the following inclusion criteria: (1) aged 55 years or above; (2) a formal diagnosis of mild-to-moderate dementia confirmed by a physician or documented in their medical records; (3) the ability to ambulate independently; (4) the capacity to understand and follow simple instructions, with or without assistance from a therapist or caregiver; and (5) the presence of at least one family member or caregiver with regular weekly contact. To ensure participant safety during the immersive VR intervention and to maintain the specificity of the sample, exclusion criteria included (1) dementia with Lewy bodies or neurodegenerative diseases of other specific etiologies (eg, Huntington disease, central nervous system infection, malnutrition, or metabolic disorders); (2) substance-induced cognitive impairment or Korsakoff syndrome; (3) severe medical conditions that could compromise safe participation, such as severe cardiovascular disease, dyspnea, or brain tumors; (4) a psychiatric diagnosis of psychosis within the preceding 6 months; (5) severe sensory impairments, including hearing loss or color blindness, that could impede task engagement; (6) a history of severe vertigo or epilepsy, which are contraindications for head-mounted display use; and (7) concurrent participation in other cognitive intervention studies.

Participant Characteristics

A total of 16 participants (5 men and 11 women) were enrolled (mean age 78.12, SD 6.61 years). Detailed demographic characteristics are presented in Table 1. Participants were recruited from the dementia outpatient clinic at New Taipei Municipal Tu Cheng Hospital and a community-based dementia day care center in Taiwan between September 2024 and December 2025. Consequently, 16 participants completed the feasibility assessments and 1 participant dropped out during the intervention. Therefore, 15 participants completed the 15-session VR intervention and were included in the final analyses.

Table . Demographic characteristics of participants.

Demographic characteristics	Feasibility (N=16)	Intervention (N=15)
Sex, n (%)		
Male	5 (31.25)	4 (26.70)
Female	11 (68.75)	11 (73.30)
Age (y), mean (SD)	78.12 (6.61)	78.57 (6.58)
Years of education, mean (SD)	7.88 (4.03)	8.00 (4.14)
Education status, n (%)		
College or above	1 (6.25)	1 (6.67)
Senior high school	4 (25)	4 (26.67)
Junior high school	2 (12.50)	2 (13.33)
Elementary school	8 (50)	7 (46.67)
No formal education	1 (6.25)	1 (6.67)

Sampling Procedures

A referral-based convenience sampling approach was used at both recruitment sites. At the hospital, attending outpatient physicians referred potentially eligible patients to the research team. At the community-based day care center, the center supervisor assisted in identifying potentially eligible attendees. In both settings, the research team confirmed eligibility,

XSL•FO
RenderX

explained the study procedures, and obtained written informed consent before enrollment. The recruitment source was independent of subsequent randomization sequence allocation.

Sample Size, Power, and Precision

The registered randomized crossover trial has a planned enrollment of 30 participants. The present analysis included all available intervention-phase data at that time: 16 participants completed the first-session feasibility assessments and 15 participants completed the intervention and pre-post clinical assessments. No formal sample size calculation was performed specifically for this feasibility-focused analysis. The sample was not powered to establish clinical efficacy or reliably detect changes across multiple clinical outcomes. Therefore, the clinical outcome analyses were considered exploratory, and 95% CIs were reported to indicate the precision of the estimates.

Ethical Considerations

The study was approved by the Institutional Review Board of Chang Gung Memorial Hospital (approval number: 202400517B0). All procedures were conducted in accordance with the Declaration of Helsinki. The study was registered with a clinical trial registry (registration number: NCT07033468). All participants provided written informed consent prior to participation. For participants with cognitive impairment, consent was obtained in conjunction with caregivers when necessary. All participant data were anonymized to protect confidentiality. Personal identifying information was removed from the dataset, and participants were assigned unique study codes for data analysis and storage. Participants received a transportation subsidy of New Taiwan dollars (NT $250 [~US $8]; NT $1=US $0.03 as of October 14, 2026) after completing each of the pretest and posttest assessments. This paper does not contain any images or photographs in which individual participants could be identified.

Research Tools and Procedures

The intervention was delivered using the HTC VIVE Pro head-mounted display (HTC Corp; Figure 1), which provides a fully immersive VR experience. The system included handheld wireless controllers for interaction and a screen-mirroring function that allowed therapists to monitor participants' performance in real time. Participants were able to interact with the virtual environment independently, while therapists provided supervision and assistance when necessary. The VR program was designed around leisure-based gardening activities, including planting, fertilizing, watering, harvesting, producing plant-based essential oils, and packaging fruit gift boxes (Figure 2). Each activity was structured into 7 levels of difficulty (levels 1 - 7), progressing from simple to more complex tasks. The system automatically adjusted task difficulty in real time based on participants' performance. The activities were designed to target multiple cognitive domains, including attention, processing speed, memory, visuospatial ability, and executive function (Figure 3). Participants completed 15 sessions of VR training over a period of 5 weeks, with 3 sessions per week on nonconsecutive days. Each session lasted approximately 60 minutes. Each session consisted of a 5-minute warm-up, four 10-minute VR training segments, 2 - to 3-minute rest periods between segments, and a 5-minute cooldown. During the warm-up phase, therapists provided instructions on task content and controller operation. Participants were allowed to perform in the training in either a seated or standing position based on their physical condition. Therapists provided verbal and physical assistance when participants experienced difficulty, particularly during early sessions. Participants were allowed to rest or discontinue the session if they experienced discomfort or fatigue. Participants' physical condition was monitored before and after each session to ensure safety.

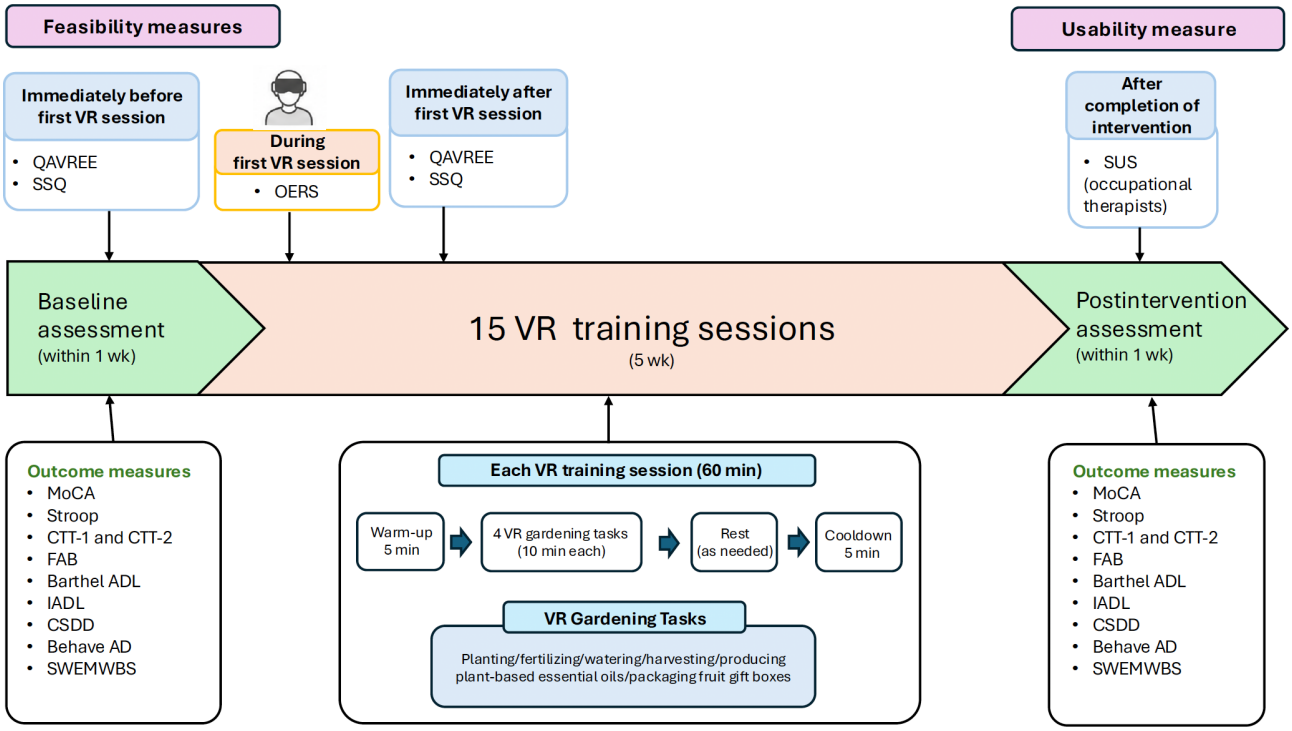
Figure 2. Representative gardening-based virtual reality training tasks: (A) harvest flowers by cutting mature blossoms; (B) water seedlings according to the target water level; (C) create bookmarks by selecting and arranging dried flowers and leaves; and (D) apply fertilizer to the appropriate pots based on the task instructions.

Figure 3. Example of the gardening-based virtual reality fruit harvesting task. (A) Memorize the target fruits and quantities displayed on the instruction panel. (B) Harvest the specified fruits using the virtual pruning tool. (C) Place the harvested fruits into the basket to complete the task.



Measures and Covariates

Assessment Procedures

The feasibility measures included the Questionnaire of Acceptance of the Virtual Reality Experience Among the Elderly (QAVREE), the Simulator Sickness Questionnaire (SSQ), and the Observed Emotion Rating Scale (OERS). The QAVREE and SSQ were administered immediately before and after the first VR training session to evaluate participants' initial acceptance of the VR intervention and simulator sickness symptoms. The OERS was administered once during the first VR training session to assess participants' emotional responses while engaging in the intervention. The cognitive and secondary outcome measures were assessed within 1 week before the first intervention session (baseline) and within 1 week after completion of the 5-week intervention program (postintervention). All secondary outcome measures were completed during the same assessment visit. To minimize potential fatigue effects, the order of the cognitive assessments was varied across participants. Repeated assessments during the intervention period were not performed because the intervention was relatively short (~5 weeks), and repeated administration of cognitive tests could introduce practice effects and increase participant fatigue, thereby affecting the validity of the outcome measures. The study design and timing of all feasibility and outcome assessments are summarized in Figure 4.

XSL•FO
RenderX

Figure 4. Study design, intervention protocol, and assessment timeline. Baseline and postintervention outcome measures were assessed within 1 week before and after the 5-week intervention, respectively. Feasibility measures (Questionnaire of Acceptance of the Virtual Reality Experience Among the Elderly [QAVREE], Simulator Sickness Questionnaire [SSQ], and Observed Emotion Rating Scale [OERS]) were administered immediately before, during, and immediately after the first virtual reality (VR) session, whereas system usability (system usability scale [SUS]) was evaluated by occupational therapists after completion of the intervention. ADL: activities of daily living; BPSD: behavioral and psychological symptoms of dementia; CTT: Color Trails Test; CSDD: Cornell Scale for Depression in Dementia; DQoL: dementia quality of life; FAB: Frontal Assessment Battery; IADL: instrumental activities of daily living; MoCA: Montreal Cognitive Assessment; SWEMWBS: Short Warwick-Edinburgh Mental Well-Being Scale.

Feasibility and Usability

In the QAVREE, older adults report their subjective perceptions of perceived usefulness, perceived ease of use, perceived enjoyment, subjective norms, and user experience across 17 items. Responses are rated on a 5-point Likert scale, ranging from “strongly disagree” (1) to “strongly agree” (5), with higher scores indicating greater acceptance. This self-report scale has demonstrated good reliability and validity [24]. In the SSQ, participants self-report symptoms related to nausea, oculomotor disturbance, and disorientation following the VR intervention. Previous studies have demonstrated that the SSQ is an effective tool for assessing cybersickness symptoms associated with immersive VR use in older adults and clinical populations [20].

The system usability scale (SUS) was administered to 5 occupational therapists involved in the intervention to evaluate the usability, functionality, and clinical applicability of the VR system from a professional perspective. This measure was completed by the occupational therapists rather than by the older adult participants themselves, given the cognitive demands associated with self-report usability assessments in individuals with dementia. The SUS consists of 10 items rated on a 5-point Likert scale, ranging from “strongly disagree” (1) “to strongly agree” (5), with higher scores indicating greater usability. The scale has demonstrated good reliability, validity, and sensitivity [25].

The OERS was used to assess participants’ emotional responses during the VR intervention. The OERS evaluates both positive and negative emotions, including pleasure, anger, anxiety, sadness, and interest, exhibited by participants during the intervention. Emotional intensity was rated according to the duration of each observed emotion, categorized as never, less than 16 seconds, 16 to 59 seconds, 1 to 5 minutes, or more than 5 minutes. The OERS was originally developed for use with nursing home residents and has been shown to be effective in detecting mood changes in individuals with dementia [26].

Cognitive Outcomes

To evaluate cognitive function before and after the VR intervention, the Chinese version of the Montreal Cognitive Assessment (MoCA), the Stroop Color and Word Test (SCWT), the Color Trails Test (CTT), and the Frontal Assessment Battery (FAB) were administered as primary outcome measures.

The MoCA was used to assess global cognitive function and is a sensitive and valid screening tool for cognitive impairment [27]. The MoCA assesses multiple cognitive domains, including orientation to time and place, attention, concentration, short-term memory, working memory, visuospatial abilities, language, and executive functions. Total scores range from 0 to 30, with scores below 26 indicating cognitive impairment; higher scores indicate better cognitive function.

The SCWT was used to assess the ability to inhibit cognitive interference [28]. Participants were required to read the words under congruent and incongruent color conditions. Performance on the SCWT was evaluated based on reaction time, with longer reaction times indicating poorer inhibitory control.

XSL•FO
RenderX

The CTT was used to assess cognitive flexibility and is sensitive in detecting early dementia [29]. The assessment consists of 2 parts. In the first part, participants are required to rapidly connect numbered circles in sequence from 1 to 25. In the second part, the task is similar but requires participants to alternately connect circles of 2 different colors (yellow and pink) while maintaining the numerical sequence. Shorter completion times reflect better performance.

The FAB is a brief tool designed to evaluate executive function and has demonstrated good sensitivity and validity in detecting executive dysfunction. The battery consists of 6 subtests assessing conceptualization, mental flexibility, motor programming, sensitivity to interference, inhibitory control, and environmental autonomy [30].

Secondary Outcomes

The secondary outcomes included ADL, emotional status, clinical symptoms, and quality of life, assessed using the Barthel Index (BI), the Lawton instrumental activities of daily living (IADL) scale, the Cornell Scale for Depression in Dementia (CSDD), measures of BPSD, the Chinese version of dementia quality of life (DQoL) instrument, and the Short Warwick-Edinburgh Mental Well-Being Scale (SWEMWBS).

The BI was used to assess ADL and is recommended for the functional assessment of older adults [31]. Total scores range from 0 to 100, with lower scores indicating poorer ADL function and greater dependence on assistance from others.

The Lawton IADL scale is an appropriate instrument for assessing independent living skills in older adults [32] and is sensitive in detecting early and less severe functional decline. The scale includes 8 domains: using the telephone, shopping, food preparation, housekeeping, laundry, transportation, medication management, and financial management [33]. Total scores range from 0 to 10, with lower scores indicating poorer IADL function and greater functional decline.

The Chinese version of the CSDD was used to assess depressive symptoms during the intervention to monitor potential effects of VR on mood. The scale comprises 19 items across 5 domains, with item scores ranging from 0 (“absent”) to 2 (“severe”). Total scores above 10 indicate probable depression, whereas scores below 6 suggest the absence of clinically significant depressive symptoms. The Chinese version has demonstrated good validity and reliability [34].

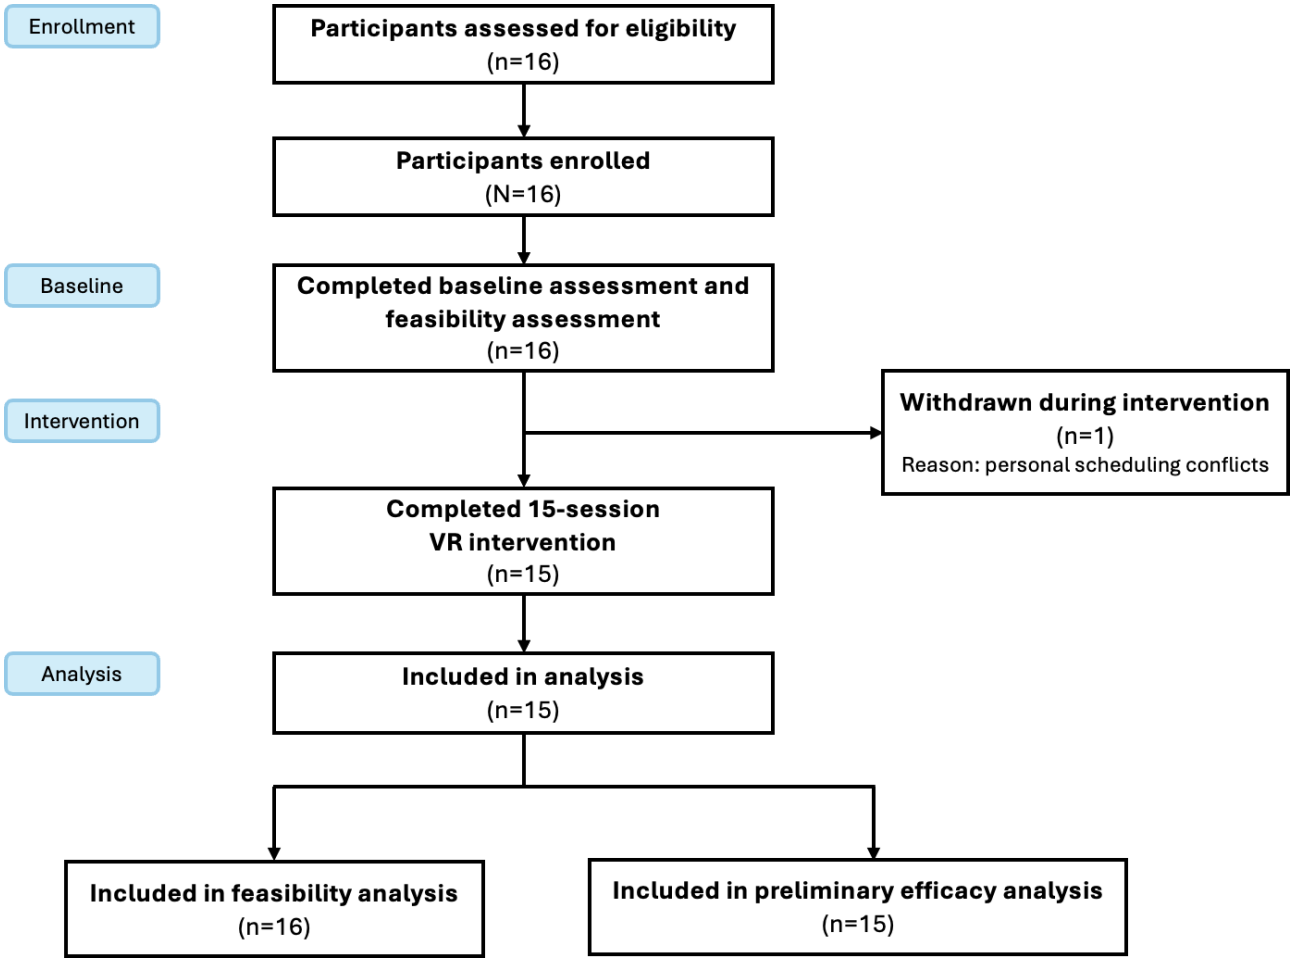
BPSD were assessed to evaluate symptoms such as delusions, anxiety, and other neuropsychiatric manifestations. BPSD represent one of the most burdensome aspects of dementia care for caregivers, and in clinical practice, they are often more readily observable and responsive to intervention [35].

The Chinese version of DQoL was used to assess quality of life in individuals with dementia during the VR intervention. The scale comprises 29 items across 5 domains: positive affect, negative affect, a sense of aesthetics, feelings of belonging, and self-esteem. Item scores range from 0 to 5, with higher scores indicating a better quality of life. The Chinese version of the DQoL has been validated in Taiwanese individuals with dementia who had Mini-Mental State Examination scores greater than 10 [36].

The SWEMWBS is a 7-item self-report measure of mental well-being and was used to evaluate participants’ overall emotional well-being. Higher scores indicate better mental health. The scale has demonstrated good reliability and validity, and it has been shown to be associated with anxiety and depression [37].

Statistical Analysis

All analyses were conducted using IBM SPSS Statistics (version 24). Descriptive statistics (means, SDs, and percentages) were used to summarize participant characteristics and outcome measures. Two-tailed paired-samples *t* tests were used to examine differences between preintervention and postintervention outcomes. Effect sizes were calculated using Cohen *d*, and 95% CIs were calculated for all point estimates. Statistical significance was set at $P<.05$. Paired-samples *t* tests were used to examine pre-post differences. To control the familywise error rate associated with multiple comparisons, Holm-Bonferroni correction was applied across all clinical outcomes eligible for inferential testing. Because no variability was observed in the BI scores, inferential testing could not be performed for this outcome. Three outcome measures had missing data at one or both time points: the CCT-1 (1/15 participant, 6.67%), the CCT-2 (2/15 participants, 13.33%), and the DQoL scale (3/15 participants, 20%). Little’s missing completely at random (MCAR) test was nonsignificant ($\chi^2_{18}=19.1$; $P=.39$), indicating that the missing data were consistent with the MCAR assumption. Paired-samples *t* tests were conducted using all available paired observations for each outcome measure; therefore, sample sizes and corresponding degrees of freedom varied across analyses according to data availability. Given the small amount of missing data, the pilot nature of the study, and the finding that missingness was consistent with the MCAR assumption, multiple imputations were not considered necessary and were therefore not performed.



Results

Participant Characteristics

A total of 16 participants were enrolled and completed baseline assessments and feasibility evaluations following the first VR session. One participant withdrew before the second session due to scheduling conflicts unrelated to the intervention. Consequently, 15 participants completed the full 15-session program and were included in the pre-post outcome analyses. Participant flow across study stages is provided in Figure 5.

XSL•FO
RenderX

Figure 5. Participant flow through the feasibility and exploratory pre-post clinical outcome analyses. VR: virtual reality.

Detailed demographic characteristics are presented in Table 1. Among the enrolled participants (N=16), the majority were women (n=11, 68.75%) with a mean age of 78.12 (SD 6.61) years. The participants generally had low educational attainment, with a mean of 7.88 (SD 4.03) years of formal schooling. Half of the sample (n=8, 50%) had completed only elementary school, while only 1 participant (6.25%) had received college-level education. The demographic profile of the participants who completed the full intervention (n=15) remained consistent with the baseline sample (mean age 78.57, SD 6.58 years; mean education 8.00, SD 4.14 years).

Feasibility Outcomes

VR Acceptance

VR acceptance significantly increased following the first VR session. The mean QAVREE score increased from 3.42 (SD 0.44) before the session to 3.85 (SD 0.39) immediately following the session (t_{15}=−5.40, 95% CI −0.61 to −0.26; P<.001), indicating enhanced positive attitudes toward the VR intervention.

Simulator Sickness

Simulator sickness, as measured by the SSQ, showed a significant reduction after the first VR session. The total SSQ score decreased from a mean of 5.61 (SD 6.26) preintervention to 2.81 (SD 3.48) postintervention (t_{15}=2.42, 95% CI 0.34-5.27; P=.03). Subscale analyses further revealed the following: nausea significantly decreased from a mean of 4.77 (SD 4.93) preintervention to 1.19 (SD 3.26) postintervention (t_{15}=3.00, 95% CI 1.04-6.12; P=.009). Disorientation significantly decreased from a mean of 9.57 (SD 14.12) preintervention to 3.48 (SD 6.23) postintervention (t_{15}=2.41, 95% CI 0.69-11.49; P=.03). Oculomotor symptoms showed no significant change (mean score preintervention: 5.21, SD 7.17; mean score postintervention: 4.74, SD 6.11; t_{15}=0.44; P=.67).

Emotional Responses During VR Use

Participants' emotional responses observed during the first VR training session are summarized in Table 2. Overall, the participants demonstrated predominantly positive affect while engaging in the intervention. The mean pleasure score was 3.38 (SD 1.63; range: 1 - 5), indicating moderate to high levels of positive emotional experience. General alertness was also high, with a mean score of 4.63 (SD 0.89; range: 2 - 5), suggesting a high degree of sustained attention and psychological engagement during the intervention.

XSL•FO
RenderX

Table . Observed emotional responses during the first virtual reality training session.

Observed Emotion Rating Scale	Mean (SD; range)
Pleasure	3.38 (1.63; 1-5)
Anger	1.00 (0; 1-1)
Anxiety	1.19 (0.75; 1-4)
Sadness	1.00 (0; 1-1)
General alertness	4.63 (0.89; 2-5)

Conversely, negative emotional responses were minimal. Anger and sadness both yielded mean scores of 1.00 (SD 0), indicating that these emotions were not observed during the session. Anxiety levels remained very low, with a mean score of 1.19 (SD 0.75), further supporting the psychological safety and tolerability of the gardening-based immersive VR intervention.

Professional Usability Assessment

Professional usability of the VR system was evaluated by 5 occupational therapists (2 men and 3 women) from the participating sites rather than by the older adult participants themselves, given the cognitive demands associated with self-report usability assessments in individuals with dementia. The mean SUS score, as rated by the occupational therapists, was 70.5 (SD 12.17, 95% CI 55.4-85.6). According to established SUS interpretation benchmarks, this score exceeded the industry average of 68, indicating that the VR system demonstrated acceptable to good usability for clinical implementation in dementia care from the perspective of experienced occupational therapists.

Exploratory Pre-Post Clinical Outcomes

Global Cognitive Function

As shown in Table 3, MoCA scores were higher at postintervention than at baseline. The mean score increased from 16.13 (SD 3.94) to 18.27 (SD 5.19), corresponding to a mean within-participant change of −2.13 (95% CI −3.28 to −0.99; t_{14}=−4.00, Cohen d=1.03; P=.001).

XSL•FO
RenderX

Table . Preintervention and postintervention outcome measures.

Measurements	Preintervention, mean (SD)	Postintervention, mean (SD)	*t* test (*df*)[a]	*P* value	Cohen *d*	Mean difference (95% CI)
MoCA[b] (score)	16.13 (3.94)	18.27 (5.19)	−4.000 (14)	.001	1.03	−2.13 (−3.28 to −0.99)
Stroop (s)	48.87 (18.52)	57.52 (18.94)	−1.298 (14)	.22	0.34	−8.65 (−22.95 to 5.64)

SWEMWBS[k] (score)	27.00 (4.57)	27.00 (5.31)	0.000 (14)	>.99	0	0.00 (−1.95 to 1.95)

[a]CTT-1 (n=14), CTT-2 (n=13), and DQoL (n=11) reflect listwise-deleted cases with missing data at one or both time points.

[b]MoCA: Montreal Cognitive Assessment.

[c]CTT: Color Trails Test.

[d]FAB: Frontal Assessment Battery.

[e]ADL: activities of daily living.

[f]The Barthel Index ADL score showed zero variance in the pre-post difference (no participant changed score), so the *t* test statistic is not defined.

[g]IADL: instrumental activities of daily living.

[h]CSDD: Cornell Scale for Depression in Dementia.

[i]BPSD: behavioral and psychological symptoms of dementia.

[j]DQoL: dementia quality of life.

[k]SWEMWBS: Short Warwick-Edinburgh Mental Well-Being Scale.

Domain-Specific Cognitive Outcomes

No statistically significant pre-post differences were observed in the domain-specific cognitive outcomes (Table 3). The paired comparisons yielded Cohen *d* values of 0.34 for the Stroop test (*P*=.22), 0.12 for CTT-1 (*P*=.67), 0.52 for CTT-2 (*P*=.09), and 0.46 for the FAB (*P*=.09). All comparisons remained nonsignificant after Holm-Bonferroni correction (adjusted *P*≥.77).

ADL

Functional independence remained stable throughout the study period. No significant changes were observed in the BI scores, which showed a ceiling effect with consistent scores at both time points (mean 99.00, SD 3.87; t_{14}=0.00; *P*>.99). Similarly, IADL scores showed no significant deviation from baseline (preintervention: 6.93 vs postintervention: 6.80; t_{14}=0.62; *d*=0.16; mean difference [MD]=0.13, 95% CI −0.33 to 0.60; *P*=.55).

Emotional and Behavioral Outcomes

Psychological symptoms remained low and stable postintervention. A nonsignificant reduction in depressive symptoms was observed on the CSDD, decreasing from 3.00 (SD 4.19) to 2.07 (SD 2.46) with a moderate effect size (Cohen *d*=0.35; MD=0.93, 95% CI −0.54 to 2.41; *P*=.19). Behavioral symptoms, as measured by the BPSD, were minimal at baseline and remained near zero postintervention (Cohen *d*=0.26; MD=0.13, 95% CI −0.15 to 0.42; *P*=.33).

Quality of Life and Well-Being

No significant changes were observed in quality of life or mental well-being. The DQoL total score showed a slight, nonsignificant increase from a mean of 100.73 (SD 16.99) before the intervention to 103.64 (SD 15.27) after the intervention (t_{10}=−1.09; MD=−2.91, 95% CI −8.87 to 3.05; Cohen *d*=0.33; *P*=.30). Mental well-being, assessed via the SWEMWBS, remained unchanged with mean scores of 27.00 (SD 4.57) before the intervention and 27.00 (SD 5.31) after the intervention (t_{14}=0.00; *P*>.99).

Discussion

Principal Findings

This study primarily examined the feasibility and professionally rated usability of gardening-based immersive VR CT and explored pre-post changes in clinical outcomes among older adults with dementia. Participants responded favorably to the VR experience, experienced limited simulator sickness, displayed predominantly positive emotional responses, and generally completed the supervised program. Occupational therapists also rated the system as acceptably usable. The clinical outcome of global cognitive function was higher postintervention, whereas the domain-specific cognitive, functional, quality-of-life, and psychosocial outcomes showed no clear changes after correction for multiple comparisons. These findings provide preliminary support for the feasibility of integrating familiar, goal-directed activities into immersive VR CT for individuals with dementia.

Feasibility, Acceptance, Tolerability, and Professionally Rated Usability

The findings provide encouraging support for the feasibility of immersive VR CT among older adults with mild-to-moderate dementia. Participants reported greater acceptance after their initial VR experience, suggesting that direct exposure with appropriate guidance may help them become more comfortable with unfamiliar technology. This finding is consistent with previous research indicating that multisensory interaction and realistic virtual environments can facilitate acceptance and engagement among older adults [16,20]. Simulator sickness symptoms were limited and decreased after the first session, particularly for nausea and disorientation. This pattern may reflect growing familiarity with the equipment and greater confidence following guided exposure. As cybersickness is a common barrier to VR implementation, these findings support the tolerability of immersive VR when delivered in a supervised setting with appropriate monitoring and individualized rest periods [20]. The observed emotional responses further support the feasibility of the program. Pleasure and general alertness were frequently observed, whereas negative emotional responses were uncommon. The familiar gardening context, clear activity goals, and an interactive experience may have contributed to participants' positive responses and willingness to engage in CT. This is particularly relevant because motivation and engagement are important components of successful CTs [5].

Therapist-rated usability remains underexplored in immersive VR CT for people with dementia. Chuang et al [38] reported moderately favorable professional usability ratings for a gardening-based immersive VR CT system developed for community-dwelling older adults, whereas Lau et al [39] obtained positive occupational therapist feedback on a VR-based reminiscence therapy prototype for people with dementia. This study extends this work by obtaining usability ratings from occupational therapists who directly supported repeated VR training among older adults with mild-to-moderate dementia. Their favorable ratings suggest that the system and its delivery procedures were manageable within a supervised setting and highlight the value of incorporating therapists' perspectives into the development of VR interventions for dementia care. Beyond demonstrating feasibility, these findings may help identify practical considerations for subsequent implementation, particularly regarding intervention delivery procedures, usability, and safety monitoring. Such information may support further refinement of the VR training program as the ongoing randomized crossover trial progresses.

Primary Clinical Outcome

Global Cognitive Function

Global cognitive performance, as measured by the MoCA, was significantly higher at postintervention than at baseline, with a large within-participant standardized difference. This finding is broadly consistent with previous systematic reviews and meta-analyses reporting favorable cognitive outcomes following VR-based interventions among individuals with mild cognitive impairment or dementia [17-19]. In this study, the gardening-based VR program incorporated different activities designed to target specific cognitive domains, including attention, processing speed, memory, visuospatial abilities, and executive function. Together, these activities provided a structured approach to CT that addressed multiple cognitive domains within an interactive virtual environment. The observed improvement in MoCA performance may be associated with the broad range of cognitive abilities addressed by the training program. As the MoCA assesses multiple cognitive domains, the inclusion of different domain-specific training activities may help explain the favorable change in global cognitive performance. These findings suggest that incorporating a variety of targeted cognitive exercises within an immersive VR program may be a promising approach to providing comprehensive CT for older adults with dementia.

Domain-Specific Cognitive Outcomes

In contrast to the improvement observed in global cognitive performance, no statistically significant pre-post differences were found in domain-specific cognitive measures, including the Stroop test, CTT-1 and CTT-2, and FAB. Although moderate within-participant standardized differences were observed on the FAB and CTT-2, these findings remained nonsignificant after Holm-Bonferroni correction. This discrepancy between global and domain-specific cognitive outcomes is broadly consistent with previous meta-analytic evidence indicating variability in the effects of VR-based interventions across different cognitive domains among individuals with mild cognitive impairment or dementia [19]. The findings indicate that favorable changes in global cognitive performance are not necessarily accompanied by corresponding improvements in specific cognitive abilities, highlighting the importance of examining outcomes across multiple cognitive domains.

Several considerations may help explain the absence of significant changes in domain-specific cognitive outcomes. First, although the VR program included activities specifically designed to train different cognitive abilities, including attention, processing speed, memory, visuospatial abilities, and executive functions, the training tasks may differ from standardized neuropsychological assessments in terms of stimulus presentation, cognitive demands, and response requirements.

XSL•FO
RenderX

These differences may influence the extent to which training-related changes are reflected in standardized cognitive test performance. Second, the duration and distribution of training across cognitive domains may have influenced the findings. Although the 5-week intervention provided repeated practice across multiple cognitive abilities, the amount of training devoted to each specific domain may have varied depending on the activities performed. In addition, improvements in trained cognitive tasks may not necessarily generalize to untrained neuropsychological assessments. These considerations highlight the importance of examining domain-specific training dosage and the transfer of cognitive skills when evaluating multidomain VR CT programs. Future studies could examine changes in performance within individual VR training activities alongside standardized neuropsychological assessments to better understand whether improvements in trained tasks extend to broader cognitive abilities.

Secondary Clinical Outcomes: Functional and Psychosocial Outcomes

ADL, quality of life, depressive symptoms, behavioral symptoms, and mental well-being remained generally stable. This finding is consistent with previous research suggesting that changes in cognitive performance do not necessarily translate directly into broader functional or psychosocial outcomes [40]. The participants' relatively preserved basic daily functioning and low baseline levels of depressive and behavioral symptoms may also have left limited room for measurable change. Broader changes in daily functioning and psychosocial well-being may require longer intervention periods or a more comprehensive approach that directly incorporates physical activity, social participation, emotional support, and opportunities to apply trained skills in everyday situations [6,40]. Future development of the program could therefore connect virtual gardening activities with real-world tasks or caregiver-supported practice to promote transfer from the virtual environment to daily participation.

Meaningful Activity Design

A distinctive feature of this program is the integration of familiar gardening activities into an immersive VR environment for people with dementia. Meaningful leisure activities are central to person-centered dementia care and have been associated with cognitive engagement and cognitive reserve [12-15]. Gardening provides recognizable goals and contextual cues that can connect an unfamiliar digital environment with activities encountered in everyday life. The positive emotional responses observed during the initial session suggest that this familiar activity context was well received and may encourage participation in CT. Although the VR tasks required participants to learn specific procedures and respond to progressively complex cognitive demands, the gardening context provided a coherent structure for completing these tasks. Cognitive-scaffolding models propose that existing knowledge and preserved abilities can support performance when individuals encounter new cognitive challenges [41]. Activities such as planting, watering, harvesting, and organizing gardening products allowed participants to practice attention, memory, sequencing, visuospatial processing, and problem-solving within recognizable situations. Embedding cognitive demands within familiar occupations may therefore make technology-assisted training more understandable, relevant, and engaging than decontextualized cognitive exercises.

Clinical Implications

The findings suggest that gardening-based immersive VR CT is a feasible approach for providing structured CT to older adults with dementia in supervised hospital and day care settings. By incorporating different activities targeting specific cognitive domains within a familiar gardening context, the program provides opportunities to engage participants in CT through interactive and goal-directed tasks. This approach may serve as a complement to conventional CT by presenting cognitive challenges within recognizable activity contexts. Furthermore, the favorable acceptance and emotional responses observed in this study suggest that such an approach may support participation and engagement among individuals with dementia.

An important consideration for clinical application is the flexibility of VR training to accommodate individual abilities and needs. In the present program, task difficulty was automatically adjusted according to participants' performance, allowing cognitive challenges to be adapted to different levels of ability. In addition, flexible seated or standing participation, therapist monitoring, and opportunities for assistance and rest enabled the training to be delivered according to participants' physical conditions and support needs. These features may facilitate individualized CT while maintaining an appropriate level of challenge and participant comfort. The favorable professionally rated usability findings further suggest that the system and its delivery procedures were manageable within a supervised care setting.

Several practical considerations are important for broader clinical implementation. Individuals with dementia may differ considerably in their cognitive abilities, familiarity with technology, and need for assistance. Therefore, appropriate participant selection, staff training, equipment management, and monitoring of participant responses should be addressed when incorporating immersive VR into clinical or community-based services. These considerations highlight the importance of establishing appropriate implementation procedures to support the safe and effective delivery of individualized VR CT in dementia care.

Limitations

Several limitations should be acknowledged. First, although the registered study uses a randomized crossover design, this report analyzes only the intervention-phase data using a single-group pre-post approach. The absence of a concurrent control condition limits causal inference; therefore, the higher postintervention MoCA score cannot be attributed solely to the VR program. Practice effects associated with repeated testing, natural fluctuations in cognitive performance, regression to the mean, social interaction, and attention from study personnel remain possible explanations. Completion of the ongoing registered trial will allow controlled comparisons and evaluation of potential period and sequence effects.

XSL•FO
RenderX

Second, the small referral-based convenience sample recruited from 2 settings limits statistical precision and generalizability. Participants who agreed to enroll may have been more receptive to technology, medically stable, or able to follow instructions than the broader population of people with dementia. Participants also demonstrated relatively preserved basic daily functioning, limiting the applicability of the findings to individuals with more advanced dementia or greater support needs. Missing data further reduced the available sample for some outcomes. Although Holm-Bonferroni correction was applied to the secondary clinical outcomes, the study was not powered to establish clinical efficacy or reliably detect changes across multiple outcomes.

Third, participant acceptance, simulator sickness, and emotional responses were assessed only during the initial VR session and may not capture changes in experience or tolerability over repeated use. Usability was evaluated by a small group of occupational therapists who were directly involved in delivering the program. Their familiarity with the system may have influenced their ratings, and these findings may not represent the perspectives of other professionals or service settings. Moreover, the SUS results reflect therapist-rated rather than participant-reported usability.

Finally, the study did not include long-term follow-up; therefore, the maintenance of the observed cognitive findings and their transfer to everyday functioning could not be determined. Participants' previous gardening experience, personal interest in gardening, and perceptions of the meaningfulness of the activities were not systematically assessed. The study also did not compare gardening activities with other VR content, making it difficult to determine whether the favorable acceptance and emotional responses were specifically related to the gardening theme. Future research should complete the controlled analysis of the ongoing registered trial and evaluate the program in larger and more diverse samples. Repeated assessments of acceptance and simulator sickness across the intervention, participant-reported usability, evaluations by independent health professionals, and longer-term follow-up should be incorporated. Further studies could also examine whether tailoring VR content to participants' interests and previous life experiences strengthens engagement and whether gardening-based activities offer advantages over other familiar or meaningful VR activities.

Conclusions

This study provides preliminary support for the feasibility, acceptability, and tolerability of gardening-based immersive VR CT among older adults with dementia. Its distinctive contribution is the integration of familiar, goal-directed gardening activities into an interactive CT environment. This extends existing VR approaches by demonstrating how a meaningful leisure activity can be translated into structured digital tasks for people with dementia. The study also combines participant-centered feasibility outcomes with occupational therapist–rated usability, thereby providing complementary perspectives on both the VR experience and its potential delivery in care settings. The favorable pre-post change observed in global cognition provides an additional rationale for further controlled evaluation. More broadly, the findings illustrate how immersive technology can be designed around meaningful occupations rather than technology-driven tasks alone. This person-centered design principle may guide the development of digital cognitive interventions that are more closely connected to the interests and everyday experiences of older adults. In clinical and community dementia care, gardening-based immersive VR may offer occupational therapists and other care professionals an engaging platform for delivering structured cognitive activities. Larger controlled studies with longer follow-up are needed to determine its clinical effectiveness, sustained benefits, and applicability across diverse dementia care settings.

Acknowledgments

The authors sincerely thank all participants and their caregivers for their valuable participation in this study. The authors are also grateful to the health care professionals and staff of the dementia outpatient clinic at New Taipei Municipal Tu Cheng Hospital and the dementia day care center in Sanxia District, New Taipei City, whose support in participant recruitment and study implementation was essential to the completion of this research. The authors also acknowledge the Ministry of Science and Technology, Taiwan; Chang Gung Memorial Hospital; and the Healthy Aging Research Center, Chang Gung University, for their generous support of this work.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2026), the following tasks were delegated to the GenAI tools under full human supervision: proofreading and editing, translation, and publication support. The generative AI tool used was ChatGPT (GPT-5.6 Sol; OpenAI). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

This study was supported by the Ministry of Science and Technology, Taiwan (MOST 111-2314-B-182-039-MY3 and NSTC 114-2628-B-182-001-MY3); Chang Gung Memorial Hospital (CORPVVP0191, BMRP553, and BMRPJ29); and the Healthy Aging Research Center, Chang Gung University from the Featured Areas Research Center Program within the framework of the Higher Education Sprout Project by the Ministry of Education in Taiwan (URRPD1Q0181).

Abstract

Background: Serious games can be custom or noncustom, each offering advantages for rehabilitation. Custom serious games developed specifically for rehabilitation allow control over feedback and adjustment of game speed and difficulty. Alternatively, noncustom games do not offer these controls but provide attractive graphics, sounds, and engaging game mechanics. The differences between these systems may affect users' exercise intensity, quality of movement, and experience during gameplay, which have implications for system and game selection in rehabilitation.

Objective: This study compared movement performance and user experience of patients after a stroke while playing custom and noncustom virtual reality balance games that were either game-paced or self-paced.

Methods: A group of community-dwelling patients in the chronic phase post stroke participated in a cross-sectional repeated measures study. They were familiarized with 12 games; half were played using the custom system (Equio, Kinestica) and half with the noncustom system (Nintendo Wii Balance Board, Wii Fit games). Over 2 gameplay sessions with randomized blocks of game type (self-paced and game-paced) and the order of the system (custom and noncustom), participants played games requiring comparable movement of the center of pressure for each system. Movement performance (weight-shift repetitions and movement amplitude) was extracted from video recordings using the Kinovea software. User enjoyment (Modified Physical Activity Enjoyment Scale), flow (Flow State Scale for Occupational Tasks), and likability were assessed twice in each study block. Comparisons between the systems were conducted using paired *t* tests or Wilcoxon tests. Effect sizes (ES) were calculated using Cohen *d*.

Results: Twenty-six participants (aged 27 - 70 years) were included in the analysis. Repetitions and movement amplitude were significantly greater (repetitions: *P* .001–.003; amplitude: *P*=.002–.03) with large ES for all noncustom game–paced games and for half of the noncustom self-paced games (repetitions: ES 0.8 - 2.5; amplitude: ES 0.6 - 0.9). Perception of exertion was greater for noncustom game-paced games (ES 0.6; *P*=.005). In contrast, users' flow state (total and subdomains of sense of control and emotional experience; ES 0.6 - 0.8; *P*≤.03) and user preference were significantly greater for custom game-paced games. There was no significant difference between custom and noncustom games for enjoyment.

Conclusions: Serious gameplay was influenced by customization and type of game pacing, both of which should be considered when selecting serious games for balance training. Repetitions, movement amplitude, and perception of effort were greatest for the noncustom game-paced games, indicating greater intensity, while also addressing the difficulty patients after a stroke have with weight-shifting to the affected side. In contrast, custom games provided a sense of control and increased flow state, which may promote better adherence. Findings from this study have implications for clinicians and game designers. Both custom and noncustom games offer training features that support stroke rehabilitation.

Introduction

For patients who are ambulatory after a stroke, virtual reality (VR)–based balance exercises and serious games, when combined with conventional therapy, have been shown to be more effective in improving balance than conventional therapy alone [1]. This is true for patients who are less than [2] and more than 6 months [3,4] after a stroke. Additionally, for patients in the chronic phase post stroke, VR balance training alone or combined with other therapies is also more effective than comparable treatments for improving mobility [3-5]. Recent meta-analyses [5,6] have confirmed that VR, compared to alternative interventions or as an adjunct to usual care, may be beneficial for improving balance and may probably reduce activity limitations after a stroke. However, due to substantial heterogeneity and risk of bias across studies, the findings regarding the magnitude and clinical relevance of effects related to dynamic balance should be interpreted with caution [5]. Systematic reviews [2,5] and clinical practice guidelines [7,8] recommend combining balance training with VR or serious games for patients after a stroke. Specifically, VR balance training in stance can be performed with pressure-sensitive balance boards that provide information about the movement of the user's center of pressure (COP) for weight-shift training [7].

VR technologies delivered as serious games may enhance balance rehabilitation in patients after a stroke by incorporating engagement, feedback, repetition, cardiovascular and neuromuscular exercise intensity, and task-oriented training [7]. Interventions using VR can be effective because of their ability to mobilize recovery mechanisms and support physiotherapy goals [9]. For example, they promote movement frequency and movement amplitude toward the affected side, which are markers for increased use of the paretic limb and achieving the therapeutic dose required for neuroplasticity and functional recovery [10]. Enjoyment of serious games and the flow state support motivation and engagement, which are necessary for therapy adherence and duration to derive benefits such as motor learning and improved functioning [11,12].

Noncustom games, such as the Nintendo Wii, originally created for entertainment or recreation, can be adapted for rehabilitation, while custom games are specifically designed for rehabilitation. The Nintendo Wii console, along with the Wii Balance Board and Wii Fit games, is the most clinically accessed noncustom serious game system [13,14], and these games are used most often in poststroke rehabilitation [15]. Custom systems are designed to incorporate neurorehabilitation and motor learning principles for movement recovery, making them potentially more effective than noncustom systems [9]. Custom systems allow for the adjustment of game speed and control of game mechanics (eg, amplitude, feedback, and dual tasking). In contrast, noncustom games are more complex and less adaptable to the needs of individual patients [16], but they generally provide attractive graphics and sounds.

The nature and application of serious games in rehabilitation after a stroke are still not fully understood. An important critique of noncustom systems for rehabilitation is that they do not facilitate desired movement patterns and therefore do not achieve therapeutic goals [16-19]. A study of patients in the chronic phase post stroke [20] showed that using noncustom VR games resulted in 5 times more repetitions and double the acceleration of affected upper limb movements compared to traditional therapy, but 3 months of training did not improve motor function in any group. It has also been shown that patients can engage with noncustom technology during rehabilitation when a therapist tailors the prescription [21]. However, the perceived benefit of using technology, along with receiving sufficient support to enable its use, appears to influence the level of patient engagement [21].

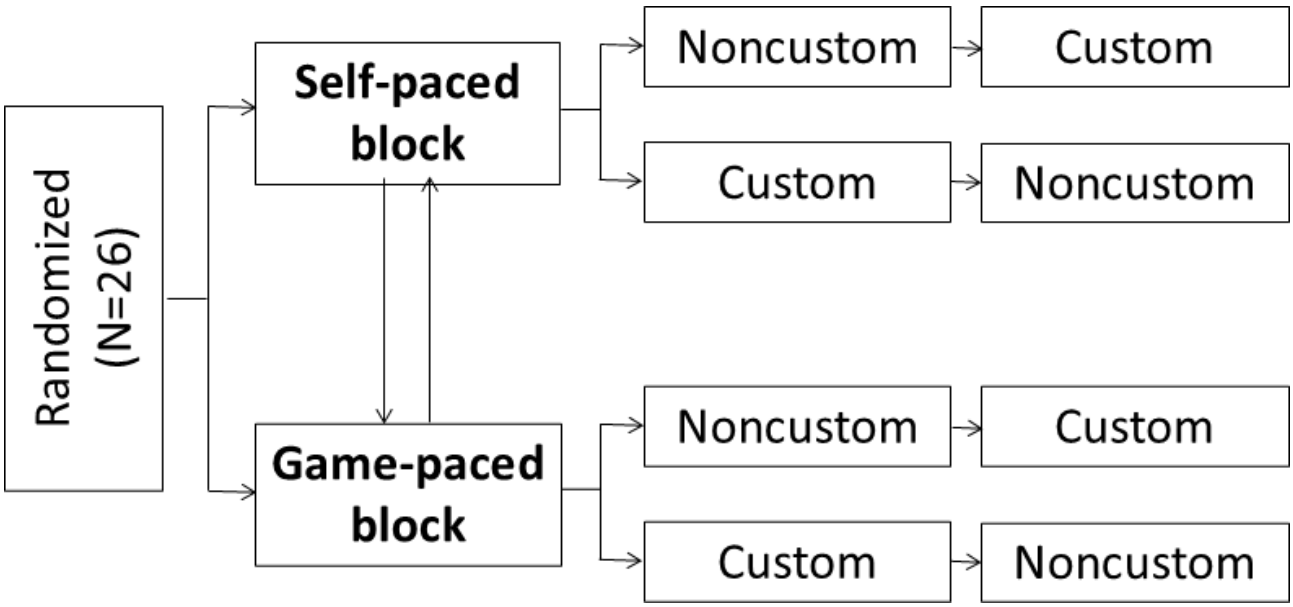
Both custom and noncustom games can be further divided into two game types: (1) self-paced games, in which speed is controlled by the user; and (2) game-paced games, in which speed is set by the game. Game pace is an important feature that has not been well-studied and is often cited as a limitation for patients after a stroke to engage with games [19].

While efficacy differences between custom and noncustom systems for upper limb training have been documented in one meta-analysis [22], and no difference in benefits was found in another meta-analysis [6], the differences for balance training post stroke are not yet known. Comparing custom and noncustom VR games for balance in the same group of patients after a stroke can provide insights into how game customization and type of game pacing influence gameplay. We have directly compared custom and noncustom game-paced VR stepping games for patients after a stroke and found that the custom game provided lower movement frequency (number of stepping repetitions) but better step accuracy, greater enjoyment and likability, and lower perceived exertion than the noncustom game [23].

In this study, we sought to extend the findings on game customization to include the type of game pacing. Therefore, the purpose of this study was to compare how patients after a stroke played custom and noncustom VR balance games that were either game-paced or self-paced and to investigate how movement performance (measured by movement frequency and movement amplitude) and user experience (exertion, enjoyment, flow, and preferences) differed. We hypothesized that patients after a stroke would have greater movement frequency (number of weight-shift repetitions to the affected lower limb) during noncustom games. In contrast, we hypothesized that users would have greater pelvic displacement to the affected side and report a better experience with custom game-paced games, but there would be no difference in user experience with self-paced games.

Methods

This study used a single-group, cross-sectional, repeated measures design and was registered at ClinicalTrials.gov (NCT06463730).



Participants

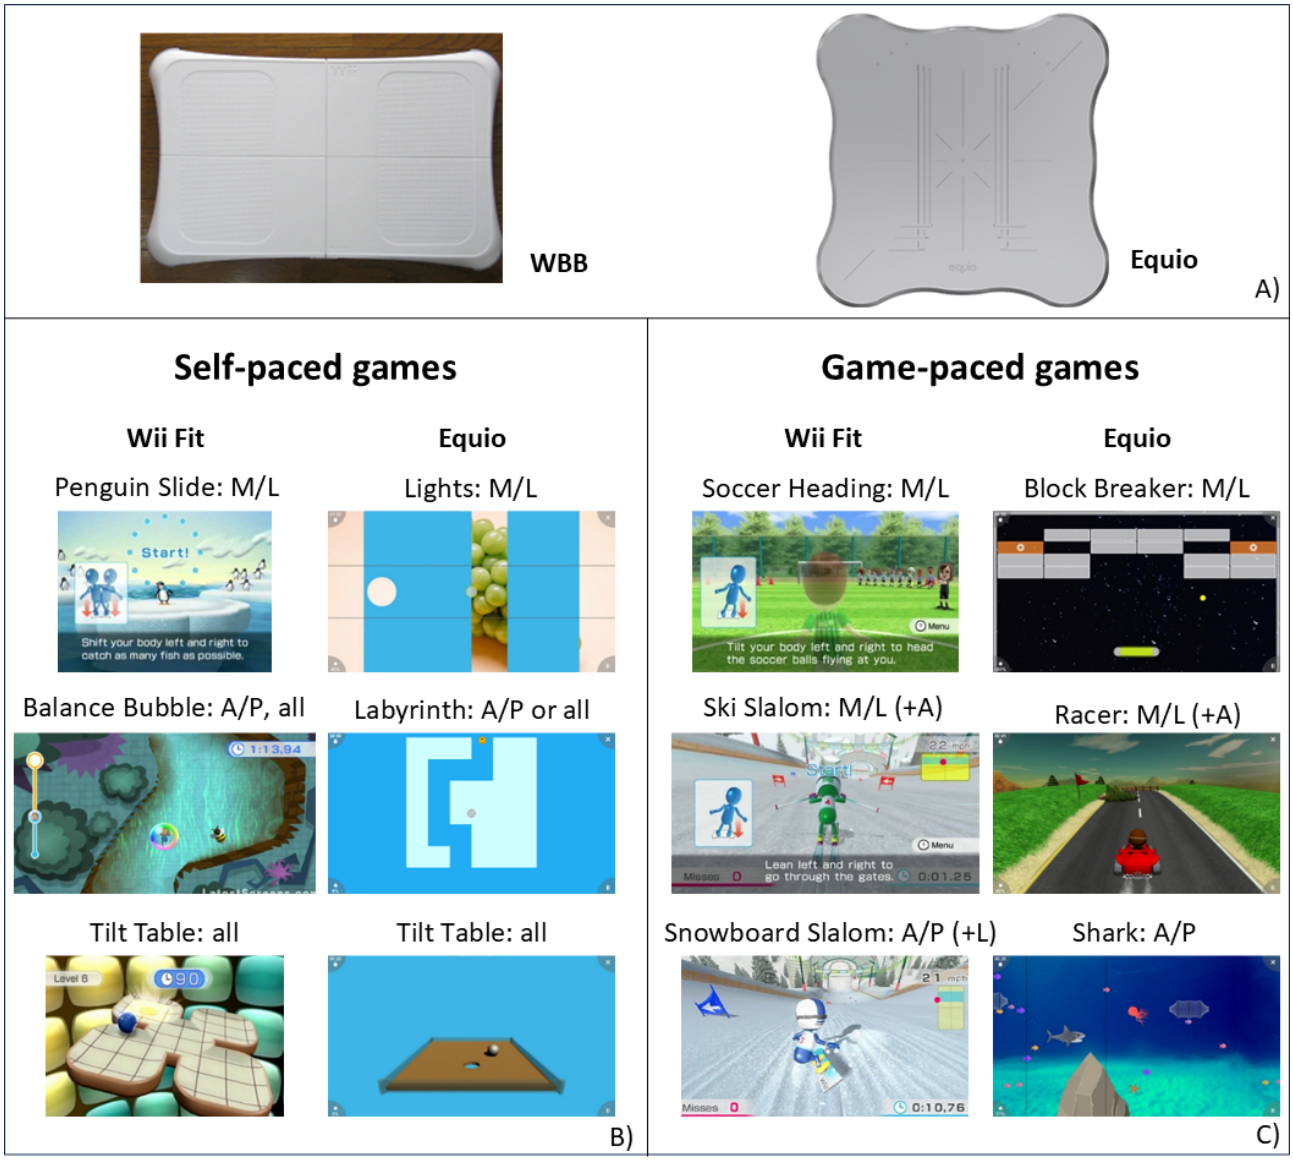
A convenience sample of community-dwelling patients was recruited through members of the Association of Cerebrovascular Disease Patients. Adults in the chronic phase

XSL•FO
RenderX

post stroke (>6 mo) were eligible to participate if they had a stable health condition, could follow simple instructions, and were able to walk with supervision or independently, with or without a walking aid, on flat ground or all surfaces (Functional Ambulation Categories [FAC] 3 - 5) [24]. Participants were excluded if they could not play games on the balance boards or had additional neurologic or musculoskeletal impairments that would interfere with performing the required tasks or completing the questionnaires. Participants were block randomized into 4 combinations (Figure 1).

Figure 1. Flow diagram of the study participants: All participants completed both study blocks in a randomized order of game types (self-paced and game-paced) and systems' order (custom and noncustom). Only one block was played per session.

Ethical Considerations



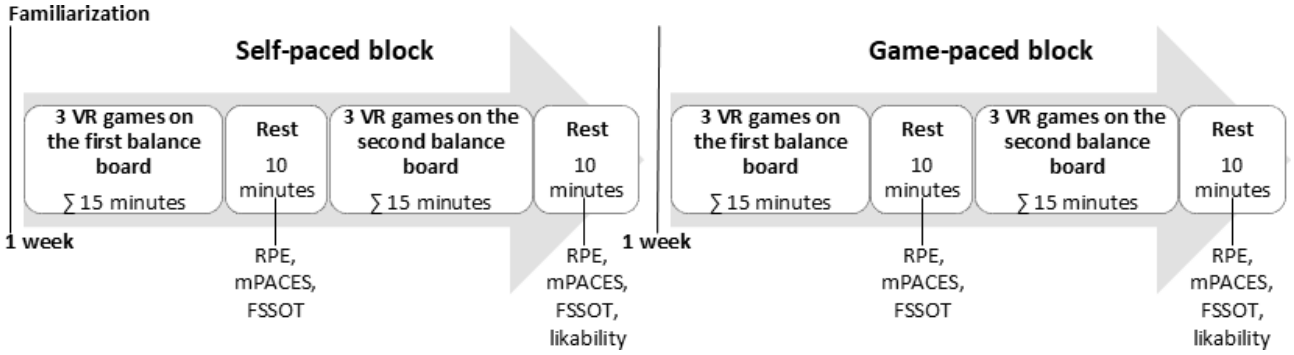
The study complied with the Declaration of Helsinki and was approved by the National Medical Ethics Committee of the Republic of Slovenia (0120-303/2021/3). All participants provided written informed consent to participate in the study. All data were anonymized. Participants did not receive any compensation.

Description of Custom and Noncustom Systems and Games

The custom system, classified as a class 1 medical device and developed for rehabilitation, was the Equio (Kinestica, d.o.o.). The noncustom system was the Nintendo Wii with the Wii Balance Board and Wii Fit games. These systems were chosen because they allow comparisons in game mechanics, as both use a balance board to interface with the game. The balance boards of both systems have 4 pressure sensors at the bottom, which calculate the COP position of the user based on body-weight transfers during standing, and both are portable. The custom board has a sampling frequency of 200 Hz [25], while the noncustom board has a sampling frequency between 35 and 100 Hz (average 63 Hz) [26]. The custom board is made of aluminum, is thinner, and has a larger surface area (496 mm × 496 mm × 12 mm; 6635 g) [25], while the noncustom board is made of plastic, is lighter, but thicker (510 mm × 310 mm × 55 mm; 4000 g; Figure 2A). The systems were connected to a TV screen 220 cm away from the participant standing on the balance boards.

XSL•FO
RenderX

Figure 2. (A) The noncustom system Nintendo Wii Balance Board (WBB) and the custom system (Equio) with their (B) self-paced games and (C) game-paced games, and the directions of center of pressure movement. +A: anterior; A/P: anteroposterior; +L: lateral; M/L: mediolateral.



Comparable self-paced and game-paced games from each system were selected based on the required movements of the center of COP direction (see Figure 2B and C). For example, the tilt table game, present in both systems, required the COP to be moved in all directions. For the noncustom games, the basic difficulty level was used for all participants, as recommended by the developer for initial gameplay. The custom games have 3 difficulty levels. Their difficulty was adjusted for accuracy requirements (eg, size of obstacles or targets), number of targets, and the addition of a dual task. Game-paced games were played at the speed required by the game, while self-paced games were played at the participants' preferred speed. Details of custom and noncustom games are described in Multimedia Appendix 1.

Protocol

Participants attended a familiarization session and 2 gameplay sessions, approximately 1 week apart, in the Physiotherapy Laboratory of the university (see Figure 3). Familiarization consisted of playing each of the 12 games for 2 minutes. To set the range of motion needed during the custom games, the COP range of motion in the mediolateral and anteroposterior directions was measured for each participant using the custom system. These values were automatically translated to the custom game scenarios and adjusted based on accuracy at the start of gameplay in all sessions. The difficulty level of each custom game was determined based on the capabilities of participants during the familiarization session.

XSL•FO
RenderX

Figure 3. The study protocol: familiarization and 2 gameplay sessions (the order of the study conditions was randomized), including assessment with the Flow State Scale for Occupational Tasks (FSSOT), the Modified Physical Activity Enjoyment Scale (mPACES), the Borg Perceived Exertion Scale (RPE), and likability-user preference. VR: virtual reality.

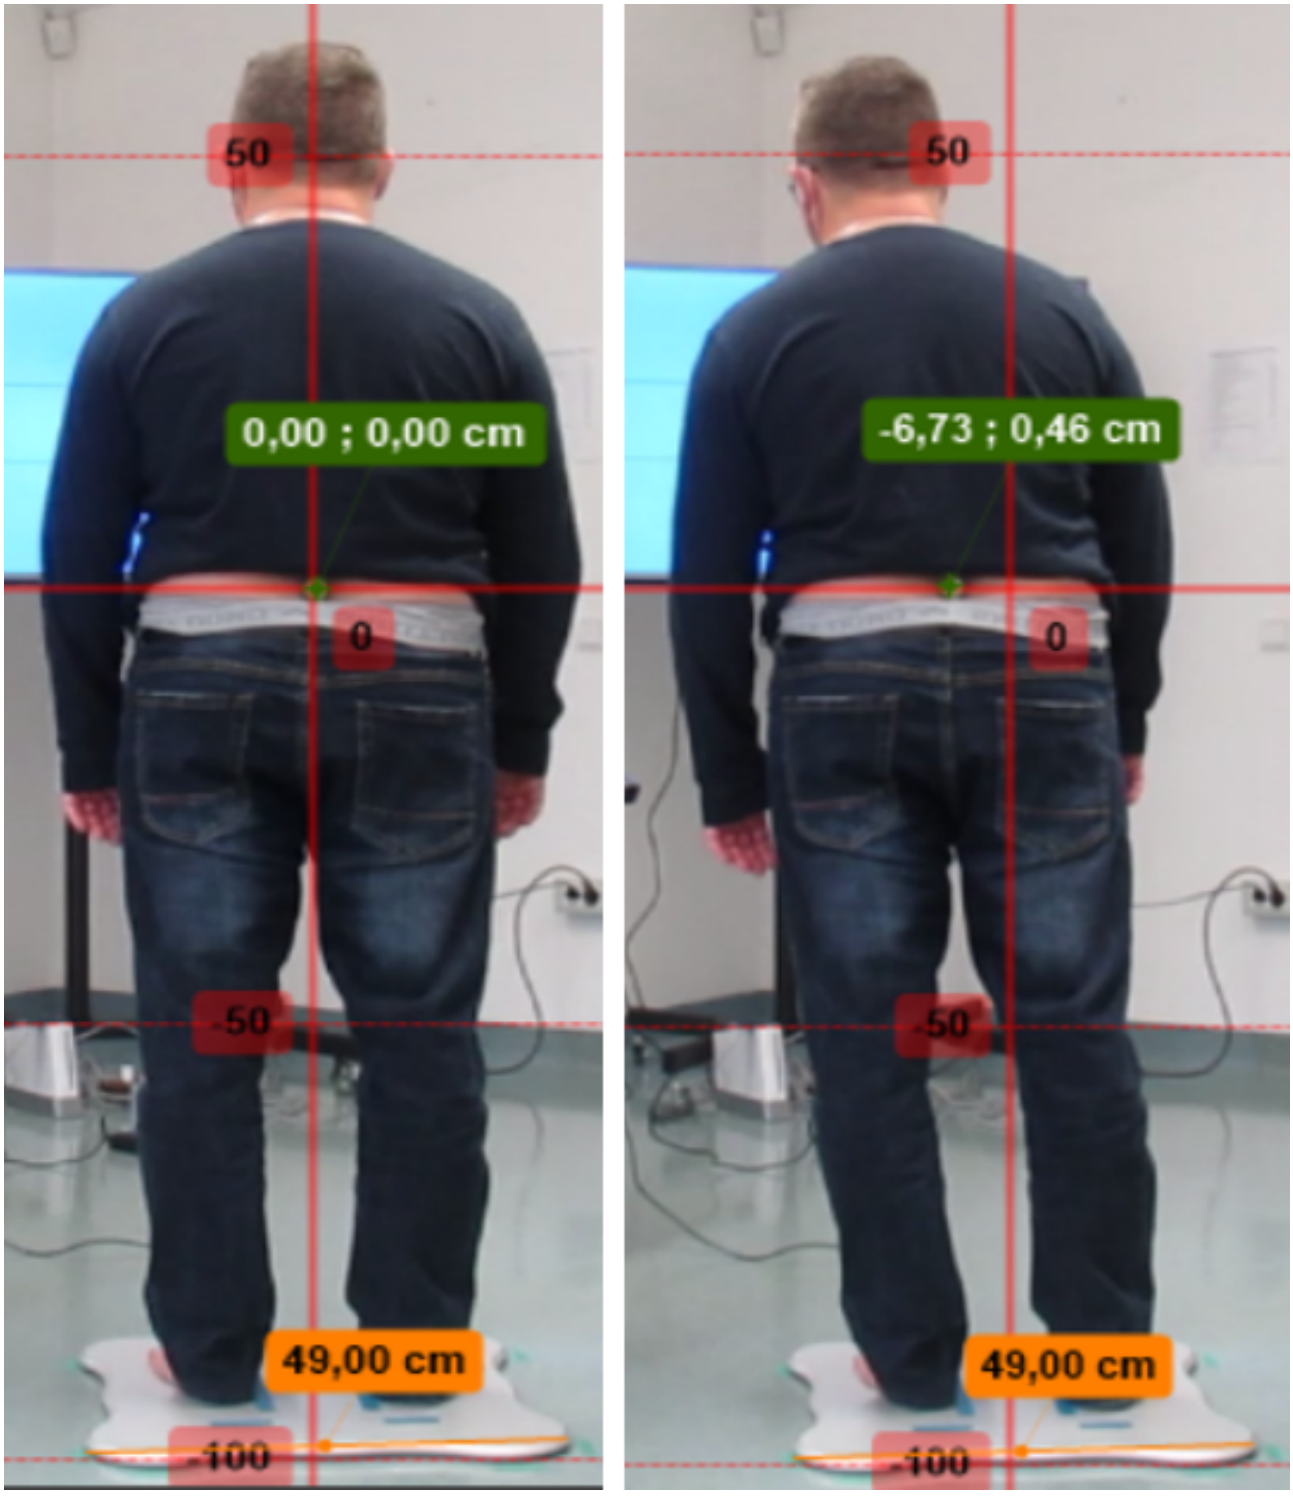
Gameplay was studied in 2 sessions. To ensure movement quality and safety, during the first minute of each game, a physiotherapist guided movement with either verbal or manual cues and positioned the participant's feet. Both the order of game types (self-paced and game-paced) and the order of the systems (custom and noncustom) were randomized (see Figure 1). In each gameplay session, participants played 1 block consisting of 3 games (5 min each) on the noncustom balance board and 3 comparable games on the custom balance board. Each gameplay session consisted of 30 minutes of training with a 10-minute rest in the middle. During the rest periods, the assessment of the user's experience was performed in a sitting position (Figure 3).

Data Collection and Reduction

Participants' balance and gait were measured during the familiarization session. Balance was assessed using the Mini Balance Evaluation System Test [27,28]. Walking capacity was rated with the FAC, and comfortable and fast walking speeds were measured with the 10- meter walk test. The latter was conducted on a 14-meter walking path [28], with 1 familiarization trial and 1 test trial performed at a comfortable speed, followed by a fast speed walking trial.

The primary outcome measures were movement frequency (number of weight-shift repetitions to the affected lower limb) and movement amplitude of pelvic displacement to the affected side. Movement performance during gameplay was recorded using a digital video camera (Canon PowerShot SX620 HS; Figure 4, first), recording at 30 frames per second. A marker used to monitor pelvic movement was placed on the sacrum at the height of the center of body mass (S2). The camera was positioned behind the participant to clearly view the participant's pelvis and torso, the marker, the balance board, the position of the feet, and the TV screen. The TV screen, balance boards, and camera were always positioned in the same place; however, the camera was moved back from this position if the participant's head was not visible in the video. The first minute of the recordings was excluded from the analysis because participants had to adjust to the game at the beginning (described above).

Figure 4. Participants after a stroke playing games with the noncustom system (first and third) and the custom system (second and fourth) balance boards.



For the 8 games that required movement of the COP in either the mediolateral direction or all directions, the number of weight shifts to the affected lower limb (repetitions/min) and the amplitude of pelvic displacement to the affected side in the frontal plane were extracted from video recordings using the Kinovea software (version 0.9.1) [29]. For each game, the last 4 minutes of gameplay were analyzed. Any voluntary movement of the pelvis to the affected side in the mediolateral direction, from the starting point to the farthest point and back to the starting position, was considered a correct repetition. The amplitude of pelvic displacement was determined by measuring the maximum displacement of the marker from the start to the end position (Figure 5). The analysis was performed for games in which the markers were not concealed in ≥50% of the

XSL•FO
RenderX

recording (eg, due to compensatory rotation of the pelvis or while the physiotherapist provided additional guidance or safety).

Figure 5. Analysis of movement performance during gameplay on video recordings using the Kinovea software. The center of the coordinate system and the green dot/marker were overlaid at the start. The first number (x-coordinate) represents the position of the pelvic marker (0.00 cm) at the start and its mediolateral displacement at the end position (−6.73 cm), indicating a weight shift toward the left (stroke-affected) leg in the frontal plane. The orange reference indicates the length of the balance board, which was used to calibrate distance measurements.

The secondary outcome measures assessed user experience: the Borg Rating of Perceived Exertion Scale (RPE) [30], the Modified Physical Activity Enjoyment Scale (mPACES) [31], and the Flow State Scale for Occupational Tasks (FSSOT) [32]. These measures were collected twice in each study block, immediately after playing the games. The Borg Scale (ranging from 6 to 20) was used to estimate the cardiovascular intensity of physical activity through RPE. The mPACES is a 5-item scale, with scores expressed as percentages, that rates enjoyment during gameplay and has been used previously in VR studies [23,31]. The FSSOT is a 14-item questionnaire assessing flow state, with scores expressed as a total or in 3 domains: sense of

XSL•FO
RenderX

control, emotional experience, and absorption [32]. At the end of each gameplay session, participants viewed a figure displaying the 6 games and ranked them from most liked (6 points) to least liked (1 point).

Data Analysis

Data were assessed for normality using the Shapiro-Wilk test. Paired *t* tests with CIs were used to determine differences between custom and noncustom games for the number of repetitions and amplitude of pelvic displacement within the game pairs. Missing data were excluded from the analysis. Paired *t* tests or Wilcoxon signed rank tests were conducted to test for differences in mPACES, FSSOT, and RPE scores between games of custom and noncustom systems within self-paced and game-paced games. Cohen *d* was calculated to estimate the ES (0.2 small; 0.5 medium; >0.8 large). Cohen *d* and CIs for nonparametric data were estimated using the Bootstrap method. To correct for multiple comparisons, the α was adjusted to .025 within pairs. To identify differences in likability within self-paced and game-paced games, the total score of each game was calculated for all participants and then ranked within each block from most liked (highest total score) to least liked (lowest total score). IBM SPSS Statistics version 29.0 was used for the analysis.

Results

Participants

Twenty-six participants completed the study. Two individuals were excluded from the original 28 because they were unable to play the games on the balance board. There were no adverse events (eg, falls) or side effects (eg, motion sickness). Some movement performance data were missing due to concealed pelvic marker.

Participants' ages ranged from 27 to 70 years. The time since experiencing a stroke ranged from 0.7 to 37.8 years. Most participants were able to walk independently on both level and nonlevel surfaces, stairs, and inclines (FAC 5; Table 1). Participants' balance ranged from moderate (8 - 13 points; n=4) to mild balance deficits (15 - 23 points; n=14) and very mild balance deficits to normal balance (24 - 27 points; n=8) [33].

Movement Performance

Movement Frequency

For self-paced games, the movement frequency (number of weight-shift repetitions to the affected lower limb) was significantly higher for the noncustom game Penguin Slide compared to the custom game requiring comparable mediolateral movement. There were no significant differences between the 2 Tilt Table games (Table 2). For game-paced games, movement frequency was significantly higher for both noncustom games (Soccer Heading and Ski Slalom) than for their custom paired games (Table 2).

XSL•FO

[a]Games requiring center of pressure (COP) movement only in anteroposterior directions were excluded from this analysis.

[b]ES: effect size of the difference.

[c]Statistically significant difference for comparison between the 2 conditions with post hoc correction for multiple comparisons $P \leq .025$.

Movement Amplitude

For self-paced games, the amplitude of pelvic displacement to the affected side was significantly greater for the noncustom game Tilt Table than for the custom one. There were no significant differences within the mediolateral direction game pair (Table 2). For game-paced games, the amplitude of pelvic movement was significantly greater for both noncustom games than for their custom-paired games (Table 2).

User Experience

Enjoyment

For both self-paced and game-paced games, there was no statistically significant difference in mPACES scores between custom and noncustom games. Notably, for game-paced games, mPACES scores were on average 8 points higher for custom games and showed a moderate ES (Table 3).

XSL•FO

[a]ES: effect size of the difference.

[b]mPACES: Modified Physical Activity Enjoyment Scale.

[c]FSSOT: Flow State Scale for Occupational Tasks.

[d]Statistically significant difference for comparison between the 2 conditions with post hoc correction for multiple comparisons $P \leq .025$.

[e]RPE: Borg Rating Scale of Perceived Exertion.

[f]*t* test values (df).

Flow State

For self-paced games, there were no significant differences in FSSOT scores between custom and noncustom games. For game-paced games, the total FSSOT score was on average 8 points higher for custom games than for noncustom games. This difference was statistically significant for the total FSSOT score and for its subscores—sense of control and emotional experience (Table 3).

Perceived Exertion

The RPE scores ranged from 7 to 17. For the self-paced games, there were no significant differences in RPE between the custom and noncustom games. For the game-paced games, RPE was significantly greater for the noncustom games; however, both mean scores fell within the light-to-moderate range of perceived exertion (Table 3).

Likability—User Preference

For self-paced games, participants liked the Tilt Table of the custom system best, followed by Lights (custom system), and then the 3 noncustom games: Balance Bubble, Penguin Slide, and Tilt Table. The least liked game was Labyrinth (custom system; Table 4). For game-paced games, the 3 custom games were preferred. The noncustom games received the fewest points, especially Soccer Heading and Snowboard Slalom (Table 5).

Table . Likability of the custom and noncustom systems' games within the self-paced game type (N=26).

Likability	Noncustom			Custom		
	Penguin	Balance Bubble	Tilt Table	Lights	Labyrinth	Tilt Table
Sum	93	95	90	98	57	113
Mode	3	3	1	6	1	5
Median (IQR)	3 (2.7-5.0)	3.5 (2.8-5.2)	4 (1.0-5.0)	4 (2.0-5.3)	1.5 (1.0-3.2)	5 (3.0-6.0)

Table . Likability of the custom and noncustom systems' games within the game-paced game type (N=26).

Likability	Noncustom			Custom		
	Soccer Heading	Ski Slalom	Snowboard	Block Breaker	Racer	Shark
Sum	65	91	58	94	125	113
Mode	2	2	1	4	6	5
Median (IQR)	2 (1.0-3.0)	3 (2.0-5.0)	2 (1.0-3.2)	4 (2.0-5.0)	5 (3.8-6.0)	5 (3.7-5.0)

Discussion

Principal Results

Participants demonstrated better movement performance, including higher movement frequency (more weight-shift repetitions) and greater pelvic displacement to the affected side during the game-paced noncustom games. Movement performance between custom and noncustom games was more similar during self-paced games. User experience, specifically flow state and preference, favored the game-paced custom games.

As hypothesized, movement frequency based on the number of weight shifts to the affected lower limb during custom games was on average 21% to 61% lower than during noncustom games, with large ESs (ES 0.8 - 2.5). These findings are consistent with our previous study [23], where the total number of step repetitions was significantly lower for the custom game compared to the noncustom Kinect game (average difference

XSL•FO
RenderX

33%). The custom system allowed calibration for movement displacement within the user's limits of support as well as selection of movement speed (game difficulty level). In contrast, noncustom games lack this customization, requiring players to move faster and farther to meet the game mechanics. This could, however, result in poor movement control, as shown in our previous work [23].

Contrary to our hypothesis, the amplitude of pelvic displacement toward the affected side was on average 13% to 21% greater for the noncustom games than for the custom games, with medium-to-large ESs (ES 0.6 - 0.9), except for one case (self-paced games: Penguin Slide vs Lights), where there was no difference. This may be due to a conservative range of motion settings for custom games, which could only be adjusted in 5 centimeter increments. The movement boundary set by customization likely limited potential displacements. However, without a 3D motion analysis, no definitive statement can be made about movement quality or lack of control in relation to movement amplitude.

As hypothesized, user experience, specifically flow state, was better for the custom game-paced games than for the noncustom equivalent games, and there was no difference between custom and noncustom self-paced games. These findings support the claim that the lack of user control is especially evident in game-paced, rather than self-paced, games [23]. An important finding is that the flow state (FSSOT) data deepen the understanding of the user experience during custom game-paced games, in which subscores for sense of control and emotional experience were significantly higher than for noncustom games. This suggests that, regardless of the serious game system used, the ability of the user to control game speed is an important feature.

The findings of flow-state–favoring, custom game–paced games in this study were supported by a medium ES (ES 0.5) in enjoyment. The construct of enjoyment has been reported to be related to engagement for training and motor learning in virtual environments and likely promotes motivation [12]. VR-game balance training, specifically, was reported to be more enjoyable than conventional weight-shift training [34]. Therefore, it is important to consider the type of game pacing as a factor for the usability of serious games for patients with neurological conditions. Game-paced games use speed to determine the level of difficulty, which, when not adjusted, can lead to frustration and affect game enjoyment and motivation [19].

There was a small but statistically significant difference in perceived exertion, with lower RPE scores for the custom games, indicating a medium ES (ES 0.6). Participants perceived the game-paced noncustom games as somewhat more exerting (a mean difference of 1.19 points) than the custom games. This confirms previous findings on perceived exertion [23] and is consistent with the greater movement frequency and pelvic displacement observed in this study. However, perceived effort was quite similar across the games, and the difference was not clinically meaningful. The range of RPE scores for the game-paced noncustom games was wide, from 7 (very, very light) to 17 (very hard), and similar for the custom games, from 7 to 15 (hard) [30]. Because VR balance games are not expected to influence cardiovascular capacity [35], we propose that other factors, such as the difficulty of the task for each individual, influenced the level of exertion experienced by participants. None of the participants needed or requested an extension of the 10-minute rest period during the study protocol.

Clinical reasoning for selecting patients after a stroke for whom serious games are meaningful is challenging, as the patient population is heterogeneous [5]. While we did not analyze subgroups in this study due to sample size limitations, we note that participants' abilities influenced gameplay. Participants in our study with moderate balance deficits (Mini-BESTest [Mini Balance Evaluation Systems Test] 8 - 13 points; n=4) frequently experienced difficulties while playing games on both balance boards, particularly in placing their feet correctly due to muscle shortening, foot deformities, and increased muscle tone. For participants with very mild balance deficits to normal balance [33] (Mini-BESTest 24 - 27 points; n=8), the custom system games were often too easy or monotonous. Therefore, we speculated that for highly functioning patients after a stroke, noncustom games are likely more suitable. However, this is strictly an observation that requires further investigation with a larger sample size.

Taken together, the findings suggest that both custom and noncustom serious games have a role in balance training for persons after a stroke. Noncustom games promote greater movement amplitude and frequency toward the stroke-affected side. Custom games may promote greater adherence based on positive flow, enjoyment, and likability findings. There has been a tendency to dismiss noncustom games, particularly those that are game-paced. However, this study suggests they have a role in stimulating exercise intensity with movement toward the affected side. Game designers may also need to guard against constraining movement displacement.

While the findings of this study generalize to patients in the early-to-late chronic phase after a stroke with moderate-to-very mild balance deficits or normal balance (Mini-BESTest 8–27/28 points), the sample size did not allow for the interpretation of the effect of balance deficit severity on gameplay movement performance and user experience. Future studies may consider the relationship between balance ability and performance on serious games with a strong balance requirement. Movement performance should also be analyzed for games that encourage COP movement in the anteroposterior direction.

Limitations of the Study

The findings of this study generalize to games that use the COP as the marker of movement. These game mechanics are shared by many other games that use some form of platform to track movement. However, it is unclear whether the findings would be similar in games that use total body tracking. Differences between the 2 VR systems used, such as sampling frequency, board dimensions, surface area, and material properties, could influence COP sensitivity and thereby affect gameplay mechanics independently of game customization. These factors were not isolated in this study, and their potential contribution cannot be fully excluded. It was not possible to perfectly match all the custom and noncustom games.

XSL•FO
RenderX

The analysis of video recordings was challenging, even though Kinovea software is a valid and reliable tool for measurements within an angle range of 90˚ to 45˚ [36], with accuracy for measuring linear positions and velocities from 30 Hz video within 9% [37]. The use of 3D motion analysis systems would increase the validity of the results. Another limitation of this study is the reduced number of participants available for movement analysis due to the concealed pelvic marker. We encountered several challenges due to compensatory pelvis rotations, which caused the marker to fall outside the appropriate plane or resulted in movements too small for measurement. Additionally, the marker was sometimes covered by the physiotherapist while providing physical guidance or ensuring safety. Consequently, for some recordings—particularly those of more demanding, faster games—we did not perform the analysis due to missing data.

Conclusions

The findings of this study indicate that both customization and type of game pacing influence movement frequency, movement amplitude, enjoyment, flow state, and perceived exertion in VR balance games after a stroke. To our knowledge, this is the first study to parse the effects of game customization and type of game pacing on balance performance and the experience of patients after a stroke. Movement frequency and movement amplitude were significantly greater for all noncustom game–paced games and for half of the noncustom self-paced games. This is important to consider because weight-shifting toward the affected side is a common problem for patients after a stroke. Users' flow state (including the sense of control and emotional experience subdomains) and likability (user preference) were significantly greater for custom game–paced games. There was no significant difference between custom and noncustom games for enjoyment. Therefore, it is important to consider both game customization (primarily for user experience, with custom games preferred) and type of game pacing (primarily for movement performance) when selecting serious games as interventions to improve balance for patients after a stroke. These findings contribute to the body of knowledge that guides clinicians' clinical reasoning in selecting serious games for rehabilitation.

Abstract

Background: Auditory discrimination training is widely used to supplement aural habilitation and rehabilitation in individuals with hearing or auditory challenges. Recently, gamification has been introduced as a strategy to enhance attention, motivation, and engagement during training. However, the relationship between user experience (UX) and auditory discrimination performance remains unclear. In addition, maintaining long-term interest in auditory training is still a challenge, particularly in younger populations, highlighting the need for more engaging and user-centered approaches.

Objective: The objective of our study was to develop and compare 2 pure-tone auditory discrimination training systems: a game-based system with dual-task gamified activities and a non–game-based control system with identical auditory tasks but without gamified elements. We further aimed to evaluate differences in UX, engagement, usability, and behavioral auditory discrimination performance between the two systems.

Methods: A 3-stage process (design, implementation, and evaluation) yielded beta versions of both systems. Both platforms were developed using identical auditory stimuli, task logic, and performance metrics to isolate the effect of gamification, differing only in the interface and game elements. In the evaluation stage, a cross-sectional study with 11 young adults (aged 18-30 y) was conducted, where participants completed usability, UX, and engagement questionnaires after using each system. Behavioral performance was assessed through mean response time, proportion of correct responses, the Balanced Integration Score, and a novel Auditory Discrimination Performance Index integrating the Weber fraction and response time. UX was measured using the User Experience Questionnaire, the Post-Study System Usability Questionnaire, and the User Engagement Scale-Short Form. Statistical analyses included Shapiro-Wilk tests, paired *t* tests, and Wilcoxon signed rank tests.

Results: The game-based system produced significantly higher scores in 6 of 11 evaluated questionnaire dimensions, including focused attention, aesthetic appeal, reward, attractiveness, stimulation, and novelty, while no significant differences were found in most auditory discrimination performance metrics. Specifically, measures such as response time, accuracy, and Balanced Integration Score showed comparable results between systems. Usability-related outcomes showed a slight advantage for the non–game-based system, whereas all engagement-related domains consistently favored the game-based system, indicating improved user involvement and overall engagement without compromising performance.

Conclusions: These findings suggest that gamification can substantially improve UX and engagement without degrading short-term discrimination performance. This indicates that gamified auditory training systems may enhance user adherence without compromising task effectiveness. This study is innovative in that it directly compares game-based and non–game-based auditory training systems under controlled conditions, isolating the effect of gamification. Unlike other studies that primarily evaluate gamified systems without a control condition, this work clarifies the specific contribution of game elements to UX and performance. These findings contribute to the development of more effective, user-centered auditory training technologies and highlight the need for future longitudinal studies to determine whether these advantages translate into sustained auditory benefits across tasks.

Introduction

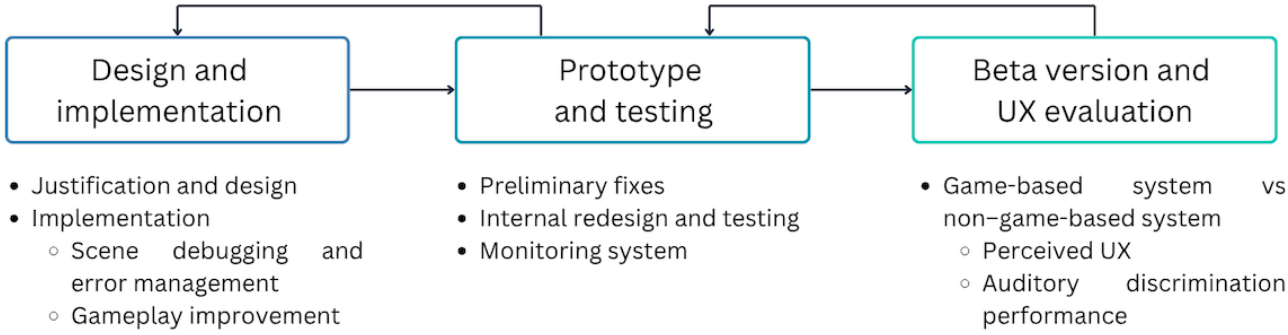
Aural habilitation and rehabilitation support individuals in adapting to challenging hearing situations such as the use of hearing aids [1], bone-conduction implants [2], or cochlear implants [3]. These approaches are also relevant for populations requiring improved auditory performance, such as those with auditory processing disorders, including difficulties in localization, lateralization, auditory discrimination, pattern recognition, and temporal processing. Adaptation at early stages can be a complex task, as individuals must learn to process whole sound domains in the best way [4]. Main difficulties include accurately identifying and discriminating speech from environmental sounds (including noise), locating sound sources, and particularly listening to music [5,6], which can be quite difficult. This adaptation process may extend over months to years, since it relies not only on sensory changes but also on neural plasticity [7]. Recommended strategies for this population include auditory-verbal therapy, mainly in children [8], and auditory training [9], which contain core exercises that enhance perceptual refinement [10]. As these activities extend over long aural rehabilitation periods, individuals often engage in lengthy sessions that must be integrated into their daily routines [8]. In this way, user-centered and engaging approaches may have better reception among young people and children [11], enhancing motivation and interest in longitudinal activities [12].

In recent decades, a series of systems and tools have been developed to improve accessibility and personalization [1,13], enhancing the population's attention and rehabilitation performance. New technologies and approaches have been followed by a user-centered design and have been validated through user experience (UX) tests [14]. Yet not all of them have followed processes of user-centered design and UX evaluation that support engagement in attractive and modern gameplay and genres, fitting auditory discrimination tasks and ensuring usability—critical elements for achieving game goals. Thus, studying the real impact and analyzing the efficiency of gamification in auditory discrimination training could be quite complex [15], especially when identifying key improvement elements when no control groups are considered.

Recent studies have evaluated game-based auditory training through questionnaires assessing usability, gameplay, and attractiveness [16,17], building design and evaluation methodologies ranging from game-user research to beta testing and assessment. Other recent studies have compared gamified auditory training performance with control groups performing different tasks [18]. However, very few studies to date have compared game-based auditory training with equivalent non–game-based auditory discrimination activities to measure both differences in general UX (focused on usability and engagement) and behavioral performance [19,20].

A key consideration of auditory training is the selected stimuli. Most speech-based training tools are mainly available in English, which makes accessibility difficult for youths and children whose first language is not English. As an alternative, some studies have suggested a transfer effect of other auditory stimuli that may improve complex auditory perception, such as speech [21,22]. Some analyses about the effects of nonverbal training, such as music and other types of auditory temporal training, have demonstrated improvement in language skills [23], while some others have reported no differences [24]. Still, this approach addresses the challenges of language-dependent systems development.

Addressing these gaps is crucial for developing inclusive, evidence-based tools that support diverse populations and, importantly, link enhanced UX to long-term performance improvements [25]. The aim of this study was to develop and directly compare 2 pure-tone auditory discrimination training systems—a game-based system and a non–game-based system—while controlling for auditory stimuli and task structure. Specifically, this study sought to evaluate differences in UX, engagement, usability, and auditory discrimination performance between both approaches. We hypothesized that the game-based system would improve engagement and UX without negatively affecting auditory discrimination performance compared to the non–game-based system. In this manner, this work makes 3 main contributions. First, it presents the design and beta evaluation of 2 matched auditory discrimination systems that isolate the effect of gamification by keeping auditory stimuli and task logic identical. Second, it introduces an Auditory Discrimination Performance Index (ADPI) that combines just-noticeable differences (JNDs) and reaction times into a single performance metric. Third, it provides empirical evidence on how specific gamification elements influence UX, engagement, and behavioral performance in pure-tone training tasks.



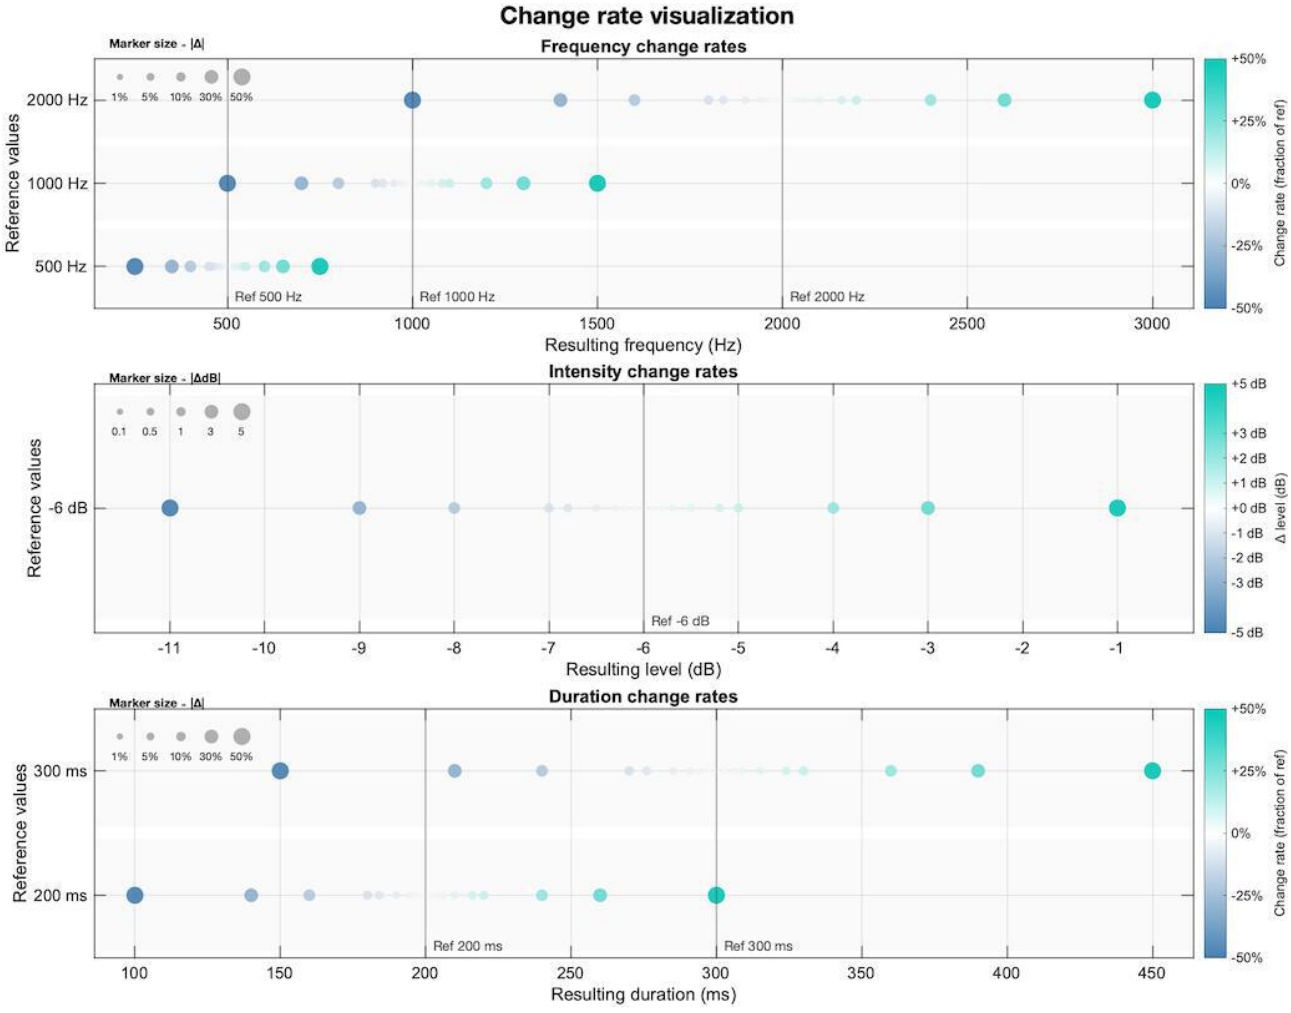
Methods

Development Stages

The methodology for both systems' design, implementation, and evaluation was adapted from [16,19] and consisted of (1) problem definition and initial design, (2) creation of a prototype and testing, and (3) UX, usability, and engagement evaluation of the beta version, as described in Figure 1.

XSL•FO
RenderX

Figure 1. Overview of the methodology for design, implementation, testing, and evaluation of both game-based and non–game-based auditory training systems. UX: user experience.



Systems Design and Implementation

Auditory Discrimination Tasks

Two different auditory training systems were developed: a game-based training system (GBS) and a non–game-based training system (NGBS). Each of them delivers sound stimuli for auditory discrimination of pitch, duration, and intensity, as the basis of the auditory discrimination hierarchy proposed in Sindrey [26]. Pure-tone pitch and intensity references and targets were selected based on the main speech features across languages [27], as shown in Figure 2. Duration references and targets were selected based on consonant-vowel timing [28], as shown in Figure 2. In the GBS, however, these tasks are presented in a gamified format based on an infinite runner genre (Licensed Infinite Runner Engine in Unity), as used by other similar game-based training systems [16,22], while the NGBS offers the same pure-tone auditory discrimination tasks in a nongame platform. To guarantee comparability, both systems used identical auditory stimuli, task logic, and performance metrics. Only the interface and gamification elements differed.

Figure 2. Pitch, duration, and frequency references and targets. Top: pure-tone pitch references of 0.5, 1, and 2 kHz and targets from 1% to 50% change rates. Middle: pure-tone intensity reference of −6 dB FS and targets from 0.1 to 5 dB changes. Bottom: pure-tone duration references of 200 and 300 ms and targets from 1% to 50% change rates. Reference tones mainly have a pitch of 0.5 kHz, an intensity of −6 dB FS, a duration of 200 ms, and an envelope with fade-in and fade-out of 5 ms.

XSL•FO
RenderX

Non–Game-Based Training Platform

The NGBS delivered the same auditory stimuli and discrimination tasks using a static, minimalist graphical interface. Visual feedback was restricted to the participant's response to each individual trial, with no indication of score, animation, time pressure, or level of engagement. This methodology required participants to focus only on sequences of pure-tone discrimination tasks, providing a low-engagement control condition.

Game-Based Training Platform

During GBS training, participants played in an infinite-runner format in which they guided an animated character through an obstacle course as they completed different auditory discrimination tasks. This dual-task structure was intended to increase cognitive load and promote sustained engagement by combining behavioral training with interactive gameplay, following a classical dual-task paradigm [25], where the primary task is a pure-tone discrimination task and the secondary task is the infinite-runner genre game. Correct responses on the primary discrimination task allowed them to continue playing and triggered positive audiovisual feedback, whereas errors reduced lives and elicited corrective audiovisual feedback. Correct responses on the secondary task allowed them to continue increasing their score but did not directly affect the primary task's performance metrics.

Implementation Process

Both platforms were implemented in Unity (C#) using the FMOD audio engine and following an iterative, multistage development cycle.

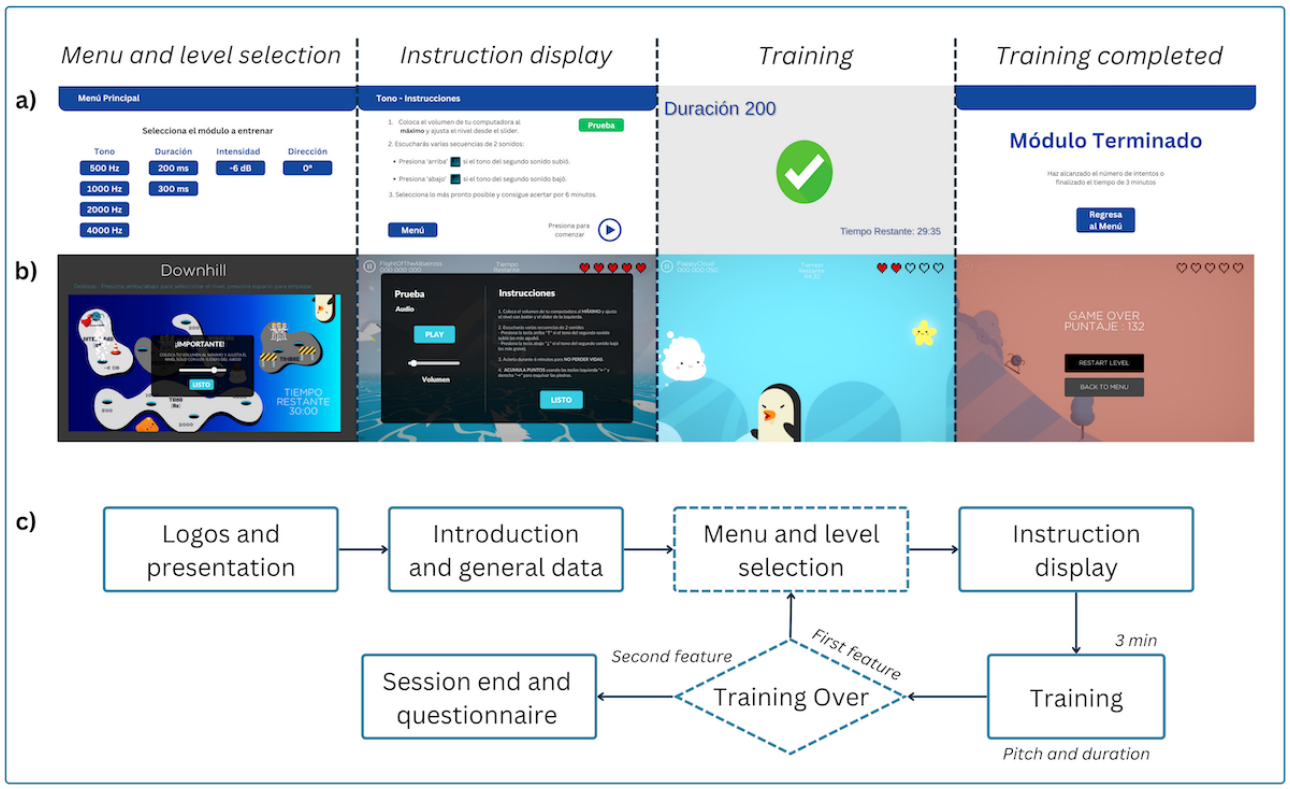
Prototype and Alpha Phase

The design and genre were selected based on popular infinite-runner mobile games and previous implementations in auditory tasks [16,22]. Core mechanics (jumping and maneuvering) were selected based on their connection with the main discrimination goal, as described in [29], and were implemented and internally tested to ensure timing precision and data integrity. Enhancements included improved instructions, sound-level adjustment, and basic visual feedback.

Beta Phase

Dynamic scoring and refined user interface elements were introduced. Feedback from pilot testing guided the correction of perceptual calibration issues, menu structure, and visual clarity. The stable versions used for validation and experimentation incorporated all refinements and enabled the automated export of performance metrics.

A comparison of platform features is presented in Table 1, summarizing differences in task presentation, feedback, scoring, and data logging between the GBS and NGBS. This table highlights how gamification elements were deliberately implemented in the GBS and omitted from the NGBS to isolate the effect of game mechanics. A more detailed game design sheet is shown in Table S1 (Multimedia Appendix 1).



A version of each auditory discrimination system was exported for Windows OS for controlled testing. Each version, as well as the system user flow, is shown in Figure 3.

Table . Comparison of game-based and non–game-based systems features.

Feature	Non–game-based system	Game-based system
Task presentation	Static auditory stimuli	Embedded within a dynamic obstacle-navigation game
Feedback	Text-based success or error	Animated success or error, points, lives, and rewards
Engagement cues	Minimal	Visual animations, background music, rewards, and challenges
Data logging	Responses, intervals, training time	Responses, intervals, scores, lives, and session data
Questionnaire integration	Pop-up reminders	Integrated pop-ups within the game flow
Instructions	Text instructions	Text and interactive in-game guidance

XSL•FO
RenderX

Figure 3. Systems interfaces and user flow. (A) Non–game-based system and (B) game-based system interfaces of 4 stages (menu and level selection, instructions display, training, and training over). (C) User flow that participants followed when testing each system for both sound features (duration and pitch).

Systems Testing and Evaluation

Stage 1: Prototype Testing

The first validation stage focused on technical reliability and preliminary user feedback. Six adult volunteers completed 5- to 10-minute sessions with each platform. Participants performed sample tasks, reported interface issues, and provided qualitative feedback on clarity, responsiveness, and sound calibration. Observations from this stage informed adjustments to auditory cue presentation, error handling, and menu navigation.

Stage 2: Beta Testing

The goal of the second stage was to evaluate usability, engagement, and performance in the near-final versions. A total of 11 participants completed structured training blocks on both platforms in counterbalanced order. After each session, they completed 3 standardized questionnaires: (1) the User Experience Questionnaire (UEQ), (2) the Post-Study System Usability Questionnaire (PSSUQ), and (3) the User Engagement Scale-Short Form (UES-SF). Feedback guided final refinements, including clearer instruction prompts, improved sound-level calibration, and enhanced data-logging reliability.

The current work focuses on findings from the beta testing stage prior to the full-scale deployment of the final version.

Ethical Considerations

This study was conducted in accordance with the principles outlined in the Declaration of Helsinki. Ethical approval was obtained from the Ethical Committee of the Instituto Tecnológico y de Estudios Superiores de Monterrey Engineering School with ID EHE-2023 - 11 and was registered in the International Standard Randomized Controlled Trial Number registry (ISRCTN43661994).

Participants were given informed consent prior to study enrollment. The consent stated the procedure and described the materials, ensuring voluntary participation. Participants' data were anonymized prior to analysis to protect participants' privacy and confidentiality. No identification of individual participants or users is included in this study. No monetary compensation was given to the participants.

Participants

Sample Size, Power, and Precision

The sample for the beta testing consisted of 11 participants. The sample size was determined based on usability testing guidelines. In general, a cohort between 5 and 10 participants is often considered sufficient to identify major usability problems [19,30]. The achieved sample size met these recommendations and corresponded to the total number of participants available during the study period.

Sampling Procedures and Participant Characteristics

Participants were recruited via online flyers and personal invitations through a voluntary response sampling process from the beginning of September to the end of October 2024. All participants were adults aged 18 to 30 years (mean 21.82, SD 3.13 y) and were enrolled in either a bachelor's or master's program at Tecnológico de Monterrey. The sample consisted of 11 participants with a male-to-female ratio of 1.75:1. All participants recruited participated in the study.

XSL•FO
RenderX

Sessions were done at the NeuroTechs laboratory within Tecnológico de Monterrey. At the beginning of the session, participants were informed about the overall purpose, procedure, and relevance of the study. Following written informed consent, participants completed an initial questionnaire comprising demographic data and questions aimed at evaluating their overall health condition and gaming hours per week.

Inclusion and Exclusion Criteria

Inclusion criteria required the participants to be aged between 18 and 30 years, report normal hearing abilities, and have no diagnosis of neurological, auditory, or attentional disorders. In addition, no participant was undergoing any medical treatment at the time of the experimental procedure. If any of these requirements were not met, participants would not be enrolled in the study.

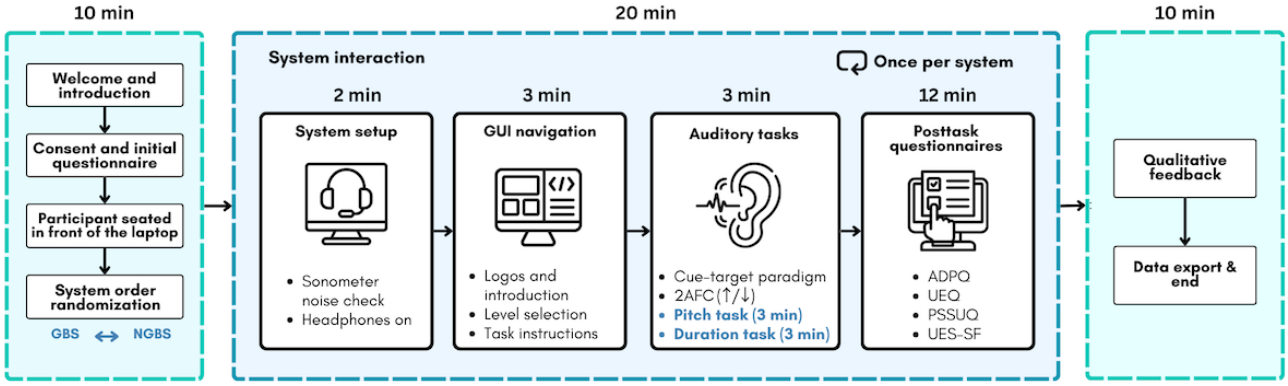
Study Design and Procedure

Conditions and Design

This study followed a within-subjects cross-sectional experimental design in which participants interacted with both systems. The order of exposure to the systems (NGBS or GBS) was randomized for each participant to avoid potential order effects. This corresponds to an experimental manipulation with a randomized condition order.

Instrumentation

A Class-1 sound level meter (B&K Type 2270) was set to register the background noise levels during the use of each system to ensure that the experimental phase was conducted in a quiet environment and that noise was not a relevant factor affecting performance. Participants were seated comfortably in front of a laptop with the required software installed. Steren AUD 230-NE headphones were provided to ensure uniform quality of the delivered audio across all sessions with participants.



Procedure and Data Collection

Participants were asked, via a written and established set of instructions, to proceed with the interaction with the first system (randomly assigned). Participants were required to navigate through the *Logos*, *Introduction*, and *Level Selection* scenes before starting the first task to ensure the graphical user interface was understandable.

Once the first feature was selected (pitch or duration), instructions were displayed with the auditory discrimination tasks they would perform. Participants had to listen to continuous auditory sequences of 2 sounds, following a cue-target paradigm with a 2-alternative forced-choice response, and determine whether the target sound had increased (pressing the up button) or decreased (pressing the down button) compared to the cue in the sound feature that was being tested (pitch or duration). Subsequently, they could select the following sound feature (pitch or duration) in the same way. Auditory discrimination tasks were run for 3 minutes per feature. Upon completion, participants completed the UEQ, the PSSUQ, the UES-SF, and the Auditory Discrimination Performance Test for Discrimination Tasks.

The procedure was then repeated for the second system, from setting up the sonometer to the completion of the questionnaires mentioned above. All data generated throughout the session were automatically saved and exported to a compressed ZIP file available for download from the systems for further analysis. An overview of the session and experimental procedure times is illustrated in Figure 4.

Figure 4. Overview of the experimental procedure for both systems. Each system (randomly assigned) received its own interaction phase with behavioral performance and user experience assessment. 2AFC: 2-alternative forced-choice; APDQ: Auditory Discrimination Performance Questionnaire; GBS: game-based training system; GUI: graphical user interface; NGBS: non–game-based training system; PSSUQ: Post-Study System Usability Questionnaire; UEQ: User Experience Questionnaire; UES-SF: User Engagement Scale-Short Form.

Measures and Covariates

Balanced Integration Score

The Balanced Integration Score (BIS) is a measure that combines speed and accuracy from task responses while attenuating the speed-accuracy trade-off by giving equal weights to both components [31]. BIS is defined as Equation 1.

$$(1) BIS = z_{PC} - z_{MRT}$$

where z_{PC} and z_{MRT} correspond to the standardized values (z scores) across the observed proportion of correct answers (PC) and mean reaction time (MRT) in seconds from all subjects and conditions.

Auditory Discrimination Performance Index

The ADPI is a proposed integrated version of the inverse efficiency score [32] for auditory discrimination tasks, considering the Weber fraction K obtained by dividing the JND

XSL•FO
RenderX

by the reference value of the corresponding attempt, and the MRT of JND, defined as the average time in seconds that each participant took to correctly answer the attempts made only at the selected JND. JND and the Weber fraction have been used to measure discrimination thresholds in challenging hearing conditions [33] or increased cognitive load tasks [34]. ADPI was computed as shown in Equation 2.

(2)ADPI=MRTJNDK×100

A JND was considered valid only if the participant achieved at least 75% accuracy for that specific stimulus. If the threshold was not yielded, the next smallest JND was evaluated until a valid one was identified. For instance, suppose a participant selected the pitch modality with a reference value of 500 Hz and was tested with pitch differences of 5, 10, and 20 Hz relative to the reference value. If they did not achieve 75% accuracy at 5 Hz, but they did at 10 Hz, then the valid JND would be set at 10 Hz. Subsequently, the corresponding *K* value would be 10/500=0.02. In addition, if the participant correctly answered 4 times for that JND stimulus, the mean response time of those 4 attempts is the MRT of the JND.

Questionnaires

To compare user engagement, usability, and experiential perceptions between systems, 3 validated questionnaires were presented to participants: UEQ, PSSUQ, and UES-SF. UEQ evaluates attractiveness, perspicuity, efficiency, dependability, stimulation, and novelty on a differential scale of 26 bipolar adjective pairs rated on a 7-point Likert scale transformed into a numerical scale of −3 to +3 [35]. PSSUQ assesses system usefulness, information quality, and interface quality through a 1 to 7 scale, where lower scores indicate better usability [36]. UES-SF measures focused attention, perceived usability, aesthetic appeal, and reward on a 1 to 7 Likert scale, where higher scores indicate stronger engagement [37].

Covariates

No covariates were included in the analyses.

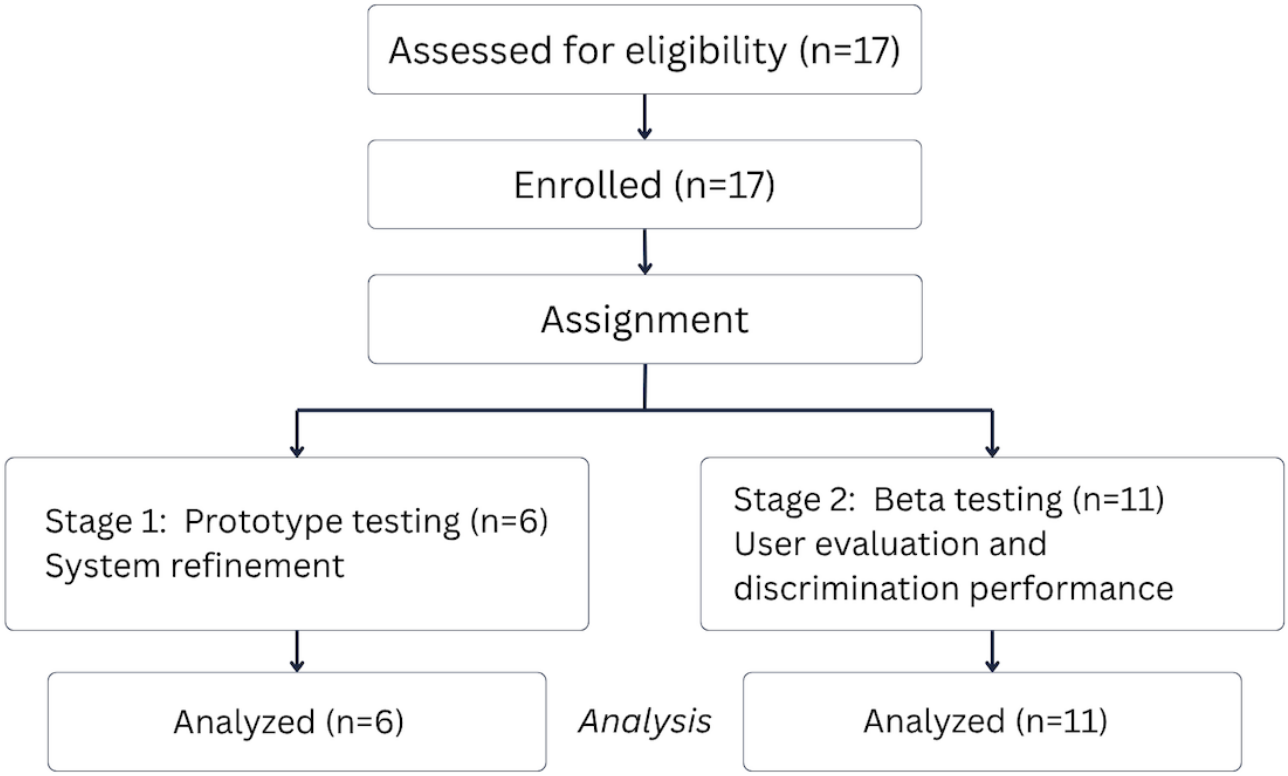
Quality of Measurements and Data Diagnostics

Measurement quality was supported using a controlled laboratory environment, standardized hardware (headphones and computer setup), and consistent task instructions across participants. All sessions and procedures were supervised from informed consent until the last task was completed by each participant. No missing data were reported. Prior to performing statistical tests, data were first inspected for normality (Shapiro-Wilk tests) to select an appropriate analysis strategy.

Analytic Strategy

Analyses were conducted to evaluate differences between systems across behavioral and questionnaire-based outcomes. For the in-game key performance indicators (KPIs), Python 3.12.12 was used to perform all statistical computations with the SciPy Stats library. The tests were carried out by comparing NGBS and GBS conditions paired by training feature (pitch or duration). Data were first inspected for normality using Shapiro-Wilk tests. The parametric paired *t* test was used when normality conditions were met. Otherwise, the nonparametric alternative, Wilcoxon signed rank test, was applied. Statistical significance was set at $P<.05$ for all tests conducted.

For questionnaire assessment, the Wilcoxon signed rank test using MATLAB 2025a and the Statistics and Machine Learning Toolbox was used to determine statistically significant differences between both systems across all questionnaire dimensions, considering the ordinal nature of the data. Mean scores, SD, *P* values, and effect sizes (*r*) values were calculated for each dimension per user, per questionnaire, and per system.



Results

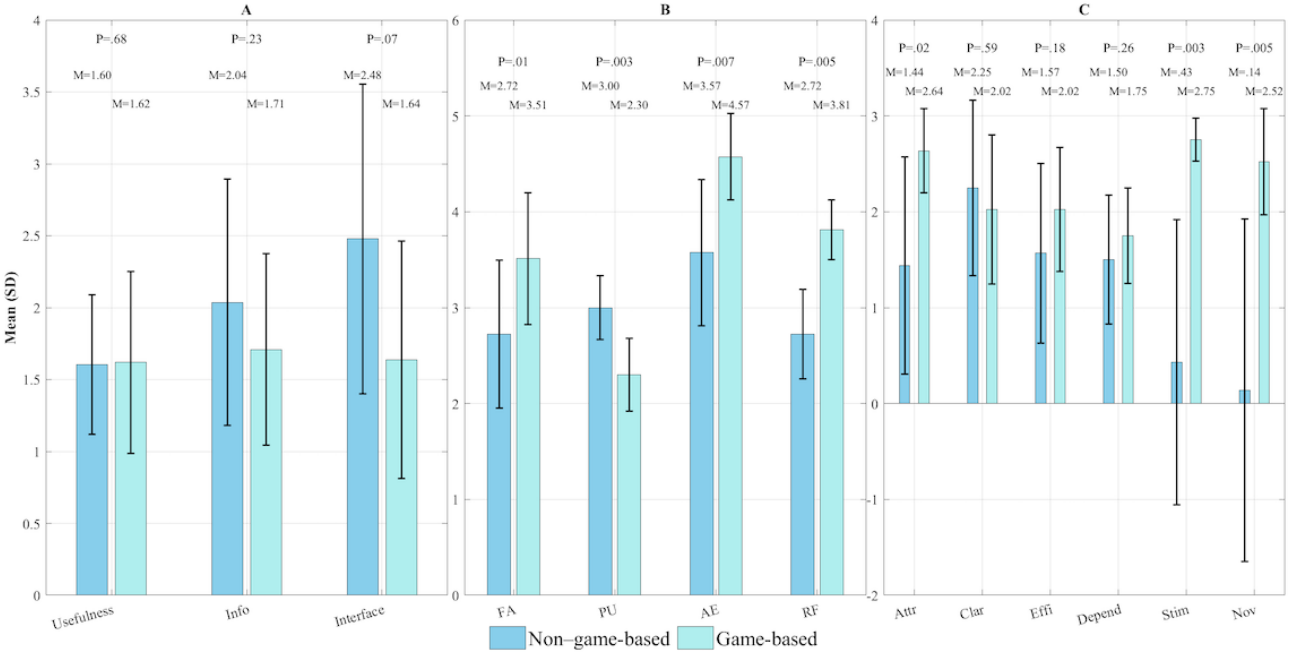
Preliminary Data

All participants reported no hearing or visual impairment, no attentional or neurological disorders, and no current use of medication at the time of the experiment. As general information for the study, participants self-reported information regarding their sleep, eating, and hydration habits, as well as their average weekly time spent in hours playing video games. A participant flow diagram adapted from JARS guidelines is presented in Figure 5.

XSL•FO
RenderX

Figure 5. Flow of participants through each stage describing enrollment, assignment, and analysis samples.

Regarding gaming exposure, 9 participants reported playing video games less than 4 hours per week, 1 participant reported between 4 and 8 hours, and 1 participant reported between 8 and 12 hours. This variable was included as a proxy for prior familiarity with interactive and gamified environments, which can influence both usability and engagement outcomes.



Due to limited variability in gaming exposure, no clear exploratory relationship was found between demographics and average weekly hours spent playing video games.

Questionnaire Outcomes

For all 3 questionnaires, participants recorded their answers across every dimension and system. For comparison between the GBS and NGBS, bar plots were generated to represent results and highlight differences in UX and overall performance patterns, as shown in Figure 6. Questionnaire responses showed significant differences and greater results in focused attention, aesthetic appeal, reward factor, attractiveness, stimulation, and novelty domains when using the gamified version.

XSL•FO
RenderX

Figure 6. Questionnaires' results for both systems. (A) Bar graphs showing mean, SD, and *P* value results in the Post-Study System Usability Questionnaire per dimension. (B) Bar graphs showing mean, SD, and *P* value results in the User Engagement Scale Short-Form per dimension. (C) Bar graphs showing mean, SD, and *P* value results in the User Experience Questionnaire per dimension. AE: aesthetic appeal; Attr: attractiveness; Clar: clarity; Depend: dependability; Effi: efficiency; FA: focused attention; Nov: novelty; PU: perceived usability; RF: reward factor; Stim: stimulation.

Although the PSSUQ domains and the perceived usability domain of the UES-SF scored slightly higher in the NGBS than in the GBS, this resulted in a significant difference in only 1 of the 4 domains.

Afterward, a comprehensive statistical analysis was performed, which included the calculation of metrics such as mean score, SD, *P* value, and *r* coefficient, as presented in Tables 2-4.

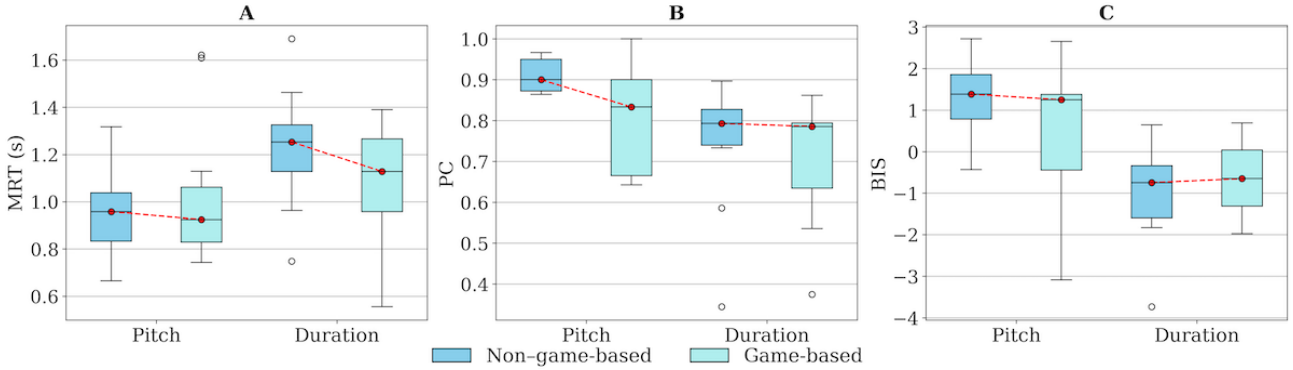
In-Game KPIs

During auditory discrimination tasks, background noise was recorded when both systems were used. Background noise for the GBS had a mean equivalent continuous A-weighted sound pressure level of 43.21 (SD 3.39), and for the NGBS, it had a mean equivalent continuous A-weighted sound pressure level of 37.79 (SD 2.08), which means that for both systems, the background noise was very low during training and may not affect discrimination performance.



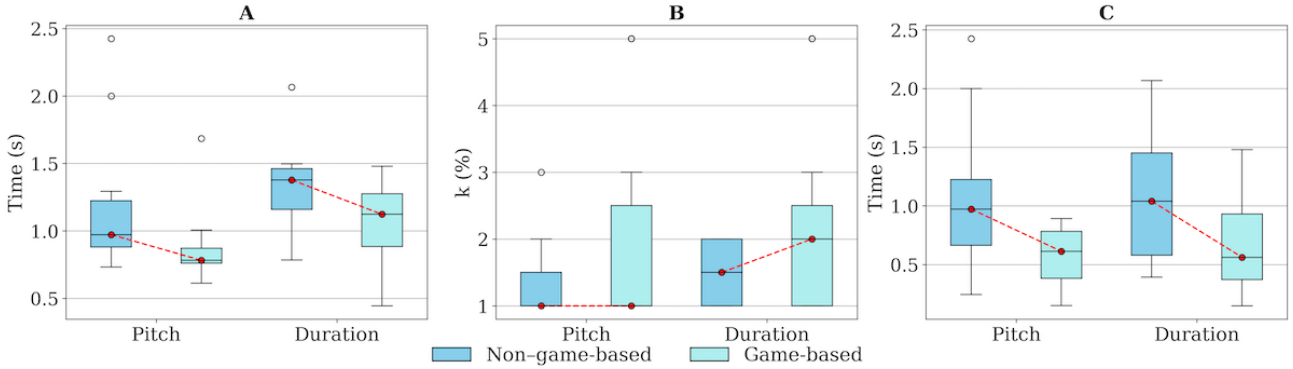
Balanced Integration Score

Figure 7 presents the results of MRT, PC, and BIS grouped by system and training feature. To facilitate visual comparisons across systems, a red dotted line connects the medians corresponding to the same training feature.

As can be seen for MRT and PC, the GBS medians tend to be slightly lower than those of the NGBS. However, this is not clearly observed for BIS.

XSL•FO
RenderX

Figure 7. Performance results for both systems. (A) Boxplots of mean reaction time (MRT) by system and training feature. (B) Boxplots of proportion of correct answers (PC) by system and training feature. (C) Boxplots of Balanced Integration Score (BIS) by system and training feature.



Auditory Discrimination Performance Index

Data used to compute ADPI, along with the resulting ADPI values, are illustrated as boxplots grouped by system and training feature in Figure 8. As in the previous figure, medians are indicated by red dots, and red dotted lines connect the medians of each training modality across systems.

From the MRT of JND and ADPI subfigures, a clear trend can be observed, with the GBS showing lower values than its NGBS counterpart. The trend is not present in the percentual Weber fraction graph, which shows no variation in pitch medians and a higher value for the GBS compared to the NGBS in the duration training feature.

To determine whether there were significant differences between systems, a statistical analysis composed of a Shapiro-Wilk normality test, followed by a paired *t* test or a Wilcoxon signed rank test, was performed.

Figure 8. Performance results for both systems. (A) Boxplots of mean reaction time (MRT) by system and training feature. (B) Boxplots of Weber fraction (*K*) by system and training feature. (C) Boxplots of Auditory Discrimination Performance Index (ADPI) grouped by system and training feature.

As shown in Tables 5-8, 9 out of 12 groups could not reject the null hypothesis of normality and therefore used a paired *t* test to analyze the relationship between the 2 systems.

Where normality could not be determined, the Wilcoxon signed rank test was performed instead.

According to the results, only 5 of the tests showed statistically significant differences ($P<.05$): MRT duration, PC pitch, MRT of JND duration, MRT of JND pitch, and ADPI pitch.

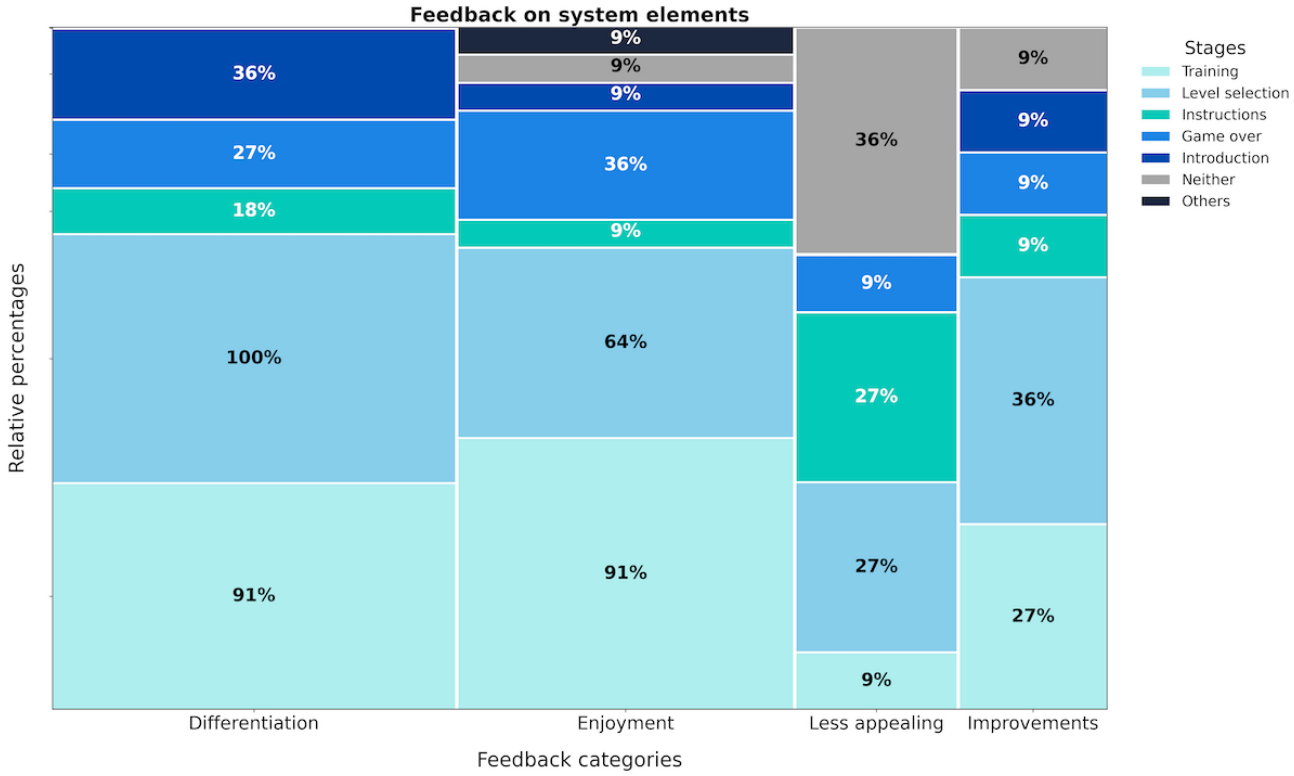
P value	.06	.11	.23



[a]The KPIs in this table met the normality assumption.
[b]KPI: key performance indicator.
[c]ADPI: Auditory Discrimination Performance Index.
[d]BIS: Balanced Integration Score.

System Elements Comparison

At the end of the experiment, participants were asked to compare both systems and answer 4 questions, mainly about the elements of the GBS that were enhanced: differentiation, enjoyment, less appealing, and improvements compared to the NGBS, as can be observed in Figure 9. They could select as many options as they considered appropriate for each question. It was observed that *Training* and *Level Selection* were the stages of the GBS that were majorly differentiated (10/11, 91% and 11/11, 100%) and enjoyed (10/11, 91% and 7/11, 64%) by the participants compared to the NGBS. Some participants suggested smooth improvements on *Training* (3/11, 27%) for having a practical tutorial and enhancement of the reward system. *Level Selection* improvements (4/11, 36%) were suggested for clearer elements and level labels.

Figure 9. Participants' percentual responses regarding game-based training system elements compared with the non–game-based training system in differentiation, enjoyment, less appealing, and improvements within system stages. Percentages for each individual section were calculated from the total number of participants.

Discussion

Principal Findings

This study aimed to design a game-based auditory discrimination training system and compare it with an equivalent non–game-based version through UEQs and behavioral performance. Main findings of this work suggest that in terms of UX, the game-based system significantly improved engagement-related and hedonic dimensions while maintaining comparable auditory discrimination performance across most metrics. In contrast, the non–game-based system showed a slight advantage in perceived usability, suggesting a trade-off between simplicity and engaging elements [38]. Behavioral results showed that the non–game-based system tended toward slower but slightly more accurate responses. Despite added cognitive load, the game-based system maintained similar efficiency and no degradation of auditory discrimination, suggesting that gamification enhanced engagement without impairing performance [39].

Our study has revealed that UEQ dimensions such as attractiveness, stimulation, and novelty were consistently higher in the GBS, indicating a more engaging and appealing UX. In contrast, usability dimensions such as clarity, efficiency, and dependability showed no relevant differences between systems. These results imply that the design of game-based auditory training did not compromise usability aspects as recommended [40]. This is important since if the system is insufficiently easy to use, the user may choose to avoid the system or use it improperly even if other aspects, such as functionality, are well thought out [41], and this can drastically impact the UX and training outcomes [42]. PSSUQ results indicated no significant differences between systems in perceived usability, suggesting that both interfaces were functionally comparable. These findings suggest that the NGBS design may be more straightforward in terms of usability, which may not be the case in more interactive systems [40]. Similarly, engagement-related dimensions in the UES-SF consistently favored the GBS, particularly in terms of focused attention, aesthetic appeal, and perceived reward. Overall, these findings indicate that gamification may enhance user engagement while not differing in levels of usability.

A factor that could be relevant and influential to interpreting UX outcomes is the rate of exposure to video games. Most participants reported "low" gaming activity (<4 h/wk), indicating limited familiarity with gamified environments. Repetitive gaming experience (replay value) can influence how users perceive and interact with gamified systems [43]. Users who regularly play video games are accustomed to dynamic interfaces, reward structures, and multitasking demands, which may reduce cognitive load, in contrast with users with limited gaming experience, who may initially perceive gamified environments as more complex and less intuitive, potentially contributing to the slightly higher usability ratings observed for the non–game-based system [44]. Still, out of the 11 participants, only 2 reported higher use of video games (4 - 8 h and 8-12 h), and no exploratory trend was found.

Interestingly, most of the KPIs showed nonsignificant differences between systems, with the exception of MRT (duration), MRT of JND (pitch and duration), PC (pitch), and ADPI (pitch), suggesting comparable auditory performance across systems. KPIs related to BIS showed slightly higher

XSL•FO
RenderX

MRT values for the NGBS when compared to the GBS across both training features, indicating an overall slower response that could be attributed to the absence of dynamic elements in the NGBS, as supported by studies comparing tasks with and without game elements [45]. NGBS also exhibited slightly higher PC results, supported by the traditional speed-accuracy trade-off, where reaction time correlates with accuracy [46,47]. However, when comparing training features, BIS shows a clear trend: both systems exhibit positive values in the pitch feature, indicating fast and accurate performance, whereas the negative values in duration training reflect slower and inaccurate performance. Regarding MRT of JND, related to ADPI, NGBS showed longer reaction times than GBS, while Weber fraction had no variation in pitch but a larger value for GBS duration, possibly indicating lower sensibility. However, significant differences were only found for MRT of JND in both pitch and duration, as well as for ADPI pitch. Additionally, since participants in the NGBS achieved higher MRTs but lower Weber fraction values, slightly higher ADPI results were obtained. This enhances the efficiency compensation of the speed-accuracy trade-off [31].

The dual-task element introduced in the game-based system did not lead to a decline in performance, as shown by BIS and ADPI results. Conversely, participants in the GBS maintained similar BIS values to the NGBS and even showed an improvement in ADPI. Similar results were found in a study involving an auditory discrimination gamified system [48], where the enhancement of learning was attributed to the reward signals playing a reinforcement role. In the present study, this may suggest that the different aspects of the game-based system (eg, animated success/error, points, lives, visual stimuli, background music) served to mitigate the monotony of the primary task—repetitive auditory discrimination—rather than acting as a source of distraction, thereby enhancing engagement and maintaining performance despite the additional cognitive load [49]. This finding also highlights the potential benefits of the infinite runner game genre in these tasks, suggesting recommended levels of cognitive load to mediate task difficulty and user performance [50].

Studying the relationships between engagement and outcomes has been suggested in game-assisted learning, as motivation may play a crucial role in effectiveness [51]. This is supported by other studies that suggest that user-perceived experience and cognitive load may be good predictors of cognitive training performance [52]. Thus, players' interactions with the systems' mechanics (dynamics) and aesthetics (feelings of players during those interactions) [53] may enhance user-perceived experience while balancing cognitive load to optimize performance.

This study has several limitations that should be considered. First, the sample size was modestly small and limited to young adults. This may bias behavioral performance significance and restrict the generalizability of the findings to other populations but may serve as a pilot study for treating auditory processing disorders [54] or hearing device users [55]. The sample size is considered enough for addressing usability-related measurements; however, the significance of differences in behavioral performance should be interpreted with caution. Second, the sample presented a slightly unbalanced gender distribution with a male-to-female ratio of 1.75:1. Although acceptable for initial studies, it can introduce bias in UX perceptions. Future studies should aim for a more balanced sample in gender distribution to ensure broader generalizability of the findings. Moreover, the evaluation focused on short-term performance and UX and therefore does not allow conclusions about long-term training effects, as auditory processing is subject to different time courses of plasticity [56]. Although the systems were carefully controlled to isolate the effect of gamification, other factors such as individual familiarity with video games and personal preferences may have influenced engagement outcomes [57].

The usability-engagement tradeoff seen in the results between both systems could be addressed through adaptive, user-centered interface design. Interface complexity may adapt to user performance and familiarity, offering simpler layouts for novices and more dynamic environments for experienced users [58]. Additionally, progressive disclosure can introduce game mechanics, scoring, and feedback incrementally, maintaining clarity while leveraging motivational benefits [59]. Over time, neuroplasticity-related adaptation may further enhance usability, as repeated exposure to gamified environments improves users' efficiency and perception of the interface [49]. Consequently, although non–game-based systems may provide immediate usability advantages, game-based systems could match or surpass them as familiarity increases and cognitive load decreases [59].

Taken together, the present findings highlight the value of incorporating gamification into auditory discrimination training, particularly as a strategy to enhance engagement and sustained attention without negatively affecting performance [52]. A key contribution of this study lies in directly comparing game-based and non–game-based systems under controlled conditions, which offers a more nuanced perspective on how specific game elements may influence UX and behavioral outcomes, although game elements may vary across conditions and other outcomes [60]. From an applied standpoint, the observed improvements in engagement-related domains suggest that such approaches may support greater adherence to auditory training protocols, which is critical for compliance in the real-world aural rehabilitation process [61]. Future research should further explore these effects over longer periods to determine the systems' efficiency in longitudinal studies, as it is suggested that gamification may perform more efficiently compared to control groups [62].

Conclusion

This study compared the use of gamification in auditory discrimination tasks. The introduction of gamified dual tasks favors a better qualitative perception of UX, particularly those related to engagement- and attention-related domains but may complicate interface understanding in a first approach, since more elements are displayed that require higher attention and cognitive workload when starting with system interaction. This is supported by qualitative feedback items suggesting longer tutorials. The introduction of a dual task did not significantly affect performance in auditory discrimination tasks for duration and pitch features in the GBS compared to the NGBS, as shown

XSL•FO
RenderX

by BIS and ADPI, even presenting slightly better scores for the GBS, although not significant except for ADPI in pitch. This also suggests that gamified discrimination tasks tend to decrease reaction time as part of the game mechanics, yielding focused attention and faster responses.

The current research also analyzes some key gamification elements that impact user perception. Findings suggest that the infinite runner game genre is flexible with auditory tasks and enhances engagement and attentional resources, supported by both questionnaire and discrimination performance results, providing important insights into genre selection for training compatibility. Additionally, longer exposure time is something to consider, as only one training session was evaluated and could yield slower responses due to first impressions. This may guide further research on the long-term impact of gamification on user evaluation and performance in auditory tasks, where improvements can be measured to compare both systems based on users' responses. More research is still needed in game-based training and user-centered design for auditory technology development to deliver better experiences to youths and children in aural habilitation and rehabilitation processes that enhance attention, fun, and lead to better auditory discrimination. Overall, our findings support the use of gamified, dual-task paradigms as a promising strategy to enhance UX and engagement in auditory discrimination training without compromising short-term performance. Future longitudinal studies should examine whether these experiential benefits translate into sustained improvements in auditory performance and clinical outcomes.

Abstract

Background: Metaverse technology is transforming health care, offering a wide range of applications in telemedicine, clinical care, education, mental health, and physical well-being.

Objective: This study aimed to explore the usability of a multidimensional metaverse rehabilitation platform for survivors of colorectal cancer. The platform integrates exercise training, dietary guidance, mental health education, and behavioral management.

Methods: A mixed research design was used. Survivors of colorectal cancer and their family members were recruited at the affiliated hospital to use the Metaverse multimodal rehabilitation platform. The platform's performance was quantitatively evaluated using Post-Study System Usability Questionnaires (PSSUQs) and System Usability Scales (SUSs). The average scores and SDs for each dimension were calculated, and the results were depicted using radar charts and violin plots. Additionally, correlation analysis was concurrently used to investigate score variations across diverse dimensions concerning different demographic factors. Structured questions were used to conduct qualitative interviews with participants to gather their opinions, suggestions, and perceived benefits regarding the platform.

Results: The data from a total of 18 participants were ultimately included, with an average age of 47 (SD 3.73) years. The overall SUS score was 65 (SD 4.157), and the average total score of PSSUQ was 80 (median 90, IQR 20). No statistically significant differences (P>.05) were observed in the overall scores and dimension scores of the SUS and PSSUQ across gender, age, and educational level distributions. The radar chart illustrates that the learnability score for the metaverse platform was the lowest (mean 61.11, IQR 5.08), while the Interaction Quality score was the highest (median 86.67, IQR 27). The results of the qualitative interviews indicated that users were generally highly satisfied with the platform's content, finding it comprehensive, diverse in format, and convenient to use. However, the platform's operation was not yet sufficiently streamlined, and its learnability still needs improvement. The metaverse multidimensional rehabilitation platform demonstrates clinical usability and holds potential to enhance the quality of life for survivors.

Conclusions: The platform demonstrated strong clinical usability and received high ratings for several parameters. Learnability, usability, and satisfaction levels were found to be satisfactory, with no significant correlations with demographic factors.

Trial Registration: ClinicalTrials.gov NCT06354595; https://clinicaltrials.gov/study/NCT06354595

RenderX

Introduction

After undergoing treatments, such as surgery, radiation therapy, and chemotherapy, survivors of colorectal cancer often face a range of physiological, psychological, and social challenges that significantly impact their quality of life [1,2]. Studies have shown that in the year following the end of treatment, survivors of colorectal cancer experience various persistent symptoms and functional impairments, including diarrhea, constipation, irregular bowel movements, urinary issues, and sexual dysfunction. Additionally, fear of disease recurrence, anxiety, and depression are common psychological issues among this group during the course of their illness [3]. Hence, there is a growing need to promote healthy behaviors and survivorship rehabilitation among survivors of colorectal cancer. However, current rehabilitation interventions in China predominantly focus on health education, offering postoperative dietary and exercise guidance. Due to this singular approach and the lack of comprehensive, targeted rehabilitation content, consistently improving patient outcomes poses a challenge [4].

The concept of "multidimensional rehabilitation" was first proposed by van Weert et al [5], who emphasized that multidimensional rehabilitation should encompass education, physical and psychological interventions, exercise training, dietary advice, and other aspects aimed at addressing cancer-related functional impairments and improving patients' quality of life. In studying the effects of multidimensional rehabilitation, Mewes et al [6] defined it as a combination of rehabilitation interventions targeting 2 or more dimensions of the International Classification of Functioning, Disability, and Health. These interventions typically involve various exercises, cognitive behavioral therapy, psychological therapy (including counseling and symptom self-management), and strategies to aid patients in returning to work. Within the biopsychosocial medical model, the concept of "multidimensional rehabilitation" based on the International Classification of Functioning, Disability, and Health framework has been formally established. Compared with single-dimensional interventions, the combined effects of multidimensional rehabilitation often yield more significant results. Multidimensional rehabilitation programs primarily focusing on physical activity and dietary interventions significantly aid survivors of colorectal cancer in maintaining long-term health and quality of life [7]. Yun et al [8] conducted a web-based health guidance program involving physical activities, dietary adjustments, and posttraumatic growth behaviors, resulting in improved health behaviors among survivors of colorectal cancer. Hawkes et al [9] provided health behavior guidance and supervision via phone calls, effectively enhancing the dietary habits, physical activity levels, and BMI of survivors of colorectal cancer.

In the current medical landscape, interventions leveraging the internet and artificial intelligence (AI) have emerged as promising strategies for promoting healthy behaviors and lifestyles, widely used in clinical intervention research [10,11]. To some extent, these technologies can address the shortcomings of the current rehabilitation management model for survivors of colorectal cancer. However, existing intelligent intervention methods face some issues, such as small-scale, irregular processes, and a lack of comprehensiveness. Furthermore, existing multidimensional rehabilitation platforms cannot fully meet the needs of survivors of colorectal cancer for multidimensional rehabilitation. Therefore, constructing a multidimensional rehabilitation platform with diversity, immersion, and sustainability is the key to addressing these problems.

Metaverse refers to a virtual space that is parallel to and independent of the real world [12]. By integrating various technologies, such as the internet, computers, AI, electronic games, and displays, a highly realistic digital virtual world is constructed. The metaverse has been widely applied in various fields, including remote health care, clinical care, education, mental health, and physical health [13]. It supports remote health care and can overcome geographical limitations [14]. Integrating the metaverse into health care has the potential to significantly impact clinical practice and improve human well-being [15].

The metaverse spans a wide range of fields, including computer science, social sciences, architecture, arts and humanities, business and economics, management, education, law, medicine, and the environment [16]. In the medical field, metaverse technologies such as 5G, virtual reality, augmented reality, mixed reality, AI, blockchain, big data, and haptic internet are actively being introduced, demonstrating significant potential in patient diagnosis, treatment, and rehabilitation. An increasing number of medical institutions use virtual reality technology for adjunctive therapy and remote rehabilitation [17]. This metaverse also shows great potential in the field of rehabilitation medicine [18]. For example, abroad, clinical application programs, such as rehabilitation, help physical therapists and medical workers to communicate efficiently with patients, and rehabilitation management systems enable real-time monitoring of patient rehabilitation training status, with results uploaded to the cloud for analysis and guidance by rehabilitation experts. Additionally, the metaverse is used to create communication platforms for patients with cancer and their families, assisting patients in improving the discomfort caused by the disease and enhancing their quality of life [19].

In conclusion, the metaverse has broad application prospects in the medical field, including in disease prevention, health management, diagnosis, and treatment. Applying the metaverse to the field of rehabilitation medicine is highly forward-thinking and innovative. With the development of technologies, such as AI and the internet of things, the metaverse is poised to bring new opportunities to rehabilitation medicine, improve the quality of life of survivors of colorectal cancer, and reduce the incidence of complications. Additionally, as a new form of participation and multidimensional interactive scene, the metaverse provides possibilities for a multidimensional rehabilitation model for survivors of colorectal cancer, aiding in the transition from "passive health care" to "active health."

In recent years, mobile health (mHealth) apps have played an increasingly prominent role in disease management, health promotion, and public health. mHealth provides health monitoring, intervention, and management services through mobile terminals, such as smartphones and wearable devices. However, the usage rates are not optimistic, and the actual

XSL•FO
RenderX

effectiveness heavily relies on the usability of the apps. This often results in high-cost apps failing to fully realize their expected scientific and clinical value. Studies indicate that many apps suffer from poor user experiences, low acceptance rates, and poor user retention due to issues like complex interfaces and cumbersome operations, ultimately affecting the achievement of intervention goals [20,21]. Particularly for the older adult population, poor usability is a critical factor hindering their adoption of mobile medical technologies [22]. An mHealth app with a user-friendly interface can enhance user satisfaction, increase accessibility, and reduce the risk of harm [23]. Therefore, improving usability is not only a technological optimization requirement but also a necessary condition to ensure user health benefits.

Usability is defined as the "ability of specific users to achieve goals effectively, efficiently, and satisfactorily through a product in a given environment" and has become a core criterion for evaluating digital health technologies [24]. International guidelines emphasize that usability testing is an indispensable part of health technology development [25]. Before using health technology as a health intervention measure, it is crucial to ensure that the technology is appropriately designed to meet the needs of end users. Conducting usability testing on mHealth apps holds significant value; well-designed products can enhance user satisfaction, increase willingness for continued use, improve user experience, enhance user retention, and better cater to the needs of different user groups (such as the disabled and older adults), bridging the digital divide and promoting health equity [26].

In conclusion, the metaverse has broad application prospects in the medical field, including in disease prevention, health management, diagnosis, and treatment. Applying the metaverse to the field of rehabilitation medicine is highly forward-thinking and innovative. With the development of technologies, such as AI and the internet of things, the metaverse is poised to bring new opportunities to rehabilitation medicine, improve the quality of life of survivors of colorectal cancer, and reduce the incidence of complications. Additionally, as a new form of participation and multidimensional interactive scene, the metaverse provides possibilities for a multidimensional rehabilitation model for survivors of colorectal cancer, aiding in the transition from "passive healthcare" to "active health."

Methods

Study Design

Based on a preliminary investigation of the home-based rehabilitation needs of survivors of colorectal cancer, we developed a Meta-Universe Multidimensional Rehabilitation Platform. This platform serves both educational and health-promotion functions. By integrating various guidelines and existing intervention practices and after expert validation, we formulated a Meta-Universe multidimensional rehabilitation program tailored to survivors of colorectal cancer. This 4-week intervention program was divided into 3 parts each week—objectives, practice, and knowledge sharing. We aimed for this 4-week intervention program to have a positive impact on health promotion. Additionally, weekly knowledge-sharing sessions serve educational purposes. Subsequently, the entire program will be implemented on the Meta-Universe platform to design and develop the Meta-Universe Multidimensional Rehabilitation Platform.

Following the design of the Meta-Universe Multidimensional Rehabilitation Platform, qualitative interviews were conducted to optimize the platform, followed by usability studies. This study primarily reports the results of the usability research.

Instrument Design and Development

The design of the Meta-Universe Multidimensional Rehabilitation Platform follows the steps outlined in Garrett's user experience elements model, encompassing 5 layers—strategic, scope, structural, framework, and presentation [27].

Strategic layer: This involves defining the positioning goals of the meta-universal Multidimensional Rehabilitation platform. The platform targets survivors of colorectal cancer and their families after curative surgery. It primarily serves as a platform for survivors and their families to engage in integrated learning and communication, encompassing goal management, practice, knowledge, and interaction.

Scope layer: This layer focuses on the content design of the meta-universal Multidimensional Rehabilitation platform. The main content areas included physical rehabilitation, dietary and nutritional interventions, mental health education, and behavior management.

Structural layer: This step primarily involves an information framework. Within the Meta-Universe, a virtual environment is created to allow users to access rehabilitation resources, participate in activities, and interact with other participants. The structural framework is as follows.

Main lobby: Serving as the primary entrance and reception area of the platform, a central area was designated for project introductions and access points to various rehabilitation learning rooms. The lobby's background music comprises gentle, soothing tunes to calm users' minds, alleviate anxiety, tension, and negative emotions, and foster a sense of warmth and hope for the future.

- Rehabilitation learning rooms: These specialized areas facilitate learning, where users can engage in weekly rehabilitation goals, practices, and knowledge sharing. In total, 4 learning rooms were established according to the intervention plan and sequentially opened weekly. Users must complete the objectives of each week to progress to the next. Each learning room features sections for weekly objectives, practices, knowledge sharing, assessments, and goal completion checklists. In addition, guided tour services led by virtual robots are provided. These virtual assistants offer 24-hour guided tours and learning services to support and guide users throughout their learning journey. Users can engage in simultaneous online learning, communication, voice, and video interactions within rehabilitation learning rooms equipped with sofas and tables to create a conducive learning and communication atmosphere.

XSL•FO
RenderX

- Multipurpose conference room: This space serves as a versatile area for user discussions and interactions. It includes a large screen for hosting lectures related to family rehabilitation and user experience sharing activities. Message boards are set up for users to make public comments, along with bulletin boards for event announcements and knowledge updates. The conference room aimed to facilitate communication among participants and knowledge dissemination.

Presentation layer: This involves perceptual design, including page layout, color schemes, and sensory experiences, to create high-fidelity prototypes. Additionally, incorporating audio, video, and other multisensory design methods enhances the user experience (providing voice reading functions for both text and graphics). These measures deliver a sleek and engaging interface design for users.

The overall layout of the platform is depicted in Multimedia Appendix 1.

Before using the Meta-Universe Multidimensional Rehabilitation Platform, users will receive an instructional video explaining how to use it. When using the platform, users were required to follow a predetermined timeline for learning. Users must enter the corresponding room for each week's learning; once the tasks for a week are completed, the room for the next week will unlock, gradually revealing the content for the third and fourth weeks. Completed rooms remain accessible for continuous learning. The ideal outcome of using the platform is for users to acquire knowledge of dietary habits, exercise routines, behavior management, and emotional regulation in daily life, develop self-management skills, and apply these practices effectively.

Procedure

After the Meta-Universe Multidimensional Rehabilitation Platform was designed, we assembled a platform optimization team comprising health care professionals, survivors of colorectal cancer, and volunteer family members. This team was primarily responsible for ensuring the platform's internal usability. External usability research was conducted once internal feedback had been provided. External usability research involved inviting survivors of colorectal cancer and their family members to use the meta-universal Multidimensional Rehabilitation platform. The duration of use was personalized based on each participant's circumstances, allowing them to use the platform until they felt that they had fully understood and mastered its functionalities. Subsequently, the usability of the platform was assessed using relevant metrics, and user experience suggestions and feedback were collected.

After users were confirmed to participate, they were instructed and demonstrated by the researchers on how to operate the platform, following which the users commenced the trial. The trial was entirely self-directed, with no researcher involvement during the process; however, users could contact the researchers at any time if they had any questions. Considering the portability during the trial and the platform's potential for future scalability, AR headphones were not used. This ensured that users could access the platform anytime and anywhere.

Study Participants

The study was conducted from February 1, 2024, to April 1, 2024. Participants were recruited offline. Patients from the Department of Colorectal Surgery and Oncology at the Xiamen University Affiliated Hospital and Hunan Xiangya Hospital were selected. Those who met the inclusion criteria among survivors of colorectal cancer were contacted through face-to-face interviews or phone calls to confirm their willingness to participate in the study. Once the patients and their family members agreed to participate, the study participants met the inclusion and exclusion criteria.

Patients who underwent curative surgery for colorectal cancer and received adjuvant therapy, aged 18 years or older but younger than 75 years, not pregnant, willing to participate in the study, and able to use a mobile phone were included. Exclusion criteria included patients with multiple cancers, those with special dietary requirements, and individuals with cognitive impairments that could affect the use of the multidimensional rehabilitation platform.

Inclusion criteria for family members were family members of patients who underwent curative surgery for colorectal cancer and received adjuvant therapy, aged 18 years or older but younger than 75 years, willing to participate in the study, and able to use a mobile phone. Individuals with cognitive impairments that could affect the use of multidimensional rehabilitation platforms were excluded.

Purposeful sampling was implemented, with a small sample size ($n<14$) sufficient to reflect usability [28]. A total of 18 survivors of colorectal cancer and their family members were included. According to the relationship curve between the number of participants and the percentage of identified issues, 10 patients could identify 80% of usability issues, and 15 participants were adequate to identify 100% of usability issues [29]. Therefore, the minimum sample size for this study ranged from 10 to 15 individuals.

Measures

The Methods section primarily involved questionnaire assessments, including basic information, a usability questionnaire, and 5 open-ended questions. The general information collected included name, age, level of education, role (patient or caregiver), and other relevant details.

The usability questionnaire assessment used 2 tools—the Post-Study System Usability Questionnaire (PSSUQ; version 3) and the System Usability Scale (SUS). The PSSUQ questionnaire consists of 3 dimensions (usefulness, information quality, and interface quality) and 1 overall evaluation item, totaling 16 items [30]. Each item was rated on a scale of "strongly disagree" to "strongly agree" with a range of 1 - 5 points. To facilitate comparisons across dimensions, scores for each dimension were converted to a percentage scale, with higher scores indicating greater user satisfaction. The SUS was used to evaluate user experience using a Likert 5-point scale method with 10 questions. Among these questions, 1, 3, 5, 7, and 9 were positively phrased, whereas 2, 4, 6, 8, and 10 were negatively phrased. The validity of this scale is 0.85 [31]. SUS scores were calculated on a percentage scale, where a score

XSL•FO
RenderX

above 70 indicated a “good” level, and above 50 indicated an “okay” level.

Additionally, the questionnaire included 5 open-ended questions, with the researchers responsible for recording the participants’ responses. The questions were as follows:

1. What is your overall impression of using this platform?

2. How beneficial is this platform for self-management and symptom management, and what are its advantages?

3. Which features of this platform are easier to use?

4. What shortcomings do you think exist in this platform?

5. How beneficial is this platform for self-management and symptom management, and what are its advantages?

Data Collection

After patients or their family members have tried the platform, both parties will agree on a time and location for a face-to-face or remote assessment. The collection of intervention data will be the responsibility of the researcher. Participants can choose to fill out the questionnaire themselves or opt for one-on-one questioning by the researcher. Throughout the process, if participants have any questions about any item, the researcher will provide answers promptly to ensure the accuracy of the responses.

Following the completion of questionnaire data collection, interview data collection will commence. The interviews will be fully recorded, and the researcher will ask questions one by one according to the interview outline. If participants do not have clear answers to certain questions, the researcher will provide appropriate neutral guidance to elicit the participants’ true feelings. If participants are unable or unwilling to participate in oral interviews, they can also fill out the answers themselves based on the interview outline.

Statistical Analysis

Quantitative data analysis: Continuous data will be presented as mean (SD) along with the range of values (minimum and maximum), while categorical data will be expressed as percentages. The Mann-Whitney *U* test and ANOVA will be used to investigate differences in the total and dimension scores of the SUS and PSSUQ scales based on gender, age, and educational level distributions. For data visualization, a violin plot will be used to display all data, while radar charts will visually represent the scores of each dimension and the total score of the usability scale.

Interview data analysis: Within 24 hours of the completion of the interviews, the interview content will be transcribed verbatim into text format. The content of the interviews will be carefully read, important information will be extracted and analyzed, and keywords and phrases that repeatedly appear will be recorded. All content and viewpoints will be summarized; similar viewpoints will be identified and organized into different themes.

Ethical Considerations

Ethical approval was obtained from the Xiamen University School of Medical Research Ethics Board (approval XDYX202308K52). All methods were performed in accordance with relevant guidelines and regulations. The study adhered to the principles outlined in the Declaration of Helsinki and was conducted under continuous supervision of the ethics committee. Informed consent was obtained from all the participants. The researchers provided a written explanation of the study’s purpose and methods to the participants, emphasizing their voluntary participation and freedom to withdraw from the study at any time, without facing any consequences. Furthermore, it was clarified that the information provided would be used solely for research purposes and not for any other purpose. To protect participant privacy and confidentiality, all personal identifiers were removed or anonymized in the data collection, storage, and analysis processes. All confidential information and research data were securely stored and only accessible to authorized researchers involved in this study. No financial or other forms of compensation were provided to the participants in this study.

Results

Participant Characteristics

Recruitment involved 21 patients and their family members, with 3 individuals excluded (1 did not provide informed consent, 1 was older than 75 years old, and 1 selected the same option on the SUS scale). Ultimately, 18 participants were included in this analysis. Refer to Table 1 for detailed information about the participants.

XSL•FO
RenderX

Table . Demographic information of the participants (N=18).

Characteristics	Participants, n (%)
Sex	
Male	12 (66.67)
Female	6 (33.33)
Age (y)	
Average value	47 (3.73)
18-44	8 (44.44)
45-59	6 (33.33)
60-74	4 (22.22)
Highest completed education	
Junior high school or below	5 (27.78)
High school or technical secondary school	5 (27.78)
College or associate college	7 (38.89)
Master's degree or above	1 (5.56)
Identity	
Survivors of colorectal cancer	10 (55.56)
Caregivers	8 (44.44)

Usability Scale Analysis

The SUS and PSSUQ scores were converted to a percentage scale, with the specific scores presented in Table 2. The overall average and average scores for each dimension of both the scales exceeded 50. There were no significant differences (P>.05) in the overall scores and dimension scores of the SUS and PSSUQ based on gender, age, and educational level distributions. For detailed information, please refer to Tables 3 and 4.

Table . Usability testing scores (N=18).

Usability indicators	Statistical value	SD/IR	95% CI
SUS[a]_score, mean (SD)	65 (4.157)	4.157	56.23-73.77
Learnability, mean (SD)	61.11 (5.086)	5.086	50.38-71.84
Effectiveness, mean (SD)	66.67 (4.434)	4.434	57.31-76.02
Satisfaction, mean (SD)	66.67 (4.261)	4.261	57.68-75.66

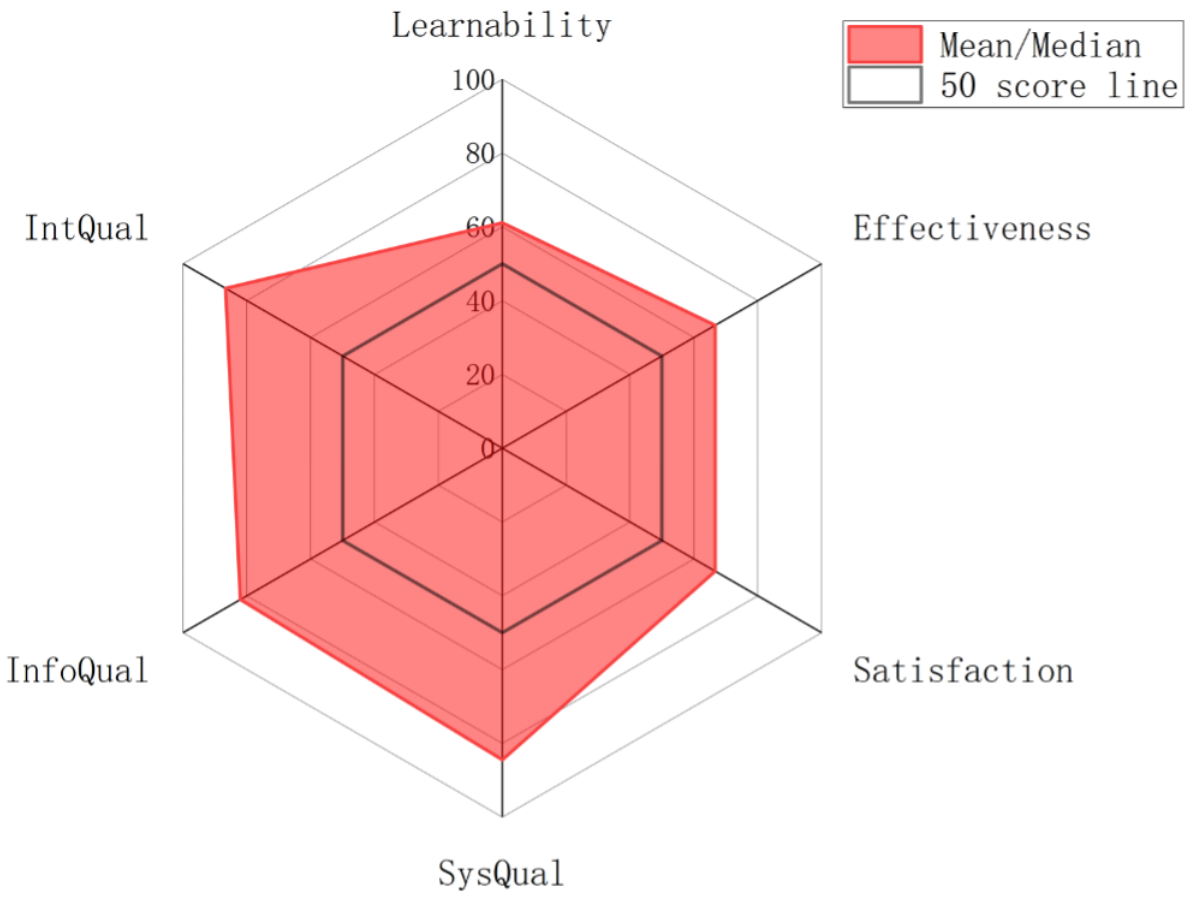
Radar Chart Analysis



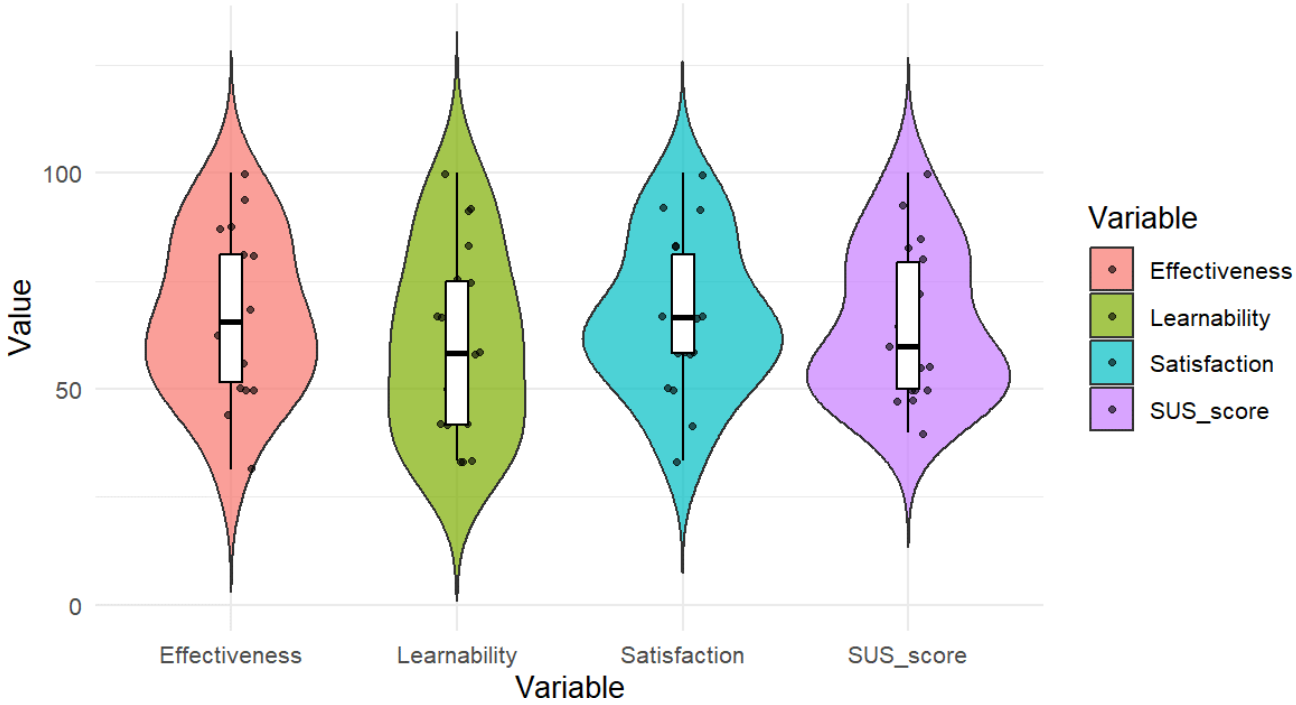
In this study, we used the average and median values of each dimension of the SUS and PSSUQ (using the mean for normally distributed data and the median for nonnormally distributed data) to create radar charts and compare the relationships and trends between different variables. These variables include Learnability, Effectiveness, Satisfaction, System Quality (SysQual), Information Quality (InfoQual), and Interaction Quality (IntQual), which represent the 6 characteristics of the

XSL•FO
RenderX

metaverse platform. Each variable is represented on a different axis, forming a closed polygonal area. The scale on each axis represents the range of the values for each variable.

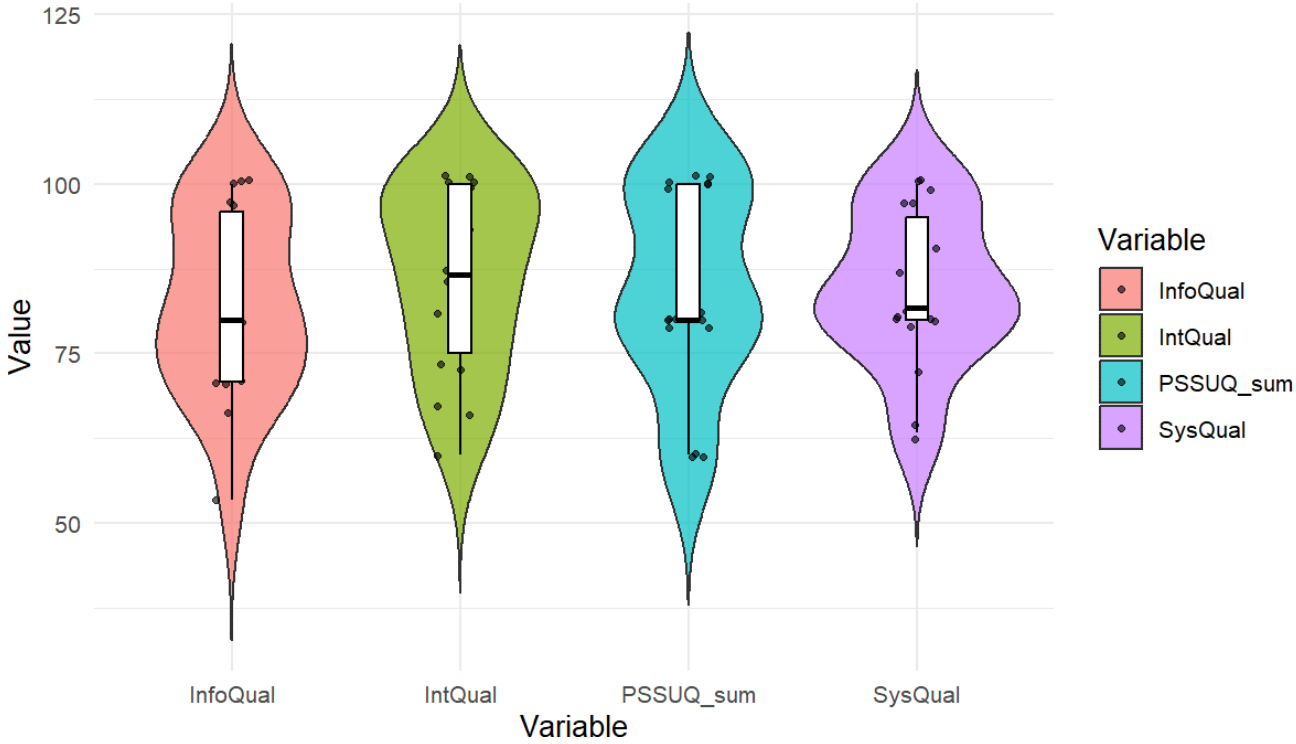
From the radar chart, it is evident that the learnability score for the metaverse platform was the lowest (mean 61.11, SD 5.09, 95% CI 50.38-71.84), whereas the IntQual score was the highest (median 86.67, IQR 73.3-100). Refer to Figure 1 for more detailed information.

Figure 1. Usability testing scores radar chart.



Violin Plot Analysis

Violin plots were used to display the distribution of scores. From the results of the violin plots, it can be observed that the distribution of the SUS total scores is relatively concentrated in the range of 50 - 60, showing distinct peaks. The distribution of the SUS total scores ranged from 40 to 100. In the various dimensions of the SUS, the maximum value for effectiveness was 100, and the minimum value was 31. For learnability, the maximum value was 100 and the minimum was 33. The maximum satisfaction score was 100, with a minimum of 33. The distribution of learnability was concentrated below 50, whereas the scores for the other 2 dimensions were concentrated above 50. The scores for satisfaction and usability were concentrated between 50 and 75, above the OK line. Refer to Figure 2 for more detailed information.



XSL•FO
RenderX

Figure 2. Violin plot of SUS scores.

The distribution of the total PSSUQ scores ranged from 60 to 100. In the various dimensions of the PSSUQ, the maximum value for InfoQual was 100 and the minimum value was 53. For IntQual, the maximum and minimum values are 100 and 60, respectively. SusQual had a maximum value of 100 and a minimum of 63. There are 2 concentration areas for the PSSUQ total scores, at 100 and 75 - 87.5 points; InfoQual scores are concentrated around 100 and 75 points; IntQual scores are relatively concentrated between 95 and 100; and SysQual scores are mostly concentrated between 75 and 87.5, with another concentration area at 100 points. Refer to Figure 3 for more detailed information.

Figure 3. Violin plot of Post-Study System Usability Questionnaire scores.

Open-Ended Question Results

Interview data from 16 participants were collected, and the interview data for each participant is numbered from N1 to N16. A total of 4 main themes were identified based on the interview titles and content, and keywords were extracted for analysis.

Theme 1: Platform Evaluation

Keywords extracted fall into 3 categories—positive evaluation, neutral evaluation (including neutral evaluations containing needs), and negative evaluation. Each category's keywords and their frequencies are as follows:

1. Positive Evaluation
   Excellent (13 times): eg, "Excellent."
   Convenient/practical (12 times): eg, "Convenient," "Practical," "Relevant," "Clear at a glance," and "Easy to operate."
   Useful/beneficial (10 times): Direct mentions of "Useful," "Helpful," and "Guiding significance."
   Comprehensive/professional Content (8 times): eg, "Comprehensive content," "Rich information," and "Professional."
   Interesting/advanced (5 times): eg, "Interesting like a game," "Looks very advanced," "High-end," and "Advanced stuff."
   Considerate/user-friendly (4 times): eg, "Considerate," "Voice function is convenient," and "Automatic playback is suitable for the elderly."
2. Neutral Evaluation
   Average (4 times): eg, "Average, some good some not so good" and "Average."
   Need guidance/optimization (6 times): eg, "Add beginner's guide," "Directory," "Signage," and "Optimize operation."
   Age adaptation issues (2 times): "Elderly people may not know how to use" and "Automatic playback is more suitable for the elderly."
3. Negative Evaluation
   Slow loading/lagging (8 times): eg, "Slow loading," "Slow response," "Takes too long to load," and "Too laggy."
   Complex operation/getting lost (7 times): eg, "Complex operation," "Getting lost," "Stuck in a corner," and "Interface not intuitive enough."
   Average (4 times): eg, "Average, some good some not so good" and "Average."

Theme 2: Platform Advantages

Keywords extracted include comprehensive and professional content, practical multimedia functions, easy operation, interesting and innovative features.

> *Found it useful, quite a lot of content, quite a few videos, don't have to strain to read, I don't like reading text stuff anyway. Will recommend it to others.* [N1]
>
> *Using this platform feels convenient, the information is quite comprehensive. Feels quite interesting, like a game, quite convenient.* [N1]
>
> *Feels pretty good, content is quite extensive, there are videos too, looks very advanced.* [N2]
>
> *Has videos, pictures and voice, not bad, sometimes can't see the words clearly, the voice is good. Feels useful, like being in class, there will be a lot of detailed guidance, it's useful if you find time to look at it.* [N2]
>
> *Overall, this platform is still practical, the content is quite comprehensive, looks quite professional, after all, it was developed by professionals, but I feel the content needs constant updating. For example, the app I'm using, Mi Jian, is very good, there is one-on-one communication with professionals, helping to read diagnostic reports, and giving advice, the response is very quick, this is something you can learn from.* [N3]
>
> *The overall user experience of this platform is very good, whether it's exercise, diet, or mental health, it covers everything.* [N4]
>
> *The features are very practical, for example, with pictures, when I click, there's actually voice, scared me! This can be noted, it's too sudden, sound comes on as soon as you click, but this feature is good, you don't have to read, you can listen while doing other things.* [N4]
>
> *Pictures can play, videos, all very practical.* [N5]
>
> *Pretty good, can learn some knowledge, the platform is quite considerate.* [N6]
>
> *Useful. After using it, taking care of patients will be much easier.* [N6]
>
> *The design is quite clear, easy to use, very convenient, and the operation is also very easy.* [N7]
>
> *Pictures, videos and such are very useful. Can learn some knowledge that is useful for diseases.* [N8]
>
> *Useful, has guiding significance for patients needing rehabilitation knowledge.* [N9]
>
> *Text comes with a reading function, suitable for a wide range of people.* [N9]
>
> *Good, I think a lot of things are quite practical.* [N10]
>
> *Useful, now at least know how to eat and exercise.* [N10]
>
> *Useful, there are a lot of things, quite comprehensive, basically whatever you want to see is there.* [N11]
>
> *(Features) are all good, but at first when I didn't understand some things, it was a bit confusing, like the arrow on the ground, didn't know what it was for at first, then realized.* [N11]
>
> *Useful, can help us learn a lot of knowledge.* [N13]
>
> *I think the information provided by this platform is quite rich, especially about psychology and behavior, very practical.* [N14]
>
> *I think the information provided by this platform is quite rich, especially about psychology and behavior, very practical.* [N14]

XSL•FO
RenderX

Theme 3: Platform Shortcomings

Keywords extracted include lack of content, difficulty in operation, lack of interactivity, insufficient personalized service, lack of prompts, not concise, information overload, and difficulty in screening.

> *Sometimes loading is a bit slow, hope it can be improved.* [N1]
>
> *The response is a bit slow, takes a long time to load, if you're not patient you might exit, if the internet speed is not good, you might exit too. Sometimes when walking it's a bit dizzying, a bit too flexible, got stuck in a corner and can't see other places, can't get out, feels lost inside. Not very easy to operate, need to be more familiar to operate.* [N2]
>
> *Not enough content, lack of interaction and personalized service, just like I said before, Mi Jian does it very well, you can download and take a look. Although the annual membership fee is not cheap, but it's worth it!* [N3]
>
> *Can be more concise, more operational prompts, at the beginning it's too troublesome, don't know where to go, it's better after watching the operation video, but still easy to get lost, stuck in a corner.* [N5]
>
> *However, sometimes the operation is a bit complex.* [N5]
>
> *More intelligent, the elderly don't know how to use it.* [N8]
>
> *The screen is a bit laggy, guidance is not straightforward, room stickers are too simple.* [N9]
>
> *Using it is quite laggy, beginners need teaching for entry.* [N9]
>
> *The platform's information classification is quite clear, but sometimes there's too much information, it's a bit difficult to choose, hope it can be more streamlined.* [N10]
>
> *But actually it's not easy to find content, if you want to look at a specific category, this platform can't search, have to look one by one.* [N11]
>
> *Entering this platform is a bit slow.* [N12]
>
> *But some functions are not very intuitive, especially in terms of exercise and physical activity, diet and nutrition, need to spend time exploring. Hope user operation convenience can be optimized.* [N16]
>
> *Too laggy, loading takes a long time.* [N16]

Theme 4: Suggestions and Recommendations

Keywords extracted include (1) adding product recommendations; (2) setting different modes based on age, automatic playback for the older adults; and (3) adding beginner's guidance. Most participants expressed no opinions or suggestions.

> *It's best to combine long-term use with product recommendations, recommend some products and services, spend a bit of money, for example, what to do with low white blood cells, need to supplement protein, at this time can have some reliable products.* [N3]
>
> *Set different modes for different ages, for the elderly it plays automatically, no need to click.* [N8]
>
> *Add beginner's guidance, reading materials can be explained in the form of animation and text, the homogeneity of the survey questions is serious, adjustments need to be made according to the current room content.* [N9]

Discussion

Principal Findings

Metaverse technology has been widely applied in various fields, such as telemedicine, clinical care, education, mental health, and physical well-being [32]. It supports remote health care, overcomes geographical limitations, and brings new and challenging opportunities to the health care sector [14]. An increasing number of medical institutions are beginning to adopt virtual reality technology for adjunct therapy and remote rehabilitation services [17]. The Metaverse multidimensional rehabilitation platform developed in this study for survivors of colorectal cancer covers exercise training, dietary guidance, psychological health education, and behavior management. It also includes a 4-week self-management intervention program aimed at helping survivors of colorectal cancer adopt healthy lifestyles, promote healthy behaviors, and ultimately improve their quality of life. Additionally, the platform serves as a remote communication platform for survivors of colorectal cancer and their families, as well as an educational platform for hospitals. The usability test results indicate that the platform performs well in terms of clinical usability, with excellent system quality, interface quality, and information quality. Learnability, usability, and satisfaction all reached a "good" level. Furthermore, the study found that the scores of usability dimensions were not related to gender, age, or educational level, suggesting that the middle-aged and older adult population (younger than 75 y old) may have potential in learning to use new platforms. Due to the limited sample size, the statistical power to detect and confidently estimate the effects of factors influencing usability is reduced, thereby potentially limiting the robustness and generalizability of the conclusions. Results from the unstructured interviews show that most users had a positive evaluation of the platform, noting its comprehensive and professional content, practical multimedia functions, ease of operation, and interesting and innovative features. However, issues with slow loading and complex operation were identified in terms of platform usability.

Our study represents the first application of metaverse technology, specifically in the family rehabilitation of survivors of colorectal cancer, offering new research perspectives in this field and providing insights for other cancer studies. We obtained a series of meaningful results with important implications for future medical practice and research.

Platform Usability and Influencing Factors

The scores for system quality, information quality, and interaction quality are relatively high, indicating a strong correlation between these performance aspects and the quality

XSL•FO
RenderX

of content provided by the platform, including convenience, clarity, and interactivity. This suggests that the platform's content design is relatively excellent. However, the score for learnability is the lowest, implying that users may find it challenging to grasp the platform's functions and operations during initial use, resulting in a higher learning cost and time investment. Effectiveness is above the passing line, indicating that the platform may not effectively assist users in achieving their goals quickly and accurately, requiring additional effort. Satisfaction is at a moderate level, possibly influenced by software operations.

Violin plot analysis reveals that while the learnability score is concentrated around the passing line (50 points), scores for other dimensions exhibit 2 concentrated distribution areas, both above the passing line. The high-score concentration area reflects that most users perceive the platform's performance as good (except for learnability), further confirming the platform's excellent performance in terms of usability. However, attention should still be paid to the platform's learnability.

This study observed that patient groups rated platform usability lower than family members. Usability fundamentally reflects the degree of human-machine adaptation in user interaction interfaces. It is worth noting that this evaluation difference may be closely related to the physiological and psychological characteristics of the evaluators. Most patients are in the treatment period (chemotherapy and ostomy), with certain physiological and psychological issues, which may have multiple impacts on evaluation results. First, treatment-related complications (such as neuropathic pain and cancer-related fatigue) may affect patients' cognitive function and technical operational abilities, thereby reducing their acceptance of technology. Second, the anxiety and depression commonly found in patients during the treatment period may influence the objectivity of evaluations, leading to a negative evaluation bias. Additionally, treatment-related physical limitations (such as peripheral neuropathy and decreased visual acuity) may directly impact the platform's utility, lowering patients' acceptance of the technology. When promoting clinical application in the future, a simple assessment of patients' physical conditions should be conducted, and based on the patients' situation, the platform's target users could be patients or family members, with family members learning the platform content and then supervising patients to complete intervention tasks, which could be a better choice.

There were no significant differences in scores between genders across dimensions. Differences in scores across dimensions were observed by age, with the 18‐ to 44-year age group generally scoring higher than those aged 45 years and older in software operation–related ratings (learnability and effectiveness), and those with a college education or higher scoring higher than those with other educational levels. In terms of software quality, the older than 60 age group scored the lowest, while the junior high school and below education group scored lower compared with the relatively higher educated group. This may be related to the characteristics of these 2 groups, as individuals with lower education levels and older individuals may prefer a simple, visually engaging, and easy-to-understand platform compared with other groups. Radar chart analysis shows that the scores across platform dimensions are uneven, especially with weaknesses in learnability and effectiveness, indicating the need for improvement.

Although there are score differences in age and educational level distributions, they have not reached statistical significance. This finding may suggest that the rehabilitation platform may be universal for individuals aged 18‐75 years, providing similar levels of service and support to different user groups. Particularly noteworthy is that age has not become a limiting factor in learning new platforms, providing more possibilities for older adults to embrace new technologies. This result differs from common perceptions. While some older adult individuals may encounter operational issues during actual use, there are also older adult individuals, especially those with higher education levels, who can easily use the Metaverse platform.

Technical experience may influence users' attitudes toward the Metaverse platform [33]. During the experiment, it was found that some young people also encountered difficulties in using the platform. These young people are usually more educated but may lack experience with online games and are predominantly female. On the other hand, some users, despite having lower levels of education, were able to use the Metaverse platform smoothly and showed higher satisfaction. These users typically have more experience with online games.

Dependence on network speed also affects the usability of the Metaverse platform. In areas with slow network speeds, users may encounter issues, such as slow loading and lagging. Additionally, the mobile phone system can also affect the user experience of the Metaverse, as older versions of mobile phone systems may not fully support Metaverse apps. Through communication with the technical team, these issues can be resolved. This is also one of the reasons for user dissatisfaction. However, with the continuous advancement of technology, issues resulting from low network speeds and operating system configurations will gradually be resolved, leading to a continuous improvement in user satisfaction with the Metaverse platform.

During the experiment, it was observed that users' initial impressions and attitudes toward the Metaverse platform also influence their enthusiasm and effectiveness in learning to operate the platform. The more positive the attitude, the easier the learning process, and users are more likely to master the platform. For those who initially believe they cannot grasp the Metaverse platform, they often encounter difficulties in practical operation. As long as they maintain a curiosity for learning, many older adult individuals can also easily get started. Therefore, the focus should be on "technological resistance." When facing "technology," do not be intimidated by it; instead, embrace it and believe in your ability to handle technology. Technology exists to serve humanity, making life more convenient and enjoyable. If a technology makes users feel difficult, it will eventually be eliminated because it does not align with the original intention of technological development. When faced with a new technological platform, maintain an open mindset and bravely try it out. Therefore, it is important to value users' initial feelings and attitudes toward the platform, as this will directly impact the degree of user acceptance and

XSL•FO
RenderX

the effectiveness of use of the Metaverse platform. It is recommended that when promoting the Metaverse platform, particular attention should be given to users' psychological attitudes and emotional feedback, and through active guidance and training, help users develop a positive perception of the platform, thereby enhancing their learning and operational effectiveness, and ultimately improving the overall user experience and satisfaction.

Due to the limited research sample and insufficient demographic variables, this study has not fully explored the factors influencing the use of the Metaverse platform, which may involve cultural levels, gender, familiarity with online games, self-efficacy, and so on. In conclusion, although the Metaverse platform holds great potential in the field of rehabilitation services, there are still some limiting factors that need to be addressed, such as the impact of user group characteristics on platform use, network speed, and mobile system compatibility issues. With technological advancements and continuous platform optimization, it is believed that these limiting factors will gradually be resolved, leading to a continuous improvement in user satisfaction and popularity of the Metaverse platform, providing a better rehabilitation service experience for more users.

Platform Advantages and Clinical Benefits

The metaverse platform, as an emerging rehabilitation tool, has demonstrated unique advantages and potential in the field of remote rehabilitation. Answers to open-ended questions indicate that users generally give positive feedback on the platform content, considering it practical, interesting, comprehensive, instructive, clear, and easy to understand. The diversity and instructiveness of the rehabilitation content enable users to better understand and absorb information, thereby enhancing the effectiveness of rehabilitation. However, issues such as the complexity of platform operation, potential lag during operation, and lack of interactivity affect user experience and platform learnability. Overall, while the platform content can adequately meet clinical needs and is well-structured, there are still some areas in operational aspects that require improvement.

The diverse intervention content and methods provided by the metaverse platform offer users a comprehensive rehabilitation service experience. First, the platform offers a wealth of graphic and video resources, providing users with multiple sensory input pathways that aid in information comprehension and absorption. Compared with plain text, videos and graphics are more vivid and intuitive, conveying information more effectively, making it easier for users to understand and remember, thus enhancing intervention effectiveness and sustainability. Second, the metaverse platform incorporates questionnaire functions to help survivors assess whether they have achieved their set goals. This personalized assessment method allows users to gain a clearer understanding of their rehabilitation progress, helping them adjust their rehabilitation plans and improve rehabilitation outcomes. Additionally, the platform introduces gamification mechanisms, including setting tasks and providing rewards, which motivate survivors during the rehabilitation process, enhancing their motivation and sense of involvement. Furthermore, the metaverse platform provides auxiliary design features to help users better receive information, such as the function of automatically reading text on images by clicking on them, digital human navigation services, and signposts, greatly facilitating the acceptance of intervention information by different age groups, enhancing intervention universality and operability. These advantages collectively make the metaverse platform the preferred choice in the field of remote rehabilitation.

Moreover, the metaverse multidimensional rehabilitation platform also offers social interaction and support systems, allowing users to interact and communicate in real time with other survivors or health experts. This social support can increase users' motivation for rehabilitation and self-management capabilities, promote information sharing and experience exchange, and build a supportive rehabilitation community [34]. Additionally, the platform has cross-platform and cross-device compatibility, allowing users to access the platform anytime, anywhere through different devices, achieving seamless connection of the rehabilitation process from the hospital to the home, providing users with a convenient and smooth rehabilitation experience.

Research results indicate that the metaverse platform has been successful in meeting user needs, providing effective information, and offering a good user experience, demonstrating the potential to provide excellent rehabilitation support for survivors of colorectal cancer and their families. Research on the effectiveness of metaverse rehabilitation therapy for cerebral palsy has shown significant improvements in various health parameters compared with traditional physical rehabilitation treatments [35]. Experts have pointed out that metaverse rehabilitation exercises can help patients with stroke improve cognitive function, attention, muscle endurance, cardiorespiratory function, maintain appropriate weight, and prevent stroke recurrence [36]. Floreo, a company in the United States, created the first behavioral therapy metaverse, teaching social, behavioral, communication, and life skills to patients with autism spectrum disorders, attention-deficit/hyperactivity disorder, anxiety disorders, and other neurodiversity disorders. Additionally, the metaverse is used to build communication platforms for patients with cancer and their families, assisting patients in improving the discomfort caused by illness and enhancing their social adaptability [19]. These applications emphasize the potential advantages of incorporating metaverse-based approaches into patient rehabilitation interventions and disease management. The metaverse holds promise for bringing new opportunities to rehabilitation medicine, improving the quality of life of survivors of colorectal cancer, and reducing the incidence of complications.

The metaverse has the potential to shorten social distances, facilitate simultaneous online learning for multiple users, and stimulate participants' rehabilitation motivation. Competitive incentives and mutual encouragement among participants can help in task completion. The research team of Mizuta et al [37] reported that compared with simply posting exercise videos on YouTube (Google), providing exercise videos through the metaverse platform can increase physical activity among young individuals with similar exercise motivations, while reducing feelings of isolation during exercise. Despite similar video

XSL•FO
RenderX

content, the viewing experience provided by the metaverse is more engaging and immersive, adding challenge and enjoyment. The metaverse also offers additional benefits, such as avoiding the embarrassment of visiting clinics and increasing the acceptance among patients who find it inconvenient to seek treatment at hospitals due to psychological barriers. Participants tend to label metaverse-based therapeutic content as entertaining, enjoyable, or convenient [33].

The metaverse holds great potential in the health care field. Simulation programs for early-onset schizophrenia care based on the metaverse can serve as an alternative for high-quality care education, replacing clinical psychiatric practice without spatial constraints [38]. The application of the metaverse in medical training programs has shown significant effects. Using the metaverse in onboarding training and nurse and resident training programs has led to improvements in participants' knowledge, skills, and confidence [39]. The application of the metaverse in clinical handover nurse training has significantly improved nurses' self-efficacy, handover skills, and satisfaction [40]. Overall, the metaverse has shown good effectiveness in the education and training fields, indirectly confirming its clinical feasibility, given that the metaverse multidimensional rehabilitation platform mainly focuses on health education. While the application of the metaverse in the rehabilitation field is limited, existing clinical experiences demonstrate significant potential, such as virtual physical therapy to guide rehabilitation patients in exercises and movements [41].

Although the metaverse brings many benefits, the current multidimensional rehabilitation platform still has some limitations, including insufficient content, complexity of operation, lack of interactivity, inadequate professional services, lack of prompts, unclear information, and difficulty in screening. To address these issues, the team has further optimized the metaverse platform, including enlarging operation buttons and changing the taskbar to prominent patterns. Additionally, content directories have been added at the entrance of each room to help users find the desired content. Outstanding issues include professional services and interactivity, mainly because the platform has not been formally deployed in clinical practice, team members have not fully engaged with the platform, and professional services and interactive content have not been fully explored. This limitation is expected to be partially addressed in formal clinical studies.

In conclusion, the metaverse platform, as an innovative rehabilitation tool, has shown tremendous potential and advantages, providing innovative solutions for the rehabilitation of survivors of colorectal cancer. Its diverse intervention content and social support system offer users a comprehensive and effective rehabilitation service experience, with the potential to enhance survivors' quality of life. However, operational aspects still require optimization, with simplification being a key focus for future improvements. Through continuous optimization and enhancement, the metaverse platform is poised to become a leading choice in the field of rehabilitation, enhancing survivors' quality of life and rehabilitation outcomes.

Limitations

This study has the following limitations. First, the sample size is small, with only 18 participants, which limits our ability to conduct detailed analyses of different participant groups and prevents an in-depth exploration of multiple potential factors affecting satisfaction with the metaverse. This also limits the statistical testing power of the results and the generalizability of the conclusions, especially when facing diverse user needs, where the representativeness of the results may be affected. Although the sample size in this study exceeds the minimum sample size recommended by the US Clinical Trial Registration Platform for usability studies (fewer than 10 people), it is still difficult to completely exclude the risk of bias caused by insufficient samples. Second, the assessment tools used in this study are mainly self-report scales, which are subjective to a certain extent. Participants' responses may be influenced by social desirability bias, memory bias, or personal emotional states, thereby introducing response bias or measurement errors that affect the objectivity and accuracy of the data. Third, there are significant individual differences in users' preferences for platform content. For example, some patients are more concerned with mental health education content, while others place more emphasis on content related to physical activities. This heterogeneity in content preferences may lead to large variations in evaluations of usability indicators, affecting the internal consistency and generalizability of the results. In addition, the data in this study are mainly based on short-term usage feedback, lacking longitudinal observation of the platform's long-term usability and long-term user satisfaction, making it difficult to reflect the dynamic changes in user experience and long-term effects. Finally, the study lacks objective behavioral data support (such as usage duration and interaction frequency) and mainly relies on subjective evaluations. Future research should combine more objective indicators to comprehensively and multidimensionally assess the platform's usability and user experience. In summary, future studies should expand sample sizes, cover a broader range of population characteristics, adopt mixed research methods that combine subjective evaluations with objective data, and conduct long-term follow-up observations to comprehensively and in-depth investigate factors influencing the usability of metaverse platforms, thereby enhancing the scientific rigor and practical guidance value of the research.

Conclusions

This study demonstrates the potential and prospects of metaverse technology in colorectal cancer rehabilitation, providing personalized and convenient rehabilitation services for patients and their families with the aim of improving patient quality of life and rehabilitation outcomes. However, integrating metaverse technology into clinical practice still presents challenges. In the future, exploring the combination of virtual reality, augmented reality, and other technologies to provide comprehensive, personalized rehabilitation platforms and integrating AI to achieve more intelligent and precise medical services could be beneficial. Emphasis should be placed on safety and privacy protection to ensure compliance with regulations and to safeguard patient privacy and data security. Additionally, integrating metaverse technology with traditional medical

XSL•FO
RenderX

models to achieve complementary advantages and to build a more complete medical ecosystem can provide patients with comprehensive and continuous medical services. Importantly, this study is the first to apply metaverse technology to the family rehabilitation of survivors of colorectal cancer, bringing new ideas and opportunities to related research and practices. Our findings not only offer innovative rehabilitation support for survivors of colorectal cancer and their families but also provide insights and inspiration for other cancer rehabilitation research. This metaverse-based rehabilitation platform has the potential to improve the quality of life of patients and their families and may offer medical institutions more effective rehabilitation services and educational outreach avenues.

Although the application prospects of metaverse technology in the medical field are broad, continuous exploration and improvement in clinical practice are necessary to achieve better medical outcomes and service quality. Through ongoing innovation and collaboration, metaverse technology has the potential to bring breakthroughs and advancements to the medical field, benefiting more patients and their families.

Acknowledgments

We would like to express our sincere gratitude to Teacher Yixian Gao (School of Medicine, Xiamen University) for her valuable contributions to this research. She participated in the software construction and provided numerous insightful suggestions throughout the study. Unfortunately, she passed away during the publication process of this manuscript, and we were therefore unable to obtain her publication consent. We hereby extend our deepest appreciation and remembrance to her.

Funding

This study was supported by the following funds: Xiamen University Student Innovation and Entrepreneurship Training Program (2024Y989) and Xiamen Science and Technology Bureau Science and Technology Benefit Program (3502Z20209017).

Data Availability

The datasets generated and/or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

All the authors contributed to the conception and design of the study. Material preparation was done by Q Shen, YH, ZH, LC, YX, and XY. Data collection was conducted by YH, HP, and ZR. Data analysis was performed by YH, Q Shen, and HP. The first draft of the manuscript was written by YH, and all authors provided feedback on earlier versions of the manuscript. All authors have read and approved the final manuscript. YH and ZR contributed equally and are co-first authors; the remaining authors are listed in the order of their actual contributions.

Conflicts of Interest

None declared.

Abstract

Background: Immersive virtual reality (VR) is promising in stroke rehabilitation; it is believed to promote motivation and intervention adherence among patients. However, existing work often lacks a structured assessment of user experience over a longer period of time.

Objective: This study aimed to assess the feasibility, user experience, and preliminary effectiveness of a VR-based rehabilitation program designed for patients with stroke to train upper limb and cognitive functions.

Methods: Thirty-two chronic (n=19, 59%) or postacute (n=13, 41%) patients with stroke (mean age 60, SD 11 years) were enrolled. All participants performed 4 weeks of training, performing exercises in the Virtual Supermarket for Stroke (VSS). The VSS is an ecological VR-based application allowing customization of difficulty to make the task of "doing the shopping" more challenging throughout the sessions. Subjective outcomes were assessed after the first and last sessions. Clinical scales were administered at baseline and at the end of the treatment.

Results: Of 32 participants, 31 (97%) completed the training. Flow (median 4.56, IQR 3.94-4.72; 5-point scale), sense of presence (Spatial Presence: median 3.44, IQR 12.85-3.85; Engagement: median 3.79, IQR 3.26-4.191; Naturalness: median 3.60, IQR 3.20-4.40; all 5-point scales), and affective state-related variables (Positive and Negative Affect Schedule; Positive Affect: median 4.60, IQR 4.00-5.00; Negative Affect: median 1, IQR 1.00-1.00) were satisfactory after the first session. Perceived ease of use was rated as very high (median 6.75, IQR 6.00-7.00; 7-point scale). No severe symptoms of cybersickness were recorded (Simulator Sickness Questionnaire [SSQ-TS]: median 11.22, IQR 0-20.57). At the end of the intervention, no significant differences were recorded in any subjective variable. Regarding clinical outcomes, significant improvements were recorded in balance (Berg Balance Scale pre: median 30, IQR 14.00-45.75; post: median 33.5, IQR 17.00-47.00; P=.02), upper limb motor functions (Motricity Index pre: median 45, IQR 15.25-69.00; post: median 46, IQR 32.00-77.00; P=.02; Box and Block pre: median 0, IQR 0-11.5; post: median 0, IQR 0-28; P=.005), and functional mobility (Time Up and Go pre: median 18, IQR 13.25-34.50; post: median 14, IQR 9.00-26.00; P=.005). No significant differences were recorded for general cognitive abilities (Mini-Mental State Examination pre: median 27, IQR 25-28; post: median 28, IQR 26-29), spasticity, and pain (visual analog scale pre: median 0, IQR 0-3.5; post: median 0, IQR 0-2).

Conclusions: The study showed the preliminary feasibility of a rehabilitation program using the VSS. It addressed the essential topic of assessing VR-based rehabilitation user experience throughout the entire training period, shedding light on the features that can contribute to an optimal psychological experience. Clinical outcomes suggested that the VSS promoted neuroplasticity and that the recorded improvements could translate into meaningful functional gains in daily activities. Further studies with larger samples and patients with more severe disabilities are needed to confirm these results.

Introduction

Stroke is the second leading cause of death and the third leading cause of disability worldwide [1,2], and the number of people affected by stroke has doubled in the last 30 years [2]. The majority of patients with stroke survive after the acute event and live with deficits in the motor, sensory, cognitive, mood, and behavioral domains for many years [3,4]. The severity of such deficits and the rate of recovery may vary depending on the type, location, and extent of the brain lesion [5]. The burden of disability after stroke is very high due to economic consequences on health care, social care, and loss of productivity.

Therefore, research and therapies aimed at improving the quality of life of patients with stroke are crucial [6]. Even though most recovery seems to occur during the first few months after stroke, patients can obtain clinical improvements even several months after the event [7]. Current literature suggests that positive outcomes can be achieved through functional training and pharmacological treatments; however, contrasting results [8] and existing barriers to implementing evidence-based recommendations [9] underscore the need for a deeper understanding of stroke rehabilitative treatments and their effects [6,8]. In addition, an open point remains on the administration of the intervention: it is currently unclear what the optimal dosage, frequency, and duration of the proposed therapy are, especially considering the variability and severity of symptoms that patients with stroke may exhibit, as well as the time from the event [9].

Although precise guidelines have yet to be defined, it is currently agreed that adherence to the proposed intervention is essential. The importance of continuing to exercise has been emphasized in several studies, which have highlighted the potential of intensive, task-specific, and meaningful exercises to recover sensorimotor functions [10,11]. Nonetheless, the average adherence rate to therapists' recommendations after discharge ranges between 40% and 70% [12].

One of the solutions that researchers have explored to improve patients' adherence and effectiveness of nonpharmacological interventions is the employment of new technologies, among which virtual reality (VR) has become one of the most popular [10,11,13]. VR is a medium that immerses the user in computer-generated scenarios and enables interaction with the surroundings. It has several characteristics that make it suitable for implementing or supporting rehabilitation interventions [11]: it allows the simulation of ecologically valid tasks, facilitates the transfer of acquired abilities to real life, controlled repetitions, and easy customization of difficulty [14]. Furthermore, VR has been shown to promote neuroplasticity and brain reorganization, thus enhancing recovery [15]. Additionally, it can provide real-time feedback that helps patients regain awareness of their performance [14] and promote training in potentially unsafe situations (eg, road crossing) that would not be feasible in reality [16].

Recently, therapeutic VR-based applications have begun to be assessed in the context of the concept of "flow." Flow is a term used to describe a subjective psychological state that people experience when they are fully engaged in an activity to the point of losing track of time and their surroundings, except for the activity itself [17]. The concept of flow was first conceptualized by Csikszentmihalyi et al [17], which described it as an "optimal experience" characterized by 9 key features: *challenge-skill balance* (the activity difficulty matches the individual's ability); *action-awareness merging* (actions feel automatic and effortless); clear goals; *unambiguous feedback* (feedback guides performance); *concentration* on the task; *sense of control* (the user can influence the situation or outcomes); *loss of self-consciousness; transformation of time* (time may seem to speed up or slow down); and *autotelic experience* (the activity is intrinsically rewarding and enjoyable).

The experience of flow was first assessed in sport, educational, and work contexts, as it was noted that positive psychological flow states are correlated with better performance. Nonetheless, it has been acknowledged that the flow concept applies well to applications developed with therapeutic purposes [18]. VR-based applications for rehabilitation must have a clear goal, provide immediate feedback, and the level of difficulty can often be customized. Additionally, these applications often incorporate gamified elements to maintain high levels of attention and challenge.

The systematic assessment of flow in the rehabilitative context could represent an opportunity. First, it would enable the determination of whether a specific VR application can promote an optical psychological experience, thereby indicating that it is usable, acceptable, and meaningful, ultimately leading to increased treatment compliance [19,20]. Second, it could suggest that it has the potential to enhance the therapeutic efficiency [18].

Although the evaluation of flow and user experience in general is often performed in sports [21,22] and work-related contexts [23], it is generally neglected or lacks analytical rigor in clinical studies [24,25]. A few studies observed a state of flow in their participants but did not assess it with appropriate tools [26]. A review conducted in 2021 analyzed the assessment of flow in VR applications developed for neurorehabilitation; the authors were able to trace only 10 studies [18]. More recently, Saric et al [27] and Pastore-Wapp et al [28] used flow to evaluate the user experience of individuals with Parkinson disease who underwent VR-based training for hand dexterity. Geiser and colleagues [29] assessed flow in patients with left neglect due to stroke who were trained with auditory motion stimulation for 3 weeks. In all cases, the positive experience was considered to be associated with the enjoyment of the experience and the motivation to continue using VR.

This work is positioned in this context by aiming to assess the feasibility, flow, and user experience of patients with stroke during a 4-week intervention with an immersive VR application specifically developed to support cognitive functions and upper

XSL•FO
RenderX

limb rehabilitation. The decision to develop an ad-hoc application was made to avoid the limitations commonly associated with commercial games, including inaccessible interactions for people with disabilities, a lack of ecological validity, and difficulty in customization [30]. The immersive VR application object of this work is derived from previous work carried out by our research group in previous years. In particular, we started with the development and validation of a virtual supermarket dedicated to the training of visuo-spatial abilities in which people could walk naturally; we assessed and demonstrated its usability and acceptance in a group of healthy young adults [31] and in older adults with mild cognitive decline or subjective cognitive decline [32]. Later, we started developing a second version with a simplified interaction, which was tested in the healthy population with positive results [33]. The application we used in this study, namely the Virtual Supermarket for Stroke (VSS), represents the continuation of this research line and, besides the simplified interaction, was specifically designed to reproduce an activity of daily living and to be customized to increase the level of difficulty throughout the 4 weeks of training.

We hypothesized that the chance of experiencing an activity of daily living (ADL) with a customized and adaptable level of difficulty could help maintain the flow levels of the exercise, as well as have other positive effects, and positively impact the sense of presence [22] and emotional state. Moreover, we expected the intervention to be feasible, with patients being able to interact with the application and not experiencing any adverse symptoms due to cybersickness.

Although this study was designed as a user-experience study, a secondary aim was to assess the effectiveness of the proposed VR-based intervention at the clinical level via standard clinical scales.

Methods

Ethical Considerations

The study obtained ethical clearance from the Insubria Ethical Committee (reference No. 70, December 1, 2020) and complies with the Declaration of Helsinki. All participants signed written informed consent before being enrolled; this consent also included permission to take pictures and record videos. To ensure the participants' privacy, data were collected in a pseudonymized form, and the keys were available only to the clinical personnel involved in the study. Also, any images included in the manuscript have been carefully reviewed to ensure that no individual can be identified. Participants did not receive any compensation for taking part in the study. This study adhered to the RATE-XR (Rationale, Accessibility, Training, and Effectiveness for Extended Reality) checklist [34] (Checklist 1).

Participants

Participants were recruited through convenience sampling among patients with stroke referred to the Villa Beretta Rehabilitation Center (Costa Masnaga, LC, Italy) at the Rehabilitation Department of Valduce Hospital, where the study was carried out. Participants were either in the postacute (time from the stroke >15 d) or chronic phase (>6 mo). All met the following inclusion criteria: age 18 years or older; clinical stability; absence of pain, postural instability, muscle hyperactivity, and impairments that prevent the accomplishment of the reaching task; Mini-Mental State Examination (MMSE) 20 or an equivalent cognitive level for patients with aphasia.

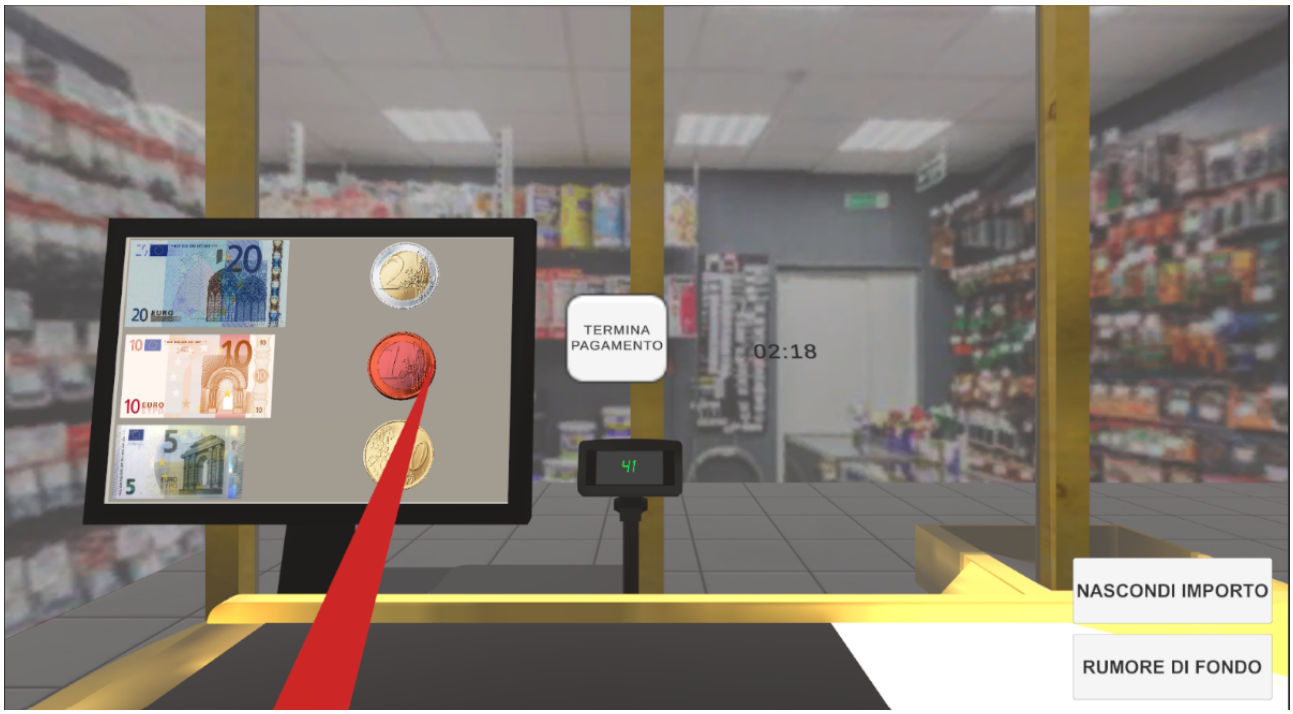
Clinical stability, particularly for individuals with subacute poststroke, was defined as a period of 2 to 4 weeks poststroke during which patients completed acute hospitalization and were medically stable. This choice allowed for an optimal enrollment window of 1 to 3 months post stroke, where there is a balance between medical stability and the neuroplasticity window.

The cutoff set for MMSE score was selected based on several considerations. First, MMSE scores 20 or higher (≥20) indicate sufficient cognitive capacity to understand VR task instructions, safety protocols, and provide informed consent for participation in experimental technology [35,36]. Second, MMSE scores below 20 (<20) have been associated with reduced rehabilitation potential and motor learning capacity in stroke populations, which could limit the ability to benefit from VR-based interventions [37,38].

Third, VR rehabilitation requires intact working memory, sustained attention, and executive function to engage with immersive environments and process multimodal feedback—cognitive domains that are relatively preserved in individuals with an MMSE score of 20 or higher [39,40]. Finally, this cutoff is consistent with previous VR stroke rehabilitation trials [41,42] and minimizes floor effects on secondary cognitive outcome measures.

Exclusion criteria were a history of seizure or motion sickness, severe visual deficits, and inability to provide informed consent. The sample size was calculated using the formula reported by Candel and van Breukelen [43] for single-arm pre-post studies, and considering flow (specifically Short Flow Scale; see Outcomes section) as the main outcome. Given previous experiences and available literature on the topic [44], the required sample was 23 participants, using SD=1.2, α=.05, power=80%, and expecting a pre-post variation equal to 0.65. The final sample size was increased to 30, considering the possibility of 20% dropouts and aligning the final sample to other studies assessing feasibility [45].

Equipment



The VSS is an immersive VR application dedicated to the rehabilitation of stroke patients. It was developed with Unity and deployed for Oculus Rift v2. The VR environment is constituted by 2 scenarios. The first is devoted to picking groceries from the shelf (Figure 1); the second is paying for such items (Figure 2). Both these tasks can be performed while staying seated to ensure all participants' safety and make the VSS accessible to patients in wheelchairs, too.

XSL•FO
RenderX

Figure 1. A screenshot of the aisle environment of the Virtual Supermarket for Stroke. To complete the shopping, the button "end shopping'' [termina spesa] has to be clicked. Buttons at the bottom-right corner are available to the therapist to change the visibility of the list [visibilità lista], to turn the background noise on/off [rumore di fondo], and to replay the list items [leggi lista]. The basket could be placed on the right or the left side, depending on the upper limb to train [46].

Figure 2. A screenshot of the payment environment of the Virtual Supermarket for Stroke. The [termina pagamento] serves to end the selection of banknotes and coins. Buttons at the bottom right corner are available to the therapist to change the visibility of the amount to pay [visibilità importo] and to turn the background noise on/off [rumore di fondo] [46].

A series of features is available to therapists to customize the difficulty of training throughout the rehabilitative path. Before starting the exercises, the therapist can adjust the position (right/left) of the shopping basket, the number of items on the shelves (9 or 15), the number of target items (ie, items to be picked from the shelves) on the shopping list (from 1 to 8), and select if grocery items are shown on the list with their names or as categories (eg, dairy products, dishware, vegetables); in this second case, the task is to pick all the items corresponding to such categories. Moreover, during the exercise, some buttons (visible only on the therapist's PC screen) allowed the therapist to play a background noise, which served as a distracting sound,

XSL•FO
RenderX

and to hide or show the shopping list or the amount of money to be paid. When the shopping list was hidden, the therapist could play a clip (created via text-to-speech) indicating to the patient the grocery items to pick. All the therapists/psychologists involved in the study were trained by the VSS developer to set up the game area and use the application, which was developed by the researchers who created the VSS.

All the interactions within the VR environment occurred using the Oculus controller. The grocery items could be picked using a direct interaction, that is, reaching for the item and pressing the controller grip button to hold it and transport it around. All the other interactions (ie, coin selection and button press) occurred using a ray interactor (Figure 2) [47].

At the end of each task (item grabbing and payment), a panel was shown to the patients reporting their performance (ie, the time needed to complete the task, the errors, the omissions, or the amount of money still to pay).

Given its features, the VSS was expected to promote the retraining of motor and cognitive functionalities, in particular, the upper limb task-related reaching movement, a goal-directed, functional movement carried out in a natural environment [48], and visuospatial search, memory, and action planning.

Protocol

Each patient underwent 12 sessions of 20 minutes, in which the tasks of doing the shopping and paying at the cash register were repeated recursively. The therapist chose the level of difficulty, the presence of distractors, and other elements that increase the complexity of the task, both at the beginning and during the session. All sessions occurred in a quiet room, where only the patient and the therapist were present. Upon arrival, patients using a wheelchair were guided into the game area, and their wheelchair was braked. Patients who walked or used crutches were accommodated in a chair. All were then helped to wear and adjust the head-mounted display. Patients completed the task with the impaired arm whenever possible; if their motor functions were too low on the impaired side, they used the other upper limb.

During the first session, each participant was presented with the VSS and the tasks to perform, along with an explanation of the interaction modalities. All performed the first session at the lowest level of difficulty. After 20 minutes of exercise, the psychologist supervising the session administered paper-based questionnaires evaluating their user experience. The same questionnaires were administered again to all patients immediately after the last session. In the case of patients with aphasia, questionnaires were answered by pointing.

Patients were also administered the clinical scales presented in the Outcomes section at baseline and after completing the last exercise session.

Outcomes

The user experience was evaluated by administering a series of questionnaires at the end of the first and last sessions. Questionnaires were administered by a psychologist, and answers were collected on paper. The collected questionnaires were:

1. The Short Flow Scale (SFS) [49], which uses 9 items to measure *flow* (ie, a measure of absorption in what one is doing and how much the subjective experience is optimized);
2. The International Test Commission—Sense of Presence Inventory (ITC-SOPI) [50], which evaluates the Sense of Presence (ie, the sense of "being there" in a computer-generated environment along 4 subscales: spatial presence, engagement, naturalness, and side effects);
3. The Positive and Negative Affect Schedule—Short Form [51] for the assessment of positive and negative traits and states (ie, joy, high levels of energy, concentration, and distress, anger, contempt, or fear, respectively);
4. The Simulator Sickness Questionnaire (SSQ) [52] to assess cybersickness according to Nausea (SSQ-N), Oculomotor disturbance (SSQ-O), and Disorientation (SSQ-D), and general score (SSQ-TS); and
5. The Technology Acceptance Model (TAM3) subscale for the evaluation of perceived ease-of-use (PEOU) [53].

SFS, ITC-SOPI, and PANAS were assessed on a Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree), whereas PEOU was evaluated with a scale ranging from 1 to 7 (maximum perceived ease of use); within SSQ, the occurrence of each symptom was assessed from *not at all* to *severe* on a 4-point scale.

To evaluate whether the proposed intervention brought clinical improvements, the following clinical scales were administered before and after the training period:

1. MMSE [54] or an equivalent for patients with aphasia: MMSE is a brief 30-point questionnaire used to screen general cognitive impairments. It includes orientation, immediate memory, attention, calculation, recall, and language tasks; it represents a common instrument to assess cognitive changes.
2. Visual analog scale for pain [55]: the scale consists of a 10 cm horizontal line going from 0 (no pain) to 10 (worst imaginable pain). It represents a quick instrument to subjectively assess pain, which, in stroke, is mostly investigated from a clinical diagnosis perspective rather than from the patient's perspective [56].
3. Motricity Index (MI) [57]: it is a clinical scale used to assess limb motor function, especially in individuals with stroke. It measures muscle strength in the upper limb (pinch grip, elbow flexion, and shoulder abduction) and lower limb (ankle dorsiflexion, knee extension, and hip flexion). Each movement is scored on a 6-point scale (0 - 33), based on the degree of movement and resistance against gravity.
4. Modified Ashworth Scale [58] for spasticity on arm abductors and pronator, elbow flexor and extensor, wrist flexor and extensor, and finger flexors (flexor digitorum superficialis and profundus, and flexor pollicis longus): an examiner performs it by moving a limb passively through its range of motion and grades the resistance felt in the muscle from 0 (no increase in muscle tone) to 4 (rigid flexion or extension).
5. Box and Block test (BnB) [59] with both arms (affected [A] and nonaffected [NA]): it constitutes a measure of manual dexterity, and it is computed as the number of

XSL•FO
RenderX

wooden blocks (2.5 cm) transferred from one compartment to another in 1 minute.

6. Berg Balance Scale [60]: it consists of 14 functional balance tasks that are rated by the examiner from 0 (unable to perform) to 4 (performs independently and safely). The maximum score is 56; scores below 45 indicate risk of falls.
7. Timed Up and Go test [61]: it is used to assess mobility, balance, and fall risk. The examinee starts seated, stands up, walks 3 m, turns around, and walks back to return seated. The time taken to perform the task constitutes its score.

Statistical Analysis

To assess the randomness of missing data, we used the Little's Missing Completely At Random (MCAR) test. Multiple imputation was performed as a sensitivity analysis to evaluate the robustness of the results with respect to missing data handling.

The reliability of the questionnaires' structure was calculated with the McDonald Ω index; a frequently cited acceptable range of the Ω coefficient is a value of 0.70 or higher [62,63]. The normality of the data distribution was assessed using the Kolmogorov-Smirnov test. Descriptive statistics are used to describe the outcomes. In the case of nonnormal distribution, the 95% CIs estimated via bootstrapping (2000 resamples) pre-post differences were assessed via Wilcoxon signed rank test. In all analyses, statistical significance was set at *P* less than .05.

Results

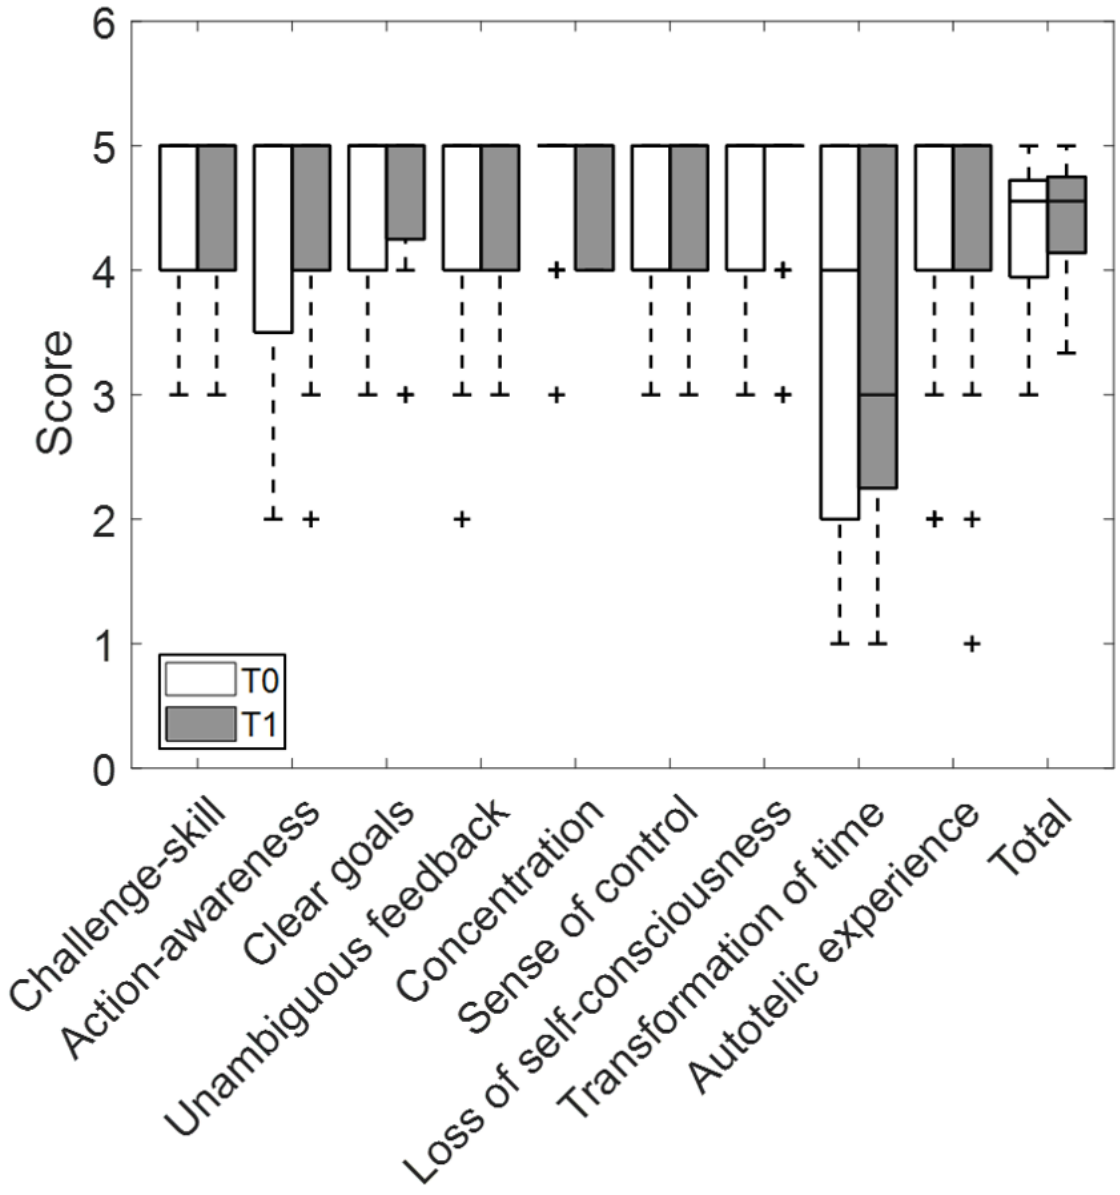
Participants and Missing Data

Thirty-two patients with a mean age of 60 (SD 11) years were enrolled in the study. One participant experiencing the VSS is shown in Figure 3. The median time from the stroke event was 7 (IQR 16, min: 16 d, max: 11 y) months, with 13 participants being in the subacute phase and 19 in the chronic stage. Twenty-three participants had right-brain damage. Demographic and baseline data of the study participants are presented in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 3. One of the participants during a Virtual Supermarket for Stroke session.

All patients except one completed the training; no adverse events were recorded. One participant left the study because they did not feel familiar with and did not feel at ease while interacting with technology. For this participant, only clinical scales were collected at T1, leading to user experience–related results being calculated on n=31. There were no other missing data.



Missing data in the clinical scales were evaluated by recoding nonparticipation cases (eg, patients unable to walk could not perform the Time Up and Go test at any time point) as valid scores. Considering this, the overall proportion of missing data was approximately 4%, with up to 12% missingness in 5 clinical scales. The Little's MCAR test was not significant (χ^2_{85}=104.308; *P*=.07), indicating that other data were missing completely at random. Using multiple imputation as a sensitivity analysis, results were highly consistent across approaches, indicating that missing data did not materially influence the findings. Therefore, complete-case data were analyzed.

User Experience

The results obtained for all flow subscales are reported in Figure 4; there are no statistically significant differences for any of them (*P*>.05). The increase in the total flow score was almost significant (*P*=.05).

XSL•FO
RenderX

Figure 4. Flow subscales collected from participants with stroke using the Virtual Supermarket for Stroke in the pretest-posttest study. Data are shown as boxplots, where whiskers extend to the most extreme values within 1.5 times the IQR and individual points denote outliers. Measurements were performed at T0, after the first session, and at T1. T1 was collected after 4 weeks of training, 3 times per week, at the end of the 12th session.

Descriptive statistics for the user experience questionnaires investigating presence, positive and negative affect, cybersickness, and perceived ease of use are reported in Table 1.

[a]Data were collected at T0 (pre), after the first session, and at T1 (post). T1 was collected after 4 weeks of training, 3 times per week, at the end of the 12th session. Data is presented as median values with IQRs, 95% CIs, and minimum and maximum values. Results of the Ω test for reliability and the Kolmogorov-Smirnov test are also reported.

[b]Not applicable.

[c]Indicates statistical significance ($P<.05$).

[d]SP: spatial presence.

[e]ENG: engagement.

[f]NAT: naturalness.

[g]PA: positive affect.

[h]NA: negative affect.

[i]SSQ-N: Simulator Sickness Questionnaire—Nausea.

[j]SSQ-O: Simulator Sickness Questionnaire—Oculomotor Disturbance

[k]SSQ-D: Simulator Sickness Questionnaire—Disorientation.

[l]SSQ-TS: Simulator Sickness Questionnaire—General Score.

[m]PEOU: perceived ease of use.

No significant difference was found between pre- and postassessment regarding negative effects, engagement, realism, spatial presence, ease of use, and positive and negative affects. No significant difference was found for nausea, oculomotor, and disorientation symptoms or the total score of the Simulator Sickness Questionnaire.

Clinical Outcomes

The measures of clinical outcomes before and after the 4 weeks of intervention are reported in Table 2. Significant improvements were recorded for the affected arm in the Box and Block test, MI (elbow and total scores). Moreover, patients improved their balance and their performance in the Time Up and Go test. Significant differences are shown in Figure 5.

Figure 5. Boxplots of the clinical scales collected from participants with stroke using the Virtual Supermarket for Stroke (VSS) in the pretest-posttest study. Whiskers extend to the most extreme values within 1.5 times the interquartile range, and individual points denote outliers. The reported scales are the ones that showed a significant (P<.05) improvement postintervention (ie, after 4 wk of training, the VSS was used three times a wk). BBS: Berg Balance Scale; BnB (A): box and block (affected side); MI: Motricity Index; TUG: Time Up and Go.

Discussion

Main Findings

This study presents a feasibility assessment of a VR-based intervention for the rehabilitation of cognitive abilities and upper limb functions in patients with stroke, focusing on user experience and preliminary effectiveness. In particular, we assessed that the ecological environment and the features of the VSS application promoted an optimal psychological experience, enhancing flow and thereby increasing motivation and adherence throughout the entire duration of the training. We found that the general experience was positive, and participants welcomed the possibility of rehabilitation with the support of immersive technologies, which also led to some improvements in functional outcomes. Also, we demonstrated that the designed intervention was feasible, with no side effects and excellent adherence among stroke survivors (97%).

Subjective Outcomes

The subjective outcomes collected after the first session showed satisfying levels, with flow and positive affect scores very close to the highest possible value. The same was recorded for PEOU, possibly indicating that the intuitive interaction with virtual objects in the VSS also mediated the positive experience. This finding aligns with a previous study that investigated the acceptance of immersive VR technologies among patients with stroke [30,64].

XSL•FO
RenderX

The choice of a simple interaction methodology was effective and made possible by the use of an ad-hoc, developed application. In fact, the application's features made the solution easily accessible, even for patients with motor limitations. On the contrary, the use of a commercially available application, which would have possibly provided more varied and engaging scenarios, would have required checking it for customization settings to enable effective interaction for patients with stroke [65].

Presence-related scales were all satisfactory; thus, patients felt present and recognized the environment as an ecological and familiar one. Conversely, negative affect was low, and median cybersickness scores were all within the acceptable range (≤20) [52]. This confirmed the outcomes obtained before with slightly different versions of the Virtual Supermarket and different populations (healthy volunteers [33] and older adults with cognitive decline [32,66]). In particular, in this case, we recorded almost no nausea-related symptoms; instead, the symptoms were mostly present in the oculomotor and disorientation domains, as more typically occurs in nonnavigational environments [67].

At the end of the period of trial, all the subjective outcomes preserved the same satisfactory and, in some cases, more than satisfactory trends. This demonstrated that the design choice we made for the application effectively addressed the maintenance of flow throughout the experience, that is, we could balance patients' skills and the challenge of the task, and provide an engaging scenario in which they could feel focused and immersed. Also, the obtained outcomes confirmed our hypothesis that introducing some challenging elements (ie, the possibility of customizing the levels of difficulty), addressing different cognitive abilities (eg, attention, memory), and the visualization of the performance could contribute to maintaining the experience engaging and able to induce positive feelings, even over a longer period of time.

These features represent essential points in the field of rehabilitation, in which prolonged, or even lifelong, interventions are often essential to counteract limb disuse or misuse, or cognitive decline [68]. As already mentioned, these variables and flow, in particular, have been explored in sport and other disciplines because of their positive association with performance, positive experience, motivation, and enjoyment [18]. Despite this, its assessment remains sparse in the health sector, which may negatively impact treatment compliance and the subsequent effectiveness of proposed VR-based interventions [65].

This has also been shown in a review performed in 2020, which focused on user experience in general and immersive VR; it showed that research in the field of human-immersive VR interaction still presents some methodological and technological gaps [69]. When examining the rehabilitation field, such gaps are even more evident: of the 65 articles included in the review, only four involved patients, and 35 included participants only in their 30 s.

Future studies should thus consider tackling the user experience assessment more broadly to evaluate patients' needs not only from a clinical perspective but also from a subjective and intrinsic motivation point of view [65,70].

Clinical Outcomes

Regarding clinical outcomes, we observed positive results in various clinical scales. We recorded a significant improvement in the Berg Balance Scale and the Timed-Up-and-Go test, indicating increased trunk control in all patients. Moreover, considering the entire sample, we recorded an increase in the impaired limb scores, with significant changes in the Box-and-Block and otricity Index (total and elbow score) tests.

The observed improvements in upper limb dexterity (Box-and-Block Test) and motor strength (MI) suggest that the intervention may translate into meaningful functional gains in daily activities such as reaching, grasping, and manipulating objects [71]. The enhanced balance and mobility indicate potential benefits for overall independence and fall prevention [72].

These changes were recorded even if some patients performed the task with the nonimpaired arm, possibly suggesting that the improvements were mostly linked to better trunk control and action planning (which have recently been reported to be related [73]) rather than the arm motor function improvement per se. To this aim, the fact that the supermarket simulated an activity of daily living may have also contributed positively to the rehabilitation of executive functions [74]. Indeed, the ecological validity of shopping tasks has been previously verified in studies that utilize this scenario to assess and train executive functions and action planning, in particular [75].

The intervention proposed using the Virtual Supermarket frames within the task-oriented training. In fact, it emphasizes functional activities and patient involvement. Furthermore, it includes task repetition, active participation, and the modulation of the training intensity. From a clinical perspective, these interventions—even those supported by VR—have demonstrated effectiveness in enhancing limb function and balance, as well as promoting neuroplasticity [76,77].

Therefore, it is possible that, in our case as well, the modulating effects of neuroplasticity allowed us to observe clinical improvements even in chronic patients exercising with the less-affected limb [78,79]. Unfortunately, the small sample size, defined for the assessment of flow, did not allow us to explore subgroup differences further (ie, considering time from the stroke event, in the postacute or chronic phases, or the use of the affected or nonaffected side). However, the positive results should encourage the conduct of more structured, clinical-oriented trials to unveil potential indications for future intervention characterization. In fact, the recorded improvements across multiple functional domains support the potential clinical relevance of the intervention. The effects of the proposed intervention on both upper limb function and balance suggest that it could be integrated into standard rehabilitation protocols to promote more holistic recovery.

Limitations

All the discussed results must be treated cautiously. We are aware that the current study presented some limitations that

XSL•FO
RenderX

prevented the generalization of the results. First, the sample size was small and estimated based on the assessment of our main outcome (ie, flow); thus, the statistical power may not be sufficient to draw conclusions at the clinical level. Second, the population was heterogeneous, including both patients in the sub-acute and chronic phases who completed the exercise with either the impaired or less-impaired side. Finally, we did not have a control group. Nonetheless, the study allowed for assessing the user experience in a systematic and multidimensional way and highlighted the potential of a customizable, ecological, and immersive VR-based application for the rehabilitation of motor functions in patients with stroke.

Conclusions

This work addressed an important aspect in the context of VR-assisted rehabilitation, as user experience is generally evaluated on a single session or by focusing on a single aspect (eg, usability).

It contributed to the current body of knowledge on the use of immersive VR for stroke rehabilitation, providing insights into the features that helped maintain high flow levels and highlighting the importance of exploring the subjective domain in clinical trials as well.

From a clinical perspective, the intervention appears feasible and well-tolerated. Its simple setup and ease of use make it potentially adaptable to a variety of clinical settings, and potentially for future use at home or in unsupervised contexts (eg, with a stand-alone head-mounted display and automatic progression of difficulty).

In the future, it would be valuable to increase the difficulty levels and include different interaction technologies (eg, hand tracking) to make the application more accessible to patients with limited arm motor function, thereby providing a longer training period.

Moreover, as already mentioned, it would be essential to enlarge the sample of participants, thus allowing for a more in-depth investigation of the optimal phase for administering the exercise and, in general, of the clinical effectiveness of the VSS application.

Funding

This work was supported by Fondazione Cariplo under Grant EMPATIA@Lecco—“EMpowerment del PAzienTe In cAsa.” The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Data Availability

The anonymized data collected during this study are available from the corresponding author upon a reasonable request.

Conflicts of Interest

None declared.

Abstract

Background: Children with developmental coordination disorder (DCD) experience motor difficulties that limit daily activities and reduce physical activity enjoyment. Immersive virtual reality (VR) offers the potential for feedback-rich movement practice, but evidence for these effects in DCD remains limited.

Objective: This study aims to investigate the effects of an immersive VR rhythm game compared to tablet-based gameplay within a home-based setting on motor performance, enjoyment, and motivation in children and adolescents with DCD.

Methods: This crossover study included 27 participants (21 boys and 6 girls) aged 10 to 16 years with DCD who completed 2 home-based interventions, each delivered over 5 consecutive days: VR gameplay using Beat Saber (Beat Games) and tablet-based gameplay using Cut the Rope (ZeptoLab). Participants were recruited in England using convenience sampling via social media; eligible participants were aged 10 to 16 years, met research criteria for DCD based on a Developmental Coordination Disorder Questionnaire screening, and had no alternative neurological or musculoskeletal diagnosis. Each condition required at least 30 minutes of daily gameplay and was separated by a 2-week or more washout period. Motor performance was assessed pre- and postintervention using the *Movement Assessment Battery for Children, Third Edition* (MABC-3) and the Box and Block Test. Enjoyment was measured pre- and postintervention using the Physical Activity Enjoyment Scale. Participants also rated their motivation and feelings during each gameplay session. Repeated-measures ANOVAs and paired-samples 2-tailed *t* tests (α=.05) were used to examine the data.

Results: For MABC-3 domains, condition × time interactions were nonsignificant, although exploratory within-condition analyses showed pre-post improvements in the VR condition. For the Box and Block Test, condition × time interactions were significant for both hands, with a greater degree of pre-post improvement in VR than tablet-based gameplay. In the VR condition, mean block transfer increased for the dominant hand (ΔM 5.93, 95% CI 3.49 - 8.36; t_{26}=−4.99; *P*<.001; Cohen *d*=0.96) and the nondominant hand (ΔM 5.11, 95% CI 2.65 - 7.57; t_{26}=−4.27; *P*<.001; Cohen *d*=0.82), whereas no significant changes were observed in the tablet condition (all *P*≥.36). VR gameplay also yielded higher enjoyment, and children reported higher motivation and feeling ratings across VR sessions than tablet sessions.

Conclusions: This study, in contrast to most of the existing literature on nonimmersive technologies, examined the effect of a home-based *immersive* VR rhythm game intervention for children and adolescents with DCD. This study provides early evidence that this VR rhythm game was engaging and may support greater short-term improvements in motor performance than tablet gameplay. These findings suggest home-based immersive VR rhythm games could be a practical adjunct to pediatric rehabilitation to increase movement practice and motivation, although larger and longer trials are needed to confirm clinical impact and identify which game features drive this benefit.

Introduction

Background

Developmental coordination disorder (DCD), or dyspraxia, is a neurodevelopmental condition characterized by marked impairment in the acquisition and execution of coordinated motor skills that interferes with daily living and academic achievement [1,2]. Motor coordination describes a range of fundamental movement skills such as object manipulation (eg, grasping, kicking, and throwing) and locomotor activities (eg, walking, running, and jumping) [1,2]. It is an essential component of human development, supporting everyday self-care, communication, and active engagement in learning environments [1,2]. These motor skills support physical play and enable independent completion of activities of daily living [2]. For school-aged children, motor tasks represent a substantial portion of everyday academic activities [3]. Approximately 46% of children's time spent at school involves participation in tasks requiring motor coordination, such as handwriting, coloring, cutting with scissors, and using tools [3]. Adequate motor coordination supports physical and cognitive development, psychosocial health, and overall well-being [4]. Deficits in motor skills could restrict participation, reduce quality of life, impair confidence, and adversely affect developmental outcomes [1].

Difficulties in motor coordination often appear in early childhood, typically around preschool age [5]. These difficulties become more evident in primary school as motor demands increase in daily routines [6]. DCD affects about 5% to 6% of school-aged children who often struggle with everyday tasks needed for home, school, and play [2,7]. Common difficulties include handwriting, dressing, tying shoelaces, brushing teeth, and taking part in sports and leisure activities [8]. As a result, participation is often less frequent, and children with DCD engage in a narrower range of activities than their typically developing peers [9]. These constraints affect current motor performance and broader psychological, emotional, and social development [1]. Early identification and effective intervention are therefore needed [10].

In recent years, growing research interest has emerged regarding innovative and engaging approaches aimed at enhancing motor performance and physical activities among children [11]. Immersive Virtual Reality (VR), characterized by an interactive computer-generated environment typically explored through full-body movements, has rapidly gained prominence within the consumer entertainment sector [12]. In this paper, we use the term immersive virtual reality (VR) to refer to computer-generated, 3D environments that surround the user and are typically accessed via head-mounted displays or comparable 3D displays, together with motion- or spatial-tracking technologies (eg, handheld controllers, optical tracking of hand and body parts, or other sensor-based interfaces) that enable active interaction with virtual objects and spaces [12]. In rehabilitation, VR offers a motivating, realistic setting with immediate and often intrinsic feedback [13,14], potentially increasing adherence to treatment programs [15] and facilitating the repetition of targeted motor tasks [16,17]. For children, motivation and enjoyment are key to sustaining activity [18]. VR-based games could stimulate intrinsic motivation and enjoyment, making rehabilitation feel playful and rewarding, encouraging persistent practice [19]. Studies report benefits of VR for skill acquisition in typically developing children [20] and in children with acquired brain injury [21], autism spectrum disorder [22], and cerebral palsy [17], but evidence on immersive VR for children and adolescents with DCD is scarce. A recent scoping review by Alharbi et al [23] found no studies using fully immersive VR systems in this population, indicating a clear research gap.

Exercise-based VR rhythm games, such as Beat Saber, involve physically interactive gameplay synchronized with rhythmic auditory and visual stimuli [24]. Beat Saber has a growing evidence base in motor control research, demonstrating improvements in reaction time and hand-eye coordination in typically developing youth populations [25-27]. In a recent Patient and Public Involvement (PPI) activity, we conducted a focus group where children and adolescents with DCD experienced various VR sports and rhythm games, including Beat Saber. Contributors in this activity identified Beat Saber as especially engaging because of its music movement coupling and simple controls. This rhythm game requires bimanual, goal-directed arm movements, precise timing, and rapid visuomotor responses, with graded difficulty that enables high-dose practice of coordinated actions. These features suggest that VR-based rhythm games may benefit motor skills in children and adolescents with DCD. Accordingly, the primary aim of this study was to investigate the impact of a home-based immersive VR rhythm game on motor performance, motivation, and enjoyment in children and adolescents diagnosed with or suspected of having DCD.

PPI Activity

This study was informed by a recent PPI activity that explored the perspectives of children and adolescents with DCD on sports participation and immersive VR games [28]. Five participants aged 13 to 16 years who self-reported as having DCD took part in this study.

The PPI activity had 2 visits. The first visit involved a focus group where contributors discussed experiences and challenges in relation to traditional sports and manual tasks and commented on promotional videos of various VR sports and rhythm-based games. In the second visit, contributors took part in a hands-on VR session, followed by brief semistructured interviews about usability, enjoyment, perceived difficulty, any adverse symptoms (eg, motion sickness), content preferences, and perceived feasibility of VR for home use and rehabilitation. Contributors played VR sports titles (eg, Rezzil Index football drills, table tennis, tennis, racket sports, volleyball, and golf) and the rhythm game Beat Saber using a Valve Index VR headset.

Contributors shared a variety of opinions about the immersive VR games. Some described the games as enjoyable and accessible; others found them less engaging because of their lack of dynamic interactions and player movement. These responses suggested that engagement with immersive VR games may vary depending on individual preference and perceived challenge. Beat Saber, a rhythm-based game included in the

XSL•FO
RenderX

session, was described as especially engaging and motivating. Contributors highlighted that they liked the combination of music, movement, and straightforward controls, which made the activity physically demanding yet manageable. The clear rhythmic structure and lack of competitive pressure were described as supporting enjoyment and confidence.

Insights from this PPI activity directly informed the study design, guiding the selection of this rhythm-based game as the primary VR task and supporting a home-based protocol with graded difficulty and repeated short sessions.

Methods

Participants

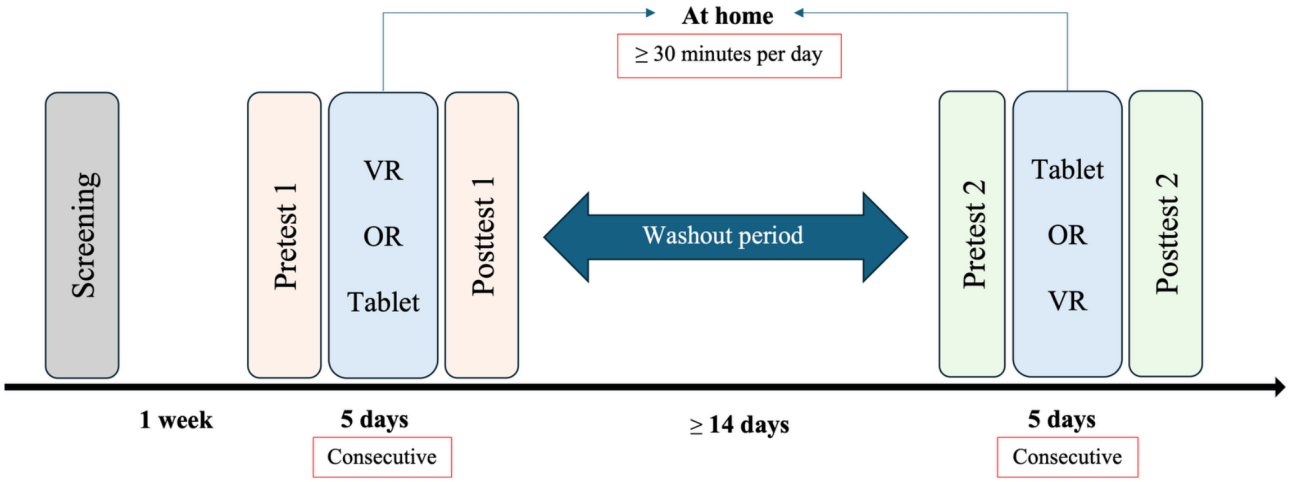
We recruited for a fixed time period of 6 months from September 2024 to March 2025; within the available recruitment period, 30 children and adolescents, aged 10 to 16 years (23 male and 7 female participants), with confirmed or suspected DCD participated in the study. With this sample size, based on an a priori power analysis conducted in G*Power (version 3.1.9.6; Heinrich Heine University Düsseldorf), using a 2-dependent-means 2-tailed *t* test with a desired power of 0.80 (α=.05), we would be able to detect a medium effect size (*dz*=.53). We selected the age range of 10 to 16 years on developmental, clinical, and practical grounds. Ten years was chosen as the lower bound because by around the age of 10 years, most children are in middle childhood, with sufficiently developed concrete reasoning, sustained attention, and independent reading skills to participate in structured, school-like tasks [29]. So, children of this age typically have sufficient cognitive, attentional, and reading abilities to follow a home-based protocol, complete self-report measures, and use an immersive VR headset safely. From a safety and feasibility perspective, we did not include children younger than 10 years because Tychsen and Foeller [30] found that those aged 4 to 10 years showed increased general discomfort, head-neck discomfort, fatigue, and visually induced motion sickness on the child-friendly Simulator Sickness Questionnaire measures after VR exposure compared with their pre-VR ratings. An age of 16 years was chosen as the upper bound to capture mid- to late-adolescence while still focusing on school-aged young people who are typically managed within pediatric and educational services for DCD.

Participants were recruited from England, United Kingdom, using convenience sampling via social media platforms including X (formerly known as Twitter), Facebook, and Instagram. Because recruitment occurred via open social-media platforms, the number of individuals reaching or viewing the advert is unknown, and a response rate cannot be calculated. Eligibility screening was performed using the Developmental Coordination Disorder Questionnaire (DCDQ) [31], which was completed by participants' parents or guardians. The DCDQ is a validated screening instrument designed to assess children's motor coordination capabilities in those aged approximately 5 to 15 years [32]. Inclusion required DCDQ scores of 57 or less on the 15-item DCDQ (total 15 - 75; lower scores indicate greater difficulty); 58 to 75 is interpreted as not indicative of DCD. For adolescents aged 16 years, DCDQ scores were used as supportive screening information alongside baseline motor assessment rather than as a diagnostic indicator to determine participation in our study, and we recognize that using the DCDQ slightly beyond its validated age range may reduce screening precision for the oldest participants. Exclusion criteria were children with co-occurring neurological or musculoskeletal conditions affecting motor or cognitive function (eg, muscular dystrophy and cerebral palsy), or children who had undergone recent surgery or suffered a severe physical injury. Participants who already owned a home VR headset were excluded to reduce variability due to differences in prior exposure, unequal device familiarity, and uncontrolled use outside the prescribed days (during 2 wk or washout period of the tablet). Families meeting the inclusion criteria were invited to the research laboratory for participation.

Three participants withdrew during the interventions (2 male and 1 female participants): one during the VR condition and two during the tablet condition. Reasons for withdrawal included difficulties managing study participation alongside school commitments, disinterest (in tablet-based activities), or a lack of motivation to continue participation. Analyses were conducted on participants who completed both conditions (n=27; mean 12.7, SD 2.07; 21 male and 6 female participants). Data from withdrawals were excluded. Among these 27 participants, the baseline of the *Movement Assessment Battery for Children, Third Edition* (MABC-3) data indicated that 25 scored at ≤16th percentile on the total motor score and, together with DCDQ ≤57 and the exclusion of alternative neurological or musculoskeletal conditions, were classified as meeting research criteria consistent with the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) for DCD. The remaining 2 participants had the MABC-3 scores in the 16th to 37th percentile range, but DCDQ<57 scores and functional motor difficulties and are therefore considered as having probable DCD. A 16th percentile or less was used as the cutoff for the total motor score in line with international clinical practice recommendations for DCD when using the MABC-3 (or equivalent objective motor measures) [33]. For brevity, we refer to this combined group as "children and adolescents with DCD" throughout the paper.

Ethical Considerations

Ethical approval was obtained from the local research ethics board at the University of Exeter (reference: 5759511). Written informed consent was obtained from the participants' parents or guardians, and all participating children provided their assent prior to the initiation of the study procedures. The consent or assent process made clear that the participation was voluntary and that families could withdraw at any time without giving a reason. To protect privacy and confidentiality, each participant was assigned a unique study ID, and all questionnaires and assessments were stored in deidentified form. Identifiable information (eg, names and contact details) was stored separately from research data on secure, password-protected university servers with access restricted to authorized members of the research team. Only anonymized data are reported herein. Participants received financial compensation of £50 (US $67.66) as a fixed reimbursement for their time and any travel costs. No



XSL•FO
RenderX

images in the study or supplementary materials include identifiable participants.

Study Design and Experimental Procedure

This study used a crossover design. Each participant completed two 1-week interventions: a tablet-based game (tablet condition) and Beat Saber on a VR headset (VR condition). A 5-day intervention period was chosen primarily for comparability with previous immersive VR studies using Beat Saber, which has demonstrated meaningful changes over a similar short, intensive timeframe. In particular, Grosprêtre et al [26] and Rutkowski et al [25] used Beat Saber–based protocols of less than 1 week and reported measurable improvements, suggesting that this duration is sufficient to elicit short-term effects while remaining acceptable and feasible for children and families. The order of conditions was counterbalanced by simple alternation based on enrollment: the first enrolled participant was assigned to the tablet condition first, the second to VR first, and so on. The interventions were separated by a washout period of at least 14 days. Participants were instructed to play a minimum of 30 minutes per day for 5 consecutive days at home (Figure 1). A minimum of 30 minutes per day for 5 consecutive days was chosen to provide a dose that clearly exceeds the minimum effective exposure reported in previous Beat Saber VR studies [25,26], where participants played for around 15 minutes per day over 5 days and still showed improvements. By doubling the daily playtime, we aimed to increase the volume of motor practice and the likelihood of detecting short-term effects. Adherence was monitored with a daily log completed after each session; entries recorded session completion and approximate duration. No device logs were used, so adherence reflects self-report.

Figure 1. Study protocol. VR: virtual reality.

Assessments were conducted both before (pre) and after (post) each intervention using the MABC-3, the Box and Block Test (BBT), and the Physical Activity Enjoyment Scale (PACES). After each gameplay session, participants were asked to report their motivation and feeling ratings in the daily log. After the postassessment, the researcher collected the device, erased participant data, and reset the game application for the next participant. Blinding was not possible because participants and caregivers were aware of the intervention being used (VR vs tablet); outcome assessments were conducted by the same assessor who was not blinded to the condition. All outcome assessments were administered using standardized instructions by a trained assessor, using the same equipment and testing environment at each visit to reduce measurement variability. This study is reported in accordance with the APA JARS-Quant (Journal Article Reporting Standards for Quantitative Research) guidelines (Checklist 1) [34].

Interventions

VR Gameplay Condition

The VR condition used Meta Quest 2 headsets (Meta Platforms, Inc; 1832×1920 pixels per eye; 120 Hz) with 2 handheld controllers. Participants played Beat Saber (version 1.40.7_7060; Beat Games), a rhythm-based VR game in which colored cubes approach in sync with music. Players use 2 virtual sabers, one per hand, to slice cubes in the specified direction with the correct hand and in time to the beat, and must avoid obstacles. Scoring is based on the number of accurately sliced cubes, the precision of the slicing motion, and alignment with the rhythm of the soundtrack. Participants were instructed to begin playing the game on the default (“normal”) difficulty setting. They were further informed that if the “normal” difficulty was too challenging, they could switch to the “easy” mode. Conversely, participants who found the “normal” mode insufficiently challenging were permitted to progress to the “hard” mode. The difficulty level was not systematically tracked during the intervention. This game was considered to be a promising intervention due to its emphasis on whole-body motor coordination, bilateral upper-limb control, visuomotor integration, and rhythmic timing [25,26], skills that are commonly affected in children with DCD [7]. Prior studies have highlighted this game as an engaging platform for motor training, offering real-time feedback and adaptive difficulty levels [35,36].

Participants completed the VR gameplay at home under caregiver supervision, in accordance with the safety instructions provided. Each caregiver received a detailed guidance sheet outlining safety protocols, including monitoring for motion sickness, ensuring a clear play area, and being present during all gameplay sessions (VR instructions can be located online)

XSL•FO
RenderX

[37]. Prior to the VR intervention, each participant received a brief orientation on how to use the VR headset and interact with the game. Adherence was monitored through self-report logs, in which participants or caregivers recorded daily gameplay duration and any issues encountered. Any adverse effects, such as motion sickness or fatigue, were also noted. No such incidents were reported.

Tablet Gameplay Condition

The tablet condition used a Lenovo Tab M8 (fourth generation) Android tablet with an 8-inch LCD (1280×800) display and dimensions of 197.97×119.82×8.95 mm. Participants played Cut the Rope (version 3.75.0; Zeptolab), a puzzle game that requires cutting virtual ropes in a planned sequence to deliver candy to the character Om Nom. The game was administered using the default settings. In this mode, levels are presented sequentially, with successful completion of a level automatically unlocking the next one. Puzzle complexity increases gradually (eg, greater numbers of ropes, obstacles, and timing constraints), but there is no separate user-adjustable difficulty setting or fixed level cap relevant to the amount of play time in this study. Players can repeat the same level as many times as needed until it is solved. Therefore, if they become stuck, progression may slow, and they may remain on earlier levels for longer. We selected this game as an active control that emphasizes problem-solving with minimal motor demands and has been used as a control in DCD research [38]. The game is self-paced and does not include rhythm- or music-based timing mechanics, and actions are not performed in synchrony with a beat or external tempo.

As with the VR condition, gameplay for the tablet condition occurred at home, and participants were instructed to play for a minimum of 30 minutes daily across 5 consecutive days. Prior to the tablet intervention, each participant received a brief orientation on how to navigate and interact with the game. Caregivers were not asked to supervise sessions. Participants were given the tablet directly and expected to engage with the game independently. Engagement and adherence were recorded in daily logs. The application was reset after each participant to protect data privacy.

In both conditions, children and parents were asked to “Play at least 30 minutes per day,” but were explicitly told there were no “right” or “wrong” amounts of play, that missing or shortening sessions were acceptable if they were tired, busy, or unwell, and that honest recording was more important than appearing highly adherent. They were also reminded that logs were for research only, anonymized, and not shared with anyone else.

Outcome Measurements

Movement Assessment (MABC-3)

The primary outcome was performance on the MABC-3, a standardized, norm-referenced assessment of motor coordination for ages 3 to 25 years [39]. The MABC is widely used in clinical and research settings to identify motor difficulties and monitor development [40]. The MABC-3 includes 10 subtests across 3 domains: manual dexterity, aiming and catching, and balance and locomotion. Tasks were administered by age band per the manual (7 - 11 y=band 2; 12 - 25 y=band 3). Trained assessors followed the standardized protocol. Testing took place in a quiet laboratory room using standard MABC-3 equipment as specified in the manual. Raw scores from each item were converted to standard scores using age-referenced normative data. A total motor score was computed by summing the standard scores from each domain, providing an overall estimate of motor proficiency. The MABC-3 scores are interpreted using percentile ranks. Consistent with published guidelines, scores above the 16th percentile are considered indicative of typical motor performance; scores between the 6th and 15th percentile suggest a risk of motor coordination difficulties, and scores at or below the 5th percentile are classified as indicative of significant motor coordination impairment. Although MABC-3 is a newer version of the widely validated *Movement Assessment Battery for Children, Second Edition* (MABC-2), both editions have demonstrated strong psychometric properties, including high test–retest reliability and construct validity for use in pediatric populations [39]. Its application in this study was chosen due to its relevance for identifying motor coordination challenges commonly observed in children with DCD.

Upper-Limb Manual Dexterity Assessment (BBT)

The secondary outcome was performance on the BBT, a standardized measure of unilateral gross manual dexterity [41]. The apparatus is a wooden box with 2 equal compartments (53.7×25.4×8.5 cm), a central partition, and 150 wooden blocks with sides measuring 2.5 cm [42]. Participants are asked to transfer as many blocks as possible, one at a time, from one compartment to the other within 60 seconds using a single hand.

Administration followed the standardized guidelines described by Mathiowetz et al [42]. Each hand received a 15-second practice trial, followed by one 60-second timed trial. Testing was completed for the dominant hand first, then the nondominant hand, at each pre- and postsession. Hand dominance was determined by self-report. Scores were the number of blocks transferred per hand; if multiple blocks were moved at once, only one was counted. The BBT shows high test-retest reliability in pediatric samples [43,44]. The BBT was administered before and after each intervention (VR and tablet), and dominant and nondominant hand scores were analyzed separately. The BBT was selected as a primary measure of unimanual gross manual dexterity because fine and gross upper-limb coordination are commonly impaired in children with DCD. The BBT was selected as a measure of unimanual gross manual dexterity because fine and gross upper-limb coordination are commonly impaired in children with DCD and are central to our motor performance objectives. This test has been used in other studies quantifying motor performance in this population [45].

Enjoyment of Physical Activity (PACES)

PACES was used to assess enjoyment during each intervention [46]. A child-appropriate 16-item version validated for pediatric physical activity research was administered [47-49]. At baseline, PACES was administered with a generic physical-activity stem, with items phrased as “when I am doing physical activity...” (eg, “I enjoy it” and “It’s very exciting”). After each intervention block, PACES was then readministered with condition-specific

XSL•FO
RenderX

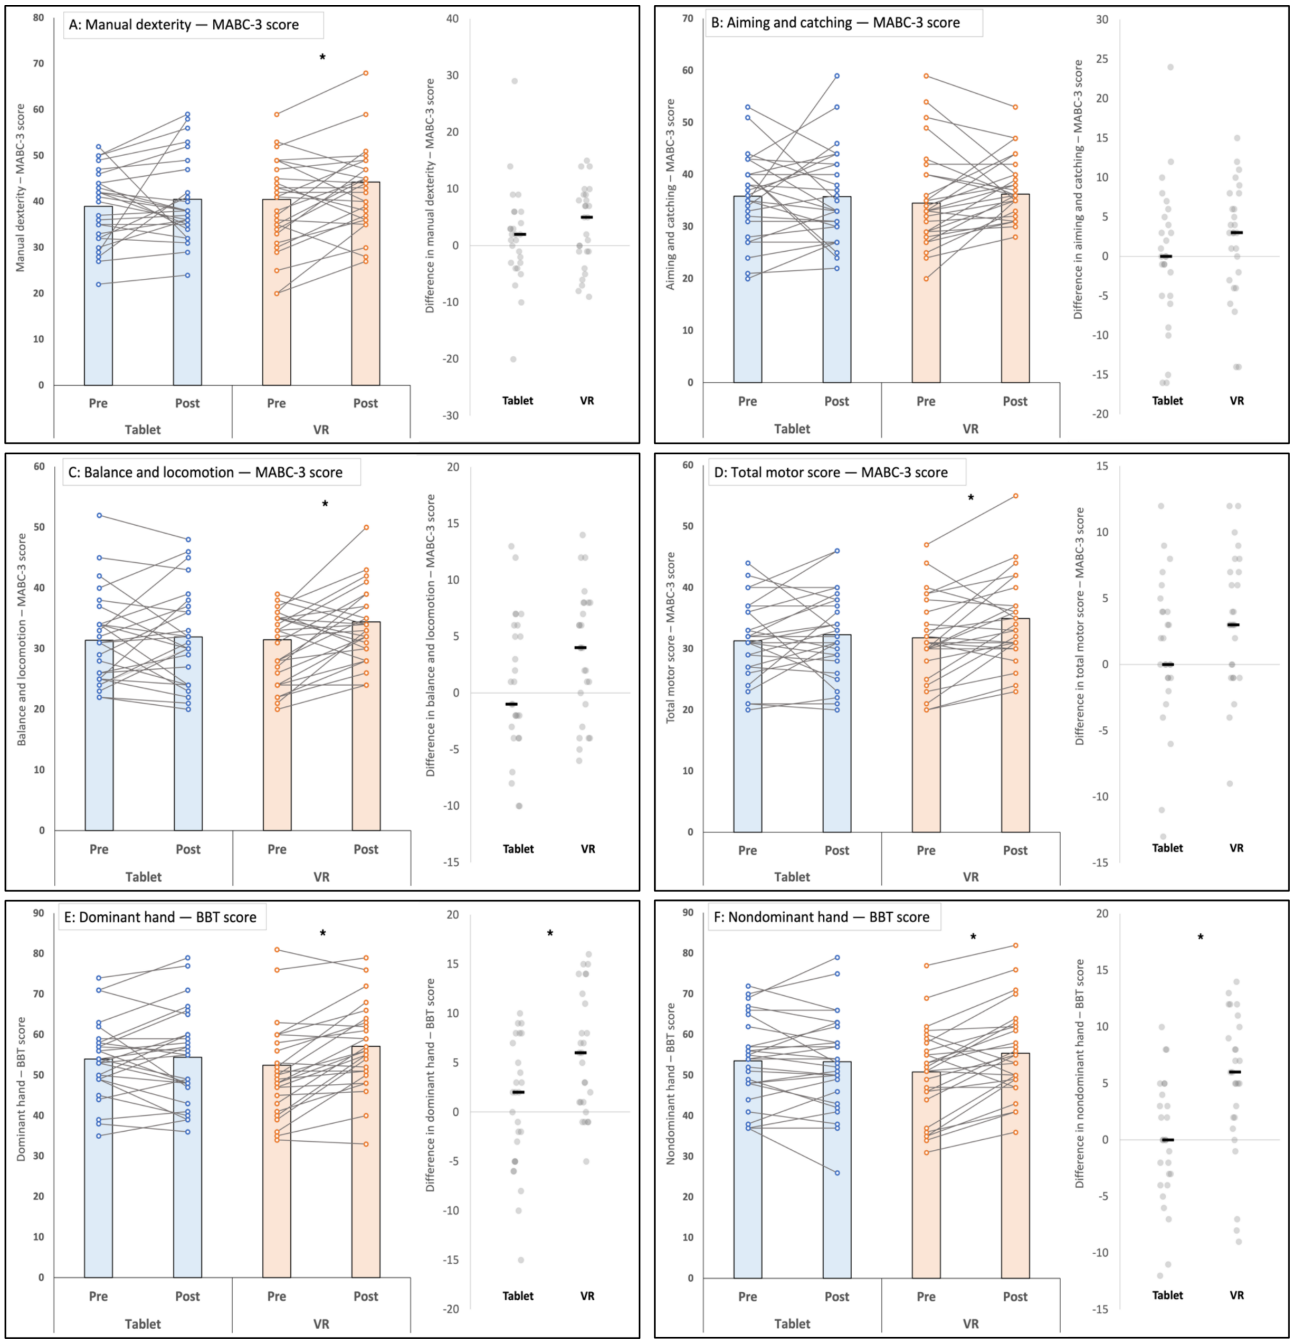
wording (“when I am playing the VR game...” / “when I am playing the tablet game...”). The questionnaire included both positively and negatively worded items (eg, “It makes me feel depressed” and “It gives me energy”), with reverse scoring applied to negatively worded items before analysis. Children were instructed to reflect on their experience during the specific condition and respond accordingly. Higher scores indicated greater enjoyment. The questionnaire was administered electronically via Qualtrics (Qualtrics, LLC) [50]. A template of the PACES questionnaire can be located online [51].

The PACES questionnaire was completed before (pre) and after (post) each condition (VR and tablet) to account for baseline expectations and effects that can distort post scores. While enjoyment is commonly assessed postintervention, relying solely on postintervention scores can obscure the effect of the activity itself, particularly if participants hold strong initial expectations or attitudes. This approach was informed by methodological concerns raised in related domains, such as tolerability studies using the Simulator Sickness Questionnaire, where assuming a symptom-free baseline has led to inaccurate conclusions [52]. It is worth noting that children may have varying levels of enjoyment or anticipation before gameplay, meaning that not all postintervention responses can be attributed solely to the gameplay experience. Capturing enjoyment both before and after each condition allowed us to account for individual baseline affect and more accurately assess the impact of the intervention. If a child requested help, the assessor or a parent read items aloud and clarified word meanings using neutral definitions, and the child selected their own response.

Motivation and Feeling

Daily motivation and feeling during gameplay were recorded using a child-friendly log adapted from Scott et al [38] for home-based DCD interventions. The adapted “Motivation and Feeling Log” (a template can be located online) [53] was aligned to the 2 conditions (VR and tablet). Each participant completed a 5-day log for each condition immediately after each session. Motivation was rated on a 5-point Likert scale (1=“very low” to 5=“very high”), with an option to add brief comments. Feeling was captured by choosing one of a series of emoji-style faces (very unhappy to very happy) and by responding to short open-ended prompts (eg, “Tell us how you feel it went” and “Did you enjoy the tasks?”).

Statistical Analyses



All analyses were conducted in Jamovi (version 2.6.44; The Jamovi project) and R (version 4.2.2; R Foundation for Statistical Computing; R.app v. 1.79, macOS Big Sur ARM). The per-protocol sample (n=27) was used for all inferential tests. There were no missing outcome data among participants who completed both conditions; therefore, no imputation was performed. For MABC-3 and BBT outcomes, 2×2 within-subjects ANOVAs tested effects of time (pre and post) and condition (VR, tablet). In addition to the primary ANOVAs, exploratory within-condition paired-samples 2-tailed *t* tests were conducted to examine pre-post changes in each outcome. Exploratory within-condition tests were not adjusted for multiple comparisons and are interpreted cautiously. For motivation and feeling across days, a 2×5 repeated-measures ANOVA tested condition (VR and tablet) by day (1-5). Assumptions of normality (Shapiro-Wilk) and homogeneity of variance (Levene test) were tested in Jamovi. Effect sizes were reported as Cohen *d* for paired comparisons and partial η^2 for ANOVA terms. Statistical significance was set at $P<.05$ for all analyses.

Results

A total of 30 participants enrolled in this study; 3 withdrew during the intervention period (one during VR and two during tablet), leaving 27 participants who completed both conditions and were included in the per-protocol analyses. Repeated-measures ANOVAs examined condition (VR, tablet)× time (pre and post) effects on motor performance outcomes. For brevity, here we report on the interactions—the reporting of the main effects can be found in a study by Alharbi et al [54]. Interactions were nonsignificant for MABC-3 domains: manual dexterity ($F_{1,25}=0.81$; $P=.38$; $\eta^2_p=0.03$; Figure 2A), aiming and catching ($F_{1,25}=0.83$; $P=.37$; $\eta^2_p=0.03$; Figure 2B), balance and locomotion ($F_{1,25}=2.42$; $P=.13$; $\eta^2_p=0.09$; Figure 2C), and total motor score ($F_{1,25}=3.36$; $P=.08$; $\eta^2_p=0.19$; Figure 2D). Significant interactions were observed for the BBT dominant hand ($F_{1,25}=7.47$; $P=.01$; $\eta^2_p=0.23$; Figure 2E) and BBT nondominant hand ($F_{1,25}=11.94$; $P=.002$; $\eta^2_p=0.32$; Figure 2F). Estimated marginal means (95% CIs) for each outcome by condition (tablet vs VR) and time point (pre vs post) are summarized in Table 1.

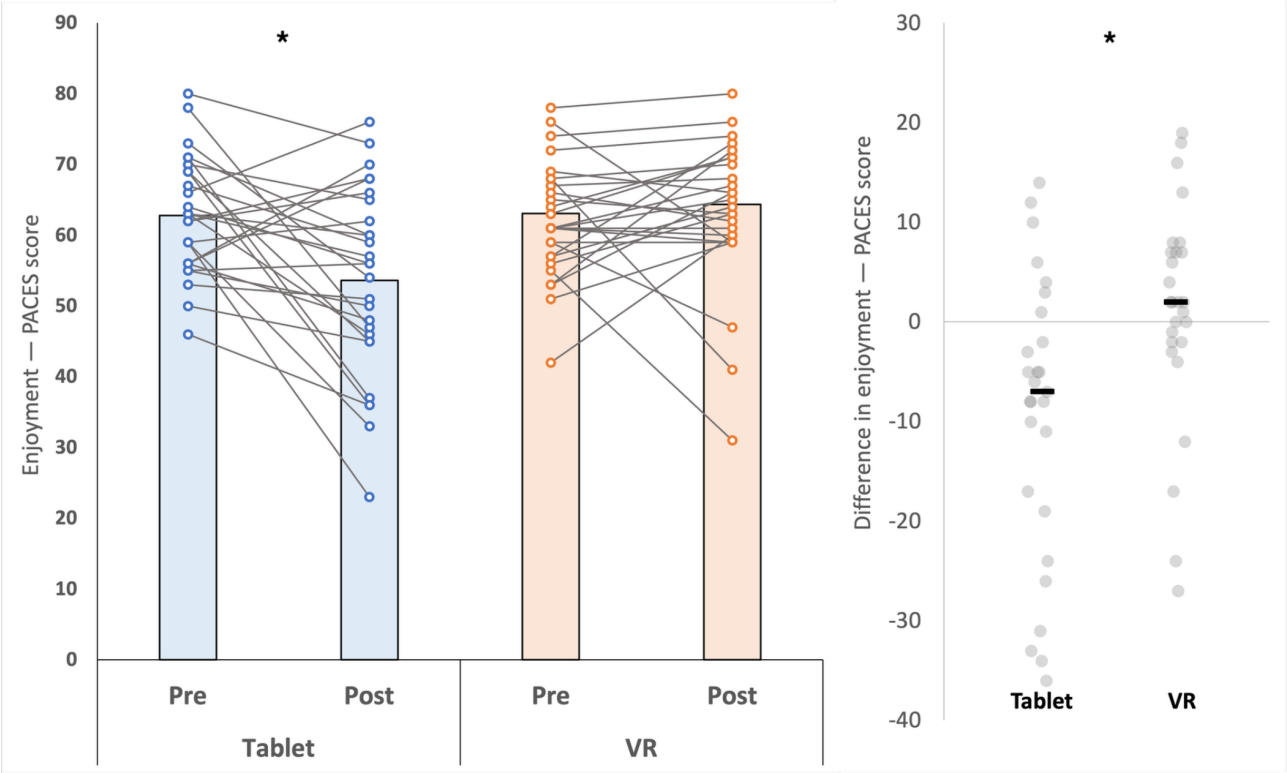
[a]MABC-3: *Movement Assessment Battery for Children, Third Edition.*

[b]BBT: Box and Block Test.

[c]PACES: Physical Activity Enjoyment Scale.



Although no significant interactions were observed in the ANOVA with MABC-3 domains as the dependent variable, exploratory post hoc within-condition (paired-samples) *t* tests were conducted to explicitly examine performance improvements in the VR and tablet conditions. Paired-samples 2-tailed *t* tests revealed significant pre-post improvements in the VR condition across the MABC-3 domains of manual dexterity (ΔM 3.3, 95% CI 0.51 - 6.08; t_{26}=−2.43; *P*=.02; Cohen *d*=0.47; Figure 2A); balance and locomotion (ΔM 3.52, 95% CI 1.3 - 5.74; t_{26}=−3.25; *P*=.003; Cohen *d*=0.63; Figure 2C), and total motor score (ΔM 3.33, 95% CI 1.34 - 5.32; t_{26}=−3.44; *P*=.002; Cohen *d*=0.66; Figure 2D). No significant change was found for the aiming and catching domain (ΔM 2.15, 95% CI −0.72 to 5.01; t_{26}=−1.54; *P*=.14; Cohen *d*=0.30; Figure 2B).

For the BBT in the VR condition, significant improvements were found for both the dominant hand (ΔM 5.93, 95% CI 3.49 - 8.36; t_{26}=−4.99; *P*<.001; Cohen *d*=0.96; Figure 2E) and the nondominant hand (ΔM 5.11, 95% CI 2.65 - 7.57; t_{26}=−4.27; *P*<.001; Cohen *d*=0.82; Figure 2F). By contrast, there were no significant pre-post changes observed across any MABC-3 domains or BBT performance in the tablet condition (all *P*≥.36).

For enjoyment (PACES), a condition × time interaction was detected ($F_{1,26}$=11.67; *P*=.002; η^2_p=0.31; Figure 3). Enjoyment decreased from pre to post in the tablet condition (ΔM −9.19, 95% CI −14.79 to −3.58; t_{26}=3.37; *P*=.002; Cohen *d*=0.65) and did not change in the VR condition (ΔM 1.11, 95% CI −3.27 to 5.49; t_{26}=−0.52; *P*=.61; Cohen *d*=0.10).

XSL•FO
RenderX

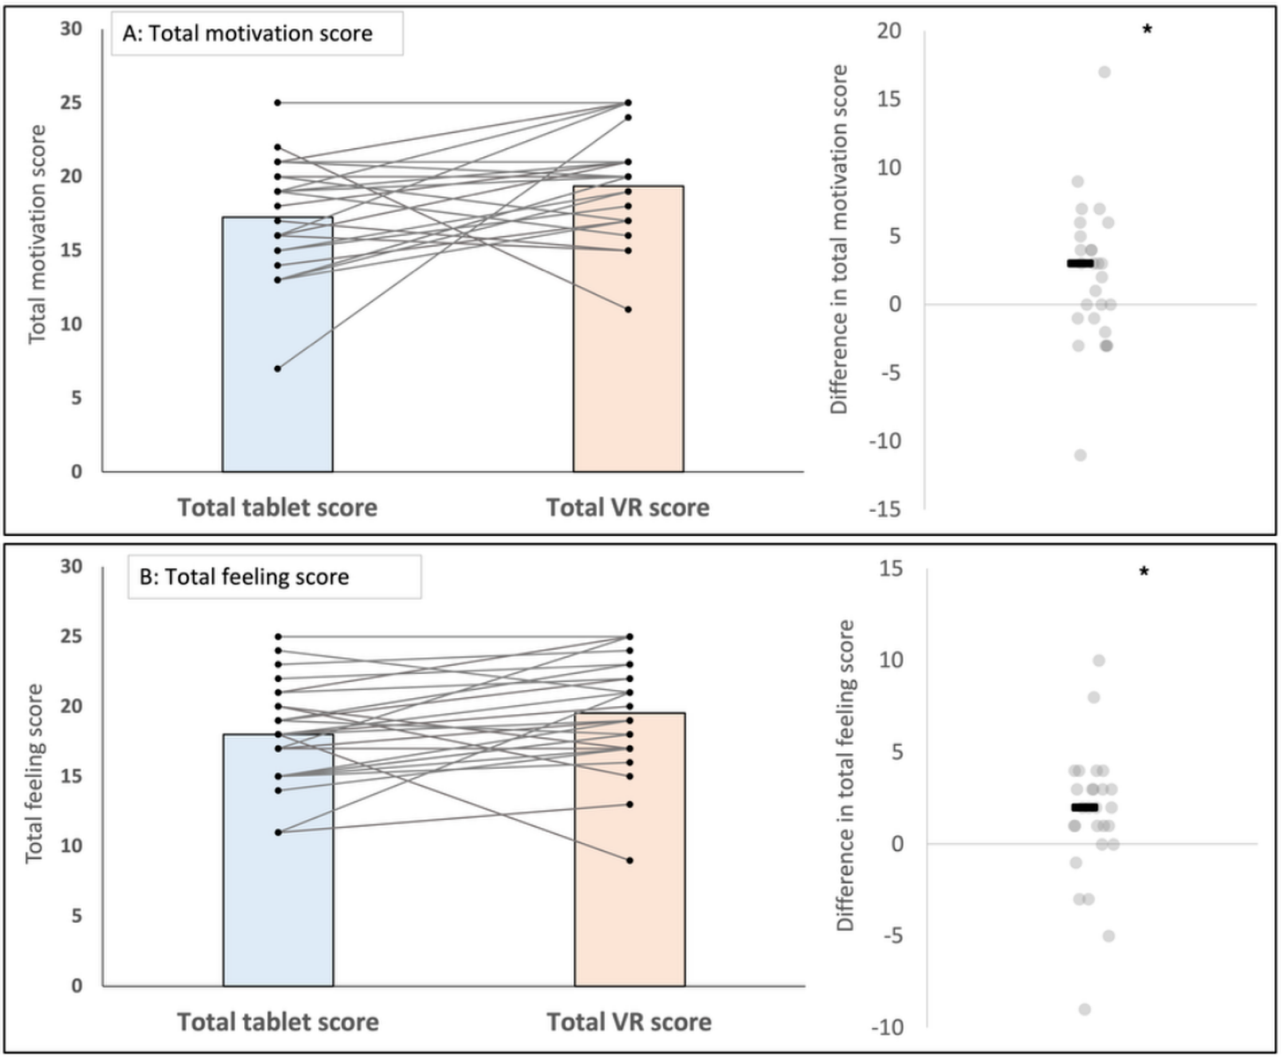


Figure 3. Within-participant pre-post enjoyment score (Physical Activity Enjoyment Scale [PACES]) across tablet and virtual reality (VR) conditions. Asterisks indicate statistically significant differences (P<.05).

Across the 5 days, there was no condition × day interaction for motivation ($F_{4,104}$=0.54; P=.71; η^2_p=0.02), or feeling ($F_{4,104}$=0.26; P=.91; η^2_p=0.01). Main effects of condition were present, suggesting that motivation was higher in VR than tablet ($F_{1,26}$=4.49; P=.04; η^2_p=0.15); estimated marginal means on the 1 to 5 scale were VR 3.87 (95% CI 3.60 - 4.15) versus tablet 3.45 (95% CI 3.15 - 3.75). Levels of positive feeling were also higher in VR than tablet ($F_{1,26}$=4.54; P=.04; η^2_p=0.15); estimated marginal means were VR 3.90 (95% CI 3.60 - 4.21) versus tablet 3.60 (95% CI 3.32 - 3.88; Figure 4A-B).

XSL•FO

Figure 4. Effect of condition (virtual reality [VR] vs tablet) on self-reported outcomes: (A) motivation and (B) feeling. Asterisks indicate statistically significant differences between the VR and tablet conditions (P<.05).

There was no evidence that the order of conditions, nor the duration of the washout period following the VR task, affected performance on the second session [54].

The raw data, full analysis figures, and optional session comments from the daily logs are available on Open Science Framework [55,56,57].

Discussion

Principal Findings

This study investigated the effects of an immersive VR rhythm game on motor performance, motivation, and enjoyment in children and adolescents with DCD. The findings highlight immersive VR rhythm games as a promising tool for movement skill development, addressing a documented gap in the literature regarding immersive VR interventions for children and adolescents with DCD [23]. Our findings tentatively suggest that immersive VR rhythm games could be associated with improvements in various aspects of motor performance and may substantially enhance intrinsic motivation and emotional engagement in children with DCD, offering a supportive approach to traditional therapeutic approaches.

The key pattern in the data provides preliminary evidence of improvement in several domains of motor performance in children and adolescents with DCD following a short-term, home-based immersive VR rhythm game. Exploratory within-condition analyses indicated that participants in the VR condition showed pre-post improvements in manual dexterity, balance and locomotion, and total motor score on the MABC-3; however, the condition × time interactions were non-significant. Consistent with this, the MABC-3 estimated marginal means showed wide and overlapping 95% CIs (Table 1), indicating limited precision for between-condition differences over this short period. Therefore, any differential effects of VR versus the tablet condition on these outcomes should be interpreted cautiously. These patterns were more clearly supported for upper-limb motor skills, where significant condition × time interactions and within-condition changes in BBT scores for both the dominant and nondominant hands suggested greater gains following VR than tablet play. The improvements in manual dexterity and bilateral upper-limb control, as evidenced by the MABC-3 and BBT results, are particularly noteworthy given that these are common areas of difficulty for children with DCD [2,7]. Taken together, these findings tentatively support the practical utility of immersive VR as a potentially

XSL•FO
RenderX

effective tool for improving functional motor skills required for daily living and academic activities in children and adolescents with DCD [1,3,58].

Descriptively, the tablet condition failed to elicit any significant pre-to-post changes across any MABC-3 domains or BBT performance (all $P>.35$). This divergence in outcomes is consistent with, although does not definitively establish, the idea that the observed motor improvements are not merely attributable to general practice effects, maturation, or nonspecific engagement with a digital device. Instead, the pattern of results tentatively suggests that features of the immersive VR game may have contributed to the observed changes in motor performance. However, the present study cannot determine whether these effects are driven primarily by the immersive VR context itself, the rhythmic, music-synchronized gameplay, the whole-body movement demands, or a combination of these elements. The overall pattern is broadly consistent with prior evidence indicating that VR can support motor skill development across other pediatric conditions, including cerebral palsy and autism spectrum disorder [17,21,22]. Moreover, this study extends these benefits specifically to children and adolescents with DCD, where empirical research on immersive VR has been limited [23]. The nonsignificant condition × time interactions for the MABC-3 domains mean that the between-condition differences in pre-post change on these measures should be interpreted cautiously. Several factors may explain the lack of interaction, including the modest sample (n=27), the relatively short exposure, variable levels of motivation and fatigue of participants with assessments often conducted after school, and reliance on self-reported adherence to the VR and tablet interventions. However, the significant condition × time interactions identified for BBT scores for both the dominant hand and the nondominant hand provide evidence that, for this outcome, the immersive VR rhythm game improved participants' motor performance more than the tablet intervention. This finding might show that Beat Saber specifically targets the rapid whole-arm coordination that underpins the BBT.

Beyond motor performance, this study also highlights the potential impact of immersive VR rhythm games, like Beat Saber, on the subjective experiences of motivation and enjoyment in children and adolescents with DCD. Participants in the VR condition consistently reported higher motivation scores and more positive emotional experiences when compared to the tablet condition. Enjoyment is closely linked to persistence, as children are more likely to continue with physical activity and learning tasks when they experience them as fun rather than purely effortful or externally pressured [18,19]. The capacity of immersive VR rhythm games to transform these experiences into intrinsically motivating activities may therefore offer a significant clinical advantage. Further emphasizing this distinction, the PACES scores revealed a significant decrease in enjoyment after the tablet condition, whereas no significant change in enjoyment was observed in the VR condition. This suggests that the tablet game's capacity to sustain enjoyment over the intervention period was limited. Moreover, the tablet game lacked the physical interactivity, multisensory stimulation, and immersive qualities that characterize the VR experience. This absence of immersive presence and direct physical engagement likely contributed to the decline in enjoyment, highlighting a fundamental difference in the experiential quality offered by the 2 modalities. This is further illustrated by a parent's observation:

> *This is interesting... [their child] played with the tablet on the way home [two days ago] but yesterday she didn't ask for it even though it was clearly in sight on the kitchen table whereas when she had the VR she was counting down the hours when she could go on it.*

This observation supports the idea that immersive VR rhythm games led to more consistent and higher levels of engagement. These findings are also consistent with early feedback from the preliminary PPI activity, where participants expressed a preference for VR-based activities. However, a parent reported that their child used the tablet "on the way home," indicating that, in at least some cases, the tablet was used outside the intended "home-based" context. This raises the possibility that either the home-use instructions were not sufficiently clear or that adherence varied between participants. Importantly, this context difference could have influenced both the amount and quality of engagement in a direction that may confound comparisons between conditions. For example, tablet use during travel may have occurred in shorter, fragmented sessions and/or alongside other activities (eg, conversations, distractions, and fatigue), which could reduce sustained attention and engagement quality despite increasing opportunities to play. Conversely, the greater portability of the tablet could increase total exposure time relative to VR by enabling additional ad hoc play. Either pattern could bias engagement-related outcomes and any dose–response relationship independent of the game content itself. Future studies should therefore strengthen monitoring and standardization of context (eg, clearer instructions specifying location and timing, brief daily logs of where or when sessions occurred, or objective in-app time-stamps) and, where feasible, match interventions on portability or include context-of-use as a planned covariate.

Several features of the immersive VR rhythm task plausibly underlie both the motor improvements and the higher motivation and enjoyment observed. The Beat Saber game demands precise, bilateral upper-limb coordination, rapid visuomotor integration, and accurate rhythmic timing, skills commonly affected in DCD [24,25]. High-dose, task-specific practice with immediate visual, auditory, and haptic feedback supports error detection and correction, consistent with motor-learning principles [16,17,35,36]. Moreover, the adaptive difficulty levels within the game, allowing participants to progress from "normal" to "hard" or regress to "easy" mode, align with principles of optimal challenge, ensuring that the task remains sufficiently demanding yet achievable, thereby maximizing learning [59], but we did not formally titrate or verify that the task was optimally matched to each child's capacity. It is therefore unclear to what extent the overall difficulty was fine-tuned for individual participants with DCD. The immersive nature of VR creates a powerful sense of "being there" (presence), which can significantly enhance engagement and reduce the perception of effort associated with physical activity [12,19]. This

XSL•FO
RenderX

transformation of therapeutic exercise into a playful and rewarding experience is particularly potent for children, who are naturally drawn to engaging and interactive activities [60]. The coupling of synchronized music, rhythmic movement, and immediate, clear feedback provides an intrinsically rewarding loop that fosters competence and self-efficacy [23-26,61]. Together, these properties can improve upper-limb coordination and related motor performance, and also sustain motivation and positive affect across sessions [25-27,60]. A participant's remark illustrates this alignment:

> *Felt confident on harder levels. Coordination (hand-eye) is getting better. I found the tasks [VR's one] pleasurable and exciting, up to my growth.*

This suggests that the level progression matched their developing skill level and maintained engagement. Thus, this adaptability may have supported adherence and sustained participation, which are common barriers in traditional rehabilitation programs [19,24,27]. By contrast, although the tablet game (Cut the Rope) also includes level progression, increases in difficulty primarily reflect greater puzzle complexity rather than changes in movement demands, and the game lacks the physical interactivity, multisensory feedback, and immersive presence of VR. These differences in the type of challenge and the absence of immersive, movement-based engagement are consistent with the tablet game being experienced as lower in direct physical demand and less engaging overall. Future work could examine how in-game performance relates to improvements in movement assessment scores to shed light on the mechanisms that underpin these effects.

At the same time, participants' comments also highlighted important drawbacks and limits to the acceptability of immersive VR. Not all children enjoyed or tolerated the VR condition as some described the headset as heavy or uncomfortable (eg, "I don't like the game and the headset [was] heavy"), and one participant characterized the experience as "too stressful." Another child reported that their "head just felt like it was going to explode even though Mum helped clean the VR lens and adjust the straps" and that they did not feel they had improved. Other comments referred to a loss of enthusiasm and concentration towards the end of the week, or a dislike of the repetitiveness of the game and its music, even when parents perceived some improvement. Together, these accounts indicate that immersive VR is not universally acceptable or tolerable for all children with DCD, and that issues such as physical discomfort, perceived stress, visual or cognitive overload, and content-specific preferences (eg, music and repetition) can limit engagement [62]. These quotes warrant more cautious conclusions about immersive VR and highlight the importance of flexible VR content that can accommodate differing preferences and tolerance levels [63].

Limitations and Future Directions

Despite the promising findings, this study is not without limitations that warrant consideration for future research. First, the relatively small sample size might constrain the generalizability of the findings to the broader population of children and adolescents with DCD. The sample included more boys than girls, which is common in DCD cohorts but may also limit the generalizability of this intervention [64]. Although the within-subject crossover design mitigates the risk that this imbalance biased the comparison between VR and tablet conditions [65], the study was not powered to examine gender as a moderator, and we cannot determine whether interest, engagement, or motor outcomes differed meaningfully between boys and girls. Future work should purposively recruit more girls and formally test gender-related differences in response to immersive VR interventions. Second, the intervention duration of five consecutive days, while demonstrating acute effects, may not be sufficient to capture long-term motor learning, skill retention, or sustained behavioral changes. Some gains, particularly in motivation and enjoyment, may reflect novelty, since VR is new to most children compared with tablets. We do not know whether this motivation difference would persist once the novelty of the intervention declines [66]. Longitudinal studies with extended intervention periods and follow-up assessments are crucial to ascertain the durability of the observed motor improvements and the persistence of enhanced motivation and enjoyment. Third, the home-based nature of the intervention posed challenges for direct supervision and objective compliance monitoring. Although caregiver and self-report logs were used, these are susceptible to social desirability bias [67]. Future studies should integrate objective measures of engagement and adherence, such as in-game metrics, wearable sensor data, or remote video monitoring, to provide more accurate and verifiable data on intervention fidelity [68]. Fourth, only one immersive VR rhythm game (Beat Saber) was used, so the findings may not generalize to all immersive VR content; whether other immersive VR games without rhythm-based mechanics yield similar benefits remains to be tested. This study, therefore, cannot determine whether the observed effects are driven primarily by immersion, rhythmic or music-synchronized gameplay, whole-body movement demands, or their combination. Future research could address this by using multiple comparison conditions (eg, nonimmersive rhythm games, immersive nonrhythm VR games, or rhythm-based games with different movement demands) to help disentangle the contribution of immersion, rhythm, and whole-body engagement. Fifth, the tablet game (Cut the Rope) was intentionally chosen to minimize motor demands, but it may be more passive than the VR rhythm task. As a result, between-condition differences may simply reflect a greater 'dose' of movement, rather than effects specific to immersive VR. Future trials could include an active, movement-based nonimmersive control (eg, a screen-based rhythm game) matched on session length and movement intensity, verified with telemetry or accelerometry or heart-rate monitoring, to better isolate VR-specific contributions. Sixth, assessments frequently occurred after school, introducing variability in fatigue and attention. Future work, therefore, should standardize testing times or record time-of-day and brief fatigue or attention ratings so these factors can be controlled [69]. Finally, because multiple exploratory within-condition tests were conducted in MABC-3 domains after a nonsignificant interaction, the risk of type I error is increased, and these findings should be interpreted with caution [70].

XSL•FO
RenderX

Conclusions

This study is the first to evaluate a home-based immersive VR rhythm game for children and adolescents with DCD in comparison to a tablet-based control condition with a crossover design. Prior literature in this area has focused on nonimmersive VR and provides limited direct evidence comparing immersive VR rhythm gameplay against nonimmersive gameplay with a similar practice dose. Our findings add early evidence that immersive VR rhythm gameplay can be highly engaging and may support short-term gains in manual dexterity relative to tablet gameplay. In real-world terms, these games could be a scalable home–based supplement to conventional therapy to increase practice opportunities and enjoyment; future trials should use larger samples, longer follow-up, objective usage or context tracking, and multiple comparison conditions to disentangle the effects of immersion, rhythm, and whole-body movement.

Abstract

Background: For children with chronic conditions affecting physical health and who require long-term care, the use of a connected treadmill for gait training as part of a home program can be a way to promote motivation in rehabilitation. Furthermore, the device must be evaluated by all user groups to ensure that its development best meets the rehabilitation needs of children.

Objective: The study aimed to assess the user experience of a connected treadmill called *Amy*—with both immersive and nonimmersive virtual reality—among children with a chronic disease impacting physical health, as well as their parents and therapists, to explore the feasibility and potential of such a device for home-based rehabilitation in this population.

Methods: Children with cerebral palsy, neuromuscular diseases, or obesity, along with one of their parents and rehabilitation therapists, were recruited. The study involved evaluating preexisting *Amy* solutions and collecting user experience feedback from participants with questionnaires. *Amy* solutions consisted of immersive virtual reality (using a virtual reality headset) and nonimmersive (tablet-based) games, both controlled through body movements on a treadmill conceived to train walking and balance. Questionnaires were the short version of the User Experience Questionnaire; the Usability Metric for User Experience; the Virtual Reality Sickness Questionnaire; a customized questionnaire evaluating comfort, fun, sense of presence and immersion; and a customized questionnaire evaluating parent's perception.

Results: Twenty-eight children, 28 parents, and 18 therapists participated in the study. Compared with User Experience Questionnaire benchmark data, the overall results with immersive and nonimmersive virtual reality in all participants were in the range of 10% best results or in the "excellent" category. The mean (95% CI) scores for each group of participants, with nonimmersive and immersive virtual reality, were as follows: 1.9 (1.6-2.2) and 2.1 (1.6-2.5) for children, 2.0 (1.7-2.2) and 2.3 (2.0-2.5) for parents, and 1.4 (1.1-1.7) and 1.4 (1.1-1.7) for therapists, respectively. User experience was significantly better for children and parents than for therapists (*P* adjusted .001). From the Usability Metric for User Experience, participants rated the *Amy* treadmill's usability as "good to excellent" on the System Usability Scale, regardless of whether immersive virtual reality was used. Immersive virtual reality was well tolerated by children. Children experienced immersive virtual reality positively in terms of comfort, immersion, presence, and fun. Parents' acceptability of the connected treadmill was positively assessed.

Conclusions: This study is, to our knowledge, the first to assess the user experience of a playful treadmill-based virtual environment controller in children with chronic conditions affecting physical health in a user-centered and multidisciplinary

XSL•FO
RenderX

team-based approach. This initial test demonstrates promising potential for using the connected treadmill as a rehabilitation tool. Therapists may need improvements to better meet their expectations, highlighting the importance of further iterations to align technological features and practical clinical context.

Introduction

Chronic diseases in children are a major public health issue. Over the past few years, their prevalence has increased, with 10%-30% of children affected by a chronic disease [1]. Cerebral palsy, neuromuscular diseases, and obesity are chronic conditions characterized by physical impairment, particularly affecting the musculoskeletal and cardiorespiratory systems [2-4]. This physical impairment affects the gross motor function and walking ability of these children. Indeed, the walking endurance is reduced in children with cerebral palsy compared with their typically developing peers, even among those with the highest functional abilities [5]. The walking endurance is also reduced in children with obesity or neuromuscular diseases [6,7]. Combined with personal and environmental factors, this physical impairment can therefore lead to activity limitations and participation restrictions, affecting the child's quality of life [2,4,6,8].

Functional gait training, including treadmill training, consists in endurance, balance, and strength training exercises. In children with cerebral palsy, neuromuscular diseases, or obesity, it can improve gross motor function, balance, and walking ability, as well as metabolic, cardiovascular, and respiratory parameters [9-14]. Gait training including treadmill training has shown promising results for physical health and functional capacities in children with chronic diseases [13-15]. Although there is no consensus due to the great heterogeneity in terms of duration, frequency, and intensity, it appears that longer programs, conducted over several weeks and with progressive intensity, are preferred [9,10,12-14,16]. Future research is required to recommend the best programs in terms of intensity and duration [11].

Rehabilitation is a huge part of clinical management in those 3 chronic diseases. Thus, maintaining motivation over a long time is a major objective. New technologies and rehabilitation methods, such as the combination of a treadmill with virtual reality, included in a personalized home-based program, could be an ideal way to promote motivation in rehabilitation [10,11]. Home-based programs are considered a useful and feasible complement to therapies in rehabilitation centers, which are sometimes located far from home [17,18]. They offer an opportunity to increase the intensity and repetition of the tasks being practiced, integrating them into children's familiar environment, while still providing a structured framework under the supervision of a therapist with regular feedback and have shown positive effects in improving motor function, cardiometabolic health, and self-care [11,12,19,20]. Virtual reality offers a real-time multisensory experience, promotes motor learning through task repetition and feedback, and enables accurate and personalized performance monitoring, even remotely, thanks to digital devices. Also, virtual reality may enhance enjoyment for children, increase their engagement in physical activity, and improve adherence to rehabilitation programs [9,10,19,21-23]. Nevertheless, the wide variability in exercise modalities, technological supports, and modes of patient participation means that no clear guidelines are currently available to inform the design of new programs [18].

New technologies such as treadmills and virtual reality were initially developed for adults and must be adapted for children, especially for children with disabilities. *Amy* is a device created by the company EzyGain for adults but that can also be adjusted for children. *Amy* is a connected treadmill, meaning that the treadmill itself, through its use, enables interaction with a virtual environment to which it is linked. It was developed as a rehabilitation tool to train walking and balance at home, in an entertaining way, within a telerehabilitation model that includes regular monitoring by a therapist.

Before trying a treadmill equipped with virtual reality and integrating it in a home-based program, we must identify key priorities to assess the device to the target population. The user experience (UX) refers to a person's interaction with a system. UX is subjective and encompasses 2 main categories [24]. The first category focuses on the pragmatic and functional aspects of the system. The second category focuses on the emotional, hedonic, and aesthetic aspects of the system. These aspects will influence the user's emotional reactions, resulting in acceptance, positive or negative evaluation of the system, and the intention to use it. A positive UX is therefore essential for prolonged use, especially in future projects involving a home-based rehabilitation program lasting several weeks. UX involves not only the person actively using the system, here the child using the connected treadmill, but also anyone passively observing the user [25]. A multidisciplinary, team-based approach that involves parents and rehabilitation therapists, as well as children, provides the necessary perspectives for user-centered design [20,26]. Parental opinion is a crucial element in the success of an intervention, especially in a home-based program where they are directly involved [20,27]. The therapists' opinion is also essential. They will need to integrate the device into their therapeutic arsenal and clinical practice, conduct the remote rehabilitation program, personalize it for each child, and educate and coach parents [15,16,22]. Involving all end users from the earliest stages of development allows to work toward finding the best fit between a technological system—in this case, the connected treadmill—and the expectations of children, parents, and therapists, ultimately supporting optimal rehabilitation outcomes [28].

XSL•FO
RenderX

In the field of pediatric rehabilitation, existing literature mainly includes papers focusing on the UX of devices designed for cognitive [29-33] or upper limb rehabilitation [34,35]. To our knowledge, and to date, few technological devices targeting gait training in children have been codeveloped using a UX-driven approach. Ammann-Reiffer et al [23] studied the UX of a virtual reality headset as a rehabilitation tool for everyday walking activities. No study has explored the UX of a treadmill, combined with VR—that is, designed as a game controller—in children with chronic diseases affecting physical health in a user-centered design and a multidisciplinary, team-based approach.

The primary objective of this study was to investigate the UX of a treadmill connected to immersive and nonimmersive virtual reality among children with a chronic disease affecting physical health, as well as their parents and therapists. The secondary objectives were to (1) evaluate the usability of a connected treadmill among children, parents, and therapists; (2) evaluate cybersickness induced by immersive virtual reality in children; (3) evaluate the comfort, fun, sense of presence, and immersion experienced with immersive virtual reality in children; (4) evaluate the parent's perception of a connected treadmill; and (5) compare UX across the different groups as well as between immersive and nonimmersive virtual reality. We hypothesized that UX would be generally positive among the sample participants, with usability expected as an area for improvement. We also expected virtual reality to be well tolerated, and that comfort, fun, presence, and immersion would receive positive evaluations in immersive mode. Additionally, we anticipated parental heterogenous acceptance of the system. Finally, we hypothesized that UX would be similar across the 3 groups but superior in immersive mode.

Methods

Study Design

A cross-sectional feasibility UX study was conducted at the Capucins Rehabilitation Centre and the University Hospital in Angers, France, in October and November 2024. During this initial user test, quantitative data were collected via questionnaires and qualitative data via focus groups. The subject of this paper focuses on quantitative data. The study adheres to the RATE-XR guideline recommended in early-stage evaluations of extended reality applications [36].

Ethical Considerations

The study was approved by the Angers University Hospital Ethics Committee (approval no. 2024-148). It was also declared to the National Commission for Information Technology and Civil Liberties (registration no. 3490000031/559947). An information letter and an opposition form were provided for each participant either in person or via email. The information letters were tailored to specific age groups (those aged 8-10, 11-14, and 15-17 years and adults). Each child gave verbal assent to participate. Informed consent was obtained from parents on behalf of their child and for their own participation, and from all participating therapists. Participation was voluntary without financial compensation, and individuals could withdraw at any time without consequences. All collected data were anonymized before analysis. All necessary measures have been taken to remove any identifying features from the images included in the manuscript. Written consent regarding the evaluator depicted in one of the figures has been obtained and provided to the journal.

Recruitment

Children with cerebral palsy, neuromuscular diseases, and overweight or obesity, along with one of their parents and therapists, were invited to participate in this study. Recruitment was based on children and parents meeting eligibility criteria and receiving medical follow-up from the pediatric rehabilitation departments of the 2 centers. Therapists in the relevant departments were invited to participate. Three groups were formed based on disease type: the "CP" group (children with cerebral palsy), the "OB" group (children with overweight or obesity), and the "NM" group (children with neuromuscular disease). Children aged 8-18 years who could walk on a treadmill for 5 minutes, with or without support or mobility aids, were included. Parents were included if their child met the study eligibility criteria. Therapists were included if they were accustomed to working with at least one of the study-eligible populations. All participants were required to (1) speak French fluently enough to complete questionnaires, and (2) provide informed consent. Children with uncontrolled epilepsy were excluded. Adults were excluded if deprived of liberty by judicial or administrative decision or if subject to legal protection measures.

Description of the Virtual Reality–Based Treadmill

Amy is a CE-marked (European Conformity) medical device designed for rehabilitation originally created for adults. It consists of a compact treadmill (65×130 cm) with a robust frame, height-adjustable support bars, an antifall harness for safety, and an integrated force plate for capturing weight shifts and controlling games through body movements. The treadmill supports walking speeds ranging from 0.2 to 3 km/h and accommodates users weighing up to 100 kg. A touch-sensitive tablet connects to the treadmill via Bluetooth Low Energy, enabling interaction games and facilitating remote communication with a therapist. Additionally, the *Amy* system is compatible with the Pico 4 virtual reality headset, allowing integration of immersive rehabilitation modules. The height of the support bars, the harness, and the tablet device stand can be adjusted to suit the child's size. The preexisting *Amy* solutions consisted of exergames aimed at training balance and gait for short periods. Exergames were composed of a sequence of mini games, each played one after the other. The progress and completion of each virtual reality game were made possible by the child's use of the treadmill. See Table 1 for description of the virtual reality games. Games were launched in an application called EzyGain app (version 4.7.3) available on the Apple store at the time of user testing.

[b]VR: virtual reality.

Procedure

The study involved evaluating preexisting *Amy* solutions and collecting UX feedback from participants (Figure 1). Each child participated in 2 consecutive 20-minute sessions the same day, accompanied by one of their parents and a therapist. Each child was first assisted in putting on the safety harness to ensure secure use of the treadmill. Once properly equipped, they stepped onto the treadmill and tried out different games. Between games, the treadmill was stopped so that the child could rest, if necessary. During the test sessions, parents and therapists were purely observers (Figure 2). An investigator was present in the room to supervise, in particular, to help the child settle in and start playing games. In the first session, children used the *Amy* treadmill combined with the tablet-based interface, experiencing 4 nonimmersive (2D) virtual reality games (see examples in Table 1). After completing this session, all participants filled in a set of UX questionnaires. In the second session, children used the *Amy* treadmill with the virtual reality headset, experiencing 2 immersive (3D) virtual reality games (Table 1). Following this session, participants again completed a set of UX questionnaires. While the specific games differed between participants, all children were exposed to a range of game types addressing various motor objectives, as summarized in Table 1.

Figure 1. Study participation timeline: testing of a connected treadmill with nonimmersive and immersive virtual reality by children with chronic conditions affecting their physical health and gathering of their user experience as well as that of their parents and therapists. UEQ: User Experience Questionnaire; UMUX: Usability Metric for User Experience; VRSQ: Virtual Reality Sickness Questionnaire.

XSL•FO
RenderX

Figure 2. Test session set up. The Amy-connected treadmill being tested by a child with obesity, observed by his parent and a therapist. An investigator is present alongside the child to supervise the session.

To minimize the Hawthorne effect and social desirability bias, participants were explicitly informed that the investigators' role was limited to data collection and that responses should reflect their personal perceptions and experiences. An investigator was present to support the children during questionnaire completion, providing clarification when necessary, given that the questionnaires were not yet validated for this young population. Throughout the entire process, participants provided informal verbal feedback and comments, which contributed to enriching the discussion of this study.

UX Assessment

Ease with technology was evaluated by a single question: "On a scale of 1 to 10, how comfortable would you say you are with technology?" This single question provided a rough estimate of participants' level of acceptance of technologies of all kinds.

UX was evaluated using the French version of the User Experience Questionnaire (UEQ) [37]. The UEQ allows for a quick assessment of UX. The short version of the UEQ was used, which consists of 8 items grouped into 2 subscales: pragmatic quality and hedonic quality, each with 4 items. Pragmatic quality assesses efficiency, perspicuity, and dependability; hedonic quality assesses stimulation and originality. Each item is formatted as a Likert scale semantic differential that represents opposites (eg, "simple-complicated") [37,38]. The range rates between –3 and 3. All participants completed the UEQ's short version. The short version of the UEQ has been scientifically validated for adults in English (Cronbach a values of 0.85 for the pragmatic quality and 0.81 for the hedonic quality) [37].

Usability was evaluated using the French version of the Usability Metric for User Experience (UMUX). The UMUX is a questionnaire of 4 items evaluating usability components: effectiveness, satisfaction, overall, and efficiency. Each item is a 7-point Likert scale (from 1 "strongly disagree" to 7 "strongly agree"). After being collected, data were converted in a range of 0-100 UMUX score following the author's guidelines [39]. The advantage of the UMUX is that it is highly correlated with the System Usability Scale (SUS), which is the most widely used usability questionnaire. The UMUX is shorter than the SUS and aligns more closely with the ISO (International Organization for Standardization) 9241-11 (1998) definition of usability and evaluates more specifically the usefulness of a system in addition to usability, unlike the SUS and the UEQ-S [39,40]. All participants completed the UMUX. The UMUX has been scientifically validated for adults in English (Cronbach a value of 0.94) [39].

Cybersickness was evaluated using the Virtual Reality Sickness Questionnaire (VRSQ). It measures motion sickness-like sensations resulting from the use of virtual reality headsets. Only the children completed the VRSQ. They assigned a severity score from 0 to 3 (none, mild, moderate, and severe) to each of the 9 VRSQ items. The 9 items are grouped into 2 subscales: oculomotor discomfort and disorientation. The total score reflects the average of the oculomotor discomfort and disorientation scores out of 100 [41]. The VRSQ has been scientifically validated for adults in English (Cronbach values of 0.847 for the oculomotor component and 0.886 for the disorientation component) [41].

A customized questionnaire covering the aspects of comfort, fun, sense of presence, and immersion in the virtual environment with the virtual reality headset was proposed. This questionnaire was based on the study by Ammann-Reiffer et al [23]. Only the children completed the questionnaire. The questions were as

XSL•FO
RenderX

follows: “How comfortable did you feel during the game?” “How much did you enjoy performing the task?” “How present did you feel in the virtual environment?” “How much of a problem was it for you not to be able to see the real environment and your body?” Children answered on a visual analogue scale from 1 to 10.

Acceptability from the parent’s point of view was assessed by a customized questionnaire also inspired by the study by Ammann-Reiffer et al [23]. The items were as follows: “The child’s movement on the *Amy* treadmill was not impaired compared with his usual walking,” “The child required no more support than usual,” “The child required no external motivation to walk,” “The child’s involvement was greater than usual (at home/in the usual physiotherapy session),” “The child remained interested and did not seem bored,” and “The use of the treadmill could be a good complement to conventional physiotherapy approaches for this child.” Parents answered on a 7-point Likert scale (from 1 “strongly disagree” to 7 “strongly agree”).

Outcomes

The primary outcome was the mean scores on the UEQ-S overall and in the pragmatic and hedonic scales. The secondary outcomes were (1) the UMUX mean scores; (2) the VRSQ median scores; (3) responses to the customized questionnaire evaluating sensations of comfort, fun, sense of presence, and immersion; (4) responses to the customized questionnaire evaluating parent’s perception; and (5) comparisons between the different groups of patients and between nonimmersive and immersive virtual reality.

Sample Size

The sampling strategy was nonprobabilistic and purposive [42]; that is, participants were recruited according to specific criteria, using maximum variation sampling [43] to ensure diversity among participants and, consequently, a wide range of perspectives within the group. The following variability criteria were considered: (1) age of the children and therapists, (2) sex of the children (including both girls and boys in each group), and (3) variety of pathological conditions. The median number of participants in UX studies reported in the literature is 20 [44]. Given the diversity among participants, we expected to include 30 children and consequently 30 parents. We also aimed to include 15 therapists for a total of 75 participants.

Statistical Analysis

Scores of the standardized scales (UEQ, UMUX, and VRSQ) were calculated as recommended by the reference methods [37,39,41,45]. Descriptive statistics reporting the mean and 95% CI were used to present UEQ-S and UMUX results. Values obtained on the UEQ below –0.8 correspond to a negative assessment, between –0.8 and 0.8 to a neutral assessment, and above 0.8 to a positive assessment [46]. Mean UEQ scores were compared with published reference values using a benchmark dataset created by the author, which contains evaluations of 452 products’ evaluation and 20191 responses [46]. This enabled the evaluated product to be placed in one of 5 categories: “excellent” (in the range of the 10% best results), “good” (10% of the results in the benchmark dataset are better and 75% of the results are worse), “above average” (25% of the results in the benchmark are better than the result for the evaluated product and 50% of the results are worse), “below average” (50% of the results in the benchmark are better than the result for the evaluated product and 25% of the results are worse), and “bad” (in the range of the 25% worst results) [45]. UMUX scores were used to position the usability of the solution on the SUS interpretation scale (“worst imaginable,” “poor,” “acceptable,” “good,” “excellent,” or “best imaginable”) [47]. Descriptive statistics reporting the median and quartiles were used to present results from the VRSQ and customized questionnaires (comfort with technology; comfort, fun, sense of presence, and immersion; and parents’ perception). These scores were calculated for each version of the product tested, that is, with nonimmersive (2D) and immersive (3D) virtual reality.

To compare between-group differences in mean or median scores, we used nonparametric statistical tests, given the low number of participants and the data distribution. Wilcoxon test was used for paired samples. Kruskal-Wallis test was used to compare more than 2 samples. *P* value of less than .05 was considered statistically significant. Bonferroni correction was used to adjust the *P* value in the case of multiple statistical tests.

Results

Demographics

Twenty-eight children (13 females; 15 males; mean age 11.9, SD 2.7 years), 28 parents, and 18 therapists participated in the study. Eleven children had cerebral palsy, 9 had obesity, and 8 had neuromuscular disease. Missing data were observed for secondary descriptive variables only (mobility aid and school level). No formal test for missing completely at random was performed. Demographics for the participants are shown in Table 2.

User Experience

The scores to the UEQ-S were all positive, mean values beyond 0.8 representing a positive evaluation according to the author [46]. For all participants, the scores for each scale, with nonimmersive and immersive virtual reality, were as follows: mean 1.8 (95% CI1.6-2.0) and mean 2.0 (95% CI 1.8-2.2) for the overall UEQ-S, mean 1.7 (95% CI 1.5-1.9) and mean 1.9 (95% CI 1.7-2.2) for the pragmatic quality scale, and mean 1.9 (95% CI 1.6-2.1) and mean 2.1 (95% CI 1.8-2.3) for the hedonic quality scale, respectively. The overall UEQ-S, as well as the pragmatic and hedonic quality scales, were also positively evaluated in both immersive and nonimmersive virtual reality separately in children, parents, and therapists, and in children's subgroups CP, NM, and OB. Mean (SD) UEQ-S responses are shown in Table S1 in Multimedia Appendix 1. Compared with benchmark data, the overall scale means with immersive and nonimmersive virtual reality in all participants were in the range of 10% best results or in the "excellent" category (Figure 3). For all participants, there was a statistically significant difference in favor of immersive virtual reality for the overall UEQ-S (P<.001), as well as in the pragmatic (P=.001) and hedonic quality scales (P<.001). There was a significant difference in favor of immersive virtual reality for children (P=.001) and parents (P<.001) but not for therapists (P=.41).

XSL•FO
RenderX

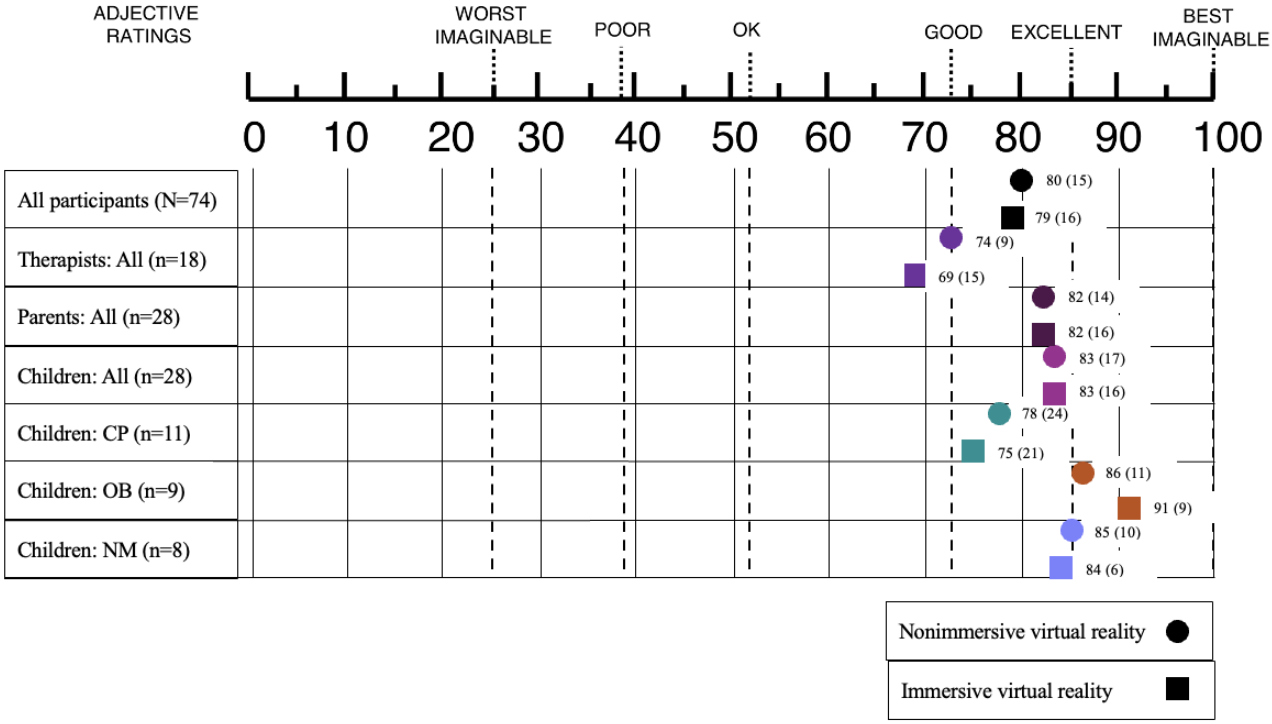
Figure 3. Mean scores and 95% CI bars for the entire short version of the User Experience Questionnaire, pragmatic, and hedonic quality scales, relative to the benchmark. The device evaluated is the Amy treadmill, which incorporates both nonimmersive (left panels) and immersive (right panels) virtual reality. It was tested by children with chronic conditions. User experience data were collected from children, their parents, and therapists. Benchmark graphs come from the Excel tool created by the author [45]. (1) For all participants (N=74), when using nonimmersive virtual reality; (2) for all participants (N=74), when using immersive virtual reality; (3) for children (n=28), parents (n=28), and therapists (n=18), when using nonimmersive virtual reality; (4) for children (n=28), parents (n=28), and therapists (n=18), when using immersive virtual reality; (5) for children, in CP (n=11), OB (n=9), and NM (n=8) groups, when using nonimmersive virtual reality; and (6) for children, in CP (n=11), OB (n=9), and NM (n=8) groups, when using immersive virtual reality. The scale ranges from –3 (fully agree with the negative item) to +3 (fully agree with the positive item). The colored bars represent the ranges for the scale's mean values. CP: cerebral palsy; NM: neuromuscular; OB: obesity.

The overall UEQ-S was significantly better for children and parents than for therapists (*P* adjusted <.001). No difference was found between children and parents (*P* adjusted >.99). Compared with existing values from the benchmark dataset, the—overall, pragmatic, and hedonic quality—scale means with immersive and nonimmersive virtual reality in children and parents were in the "excellent" category. On the contrary, for therapists, the pragmatic quality scale means with immersive and nonimmersive virtual reality were in the "above average" category, and the overall and hedonic quality scale means with immersive and nonimmersive virtual reality were in the "good" category.

No statistical difference was found between the children's subgroups (*P*=.41). A significant difference in favor of immersive virtual reality compared with nonimmersive virtual reality was found in the OB children's subgroup (*P*=.001), as opposed to the CP group (*P*=.80) and NM group (*P*=.10).

Usability

Raw UMUX scores are shown in Table S2 in Multimedia Appendix 1. Overall, participants rated the *Amy* treadmill's usability as "good to excellent" on the SUS scale. Mean (95% CI) scores were 80 (78-82) in 2D and 79 (77-81) in 3D (Figure 4). There was no statistically significant difference between



XSL•FO
RenderX

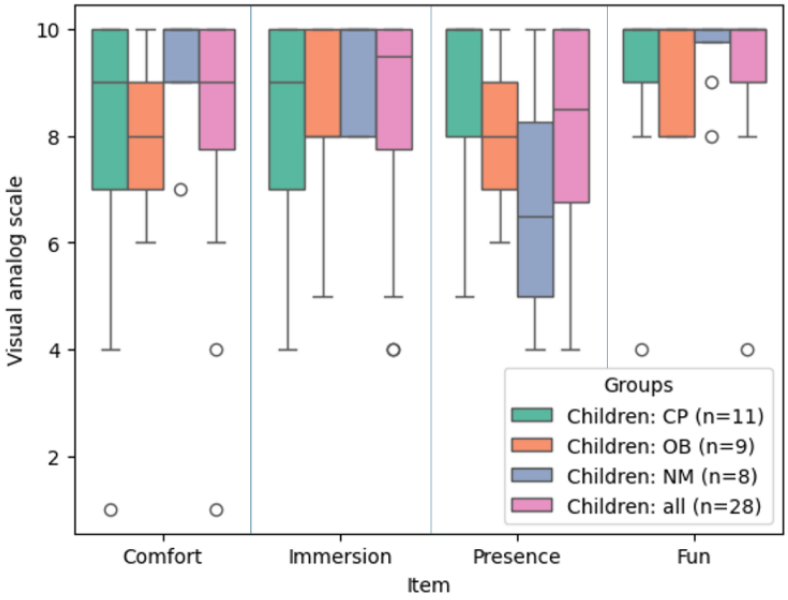
nonimmersive and immersive virtual reality for all participants (*P*=.72).

Children and parents reported similar positive experiences, mean (95% CI) scores being 83 (79-86) and 82 (79-84) in 2D, and 83 (80-86) and 82 (79-85) in 3D, respectively, that is "good to excellent" on the SUS scale. There was no statistically significant difference between nonimmersive and immersive virtual reality for either children (*P*=.47) or parents (*P*=.60), and there was no statistically significant difference between children and parents (*P* adjusted>.99). Therapists rated the system's usability as "OK to good" on the SUS scale, with mean (95% CI) scores of 74 (72-76) in 2D and 69 (66-73) in 3D, with a significant difference in favor of nonimmersive virtual reality (*P*<.02). The usability was significantly better for children and parents than for therapists (*P* adjusted <.001).

Among children, those with obesity found the system more usable (mean 86, 95% CI 82-90 in 2D; mean 91, 95% CI 88-94 in 3D), followed by those with a neuromuscular disease (mean 85, 95% CI 82-89 in 2D; mean 84, 95% CI 82-86 in 3D) and cerebral palsy (mean 78, 95% CI 71-85 in 2D; mean 75, 95% CI 69-81 in 3D). A significant difference was found only between the OB and CP children's subgroups (*P* adjusted=.004). A significant difference in favor of immersive virtual reality was found in the OB children's subgroup (*P*=.005), as opposed to the CP group (*P*=.50) and NM group (*P*=.30).

Figure 4. Comparison of Usability Metric for User Experience scores converted to the System Usability Scale normative scale [47]. The score is between 0 and 100. Data are expressed as means (SDs). The device evaluated is the Amy treadmill, which incorporates both nonimmersive (rounds) and immersive (squares) virtual reality. It was tested by children with chronic conditions. Usability data were collected from children, their parents, and therapists. CP: cerebral palsy; NM: neuromuscular: OB: obesity.

Cybersickness



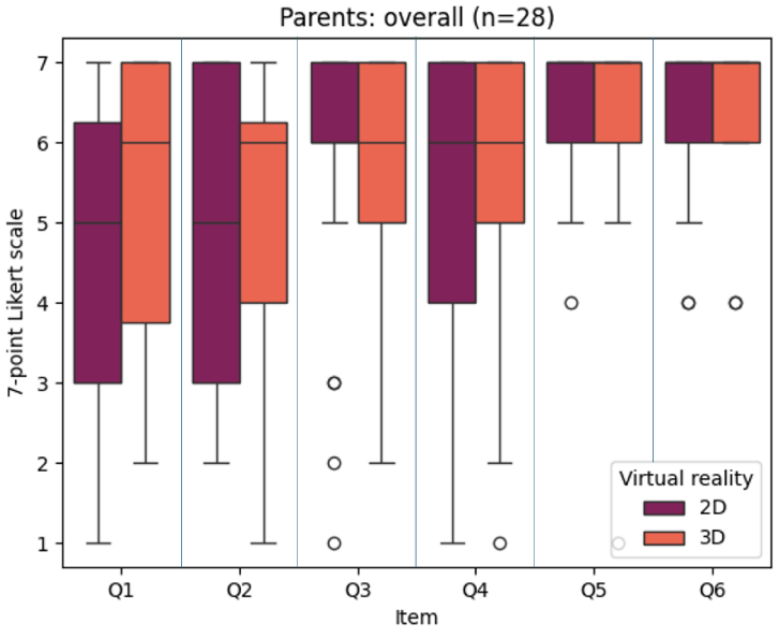
Immersive virtual reality was well tolerated by children, apart from 1 participant in the cerebral palsy group. Overall, symptoms of cybersickness were minimal with a median total score on a 0-100 scale of 4 [3-12]. When present, these symptoms primarily involved oculomotor discomfort rather than disorientation, as indicated by the VRSQ, with a median of 8 (IQR 0-17) for oculomotor discomfort and 0 (IQR 0-7) for disorientation, respectively.

Comfort, Fun, Sense of Presence, and Immersion

Children experienced immersive virtual reality very positively in terms of comfort, immersion, presence, and fun (Figure 5). They felt comfortable during the game (median 9, IQR 8-10). The children reported no difficulty with immersion in the virtual environment (median 10, IQR 8-10). Children reported a strong sense of presence within the virtual environment (median 9, IQR 7-10) and expressed enjoyment while using the treadmill games (median 10, IQR 9-10). Results were similar in children with cerebral palsy, obesity, and neuromuscular disease (*P*=.52).

XSL•FO
RenderX

Figure 5. Box plots expressing the scores obtained from the customized questionnaire assessing children's comfort, immersion, sense of presence, and fun with immersive virtual reality on the Amy treadmill. The scale is a visual analogue scale from 1 to 10. CP: cerebral palsy; NM: neuromuscular; OB: obesity.



Acceptability

Parents' perception of the connected treadmill was positively assessed (Figure 6). According to the parents, out of 28 children, 8 (28%) exhibited impaired walking on the treadmill when using nonimmersive virtual reality versus 7 (25%) with immersive virtual reality. Parents reported that 8 children needed more support than usual when using nonimmersive virtual reality (8/28, 28%), compared with 5 children with immersive virtual reality (5/28, 18%). Most of the children did not require any external motivation to walk (24/28, 86% with nonimmersive virtual reality and 25/28, 89% with immersive virtual reality). Their engagement seemed increased compared with conventional physiotherapy (24/28, 86% with nonimmersive and immersive virtual reality). Only 1 child seemed bored with immersive virtual reality. All the children remained interested with nonimmersive virtual reality. Apart from a neutral opinion, all parents felt that using the connected treadmill could be a good complement to conventional physiotherapy approaches for their child. Overall, for parents, results were similar between nonimmersive and immersive virtual reality (P=.19).

XSL•FO
RenderX

Figure 6. Box plots illustrating the scores obtained for each item in the customized questionnaire measuring parents' acceptability of their children's experience with the Amy treadmill under both nonimmersive and immersive virtual reality conditions. Q1: The child's movement on the Amy treadmill was not impaired compared with his usual walking. Q2: The child required no more support than usual. Q3: The child required no external motivation to walk. Q4: The child's involvement was greater than usual (at home or in the usual physiotherapy session). Q5: The child remained interested and did not seem bored. Q6: The use of the treadmill could be a good complement to conventional physiotherapy approaches for this child. The scale ranges from 1 (strongly disagree) to 7 (strongly agree). Q: quartile.

Discussion

Principal Findings

In this study, we evaluated the UX of a virtual reality–based treadmill as a rehabilitation tool in a sample of 74 individuals, including children with a chronic disease impacting physical health, their parents, and therapists. Participants reported an excellent UX from testing the connected treadmill about hedonic and pragmatic aspects. The findings showed that the virtual reality–based treadmill presented excellent usability. The immersive virtual reality system was well tolerated in terms of cybersickness; feelings of comfort, fun, sense of presence, and immersion were highly positive. For all participants, UX was better with the immersive virtual reality system than with the nonimmersive virtual reality system. The virtual reality–based treadmill was largely perceived positively by the parents. Children and parents reported greater UX than therapists.

Interpretation and Comparison With Prior Work

The overall UX evaluation of the virtual reality–based treadmill was excellent, as shown by the results of the UEQ-S. Compared with the benchmark reference data, the results on the connected treadmill were in the top 10%, indicating a product of excellent quality [45]. The pragmatic qualities of the connected treadmill were evaluated positively in terms of dependability, perspicuity, and efficiency. The virtual reality–based treadmill was easy to understand and use, secure, and predictable. This was supported by the results of the UEQ and the UMUX. The UMUX also adds the dimension of usefulness, as the system has been assessed as meeting the children's needs. The hedonic qualities of the connected treadmill were evaluated positively in terms of stimulation and novelty. Good rates in the UEQ-S were reported on interest, fun, motivation, innovation. Feelings of comfort, immersion, sense of presence, and fun with immersive virtual reality were positively rated by all children. Moreover, the virtual reality headset was well tolerated. Only 1 child, aged 9 years, showed important signs of cybersickness, especially oculomotor discomfort. These results are in line with those reported by Ammann-Reiffer et al [23], who investigated the UX of an immersive virtual reality system to train everyday walking activities in children with a neurologic disease. This virtual reality–based treadmill, designed as a rehabilitation tool for gait and balance training through direct interaction between the treadmill and virtual reality games, generated a positive UX in terms of pragmatic and hedonic qualities, with positive emotions reported in all participants. Control of both immersive and nonimmersive environments is achieved directly through the treadmill, via weight shifts under static and dynamic conditions and adjustments in treadmill speed, providing a convincing UX. Therefore, it has the potential to be adopted by all end users and to motivate children to participate in physical rehabilitation, either more often or for an extended period. As previously showed in the study by Phelan et al [34], who tested immersive virtual reality in children with upper limb injuries, being entertained by virtual reality can increase children's participation to rehabilitation, as the fun induced by virtual reality keeps them distracted from the difficulties of exercising. This has to be confirmed by a subsequent feasibility study with long-term use of the device in the target environment, that is, at home.

From the parents' perspective, only a few children exhibited gait disturbances and required additional support (from the bars or the harness), both with nonimmersive and immersive virtual reality. Parents felt that their child was motivated, interested,

XSL•FO
RenderX

and engaged during the session, and they considered the use of the connected treadmill to be a valuable complement to conventional rehabilitation methods. The findings align with those of Phelan et al [34], where parents reported a positive UX and showed interest in using the virtual reality system at home. For all participants, there was a statistically significant difference in favor of immersive virtual reality in the UEQ but not in the UMUX questionnaire. The difference could therefore lie in the hedonic aspects that the UEQ investigates unlike the UMUX [40]. According to Winter et al [48], who tested the UX of treadmill training with semi-immersive and immersive virtual reality for patients with gait disorders, better results are explained by the higher sense of presence experienced in the immersive condition compared with the semi-immersive condition.

While the results were positive overall, they were significantly better in children and parents than in therapists, in both the UEQ and the UMUX. Possible explanations could be, on the one hand, functional—relating to the technical aspects of the treadmill—and, on the other hand, associated with the games, such as their design, interactivity, and coordination with the treadmill. Some participants complained about the mismatch between the speed of the games and the speed of the treadmill, which is limited to 3 km/hour. They reported some technical difficulties and simplistic esthetics of the different games. We hypothesize that during this first session, therapists anticipated using the connected treadmill in a more complex situation, that is, at home, under supervision, as part of a rehabilitation program lasting several weeks. As a result, and because of their technical knowledge, they may have had higher expectations of the virtual reality–based treadmill. Given their role as therapists, they may be looking for a device that is safe, reliable, as unobtrusive as possible so that it can be integrated into their workload, and as personalized as possible for patients. The engagement of therapists remains essential for the future implementation of a virtual reality rehabilitation device [28]. In the study by Phelan et al [34], therapists report that immersive virtual reality in children with upper limb injuries can be a good alternative rehabilitation tool and can promote positive interaction between patients and therapists. However, this is subject to several conditions: the system must be customizable to each patient, activities must be varied and progressive, and therapists must be properly trained [34]. Ammann-Reiffer et al [23] reported favorable results in terms of therapists' acceptability. They found that children were focused and motivated and, above all, were not restricted in their movements by the virtual reality system.

The results were in favor of some difference between the children's subgroups. Children with obesity showed better usability results than other children, especially with immersive virtual reality. Children with cerebral palsy and neuromuscular diseases were younger and more functionally limited than children with obesity. None of the obese children required a mobility aid. We hypothesize that younger age and greater functional impairment could make it more difficult to use the connected treadmill. Cerebral visual impairment, which is frequently observed among children with cerebral palsy [49], could account for the poorer results observed in this population, although very limited data are available in the literature and further research is warranted.

Limitations

This study has several limitations. The participant group was heterogeneous, particularly among children, in terms of age and pathology. This enabled us to provide a range of opinions for a UX study but made comparisons difficult and is not intended to be generalized. Regarding UX, and especially usability, part of the virtual reality system was set up by the caregiver. As a result, children did not test the usability of the connected treadmill in its entirety. It could also be interesting to involve parents in the installation of the system in a future context of a home program where one of their roles would be to supervise the treadmill sessions. Ensuring usability is essential, especially for systems intended for long-term use. Two 20-minute sessions UX test were insufficient, and test sessions will need to be repeated throughout the design and improvement process to confirm the trend of these initial results and to project long-term use.

Acceptability from the therapists' point of view could not be assessed, as it was not possible to match the children with their respective therapists for logistical and organizational reasons. This could be interesting for future studies in order to supplement the results. Although the questionnaires have been translated into French and used in several French language studies and/or with children, they have not yet been formally psychometrically validated in an independently published study. The various items were not specifically adapted to the vocabulary and cognitive abilities of children. Some items of the customized questionnaires were possibly too complex or not clear enough, which may have led to inconsistent answers. This may have been the case in the parents' perception questionnaire, particularly for the first 2 questions, where a wide variety of responses was observed. Furthermore, the risk of the Hawthorne effect and social desirability bias on participants' responses to questionnaires cannot be ruled out. Methodologically, and in order to limit the order effect, it could have been valuable to randomize the 2 test sessions. It might have also been interesting to consider motivation for physical activity and the family's socioeconomic context, as these factors could potentially have an impact on subsequent use of the device in a several-week home rehabilitation program.

Future Directions

This initial UX session of the connected treadmill, conducted in a supervised environment, demonstrated promising potential within our sample. These findings represent a first step in the iterative codevelopment of the connected treadmill. The device and its UX will be refined based on user feedback to strengthen children's and parents' engagement and foster greater acceptance from therapists. Integrating the findings from both quantitative and qualitative studies may enhance accuracy through complementarity. Thus, future studies, quantitative and qualitative, will be necessary to assess UX after the company has developed the games and the treadmill—first in a supervised environment and subsequently in real-life situations in the children's homes. The objective, from a home program perspective, is to provide a comprehensive program featuring

XSL•FO
RenderX

numerous progressive games through an engaging interface, enabling children to participate actively while being supervised by therapists.

Conclusions

This is the first study to explore the UX of a treadmill designed as a playful game controller of virtual environments, in children with chronic diseases affecting physical health, in a user-centered design and a multidisciplinary, team-based approach. This initial test demonstrates promising potential for using the connected treadmill as a rehabilitation tool. Improvements are required to better meet therapists' expectations. This underlines the importance of further iterations to achieve the best alignment between technological features and practical clinical context for those children. Consequently, UX will be reassessed after the games and the treadmill have been enhanced, first in a supervised environment and subsequently in real-life settings within the children's homes, through extended-duration trials.

Acknowledgments

The authors would like to express their gratitude to all the study participants for their support. The study received funding from France 2030 as part of the Tiers-Lieu MOBIS initiative (CHU ANGERS, France and Caisse des Dépôts). The authors declare the use of generative artificial intelligence (GAI) in the writing process. According to the GAIDeT taxonomy (2025), translation, proofreading, and editing were delegated to GAI tools under full human supervision. The GAI tool used was Perplexity AI (2025 version). Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

The study received funding from France 2030 as part of the Tiers-Lieu MOBIS initiative (CHU ANGERS, France, and Caisse des Dépôts).

Data Availability

The datasets generated during this study are available from the corresponding author on reasonable request.

Abstract

Background: Immersive virtual reality (IVR) is increasingly used for task training. Adjusting sensory and cognitive complexity to individual capacity is important for effective training, yet it remains unclear how varying visual, auditory, and cognitive demands influence behavioral responses, physiological activity, and task performance during goal-directed activities in IVR.

Objective: This study aimed to examine how 2 levels (low and high) of visual, auditory, and mental demands affect self-reported mental demand and effort (MDE), task performance, heart rate, gaze behavior, and head movements during a virtual grocery shopping task.

Methods: A within-subjects study was conducted with 22 unimpaired university students (11 women, 11 men; aged 23-27 years) recruited via convenience sampling at TU Delft, the Netherlands. Participants completed a grocery shopping task (collecting products from shelves during 122-second trials) under 7 conditions: baseline, visual low/high (background characters), auditory low/high (background sounds), and mental low/high (0-back/2-back tasks), in random order. Outcome measures included MDE (0-100), task performance (products placed in the cart), mean heart rate (from electrocardiography), head-stillness duration, and gaze duration on areas of interest (via integrated eye-tracking). Two-tailed paired-samples *t* tests with Bonferroni correction (α=.008) were supplemented by linear mixed-effects models.

Results: The mental high condition produced the largest effects: MDE increased relative to baseline (mean difference [M_{diff}] 52.73, 95% CI 44.01-61.44; t_{21}=12.58; *P*<.001), performance decreased (M_{diff} –8.00 products, 95% CI –9.57 to –6.43; t_{21}=–10.58; *P*<.001), head-stillness duration increased (M_{diff} 13.54 s, 95% CI 9.94-17.14; t_{21}=7.83; *P*<.001), and gaze on the shopping list increased (M_{diff} 9.89 s, 95% CI 5.36-14.43; t_{21}=4.54; *P*<.001). Auditory high demands increased MDE (M_{diff} 17.05, 95% CI 9.15-24.94; t_{21}=4.49; *P*<.001) without significantly affecting performance. Visual high demands redistributed gaze away from the main shelves (M_{diff} –6.11 s, 95% CI –8.70 to –3.52; t_{21}=–4.91; *P*<.001) without reducing performance. Heart rate increased under mental low demand (M_{diff} 4.02 bpm, 95% CI 1.69-6.34; t_{21}=3.59; *P*=.002); the mental high effect did not reach corrected significance in the paired-samples test (*P*=.02), possibly due to reduced physical activity in this condition. Under high cognitive load, participants spent more time checking the shopping list and showed greater head-stillness, consistent with task-serialization and memory-offloading strategies.

Conclusions: Cognitive demands strongly impacted workload, performance, and behavior, while sensory demands affected attention distribution and perceived workload, with no significant performance decrements at the Bonferroni-corrected threshold. By comparing 2 demand levels against a no-demand baseline and incorporating gaze and head-movement measures not previously examined, this study extends prior work in this domain. The findings suggest IVR environments can incorporate sensory richness

without large performance reductions in unimpaired young adults, and that behavioral strategies under cognitive load may support real-world workload monitoring and adaptive task adjustment, pending clinical validation.

Introduction

Immersive virtual reality (IVR) visualized through head-mounted displays (HMDs) is increasingly used for training and shows promise for neurorehabilitation [1-3]. IVR allows the creation of personalized, simulated real-life environments that can support the intensive and safe practice of task-specific movements, for example for users with neurological conditions such as stroke [4] and Parkinson disease [5]. These characteristics are especially relevant for brain-injured individuals, as neurorehabilitation evidence encourages high-dose, task-specific, personalized motor practice [6-8]. However, conventional training environments may lack adequate stimulation or appropriate difficulty [9], whereas IVR can provide stimulation calibrated to individual capacity [4,10]. This adaptability is particularly relevant for individuals with sensory sensitivity after acquired brain injury, for whom adjusting task and stimulus complexity may help optimize the level of challenge, avoid over- or underexertion, and maintain focus on core tasks.

Previous research has shown that environmental complexity and additional sensory stimuli in immersive virtual environments can influence users' mental workload [11] and task performance [12]. Additionally, research on cognitive workload under noise conditions suggests that noise may require additional cognitive resources to maintain performance on a primary task, and that psychophysiological measures can help quantify this compensatory workload depending on the type of auditory stimulation and cognitive task involved [13]. Cucinella et al [14] investigated the impact of visual, auditory, and cognitive demands on unimpaired users' mental demand and effort (MDE) and physiological activity during a grocery shopping task in an immersive virtual supermarket. Under conditions of added visual (background characters), auditory (background noise), and cognitive demands (concurrent arithmetic), the cognitively demanding task competed with the shopping task's cognitive requirements, substantially increasing completion time, heart rate, and MDE relative to sensory-only conditions, consistent with competition for shared central/working-memory resources [15]. However, that study did not examine higher levels of visual and auditory demands, did not include a no-demand baseline, and did not record behavioral measures such as gaze direction. It therefore remains unclear how graded sensory demands influence users' behavioral responses during IVR task execution. Such behavioral data could give trainers insight into how users engage with tasks, where they struggle, and what strategies they adopt.

Therefore, we experimented with 22 unimpaired participants (ie, without known sensorimotor, cognitive, visual, or auditory impairments) to examine how 2 levels of visual, auditory, and cognitive demands influence MDE, task performance, gaze behavior, and head movements during a virtual shopping task in an immersive virtual supermarket (modified from Cucinella et al [14]). The design also included a baseline condition without added demands. The virtual supermarket replicates an activity of daily living used in IVR for cognitive and functional assessment [16,17] and in consumer research on shopping behavior [18-20]. Here, the virtual environment serves to establish a baseline understanding of how sensory and cognitive demands affect performance, workload, and behavior in this specific IVR task and population, rather than consumer behavior. We used the NASA task load index (NASA-TLX) questionnaire to assess MDE and recorded task performance (total number of products placed in the cart) [21,22]. Although traditionally associated with physical demands [23], heart rate [24,25] also responds to mental workload, warranting investigation in this context. We also recorded head-stillness duration, since increased mental demands are associated with altered head-hand coordination [26], and gaze behavior on specific areas of interest (AOIs), given that mental demands influence fixation patterns and durations [27-29].

We tested the following hypotheses: (1) compared to baseline (no added demands), high visual and auditory demands primarily distract attention, leading to more head movements and gaze toward nontask-relevant elements, and (2) mental demands negatively affect task execution, increasing MDE, reducing performance, and producing behavioral adaptations such as reduced head movement and increased focus on the shopping list.

Methods

Participant Characteristics

A total of 22 unimpaired participants took part in the experiment. The participants were all university students aged between 23 and 27 years without known sensorimotor, cognitive, visual, or auditory impairments, including 11 women and 11 men. Handedness was not an inclusion criterion; however, task interaction was restricted to the participant's right hand due to the placement of electrodermal activity (EDA) sensors on the left hand. While EDA data were recorded, these were excluded from the analysis as hand movements caused frequent data corruption for most participants.

Sampling Procedures

Participants were recruited from TU Delft, the Netherlands, via word of mouth (convenience sampling). The experiment was conducted in a laboratory at TU Delft between October 27, 2023, and November 3, 2023.

XSL•FO
RenderX

Sample Size

The sample size of 22 participants was based on our previous study [14], which used a comparable within-subjects design and task with 24 participants. No formal a priori power analysis was conducted. A post-hoc sensitivity analysis indicated that, at the Bonferroni-corrected significance level (α=.008) and 80% power, the design could reliably detect within-subject effects of $|d_z| \geq 0.81$ in a 2-tailed paired *t* test (*df*=21).

Ethical Considerations

The study was approved by the Human Research Ethics Committee (HREC) of TU Delft under approval number 3417. All participants provided written informed consent for participation in the study and for the collection and use of their data, including physiological recordings (electrocardiography [ECG], eye-tracking, and EDA), audio and screen recordings, and questionnaire responses. Participant data were de-identified using numerical codes, signed consent forms were stored separately in a locked cabinet, and only the research team had access to the study data. Participants received a 15-euro gift card as compensation. No adverse events, such as motion sickness requiring session termination, were reported. No identifiable images of individual participants are included in the manuscript or supplementary material.

Masking

Participants were not informed of the specific condition before each trial, except for the mental low and mental high conditions, which required pretrial instructions for the concurrent *n*-back task. Visual and auditory manipulations became apparent once the trial began. The researcher administering the experiment was aware of all condition assignments. No formal blinding of outcome assessors was implemented, as all dependent measures were recorded automatically via the HMD, eye tracker, and ECG system.

Instrumentation

The experiment was conducted in a laboratory room with a walkable area of approximately 5.0 m × 2.5 m (12.5 m^2), providing enough space for participants to perform physical movements without risk of collision.

The experimental setup featured an HTC VIVE Pro Eye HMD. This HMD provided a 110-degree field of view, dual OLED screens with a resolution of 1440 × 1600 pixels per eye (2880 × 1600 combined), and integrated eye-tracking with a native sampling rate of 120 Hz. The setup also included 1 HTC VIVE tracked controller (HTC VIVE Pro Controller 2.0) and 2 base stations. Eye-gaze data, participants' actions, and HMD tracking data were all logged once per rendered frame at approximately 86 Hz and interpolated to a constant frequency of 100 Hz using nearest-neighbor interpolation. Each frame, Unity's raycasting engine assigned the gaze to a single AOI based on the nearest object intersected by the gaze ray. No temporal smoothing was applied to AOI labels in the statistical analysis. Frames with gaze tracking loss, identified by a null ray direction vector, were classified as "Tracking loss", a category separate from the 4 AOIs and from "Other." "Other" comprises gaze on nontask elements (eg, characters) and valid gaze rays landing outside all AOIs. This distinction is described further in data diagnostics.

We developed the virtual environment in Unity (v2021.3.11f1) and displayed it via the SteamVR plugin (v2.7.3). Eye-tracking data were collected within Unity using the integrated Tobii XR and SRanipal SDKs. The experiment used a virtual supermarket environment modified from Cucinella et al [14], populated with product and character assets (eg, onions, bread, NPC populator, low poly animated people packages) from the Unity Asset Store. Auditory stimuli (soundtracks from Envato Elements, Pixabay) were delivered through the HTC VIVE Pro Eye headphones. The participant's view was screen-recorded using Windows Xbox Recorder.

ECG data were acquired at 1024 Hz via Bluetooth using BioTrace+ software (MindMedia, NeXuS-4) with electrodes in a Lead II configuration. The experiment ran within the Unity Editor on a Windows 10 64-bit PC (AMD Ryzen 9 5900X CPU @ 3.70 GHz, 32 GB DDR4 RAM, NVIDIA GeForce RTX 3080 GPU).

Virtual Grocery Shopping Task

Participants engaged in a virtual shopping task, collecting products from 4 shelves in front of them according to a sequentially ordered list of 30 products, and placing them in a cart (Figure 1). Each trial lasted 122.4 seconds.

XSL•FO
RenderX

Figure 1. Overview of the immersive virtual supermarket task environment used in this study, showing the four shelves, the shopping list, and the cart, from a remote perspective.

To investigate how external task demands influence task performance, perceived workload, physiological activity, and behavioral strategies, we varied the order and locations of products across trials. The 4 identical, equidistant shelves contained 33 or 34 products (6-11 per shelf), depending on the condition. Each shopping list contained 30 items distributed across 4 shelves; in some conditions, 1 or 2 products appeared twice on the list. The listed subset, list order, and product-shelf assignments varied across conditions but were fixed across participants within a condition. Consecutive list items were grouped in sets of 4, 1 per shelf. This constraint held for positions 1-16 in all conditions and for positions 1-28 in baseline. With a mean of 19 products collected at baseline, the majority of task execution fell within the balanced range.

Participants could move freely and used the controller button (hold to grab, release to drop) to interact with products via a visible virtual right hand (no virtual body was shown). In a within-subjects design, all participants performed 7 conditions, whose order was randomized per participant.

Conditions and Design

The experiment included 7 conditions, summarized in Tables 1 and 2. The baseline condition consisted of the shopping task without any additional stimuli and was used as the reference condition for all comparisons. The 6 experimental conditions added visual, auditory, or cognitive demands on top of the same core shopping task; the core task procedure was the same across all conditions.

Table 1. Descriptions of visual demand manipulations across the visual conditions in the immersive virtual supermarket during the shopping task.

Factor	Visual low	Visual high
Character type	Only casual characters	Also, unusual and remarkable characters
Character actions	Only characters walking, waving, and looking at the participant	Also, doing additional moves, such as dancing
Events	Only characters	Also, noncharacter elements as visual distractors, such as a flashing alarm
Location	Only characters behind the main shelves, at least 4 meters from the participant's starting point	Also next to the main shelves, at least 2 meters from the participant's starting point
Examples	Casually dressed characters walking, waving, or looking at the user	Also, unusually dressed characters, such as clowns and pilots, flashing alarms, and characters dancing, jumping, and calling

XSL•FO
RenderX

Table 2. Description of auditory demand manipulations across the auditory conditions in the immersive virtual supermarket during the shopping task.

Factor	Auditory low	Auditory high
Motion	Only static sounds or moving at a walking pace	Also, moving at a running or driving pace
Duration	Continuous audio fragments	Also, short and repeating audio fragments
Location	At least 5 meters from the participant's starting point	At least 2 meters from the participant's starting point
Examples	Checkout desk sounds, beeps, a couple arguing, crowd conversations, walking footsteps in front of the participant	Also, sirens from police cars, a nearby person calling to the participant, running footsteps behind the participant, a truck in reverse, and bottles falling

1. Baseline: it consisted only of the experimental task. No extra stimuli were presented.
2. Visual low: the scene included 8 idle characters (eg, standing in the environment) and 22 moving characters (eg, spawning, following a trajectory, and disappearing). Eight of these 22 moving characters performed specific actions, such as sending messages to the participant by waving or using a thumbs-up gesture. Some moving characters navigated freely through walkable areas delineated by the shelves. All the characters were casually dressed. Their actions took place behind the shelves and in the neighboring aisle. Characters in the same aisle as the main shelves remained idle and were positioned at least 4 meters from the participant's starting position (Figure 2).
3. Visual high: in this condition, 11 idle and 44 moving characters were presented; 28 of the moving characters performed specific actions. This condition differed from the Visual low condition regarding character types, actions, events, and locations. Characters were positioned closer (at least 2 meters from the participant's initial position) and had distinct appearances (eg, policeman, clown, viking, and chef). Additionally, 2 alarm lights were installed on the ceiling above the main shelves (Figure 3).
4. Auditory low: participants experienced spatial stereo audio delivered via the HMD's headphones. The audio sources were dynamic: their perceived direction rotated in sync with the participant's head movements (tracked via the HMD), and their volume attenuated based on the virtual distance between the participant and the sound source. To achieve this in the Unity environment, the resonance audio listener plugin was used. The sound field represents full 360-degree spatial audio by encoding sound waves on a virtual sphere around a listener. The auditory environment included 2 different footstep sound sequences moving along predefined trajectories and 3 stationary ambient sounds. The footstep sounds simulated a standard walking pace and originated from virtual locations kept at least 5 meters away from the participant's starting position.
5. Auditory high: spatial stereo sounds were played, consisting of several components: 3 footstep trajectories, 5 continuous idle sounds, 2 intermittent idle sounds (repeating with breaks), and 6 incidental sounds (eg, short fragments originating from 2 meters away). The footstep sounds simulated movement at both walking and running paces. The perceived sound sources were at least 2 meters from the participant's initial position.
6. Mental low: a 0-back task was added to the main task. Participants listened through the HMD's headphones to a prerecorded voice, giving 4 sets of random single-digit numbers and then repeating aloud the last number they heard. The first 3 sets consisted of 10 numbers, but the fourth had only 8. Digits were presented with 2.5 seconds between the start of 1 digit and the start of the next. The 0-back task was used rather than a neutral control (eg, button pressing) to approximate the sensory and motor requirements of the 2-back task (see below).
7. Mental high: a 2-back task was added to the main task. Similar to the 0-back task, participants repeated aloud the number they heard 2 numbers earlier through the HMD's headphones. Again, the first 3 sets consisted of 10 numbers, but the fourth had only 8.

XSL•FO
RenderX

Figure 2. The immersive virtual supermarket task environment during the visual low condition, shown from a remote perspective. Casually dressed characters were positioned behind the main shelves, at least 4 meters from the participant's starting position.

Figure 3. The immersive virtual supermarket task environment during the visual high condition, shown from a remote perspective. Additional characters with distinct appearances were positioned closer to the participant, compared to the visual low condition.

All experimental manipulations were delivered as programmed in Unity. No technical failures affecting the visual, auditory, or cognitive manipulations were observed during data collection.

Measures and Covariates

The following dependent measures were calculated per trial:

1. Self-reported MDE (0 to 100): the NASA-TLX [21] was administered after each trial. As in [14], only scores from the MDE items were taken since the questions consider the mental or cognitive aspects of the task, which are the focus of this study. Therefore, our current analysis focuses on the average of 2 items: mental demand (how mentally demanding was the task?) and effort (how hard did you have to work to accomplish your level of performance?). Participants rated the 2 items on a 100-point interval scale in 5-point increments, ranging from 0 (low) to 100 (high).
2. Performance: the total number of collected products that are placed in the shopping cart.

XSL•FO
RenderX

3. Heart rate (beats per minute, [bpm]): we used a MATLAB implementation of the Pan-Tompkins QRS Detector, as developed by Sedghamiz [30], to extract heartbeats from the ECG signal. The method involves a sequence of signal processing steps designed to identify the QRS complexes in an ECG signal. Interbeat intervals (IBIs) were screened for artifacts (see Data Diagnostics). The mean heart rate for a particular trial was calculated as 60 divided by the mean of the remaining valid IBIs.
4. Head-stillness duration: we quantified head-stillness duration, defined as the total time angular head speed remained below a threshold of 0.2 rad/s (11.5 deg/s). This threshold is a heuristic, but informed by amplitude and velocity criteria previously used to identify and classify head movements in eye-head coordination studies [31,32]; it was chosen to capture periods in which the head was not engaged in active reorientation. To calculate this measure, we first smoothed the quaternion head orientation data using a geometry-aware filter: quaternions were mapped to their logarithmic representation (axis-angle vectors), filtered using a zero-phase, 2nd-order Butterworth lowpass filter (2 Hz cutoff), and then converted back to orientations. Angular head speed was calculated based on the rate of orientation change between consecutive time points of the smoothed quaternions, measured as twice the arccosine of the absolute value of the dot product of each pair of consecutive quaternions. The total head-stillness duration represents the cumulative time in seconds of all sampling intervals for which the computed angular speed satisfied the stillness threshold.
5. Gaze duration on AOIs: we defined several AOIs within the environment: the shopping list, the main shelves, the shopping cart, and human characters. Gaze data from the human characters AOI and outside designated AOIs were combined into a single category labeled “Other.” The time spent gazing at the other category might reflect moments of distraction or difficulty maintaining focus on task-relevant elements. In contrast, increased gaze time on the shopping list may reflect that participants used it during task execution, which is consistent with previous research showing that offloading cognition onto external resources can support task performance [33-35].

Data Collection

After providing informed consent upon arrival, participants received instructions for the shopping task. They learned the primary goal was to read products from a list, retrieve them from designated shelves using the controller in their right hand (with specific button presses for grab/release), and place them into the shopping cart. Participants were asked to keep their left hand still, avoid throwing products, follow the list chronologically, and not search outside the specified areas. It was pointed out that the list was intentionally long and not meant to be completed, and that they should not rush. They were also informed that products would vanish from the cart shortly after placement, advised about potential motion sickness, and reminded that they could withdraw at any time.

A familiarization session before putting on the HMD specifically addressed potentially confusing products. Examples given were a blue foil pack, a Fanta bottle labeled “Santa,” and leeks, which the researchers noted might be an unfamiliar term for Dutch participants. The need to pay attention to color was also highlighted, using different colored yogurts as an example.

Participants then self-applied ECG electrodes (lead II configuration), and the researcher started screen-recording the HMD view. Once the HMD was fitted, the eye tracker was calibrated. During calibration, the virtual height was set to 185 cm to ensure consistent visibility across participants, particularly for shorter individuals viewing top-shelf products.

An initial practice trial of approximately 1.5 minutes allowed participants to acclimatize to the environment and controls without task demands. Subsequently, participants underwent 7 experimental trials, each featuring a different condition (eg, visual low and auditory high) presented in random order. Eye-tracking recalibration occurred before each trial. For the n-back trials, participants were briefed on the concurrent task requirements, informed of its equal priority with shopping, and provided an audio example.

Posttrial procedures involved removing the HMD and completing a condition-specific NASA-TLX questionnaire via Qualtrics. A final NASA-TLX for item weighting was completed after the last trial, although these weights were not used in the analysis.

The experiment concluded with a gift card compensation. Each participant’s session took roughly 75 to 90 minutes.

Data Diagnostics

No participants were excluded after data collection. Heart rate data were unavailable for 3 out of 154 trials (3/154, 1.9%; participant 22: visual low and visual high; participant 12: auditory low), likely due to electrode displacement. Given the small proportion of missing data, no imputation was performed; these trials were excluded pairwise for heart rate analyses, resulting in 20 degrees of freedom for the affected comparisons. Little’s missing completely at random (MCAR) test, conducted across the 8 trial-level dependent measures (MDE, performance, heart rate, head-stillness duration, and the 4 gaze AOI durations), did not reject the MCAR assumption (χ^2_7=5.26; P=.63). IBIs were screened for artifacts using the Berntson et al [36] criterion with the placement parameter set to 0.75 (ie, 75% from the maximum expected difference toward the minimum artifact difference), resulting in the rejection of 902 of 27,063 IBIs (3.3%) across all trials. One participant had substantially higher rejection rates in individual trials (up to 66.5%), though their remaining valid IBIs were retained for analysis.

Gaze tracking loss occurred on a mean of 5.3% of frames per trial (SD 2.8%; mean 561 of 10,516 frames per trial at the ~86 Hz logging rate, across 154 trials). In total, 86,364 of 1,619,535 frames (86,364/1,619,535, 5.3%) were affected. These frames were classified as Tracking loss, separate from the other gaze category, which includes only gaze with a valid ray direction that did not intersect any AOI. Tracking loss was similar across conditions (range 4.7%-5.2%) except in the mental high condition (7.8%), where it was significantly elevated relative to baseline (baseline: mean 5.83, SD 2.72 s; mental high: mean

XSL•FO
RenderX

9.41, SD 4.38 s; mean difference 3.58 s, 95% CI 1.84-5.31; t_{21}=4.29; *P*<.001). An episode-level analysis based on episode duration showed that across all conditions, 4213 of 7339 tracking-loss episodes (4213/7339, 57%) lasted 100-400 ms, consistent with the typical duration of spontaneous eye blinks. Under mental high, the elevated tracking loss reflected increases across multiple duration categories: typical blinks (100-400 ms) rose from 4.56 seconds to 6.39 seconds per trial (t_{21}=3.64; *P*=.002), long blinks (400-1000 ms) rose from 0.37 seconds to 1.51 seconds (t_{21}=3.26; *P*=.004), and very long gaps (>1000 ms), absent in all other conditions, contributed 0.47 seconds per trial. By contrast, the duration of short jitter episodes (<100 ms) did not increase significantly (mental high: 1.07 s vs baseline: 0.98 s; t_{21}=0.73; *P*=.48).

No statistical outliers were removed. The degree of nonnormality of the paired difference scores (condition minus baseline) was assessed descriptively. Of 48 comparisons, 31 had |skewness| < 0.5, 8 had |skewness| between 0.5 and 1.0, and 9 had |skewness| > 1. The most skewed comparisons involved gaze on other elements (auditory low: 3.06; mental low: 2.24; mental high: 2.06) and heart rate, auditory high (2.23). In each case, the skew was traced to a single participant with an extreme difference score; excluding the respective participant did not change the significance of any comparison for gaze on other elements or heart rate. The 2-tailed paired-samples *t* test is relatively robust to outlier contamination [37].

Analytic Strategy

To quantify the size of the differences between conditions, we calculated Cohen *d* (measuring the overall difference between conditions) and Cohen d_z (measuring the degree of change within participants). Since we performed 6 comparisons against the baseline, we applied a Bonferroni correction, adjusting our significance threshold to *P*<.008 (α=.05/6) to control the risk of false positives. As a robustness check, we fitted linear mixed-effects models for each dependent measure (Multimedia Appendix 1). Model B corrects for presentation order (trial position 1-7) as a linear covariate to control for learning or fatigue effects across the experimental session. Effect sizes were computed following the convention of the emmeans package [38]. Full results are reported in Multimedia Appendix 1.

Exploratory Behavior Analysis

While the above dependent measures provide global indications of participants' behaviors, understanding how they adapted their strategies requires examining their behaviors more closely. Gaze behavior on AOIs, task performance, and product-grabbing actions were used to create "behavioral charts" for a representative participant in the baseline, visual high, auditory high, and mental high conditions. To reduce high-frequency jitter in the visualized AOI labels, a 1-dimensional mode filter with a window size of 19 samples (190 ms) was applied. This chart shows how either the sensory or the cognitive demands affected a participant's shopping routine of reading the shopping list, locating products on the main shelves, and grabbing and placing them in the cart. The x-axis represents the elapsed time within the trial in seconds. The y-axis categorizes gaze targets (ie, list, main shelves, and cart) and activities (ie, grabbing products). These actions are visualized in the form of colored bars of variable length, corresponding to the duration of each behavior. Additionally, we analyzed the percentage of time spent looking at the shopping list as a function of normalized time between consecutive product placements to examine differences in the participants' strategies compared to the baseline.

Results

Differences Between the Six Experimental Conditions and Baseline

Table 3 shows descriptive statistics (ie, mean, SD) calculated over the 22 participants and the 2-tailed paired-samples *t* test results for each dependent measure (ie, MDE, performance, heart rate, head-stillness duration, gaze duration). We also included Cohen *d* and the within-subject effect size Cohen d_z, as well as the mean difference from baseline with 95% CIs.

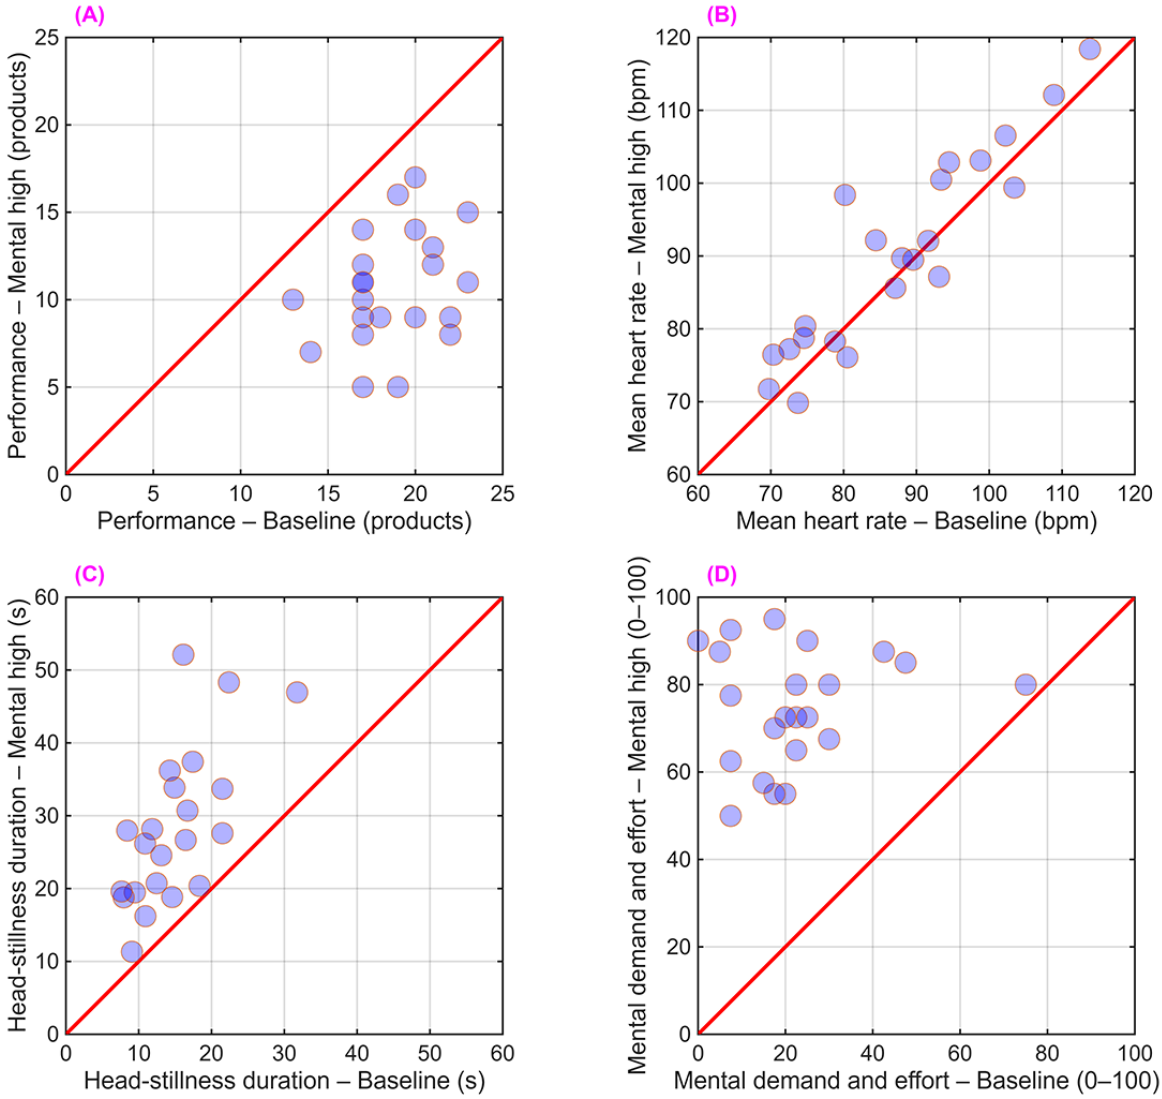
[a]*P* value<.008 (.05/6) was considered statistically significant; *t*, *P* value, d_z, M_{diff}, and 95% CI are based on paired differences. Degrees of freedom are 21 for all comparisons except the three heart rate comparisons affected by missing data (visual low, visual high, and auditory low: *df*=20).

[b]Not applicable.



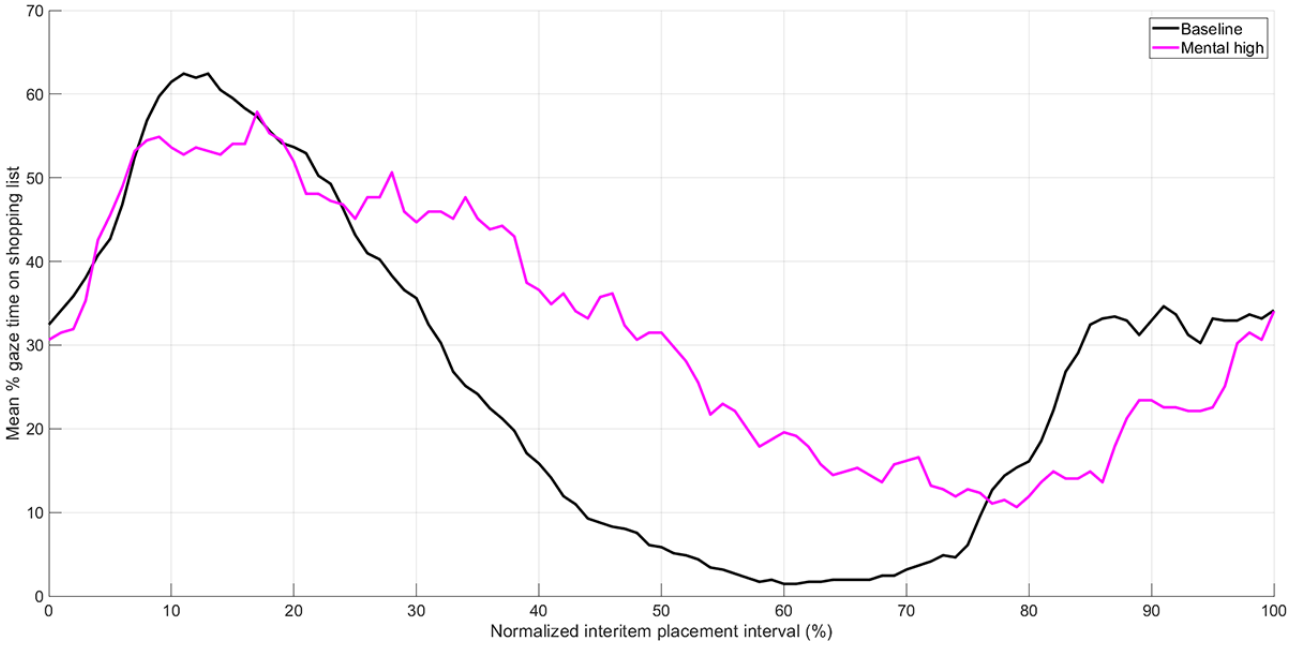
The mental high condition produced the largest and most consistent effects, with statistically significant differences from baseline on all dependent measures except heart rate, gaze on the cart, and gaze on other elements (Table 3). The mental low condition also showed significant effects on MDE, heart rate, gaze on the shopping list, and main shelves.

In the 2-back task, 38 items were presented, of which the first 2 items in each block were not scorable, yielding 30 scorable items. Mean accuracy was 19.1 (SD 6.3) out of 30 scorable items (19.1/30, 64%; scored for 21 of 22 participants; audio recordings failed for 1 participant), confirming that the task was cognitively demanding.

For some dependent measures, d_z was larger than d, notably heart rate (Figure 4B). Among the sensory conditions, only the auditory high condition significantly increased MDE, and only the visual conditions significantly redistributed gaze (for visual high: less on main shelves; for visual low and visual high: more on other elements, ie, likely the characters). No sensory condition significantly affected performance.

XSL•FO
RenderX

Figure 4. Scatter plots of four dependent measures (A: performance; B: mean heart rate; C: head-stillness duration; D: mental demand and effort [MDE]), comparing scores in the baseline condition to those in the mental high condition during the immersive virtual shopping task. Each marker represents one participant. Transparent markers are used to see overlapping data points more clearly. Red diagonals indicate equal values for both conditions.



Participants' Behaviors

Figure 5 illustrates the average percentage of time participants gazed at the shopping list during the interval between placing consecutive products in the cart. Participants during the baseline condition showed a peak of attention toward the shopping list early in the interval, which then dropped, indicating they likely encoded the next product and focused on searching for the product on the shelves. Conversely, participants in the mental high condition maintained a relatively higher percentage of gaze time on the shopping list throughout the mid-to-late stages of the interval, indicating more frequent rechecking or consultation under increased mental demand.

XSL•FO
RenderX

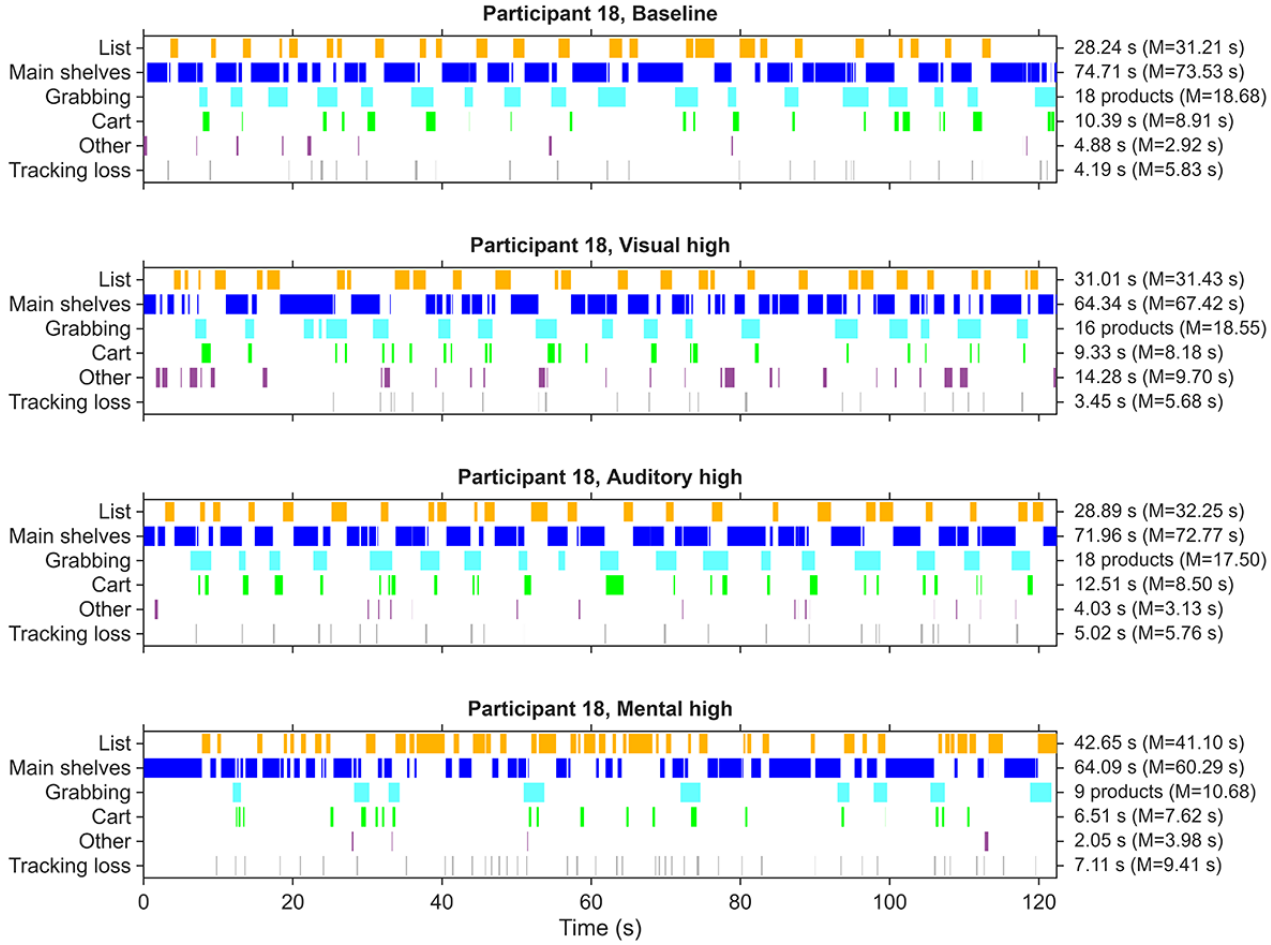


Figure 5. Mean percentage of gaze time on the shopping list as a function of normalized time between consecutive product placements, comparing the baseline and mental high conditions during the immersive virtual shopping task. Data are averaged across all unimpaired participants and interplacement intervals.

Behavioral charts in Figure 6 show, over time, the gaze patterns on the shopping list, the main shelves, and the shopping cart, as well as the time products were held, for a single participant (Participant 18, selected because their baseline performance was close to the group mean) in the baseline, visual high, auditory high, and mental high conditions.

XSL•FO
RenderX

Figure 6. Behavioral charts for the unimpaired young participant 18 during the immersive virtual shopping task at baseline, visual high, auditory high, and mental high conditions of the within-subjects experimental study. Colored bars indicate gaze on the shopping list (orange), main shelves (blue), cart (green), other elements (purple), eye-tracking loss (gray), as well as product grabbing (cyan), over the 122.4-second trial. Values on the right show the participant's gaze durations and products collected, with the mean of participants (M) in parentheses.

Observations from the behavioral charts indicate that participants in the baseline condition generally followed a consistent strategy: first checking the shopping list to identify the target product, then locating it on the main shelves. After locating the product, participants grabbed it and placed it in the shopping cart. However, we observed some variations: some participants reduced the frequency of checking the shopping list, collecting multiple products consecutively before revisiting it, while others checked the list for the next product while placing the previously collected product in the cart. As illustrated in Figure 6, this general strategy remained largely the same in the auditory high condition, with gaze durations and products collected comparable to the baseline. In the visual high condition, the overall collection strategy was similar, but gaze was redirected away from the shelves (see also Table 3), suggesting that the visual distractors competed for attention without disrupting task execution. Yet, in the mental high condition, participants' behaviors changed considerably: there were fewer grabs (reflecting lower performance, as reported in Table 3), more frequent revisits to the shopping list, and a longer overall proportion of time spent attending to the shopping list compared to the baseline (also observed in Table 3).

To further understand participants' behavior and strategies, we qualitatively analyzed video recordings showing their first-person perspective from the HMD during the shopping task. This analysis helped identify specific behaviors within the baseline and mental high conditions that could not be seen directly in the behavioral charts. For example, in the mental high condition, we observed that many participants adopted a step-by-step approach, prioritizing either the shopping or the 2-back task rather than performing both simultaneously; they would pause 1 task to execute the other. In 2 participants, we observed them using a finger-pointing strategy, presumably to assist with checking the shopping list (Figure 7), whereas in another case, 1 participant switched from English to Dutch (their native language) when performing the 2-back task.

Figure 7. The immersive virtual supermarket from a first-person perspective during the mental high condition, showing an example of a finger-pointing strategy presumably used to identify the next product on the shopping list.

Discussion

Principal Findings

This study examined how visual, auditory, and cognitive demands at 2 intensity levels influenced perceived workload, task performance, heart rate, gaze behavior, and head movement during a virtual grocery shopping task in immersive VR. The results are discussed below in relation to the 2 hypotheses.

Hypothesis 2, which predicted that cognitive demands would negatively affect task execution, was supported. Under mental high, the 2-back task substantially increased MDE, reduced task performance, prolonged head-stillness, and shifted gaze away from the shelves toward the shopping list. The 0-back condition showed a similar but attenuated pattern. This interference likely reflects competition for working memory, as both the n-back and the shopping task require maintaining and updating information in memory, creating a central bottleneck despite their different input and output modalities [15]. Heart rate was significantly elevated under mental low demand; the mental high effect did not reach corrected significance in the 2-tailed paired-samples *t* test, possibly because reduced physical activity under mental high partly offset any cognitive heart rate increase. Both mental conditions involved speaking aloud, which may also have contributed to the heart rate elevation relative to baseline.

Hypothesis 1, which predicted that high sensory demands would primarily distract attention and increase head movement, was only partially supported. Visual distractors redirected gaze toward other elements without reducing performance. Auditory demands increased self-reported MDE but had limited effects on behavior or performance. Neither modality increased head movement. Unlike the n-back task, these sensory manipulations were passive distractors that did not compete for working-memory resources, which likely explains their limited behavioral impact.

Comparison With Prior Work

In the visual high condition, participants spent significantly less time gazing at the main shelves and significantly more time gazing at other elements compared to the baseline. A similar pattern was observed in the visual low condition, although there the decrease in gaze on the main shelves did not reach statistical significance after Bonferroni correction. These findings suggest that the nontask-relevant visual elements captured attention at the expense of task-relevant areas. However, this gaze redistribution did not affect performance or perceived workload. Contrary to the head-movement prediction in hypothesis 1, head-stillness duration did not differ from baseline under any visual or auditory condition. This pattern may be explained by perceptual load theory [39]: if the shopping task involved low perceptual load, spare capacity would allow processing of peripheral elements, explaining the gaze redistribution. The absence of a performance cost may reflect that the time spent glancing at distractors was short enough to be absorbed without reducing the total number of products placed in the cart. In the auditory high condition, participants reported significantly higher MDE than at baseline. The spatialized, semantically varied, and dynamically changing sounds from varying distances were likely difficult to ignore, imposing additional cognitive effort to sustain attention on the core task and thereby increasing perceived workload. Although task-irrelevant sounds and demanding acoustic conditions can affect performance in other settings [12,40], the auditory demands in this study did not

XSL•FO
RenderX

significantly affect shopping performance, visual attention distribution, or head-stillness.

Mean heart rate was approximately 90 bpm across all 7 conditions, compared with approximately 105 bpm in [14], where participants were instructed to work as accurately and quickly as possible. The present instructions not to rush likely reduced the physical intensity of the task. Because heart rate reflects both physical [23] and mental demands [25], interpreting condition differences requires considering both components. Under mental high, participants collected significantly fewer products (~11 vs ~19 at baseline), meaning they probably moved less. This reduced physical activity may have suppressed heart rate, partly offsetting any increase associated with higher cognitive load and helping to explain why the raw mental high vs baseline difference was modest. An exploratory linear mixed-effect model adjusting for the total number of products placed in the cart suggested that a cognitive component may remain after accounting for reduced number of products collected (Table S3 and Figure S1 in Multimedia Appendix 1). However, the model estimates heart rate at product counts that rarely occurred within each condition and should be interpreted as an extrapolation-dependent sensitivity analysis. Speaking aloud in both mental conditions could also have contributed to their heart rate elevation relative to baseline, as speech has been shown to increase autonomic arousal [41]; the present data cannot fully separate this speaking component from a cognitive one. Converging evidence for a cognitive contribution comes from our earlier study [14], in which all participants collected the same number of products by design; heart rate was still significantly higher under cognitive demands (~108 vs ~102 bpm), supporting a cognitive effect that does not depend on the product-adjusted model.

The behavioral analysis revealed several adaptations to increased cognitive demands. Under mental high, participants tended to prioritize either the shopping or the 2-back task rather than performing both simultaneously, a pattern broadly consistent with the compensatory task-serialization strategies described by Boer et al [42] in older drivers at intersections. Participants in the mental high condition also frequently looked back at the shopping list and, in some cases, pointed toward it with their virtual hand (Figure 7). Despite collecting fewer products, participants spent substantially more time gazing at the shopping list than at baseline, suggesting that the increase in list-checking reflects cognitive load rather than simply being proportional to the number of products collected. This increased list-checking may reflect cognitive offloading, where individuals rely on external information to reduce demands on working memory [33,35]. The finger-pointing behavior observed in some participants may have served a comparable function, as pointing can support the processing of spatially separated information [34] and gestures have been shown to reduce working memory load [43,44] and improve comprehension [45], consistent with cognitive-load theory principles [46]. Gaze on other elements did not differ significantly between mental high and baseline. However, tracking loss duration did increase significantly under mental high. This suggests that high cognitive load may have increased spontaneous blinking, in line with research showing that blink rate may increase under higher cognitive load [47,48]. Yet, hardware tracking loss is an imperfect blink proxy, as gaps can also reflect headset slippage, extreme gaze angles, or downward gaze toward the cart. Only the 100-400 milliseconds range corresponds to canonical blink durations; the longer gaps observed under mental high are more susceptible to these alternative sources.

Prolonged gaze on AOIs may also reflect increased processing demands, consistent with research showing that higher cognitive load affects oculomotor behaviors such as fixation duration [27-29,49]. Head-stillness also increased significantly under high mental demand. However, because participants collected fewer products and therefore moved less in the mental high condition, this increase may partly reflect reduced physical task activity rather than a purely cognitive effect. Monitoring such behavioral adaptations may serve as a noninvasive method for estimating user state in IVR, as eye-tracking can provide behavioral information in IVR [50], and IVR behavioral metrics, including head and hand movement patterns, have been proposed as objective indicators of cognitive load [51]. Cucinella et al [14] previously noted that physiological measures exhibit large individual differences and require person-specific baselines to be practical. Combining performance metrics with observable behaviors such as gaze patterns and pointing gestures could offer a more accessible approach to workload assessment, potentially enabling IVR systems to adapt task complexity in real time to the user's capacity.

Limitations

This study has several limitations. First, the sample consisted of 22 unimpaired university students, and it is unclear whether the findings generalize to other populations, such as older adults or individuals with cognitive impairments. Older adults may also use compensatory strategies to support everyday functioning [52]. In contrast, cognitively impaired populations, for example, individuals with acquired brain injury, often show altered sensitivity to visual and auditory demands, ranging from hyposensitivity to hypersensitivity [53], and may rely less on compensatory behaviors, as awareness deficits following brain injury can limit recognition of one's own impairments and the spontaneous use of compensatory strategies [52,54,55]. Accordingly, the present findings may underestimate the impact of sensory manipulations in clinical populations. Future studies should involve larger and more diverse samples, including participants of different ages, cognitive abilities, and cultural backgrounds.

Second, product-shelf assignments were fixed per condition rather than randomized per participant. The 4-shelf grouping constraint held fully only for the first 16 list positions in the experimental conditions (the first 28 positions in baseline), though most participants collected fewer than 19 products. We cannot fully exclude that differences in product placement across conditions influenced task difficulty. Third, participants' search strategies (eg, scanning shelves left-to-right) were not quantified. Future studies should examine whether such strategies influence vulnerability to distractions. Fourth, while the increased gaze duration on the shopping list may reflect cognitive offloading [33], alternative explanations such as forgetting the target product, losing one's place on the list, or pausing at the list

XSL•FO
RenderX

during task switching cannot be excluded. Future studies could include task-related error metrics (eg, order of collection, missing products) to more directly assess memory strategies. Finally, although the n-back task is a widely used cognitive task [56], it may not fully reflect real-world shopping demands. Future studies could adopt realistic secondary tasks, such as answering a phone call or sending a text message [57], embedded within a naturalistic virtual shopping environment.

Conclusions

The cognitive (2-back) task had a strong impact on perceived workload, performance, and behavioral measures, while visual and auditory demands primarily affected gaze distribution and perceived workload, respectively. Unlike prior work, this study compares 2 demand levels against a no-demand baseline and adds gaze and head-movement measures not previously examined. The absence of significant performance decrements under visual and auditory demands suggests that IVR environments can incorporate sensory richness without large reductions in task execution in this sample of unimpaired young adults, although the present design had limited power to detect small effects. Heart rate effects may have been partly masked by reduced physical activity under high cognitive load, limiting the use of heart rate as a standalone workload indicator in this task. By contrast, participants spontaneously adopted observable behavioral strategies to cope with high cognitive load, such as task serialization and increased list-checking. These behavioral adaptations, detectable from gaze and head movement data without physiological sensors, may offer a more practical approach to workload monitoring in IVR. As these findings were obtained with unimpaired young adults, their generalizability to clinical populations remains to be established. Future work in neurorehabilitation and training applications should investigate whether such behavioral markers can support the dynamic adjustment of task difficulty and environmental complexity to the individual user's capacity.

Acknowledgments

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), the following tasks were delegated to GenAI tools under full human supervision: code optimization and proofreading and editing.

The GenAI tools used were ChatGPT 5.4 (OpenAI) and Claude Opus 4.6 (Anthropic). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. This declaration was submitted by SLC.

Data Availability

The anonymized data are publicly available in the Zenodo research data repository [58].

Abstract

Background: Virtual reality (VR) sickness is a recognized barrier to the clinical adoption of immersive rehabilitation. Evidence on the tolerability of purpose-built clinical VR systems used at scale remains limited.

Objective: This real-world feasibility and safety study aimed to describe the frequency of recorded VR sickness in a primary cohort using a purpose-built, seated VR rehabilitation system (mediVR KAGURA), integrating 7 multisensory engineering principles, and characterize serious adverse events in a secondary postmarketing surveillance (PMS) cohort without assessing the causal effects of individual features.

Methods: We conducted a single-arm, retrospective observational cohort study (no comparison group) of 2 cohorts following the Journal Article Reporting Standards for quantitative research. The primary cohort comprised 3572 unique users (patients and the public; aged 3-100 years) identified from company records and server logs between November 2023 and June 2025 at our rehabilitation centers (n=578), institutional demonstrations (n=1715), and academic exhibitions (n=1279); typical exposure was 20 to 60 minutes at our rehabilitation centers and 5 to 10 minutes elsewhere. Its primary end point was VR sickness (user-reported nausea, dizziness, or malaise during or immediately after a session); secondary end points were adverse events (eg, falls or injuries). The secondary PMS cohort comprised all 337,577 therapeutic sessions (approximately 9306 patients) at 170 medical institutions from 2019 to 2025; its end points were serious adverse events and VR sickness requiring medical intervention. Sex and diagnoses were not available. All eligible records were analyzed without exclusions, and no outcome data were missing. Analyses were descriptive (95% CI through the Wilson score and exact binomial methods); no hypothesis tests were performed.

Results: In the primary cohort, 0.36% (13/3572) of users (95% CI 0.21%-0.62%) had recorded VR sickness, mostly mild and transient, and 0.03% (1/3572; 95% CI 0.005%-0.16%) discontinued a session early. No user required medical intervention, and no falls or injuries were recorded. In the PMS cohort, no serious adverse events or VR sickness requiring medical intervention were reported across 337,577 sessions (exact 95% CI 0%-0.0011%), although mild unreported symptoms cannot be excluded.

Conclusions: In this real-world dataset, recorded VR sickness was uncommon and mostly mild with a purpose-built seated VR rehabilitation system, and no serious adverse events or medically attended VR sickness were reported in the PMS. Earlier work mainly tested individual design features under controlled conditions, whereas this study documents an integrated multisensory design at scale in routine practice. Because it was uncontrolled and applied all features together, it cannot establish causality, attribute effects to individual features, or support comparison with other systems; the findings are proof-of-concept evidence. They suggest that seated, visually stable, and predictable designs can be deployed safely at scale in clinical rehabilitation and motivate prospective controlled studies with standardized symptom measures.

KEYWORDS

biomedical engineering; motion sickness; somato-cognitive coordination therapy; virtual reality; sensory conflict; cybersickness; rehabilitation; patient safety; postmarketing product surveillance

Introduction

The application of virtual reality (VR) technology is expanding in medical rehabilitation, serving as a tool to supplement conventional therapies by providing immersive, engaging, and precisely quantifiable therapeutic environments [1-3]. VR systems permit clinicians to create individualized and reproducible interventions for patients with neurological disorders, gait and balance deficits, and chronic pain [1-3]. However, VR sickness remains a primary barrier to the clinical adoption of immersive technologies, often contributing to hesitation in its adoption by clinicians and difficulties with patient adherence to treatment [4-7]. Recent clinical studies have reported differing levels of cybersickness during immersive VR interventions. In a pilot randomized trial of VR-assisted lower-limb exercise for knee osteoarthritis, 33% (5/15) of participants in the immersive VR group reported cybersickness [8]. In contrast, a feasibility study of VR-based neurorehabilitation in 20 inpatients with acquired brain injury reported a low mean Simulator Sickness Questionnaire (SSQ) score and no notable cybersickness symptoms [9]. Because these studies differed in participants, tasks, exposure, and symptom measurement, their results are not directly comparable; however, both emphasize the importance of assessing tolerability for each specific clinical VR application.

VR sickness is a form of cybersickness specifically defined as visually induced motion sickness that occurs in response to VR exposure [4,5]. This syndrome, characterized by symptoms including nausea, dizziness, and malaise, is reported to affect a high proportion of users. Incidence rates in nonspecialized VR applications are cited across a wide range, often from 20% to 80% [6], with some studies finding 65.2% of participants experiencing symptoms, of whom 23.9% report severe symptoms [7]. These figures derive from heterogeneous applications that differ in content, visual motion, populations, exposure duration, and symptom assessment; they are therefore presented as background only, and direct numerical comparison with data from a static, seated clinical system is not statistically valid. Reported cybersickness incidence also depends on how symptoms are assessed and documented. A systematic review of adverse effect reporting in VR and augmented reality interventions in psychiatry found considerable variability: 45 of 73 studies did not mention adverse effects, and 21 reported none despite documenting mainly cybersickness in their own results [10]. Although that review concerned psychiatric rather than rehabilitation applications, it illustrates how assessment methods shape the conclusions that can be drawn. Standardized instruments such as the SSQ and the more recently validated Cybersickness in Virtual Reality Questionnaire can characterize the severity and type of symptoms beyond a binary report of sickness [9,11]. These measurement differences complicate comparisons across studies and underline the importance of clearly defined safety outcomes.

The prevailing etiological explanation for this phenomenon is the sensory conflict theory [4-7]. This theory posits that sickness arises from a neural incongruence between sensory inputs—primarily a mismatch between the visual system, which perceives motion in the virtual environment (eg, navigating a scene), and the vestibular and somatosensory systems, which sense that the body is stationary [6]. This visual-vestibular conflict is the physiological foundation of VR sickness symptoms [5-7].

Recent experimental studies have linked cybersickness to display lag–related differences between physical and virtual head pose [12] and have examined the roles of vection type and postural instability [13]. In a preliminary experiment, optical flow stimuli presented through a head-mounted display (HMD) induced body sway and visually induced motion sickness in healthy participants [14], and a visual rest-frame approach has been proposed as a mitigation strategy [15]. These findings provide a rationale for investigating stable visual environments, predictable spatial cues, and responsive display performance. However, evidence on individual mechanisms, largely from healthy participants under experimental conditions, does not establish the safety or tolerability of a complete clinical VR system, and large-scale clinical evidence from systems used in routine practice remains scarce.

To address this challenge, we developed a VR medical device incorporating integrated engineering principles designed to mitigate the root causes of sensory conflict. The aim of this study was to describe the frequency of recorded VR sickness in a primary cohort of users of this purpose-built, seated VR rehabilitation system and characterize reports of serious adverse events or VR sickness requiring medical intervention in a separate postmarketing surveillance (PMS) dataset. This descriptive study did not test prespecified hypotheses; the engineering principles are described as part of the system rather than as experimentally tested factors.

Methods

Study Design (Conditions and Design)

This was a single-arm, uncontrolled, retrospective observational cohort study of naturally observed use of the mediVR KAGURA system. No condition was experimentally manipulated, and no randomization or masking was applied (a nonexperimental, single-group design). It was intended to document real-world feasibility and safety rather than comparative effectiveness against conventional VR systems. The report follows the Journal Article Reporting Standards for quantitative research of the American Psychological Association for nonexperimental designs.

Setting

Data for the primary cohort were collected between November 2023 and June 2025 at 3 settings: clinical rehabilitation sessions at our specialized centers (mediVR Rehabilitation Center Osaka,

XSL•FO
RenderX

Tokyo, or Fukuoka), on-site demonstrations at internal and external medical institutions, and public exhibitions at scientific congresses. To complement the primary analysis with a broad assessment of safety and repetitive tolerability, we concurrently reviewed large-scale PMS records and server-side logs from 2019 to 2025 covering 170 medical institutions.

Inclusion and Exclusion

For the primary cohort, all unique users of the mediVR KAGURA system at the 3 settings during the study period were included. Eligibility was defined by use of the system only; no exclusion criteria were applied, and no users were excluded. For the PMS dataset, all therapeutic sessions recorded in PMS documentation and server-side logs from 2019 to 2025 were included without exclusions.

Participant Characteristics

The primary cohort spanned the ages of 3 to 100 years and included both clinical patients and members of the general public. Detailed demographic and clinical characteristics (eg, age distribution, sex, diagnosis, and baseline severity) were not recorded in the source records and, therefore, could not be reported (see the Limitations section). The PMS dataset covered a diverse clinical population with a broad range of ages and underlying conditions (Table 1 lists the conditions for which the therapy is used in clinical practice).

Table 1. Clinical domains with potential indications for somato-cognitive coordination therapy in current practice[a].

Clinical specialty	Specific conditions and clinical manifestations
Neurology and neurosurgery	• *Stroke* sequelae (infarction and hemorrhage), including hemiplegia • *Parkinson disease* • *Cerebellar ataxia* (eg, spinocerebellar degeneration and multiple system atrophy) • *Unilateral spatial neglect*
Orthopedics and musculoskeletal disorders	• *Spinal cord injury* and spinal cord infarction • *Adhesive capsulitis (frozen shoulder)* • Hip osteoarthritis • Knee osteoarthritis • Chronic pain conditions with a prominent nociplastic component
Pediatric neurology	• *Cerebral palsy* (particularly for spasticity management) • *Neurodevelopmental disorders* (eg, *autism spectrum disorder and attention-deficit/hyperactivity disorder*) • Spinal muscular atrophy
Oncology and cancer survivorship	• *Chemotherapy-induced peripheral neuropathy* • *Cerebellar ataxia following medulloblastoma treatment* (eg, tumor resection or radiation necrosis) • Cancer-related cognitive impairment (chemo brain)
Pain medicine and anesthesiology	• Central poststroke pain • Complex regional pain syndrome • Fibromyalgia • Restless leg syndrome
Internal medicine and geriatrics	• *Sarcopenia* (primarily for balance and postural control rather than muscle strengthening) • Frailty
Psychiatry	• Schizophrenia • Bipolar disorder (particularly in the depressive phase)

[a]The listed conditions are provided as representative examples, with disease entities and clinical manifestations intentionally presented in parallel for clarity. Conditions shown in italics indicate those most commonly applied in current clinical practice. The target population therefore spans a broad spectrum of central and peripheral nervous system disorders characterized by impaired neural coordination; notably, primary myopathies such as muscular dystrophy are excluded as the intervention specifically targets neural processing rather than intrinsic muscular pathology. While therapeutic gains are often sustained in most neurological conditions, chronic pain management, particularly for conditions with a prominent nociplastic pain component, typically requires repeated, periodic treatment cycles to maintain long-term clinical efficacy.

Sampling Procedures

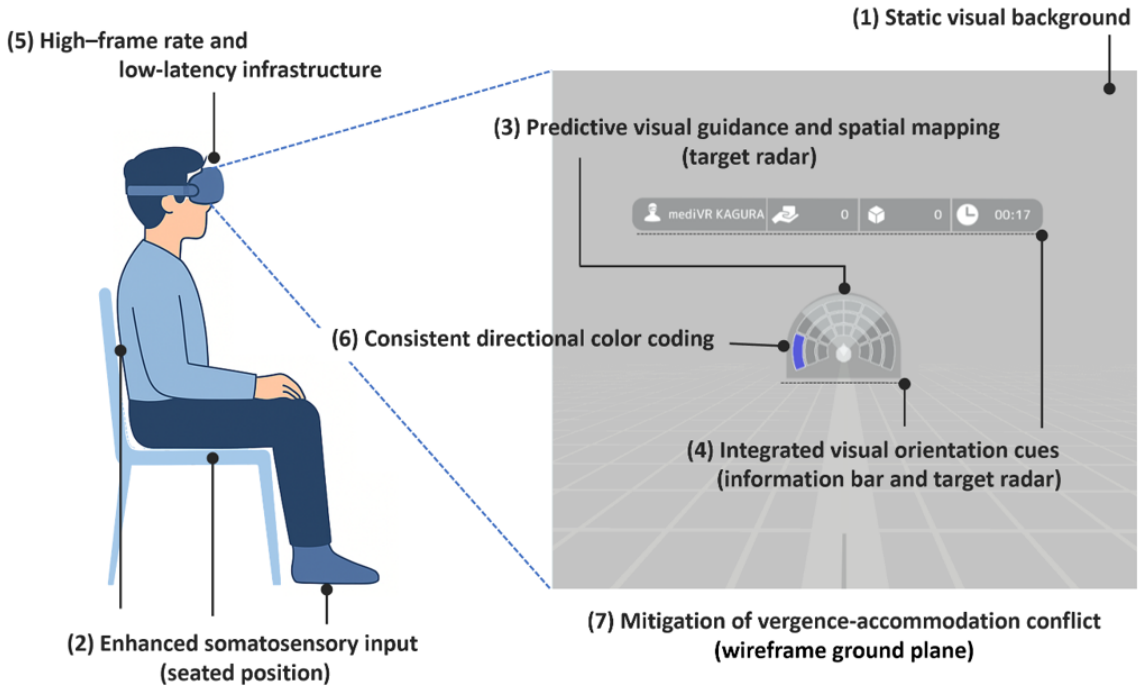
No sampling or recruitment procedure was applied. All available records were analyzed (complete enumeration), so users were not approached for enrollment, and the percentage of those who participated is not applicable. Self-selection occurred at the level of attending the rehabilitation centers, the institutions arranging demonstrations, and congress attendees trying the system, which may limit generalizability. Study information was publicly disclosed with an opportunity to opt out (see the Ethical Considerations section); no opt-out requests were received, and no records were removed.

Sample Size, Power, and Precision

No a priori sample size or power calculation was performed because all available records were analyzed; the achieved sample size equaled the intended sample size (primary cohort: n=3572 users; PMS dataset: n=337,577 sessions). Because events were

XSL•FO
RenderX

expected to be rare, precision was expressed through 95% CIs for all proportions rather than through power for hypothesis tests. No interim analyses or stopping rules were used.



Intervention

The exposure, somato-cognitive coordination therapy (SCCT), is delivered via the mediVR KAGURA system. This immersive VR rehabilitation method reestablishes proprioception-based motor control by removing visual representations of the patient's body. SCCT is hypothesized to enhance the function of the somato-cognitive action network, a cooperative motor control network associated with the primary motor cortex and higher-order sensorimotor integration [16,17]. Through seated, alternate reaching tasks, SCCT has been reported to induce cross-modal functional improvements, including hand dexterity, gait performance, articulatory motor function, and selected cognitive impairments, regardless of the underlying pathology (Table 1) [17-24]. Diffusion tensor tractography suggests that SCCT may facilitate neural network reorganization and neuroplastic changes beyond spontaneous recovery [23,24].

Engineering Principles

The mediVR KAGURA system is founded on 6 primary engineering principles intended to limit sensory conflict and a secondary principle to reduce oculomotor strain. These principles are visually summarized in Figures 1 and 2.

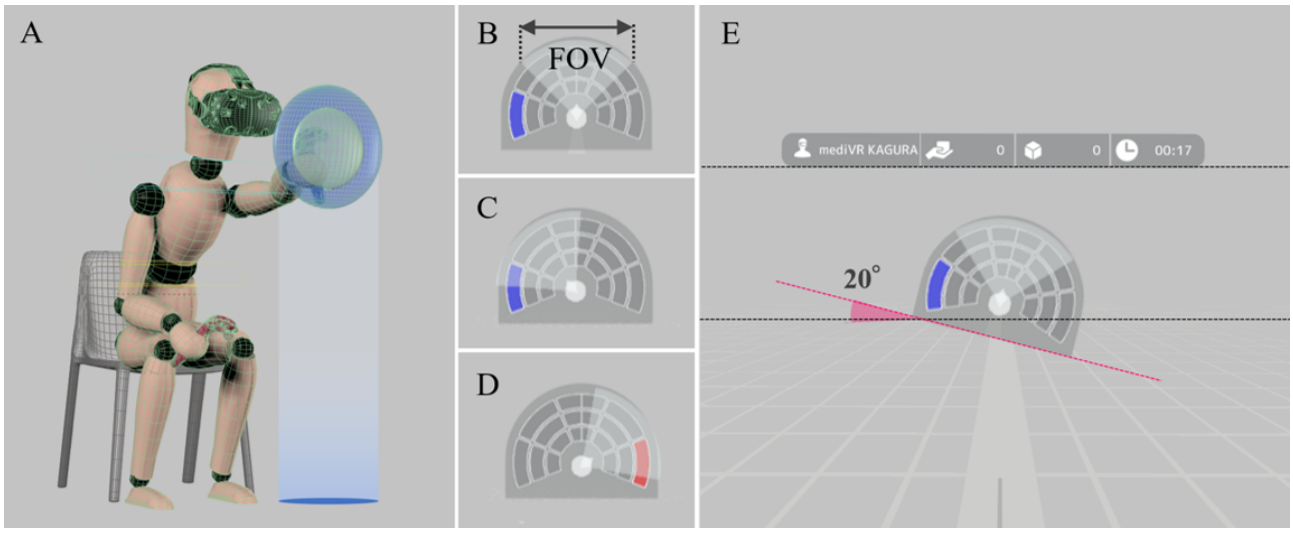
Figure 1. Integrated engineering principles intended to reduce virtual reality (VR) sickness. The numbered labels (1-7) correspond to the engineering principles described in the Methods section.

Static Visual Background

The system uses a visually simple, nonmoving (world-fixed) background. This provides a stable visual rest frame that remains congruent with the user's stationary vestibular and somatosensory state. By eliminating large-field optic flow, the system avoids inducing vection (the illusion of self-motion), thereby limiting a potential source of visual-vestibular conflict.

Enhanced Somatosensory Input (Seated Position)

All therapy is primarily conducted in a stable, seated position using a chair with a backrest, with the user's feet planted firmly on the floor. For patients who require it, the intervention can also be performed in a semiseated position by elevating the backrest of a medical bed. This setup ensures continuous tactile and proprioceptive feedback, providing a solid physical rest frame that reinforces the brain's perception that the body is stationary. By aligning these somatosensory cues with vestibular signals, the system achieves multisensory grounding and is intended to limit the postural instability that contributes to motion sickness. The use of armrests is an optional addition that can further enhance the precision of this sensory feedback.



Predictive Visual Guidance and Spatial Mapping (Target Radar)

A central reticle is permanently displayed at the center of the field of view (FOV). Throughout the intervention, an 18-block radar interface—comprising 9 blocks per side spanning a 180° horizontal arc across 3 depth levels—remains visible as a permanent user interface element. Upon the onset of a task, the specific block corresponding to the target's spatial coordinates is illuminated (blue for the left side and red for the right) and remains lit until the task is completed, providing an instantaneous visual cue of the task's location. This radar functions as a dynamic spatial map visualizing the orientation of the HMD and its current FOV relative to the target. This feature allows the user to determine whether a target is within their direct line of sight or in the periphery. Crucially, the

XSL•FO
RenderX

provision of spatial information regarding targets located outside the immediate FOV is intended to effectively bridge the gap between natural peripheral vision and the hardware-limited FOV of the HMD. Figure 2B-D illustrates this function: a target at the leftmost 0° position lies outside the current FOV (B), becomes partially visible as the user rotates the head approximately 45° leftward (C), and the 180° target becomes clearly visible after a head turn of approximately 150° rightward (D). By enabling the brain to establish an accurate predictive model—analogous to how a driver anticipates a vehicle's motion or how a passenger mitigates nausea by looking far ahead at the horizon to predict upcoming changes in trajectory—the system is intended to reduce the sensory surprise and mismatch between expected and actual sensory feedback that typically trigger nausea.

Figure 2. Visual interfaces for predictive spatial mapping and real-time orientation monitoring. (A) Representative clinical application of somato-cognitive coordination therapy. (B-D) Target radar function. (E) Integrated orientation cues.

Integrated Visual Orientation Cues (Information Bar and Target Radar)

The system provides coordinated visual references to maintain spatial orientation. A fixed information bar at the top of the display, together with the wireframe ground plane in the core training modes, functions as a stable artificial horizon representing the earth horizontal plane. While the target radar tilts in coordination with the user's head movement, these specific visual elements remain level and stationary. Figure 2E illustrates these cues during a rightward head or trunk tilt. Together with the target radar acting as a spatial anchor, these components provide a constant, earth-fixed reference for posture, anchoring the user in the stationary environment and reducing the spatial disorientation that often leads to discomfort.

High–Frame Rate and Low-Latency Infrastructure

The system uses a performance-first infrastructure that maintains a constant rate of 90 frames per second with motion-to-photon latency under 20 milliseconds [6]. This high level of stability is achieved by combining optimized low-polygon graphics to minimize graphics processing unit load, high-specification dedicated workstations for consistent processing power, and enterprise-grade VR hardware for precise tracking. By minimizing temporal lag, the system aims to limit the sensory mismatch between visual and vestibular inputs, providing the seamless integration needed to support therapeutic exercise.

Consistent Directional Color Coding

To further reduce cognitive load and spatial disorientation, the system uses a consistent, system-wide color-coding rule, with blue for movements on the left side and red for movements on the right side. This intuitive logic can help users recognize directional cues quickly. By simplifying spatial navigation and reducing the mental processing required for orientation, this color anchoring is intended to help maintain a stable mental state and reduce confusion that may contribute to VR sickness.

Mitigation of Vergence-Accommodation Conflict

As a secondary strategy, the system aims to reduce vergence-accommodation conflict—an oculomotor strain where the eyes' vergence (focusing on a 3D depth) conflicts with the fixed accommodation (focusing on the physical screen). To facilitate rapid and accurate spatial perception, the system provides unambiguous depth orientation cues: a target radar interface for depth anticipation, a wireframe ground plane for consistent environmental reference in the core training modes, and vertical pillars of light extending from the ground to each interactive object. These features enable the user to triangulate the target's precise spatial coordinates relative to the stationary environment. By providing the brain with clear, multimodal evidence of depth, the system is intended to reduce the physiological stress of ocular adjustment and visual fatigue.

Measures and Covariates

The primary outcome was the incidence of VR-induced sickness, defined as any patient-reported symptom (eg, nausea, dizziness, or malaise) sufficient to interrupt the session or be noted immediately following the SCCT. The secondary outcomes were the incidence of other adverse events, such as falls from the chair or injuries. Early session discontinuation due to discomfort was documented as part of VR sickness. In the PMS dataset, the outcomes were serious adverse events and VR sickness requiring medical intervention. The exposure was use

XSL•FO
RenderX

of the mediVR KAGURA system (single-exposure group); setting and typical exposure duration were the only contextual variables available, and no other covariates or potential confounders were recorded or adjusted for.

Data Collection

Data sources were company records and synchronized server-side logs, which were reviewed for user identification, session counts, and adverse event documentation. Data were extracted from the company records and server-side logs by a systems engineer employed by mediVR. For the primary cohort, meticulous documentation was maintained using high-sensitivity monitoring to capture even mild, transient symptoms of VR sickness (eg, slight dizziness) that did not require medical intervention. In contrast, PMS documentation, in accordance with regulatory standards for medical device manufacturers, specifically targets the reporting of serious adverse events and incidents necessitating medical intervention. Symptom ascertainment therefore differed between the 2 datasets.

Quality of Measurements

To enhance data quality, the number of unique users identified from company records was cross-referenced with synchronized server-side logs (see the Results section). Training and interrater reliability of data collectors were not formally assessed.

Instrumentation

The exposure instrument was the mediVR KAGURA system (see the Intervention and Engineering Principles section). No validated or ad hoc symptom questionnaire was used; VR sickness and adverse events were documented as binary clinical reports.

Masking

Masking was not applicable because there was no experimental manipulation or condition assignment. Outcome documentation was not masked.

Psychometrics

Psychometrics were not applicable. VR sickness was recorded as a binary clinical report rather than using a standardized scale, so no reliability or validity coefficients were estimated (see the Limitations section).

Data Diagnostics

All eligible records were extracted (complete data extraction). No records were excluded after data collection, and no data were missing for any analyzed variable. Therefore, no test of the missing data mechanism and no imputation were required or performed. Outlier handling and data transformations were not applicable to the count-based outcomes.

Analytic Strategy

Analyses were descriptive given the retrospective design and the expected rarity of events. The primary outcome was the incidence of VR sickness; secondary outcomes were other adverse events. No hypothesis tests, exploratory subgroup analyses, or adjusted analyses were planned or performed. Categorical outcomes were summarized as numbers and percentages with 95% CIs (Wilson score method for the primary cohort; exact binomial method for the PMS dataset, in which 0 events were observed); the 95% CI corresponded to a 2-sided α level of .05. Because all 7 engineering principles were applied simultaneously and uniformly to every user with no experimental variation of individual components, the dataset did not permit correlation, regression, or clustering analyses to isolate the contribution of individual design elements; this constraint is inherent to the real-world, nonexperimental nature of the data rather than an analytical omission. The statistical analyses were performed by YM and MH, who are affiliated with mediVR (see the Conflicts of Interest section). The analyses were therefore not performed by an independent third party. All data processing and statistical calculations were performed using the Microsoft R Open software (version 4.0.2).

Ethical Considerations

Ethics Review and Approval

The study protocol complied with the Declaration of Helsinki and was approved by the external institutional ethics committee of the Japan Society of Clinical Research (approval 202501; approved on January 8, 2025) as part of the RECOVER RECORD (Reprogramming Coordination Through Virtual Environment Rehabilitation: Real-World Evidence From Clinical Observations and Records) trial, registered in the University Hospital Medical Information Network Clinical Trials Registry (UMIN000056624) on January 8, 2025.

Informed Consent

Given the retrospective nature of the data and the use of anonymized records, the ethics committee waived the requirement for written informed consent. In accordance with this waiver, study information was publicly disclosed on the University Hospital Medical Information Network Clinical Trials Registry website and the website of the Japan Society of Clinical Research, providing users with an opportunity to decline inclusion of their data (opt out). No opt-out requests were received.

Privacy and Confidentiality

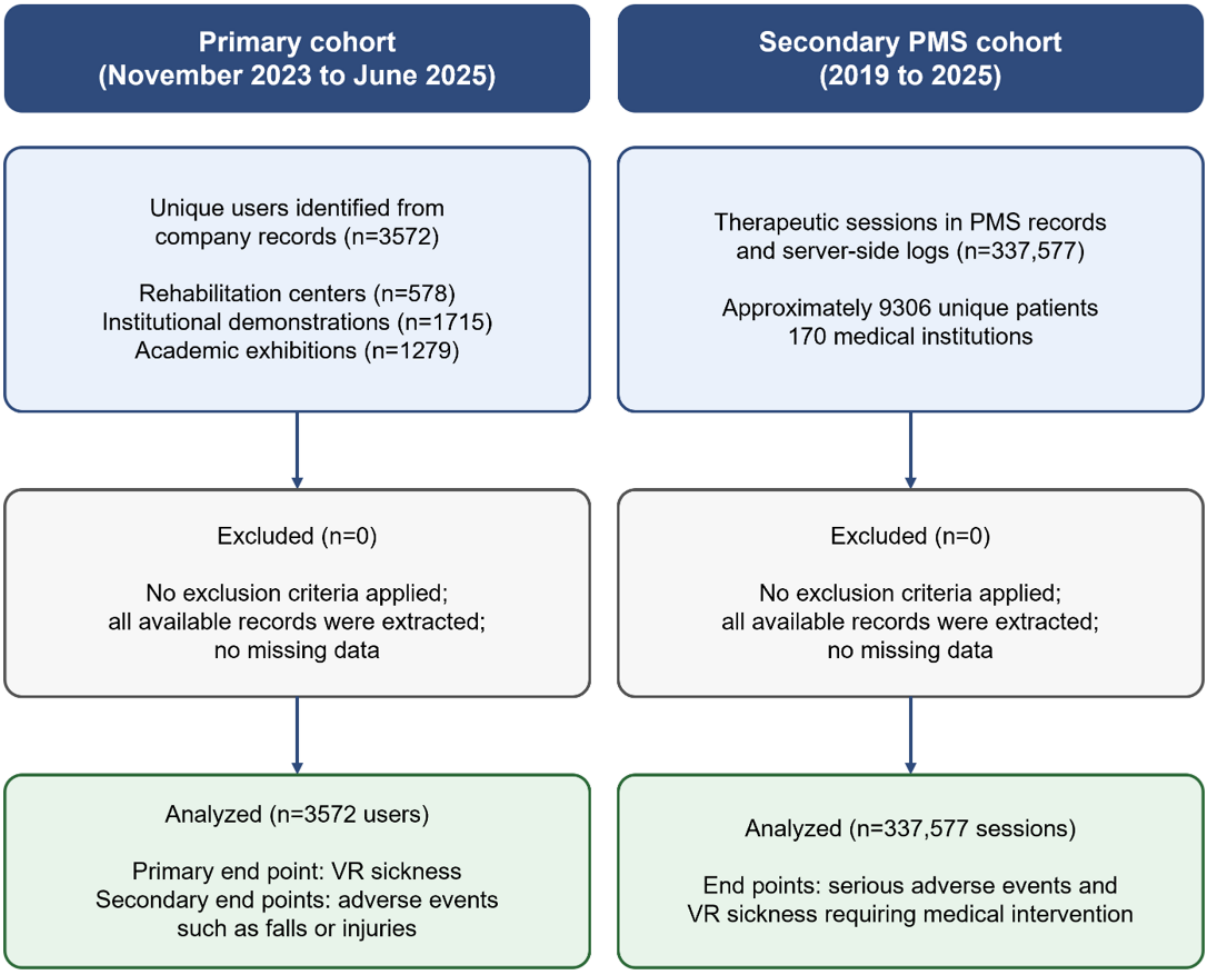
Anonymized records were used for the analysis, and no personally identifiable information is reported in this manuscript.

Compensation

No compensation was provided to participants because the study was a retrospective analysis of existing records.

Identifiable Images

This manuscript and its supplementary material contain no images that could identify individual participants.



Results

Participant Flow

Figure 3 shows the flow of users and records. All identified users and all recorded sessions were analyzed; no records were excluded, and no data were missing.

XSL•FO
RenderX

Figure 3. Flow of users and records in the primary cohort and the postmarketing surveillance (PMS) dataset. VR: virtual reality.

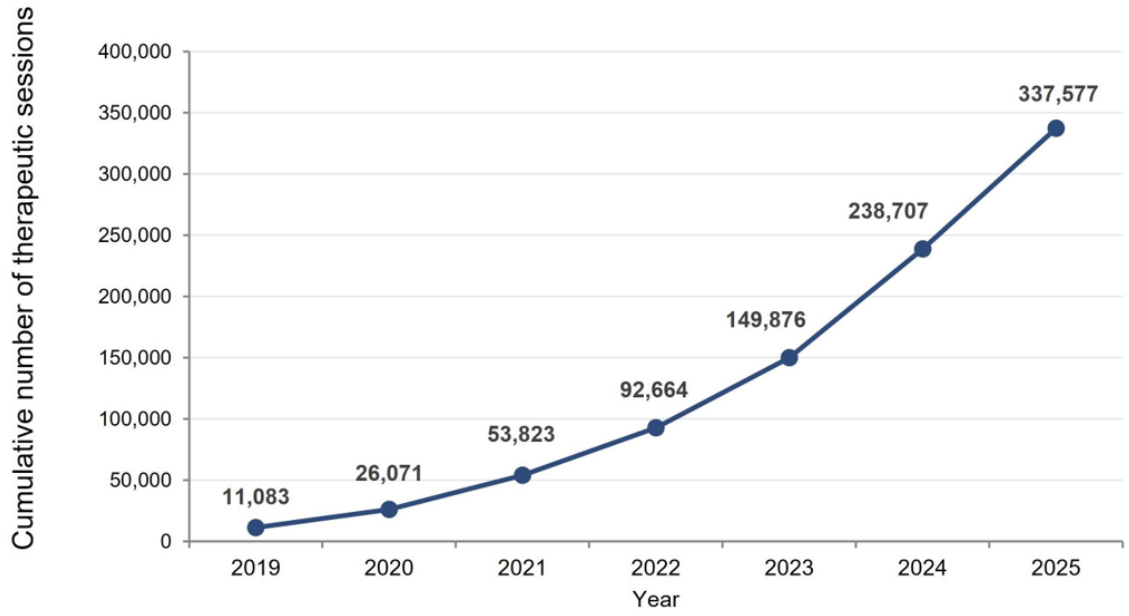
Recruitment

No recruitment was conducted. The primary cohort covers users recorded between November 2023 and June 2025, and the PMS dataset covers sessions recorded from 2019 to 2025.

Primary Cohort Analysis

A total of 3572 unique users were identified from company records between November 2023 and June 2025. This cohort included 16.2% (578/3572) at our rehabilitation centers, 48% (1715/3572) at institutional demonstrations, and 35.8% (1279/3572) at academic exhibitions. To validate this cohort size, we cross-referenced the data with server-side logs, which identified 3581 unique users over the same period. The 9 additional entries (0.25%) had names registered but no session data because the scheduled experience was canceled, supporting the reliability of our dataset.

Of 3572 users, 13 (0.36%; 95% CI 0.21%-0.62%) had a recorded event of mild VR sickness. The vast majority of these were mild, transient symptoms (eg, “felt slightly dizzy”) reported after the session concluded. Only 1 case (1/3572, 0.03%; 95% CI 0.005%-0.16%) resulted in the user stopping the session prematurely due to discomfort. No users required medical intervention, and all reported symptoms resolved spontaneously without sequelae. No secondary adverse events, such as falls from the chair or other injuries, were recorded during any session. Because all eligible records were analyzed, there were no missing outcome data.



Large-Scale Real-World Safety Record

Analysis of the cumulative PMS data from 2019 to 2025 revealed a rapid and consistent growth in clinical adoption (Figure 4). As of the end of 2025, the system reached a clinical footprint of approximately 9306 unique patients, accounting for a total volume of 337,577 therapeutic sessions conducted across 170 medical institutions.

Throughout these 337,577 sessions, no serious adverse events such as falls or physical injuries and no cases of VR sickness requiring medical intervention were reported (0%, exact 95% CI 0%-0.0011%). This does not exclude mild symptoms that were not reported in PMS documentation, and the denominator was sessions rather than patients.

XSL•FO
RenderX

Figure 4. Cumulative growth in total therapeutic session volume of somato-cognitive coordination therapy (SCCT). Exact values are shown at each data point.

Discussion

Principal Findings

In this large real-world study, recorded VR sickness during use of the purpose-built seated VR system was uncommon in the primary cohort, was mostly mild and transient when it occurred, and rarely led to early session discontinuation. A separate, much larger PMS dataset recorded no serious adverse events and no VR sickness requiring medical intervention. These descriptive findings address the study aims by documenting the feasibility and tolerability of the system in routine clinical and nonclinical exposure settings. They do not establish that the engineering features caused the observed tolerability because there was no control group and the features were applied together. Cybersickness incidence in the literature varies widely [6-9]. Because these studies differ from ours in populations, tasks, visual motion, exposure duration, and symptom assessment, they provide context only; they are not a statistical comparator and should not be read as evidence of a relative risk reduction.

Integrated Engineering Design for Clinical Application

The favorable tolerability of our system may be attributable to its foundational design philosophy: the simultaneous alignment of 7 engineering principles intended to limit sensory conflict or vergence-accommodation conflict [4-7]. Because these 7 principles were applied together and uniformly to every user, this dataset cannot quantify the specific contribution of each component or rank their relative importance. On the basis of the sensory conflict theory [4-7], we speculate that the static visual background (principle 1) may play a particularly important role as it directly addresses the visual-vestibular mismatch underlying vection-induced discomfort [13-15]; however, this remains an untested hypothesis that would require a future controlled, dismantling-style study to confirm.

In addition, we highlight 3 factors that we hypothesize may have contributed to our system's favorable tolerability, consistent with sensory conflict theory although not individually tested in this dataset. First, enhanced somatosensory input (principle 2), through a stable seated posture with continuous tactile feedback, plausibly provides a reliable physical frame, potentially reducing postural instability and reinforcing congruence between vestibular and somatosensory inputs; postural instability has been examined in relation to cybersickness in recent experimental work [13]. We deliberately integrated the seated position as an engineering element of the system rather than only as a clinical instruction, but whether it contributes to tolerability was not evaluated here. Second, predictive visual guidance and spatial mapping via the target radar (principle 3) introduces a high degree of anticipatory control, allowing users to proactively coordinate required head movements before visual targets enter the FOV. Because unexpected vection has been associated with cybersickness [13], we speculate that minimizing sensory surprise through anticipatory cues may reduce VR-induced discomfort, although this remains to be formally tested [6]. Third, as integrated visual orientation cues, the system provides a permanent, earth-fixed visual reference. This is implemented via an information bar in the upper central FOV working in tandem with a centrally located target radar, offering continuous orientation anchoring. While the target radar serves as the primary focal point at the exact center of the display, its lower boundary dynamically reflects head tilting and provides an intuitive cue for angular deviation, whereas the information bar immediately above it provides a constant, earth-fixed horizontal reference. Our system concentrates these stable orientation anchors within the user's core FOV; whether this affects the sense of presence or task engagement was not assessed in this study. By providing constant access to a level reference, this implementation is intended to help users interpret head tilt and spatial alignment relative to a stable environment. Visual rest-frame approaches

XSL•FO
RenderX

have been proposed as a mitigation strategy [15], and we speculate that a permanent, earth-fixed reference may play a similar role, although the information bar used here differs from the approach tested in the aforementioned work, and its effect was not evaluated. Together, these 3 factors illustrate one plausible route through which theoretical constructs can be translated into concrete, user-facing design elements; confirming their individual contribution, as noted above, would require future controlled, dismantling-style studies.

Clinical and Health System Implications

From a clinical perspective, the stabilization of spatial orientation may have implications beyond the mere prevention of VR sickness. By potentially reducing visual-vestibular sensory conflict, the system may support functional neural integration, which could be particularly relevant for patients with vestibular disorders such as persistent postural-perceptual dizziness, as suggested in a prior proof-of-concept report [18]. In such cases, our design may help attenuate visual hypersensitivity while providing the stable reference frames that could assist in reconstructing distorted spatial perception [18]. Furthermore, the noise-free sensorimotor signals provided by this integrated engineering design may plausibly serve as a substrate for neural plasticity. Unlike traditional task-oriented training, our approach emphasizes the generation and updating of internal body images through voluntary movements. The bilateral, alternating reaching tasks are hypothesized to facilitate cross-modal effects, potentially engaging neural networks that extend beyond simple motor execution [16,17]. In this context, a case-level report using diffusion tensor tractography has suggested that SCCT via this system may facilitate the reorganization of motor pathways following intracerebral hemorrhage [23], with reorganization observed involving not only the descending motor tracts but also transcallosal and cerebellar-cerebral connectivity; given the cerebellum's role in predictive motor control and the corpus callosum's function in interhemispheric integration, this observation is consistent with, though not proof of, a broader restructuring of the brain's internal motor models [23,24], which would require confirmation in larger, controlled samples. Finally, while experimental research often seeks to isolate single causal factors, the low frequency of recorded VR sickness in real-world settings is consistent with the pragmatic value of a multicomponent engineering approach. The accumulation of 337,577 clinical sessions without serious adverse events suggests that an integrated, digital polypill-like strategy—where multiple design elements are combined to address sensory conflicts—may be a promising model for future digital health and medical device development pending further validation.

Study Limitations

This study has several limitations that should be considered when interpreting the results. First, as noted in the Methods section, this was a single-arm, uncontrolled retrospective cohort study; it lacked a concurrent control group using conventional VR and, therefore, cannot support causal or comparative effectiveness claims regarding VR sickness rates. In addition, because all 7 principles were applied together, the contribution of individual design elements cannot be identified. Second, our assessment of VR sickness in the primary cohort and the PMS dataset relied on binary clinical reports, not a standardized, quantitative measure such as the SSQ [5,7]. Symptom ascertainment also differed between the 2 datasets, and the absence of reported serious or medically attended events in the PMS dataset does not exclude mild symptoms. It is possible that very mild, subclinical symptoms went unreported, and adverse effect reporting is known to vary across VR studies [10]. Future prospective protocols could incorporate repeated standardized symptom measures such as the SSQ or a more recently validated questionnaire [9,11] to capture subclinical or mild transient symptoms more precisely and should prospectively document exposure duration and clinical characteristics. Third, exposure duration varied by setting (typically 20-60 minutes at our rehabilitation centers and 5-10 minutes at demonstrations and exhibitions) and was not analyzed at the individual level; short exposures may not be long enough to induce sickness in all susceptible individuals. Fourth, the dataset lacked granular patient demographics such as precise age and gender distributions or detailed clinical profiles. This lack of patient background information precludes subgroup analyses to identify whether specific populations may be more susceptible to discomfort and precludes adjustment for covariates. In addition, the PMS dataset counts sessions rather than patients (approximately 9306 unique patients), so repeated sessions by the same patient are not independent observations. The exact CI assumes independence of sessions and should therefore be interpreted as approximate. Finally, all data were derived from a single specialized system and the device's developer, and participation reflected self-selection into clinical care, demonstrations, or exhibitions. This could introduce supervision or reporting bias and may not be directly generalizable to other VR hardware or software configurations that do not adhere to these specific multisensory design principles. Nevertheless, the scale of the PMS dataset (337,577 sessions) offers reassuring real-world context that should be interpreted alongside rather than as offsetting the methodological limitations mentioned above; prospective, controlled studies remain needed before broader claims about clinical adoption can be made.

Conclusions

This study provides real-world descriptive evidence that recorded VR sickness was uncommon and mostly mild during use of a purpose-built, seated VR rehabilitation system and that no serious adverse events or medically attended VR sickness were reported in a large PMS dataset. Its innovation lies in documenting an integrated multisensory design at scale in routine practice, whereas earlier work has largely tested individual design features in controlled settings. It thus adds real-world tolerability data on which clinicians, developers, and regulators can draw when considering immersive rehabilitation. The findings are descriptive and cannot establish that the engineering design caused the observed tolerability, attribute effects to individual features, or support comparison with other systems. In practice, they suggest that seated, visually stable, and predictable interface designs can be deployed safely at scale in clinical rehabilitation, and they motivate prospective controlled studies with standardized symptom measures to test

XSL•FO
RenderX

individual design elements and determine generalizability to other populations and VR systems.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Data Availability

Anonymized data that support the findings of this study are available from the corresponding author on reasonable request and subject to a formal data sharing agreement.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the Generative AI Delegation Taxonomy (2026), the following tasks were delegated to GenAI tools under full human supervision: text generation, proofreading and editing, and translation. The GenAI tools used were ChatGPT (GPT-6; OpenAI) and DeepL (DeepL SE). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. The authors reviewed the text and take full responsibility for the content of this manuscript.

Authors' Contributions

JD, BS, AG, KZ, ZF, DP, YM, MT, and MH provided substantial contributions to the conception or design of the study or the acquisition, analysis, or interpretation of the data; drafted the paper or revised it critically for important intellectual content; provided final approval of the version to be published; and agreed to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Conflicts of Interest

MH is the chief executive officer and a shareholder of mediVR. MT is an auditor and a shareholder of mediVR. YM is a director and holds stock in mediVR. mediVR holds 39 patents worldwide pertaining to the technology (mediVR KAGURA) evaluated in this study. All other authors declare no other conflicts of interest. mediVR develops and commercializes the mediVR KAGURA system evaluated in this study, and the analyzed data were derived from the company’s own records and server logs. The study protocol was approved by an external ethics committee (see the Ethical Considerations section), and the potential for reporting or interpretation bias arising from these affiliations is acknowledged in the Limitations section.

Abstract

Background: Computerized cognitive training (CCT) aims to mitigate cognitive decline in subjective cognitive decline (SCD) and mild cognitive impairment (MCI). However, adherence and long-term engagement remain challenging in remote CCT interventions.

Objective: Describe the development and design of the Bern Brain Training (BBT), a tablet-based app to remotely train cognitive functions and assess its feasibility, usability, and acceptability. This is a secondary analysis of a previously published randomized controlled trial (RCT).

Methods: Unity Game Engine and C# programming were used to design 16 games targeting episodic, semantic, and working memory, and spatial abilities. We assessed feasibility, usability, and acceptability of the BBT (50 sessions in 10 weeks, each 24 minutes) in 116 participants with subjective cognitive decline (SCD, n=89) or mild cognitive impairment (MCI, n=27). One session per week was played in-clinic in a group setting of 4 - 6 participants. Within the main RCT with parallel groups, participants were pseudo-randomized to one of three groups, with an allocation ratio of 1:1:1. The BBT was administered in all three treatment groups at different time points. Group 1 (n=36, 31%) started with the BBT (10 weeks); Group 2 (n=34, 29%) started with active control training (10 weeks), and then moved on to the BBT (10 weeks); Group 3 (n=46, 39%) started with the BBT (10 weeks) after a waiting period of 10 weeks.

Results: Feasibility was high (adherence rate: mean 5.10, SD 0.69 BBT sessions/week; weekly group sessions: mean 9.18 SD 1.05; concluded BBT sessions: 5891, 91%). On a 7-point Likert scale, participants showed high motivation across cognitive domains and training groups (mean 6.15, SD 1.05), and groups did not differ significantly in adherence (P>.05). Usability was good with 61 (0.94%) help button presses recorded across 6489 sessions played. Acceptability (7-point Likert scale) was satisfying in game experience ratings of entertainment (mean 5.43, SD 1.39), with low frustration rates (mean 3.01, SD 1.79), despite the BBT being perceived as challenging (mean 5.52, SD 1.22). The games were perceived as most efficient in training memory (mean 5.7, SD 1.20) and thinking abilities (mean 5.43, SD 1.18). SCD and MCI did not differ significantly in game experience and perceived game efficacy (P>.05).

Conclusions: The BBT demonstrated high feasibility, usability, and acceptability. Its innovation lies in the participatory and professional game design, task diversity, adaptivity, and social elements, with a large sample size that sets it apart from other studies. These findings advance the field by demonstrating that tablet-based, remote cognitive training is feasible and well accepted in older adults with cognitive impairment, emphasizing the importance of these parameters for high training adherence and supporting its potential integration into clinical practice. Future research should extend evaluation to care-home settings and populations with more advanced cognitive impairment.

Introduction

Nonpharmacological prevention and treatment options, such as computerized cognitive training (CCT), are vital in counteracting cognitive decline in neurodegenerative disorders. CCT is used to target cognitive functions typically affected in the course of subjective cognitive decline (SCD) and mild cognitive impairment (MCI), including episodic memory, spatial abilities, semantic memory, and executive functions [1,2]. Multidomain CCT appears to be particularly effective, with some studies reporting long-lasting cognitive improvements and far transfer effects to everyday functioning and activities of daily living in healthy older adults [3]. Positive effects of CCT on memory, executive functions, and activities of daily living have been shown in individuals with SCD [4], MCI [5], and Alzheimer disease (AD) [6,7].

Remote administration of CCT is an important avenue to follow given the rise in the adoption of digital technologies by older adults. Alone in the past few years, internet use in European adults between 65 - 74 years has risen from 57% in 2019 to 67% in 2022 [8]. In the United States, 79% of those 65 years and older report being internet users, and 44% are tablet owners [9]. We can leverage this shift in digital engagement to move towards home-based treatment options as technology becomes more pervasive and accessible. Remote administration of CCT (eg, using tablets and smartphones) offers advantages in terms of convenience and accessibility, allowing individuals to engage in training activities in their home settings. Remote administration enables longer training durations and higher frequency, while keeping costs low and facilitating the inclusion of underserved populations.

However, adherence and long-term engagement can be challenging, as some individuals may have difficulty using the technology or maintaining motivation over time. Several factors have been singled out as predictors of adherence: (1) Feasibility: familiarity with the device is vital for reaching high levels of adherence [10], which in turn results in larger benefits; (2) Adaptivity: tailoring the CCT to the needs of the population increases adherence, which can be further supported with rewards during the game [11]. CCTs developed for patient populations often offer a restricted set of games with unappealing designs and limited adaptivity, which can result in reduced motivation and adherence. Individually adapted levels of difficulty are important to maximize the efficacy of a CCT, as a “mismatch” between task demands and performance level is key to neuroplasticity [12]; (3) Quality: the motivation to repeatedly play a set of games demands an enjoyable game experience, which can be reduced by software issues or low-quality visuals [13]. Despite the growing number of remote and tablet-based CCT programs, several gaps remain in existing literature. Many programs are developed with limited public involvement of the intended end users, although participatory design may be particularly important for older adults and individuals with cognitive impairment to ensure usability, accessibility, and sustained engagement [14]. Furthermore, existing CCT studies often rely on relatively small samples and short training periods, limiting conclusions about feasibility and long-term adherence [15].

Building on these considerations, our objective was to develop and design the Bern Brain Training (BBT) app, a tablet-based CCT for individuals with SCD and MCI, and assess its feasibility, usability, and acceptability. The BBT was developed to address these gaps by involving end users in the co-design process, enabling independent home-based training with detailed instruction on a tablet with accessible touch interaction, adapting task difficulty to individual performance, and combining a variety of exercises that challenge multiple cognitive as well as visual functions. The BBT also draws on principles from commercial games to create a more enjoyable, motivating, and less clinical training experience while still targeting cognitive domains relevant to SCD and MCI. Here, we present the secondary analysis of a randomized controlled trial (RCT), for which the BBT was developed and the efficacy results published [16]. The BBT is designed to target key cognitive domains affected by age- and disease-related cognitive decline. Our objectives within this secondary analysis were to (1) evaluate the feasibility, usability, and acceptability across the study population from a 10-week daily training program [16,17] and (2) to assess participants’ perception of the app’s effectiveness in improving cognitive performance.

Methods

Eligibility Criteria and Randomization

Participants reporting SCD or with objective cognitive impairment were screened and categorized as SCD or MCI participants based on existing diagnosis from the Memory Clinic Bern or, if no established clinical diagnosis was available, on predefined Montreal Cognitive Assessment (MoCA) cutoff scores (SCD: MoCA>25, MCI: MoCA between 18 and 25). MoCA scores below 18, indicating dementia, were not included in the current analysis to avoid bias caused by stronger cognitive impairment. Participants were recruited in the larger Bern and Lucerne area from October 2020 until February 2023 (last follow-up in November 2023). Recruitment sources were the respective Memory Clinics and local newspapers. They were included according to the following criteria: (1) ability to give written informed consent, (2) aged 60 - 85 years, (3) native or fluent in German, (4) normal or corrected to normal vision and hearing, (5) ability to visit the study location, (6) MoCa >=18 [18]. Digital literacy was not an inclusion criterion. Exclusion criteria included substance abuse and severe medical conditions. The study adhered to the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Checklist 1 and 2), and participants were pseudorandomized to one of three study arms (training, active control, or waitlist group) based on a stratified Mahalanobis distribution. Stratification was based on cognitive impairment level (Cognitive Telephone Screening Instrument,

XSL•FO
RenderX

COGTEL [19]), age, and sex. The COGTEL was selected as the cognitive stratification factor due to its ability to provide a more comprehensive screening of memory and executive function compared to the MoCA. Pseudorandomization was chosen as it continuously adjusts probabilities to balance groups across stratification factors, ensuring well-matched baseline characteristics across study arms. By minimizing imbalances, it effectively reduces the risk of potentially confounding effects. Participants, investigators, and outcome assessors were blinded to group allocations. The first participant was enrolled on October 1, 2020.

Ethical Considerations

This concluded study was registered prospectively on July 1, 2020 (NCT04452864). The study was approved by the local Ethics Committees (Kantonale Ethikkommission für die Forschung, Kanton Bern; Ethikkommission Nordwest- und Zentralschweiz, ID: 2020‐00630) and was conducted in accordance with the Declaration of Helsinki. The methodology of the protocol follows the Standard Protocol Items: Recommendations for Interventional Trials (SPIRIT) guidelines. Written informed consent was obtained from all participants for the original study, and the ethics approval covers the present secondary analysis without requiring additional consent. All participant data were pseudonymized prior to analysis; no directly identifying information was retained in the study dataset. Participants received no financial compensation for their participation. No individuals are depicted nor can be identified in any images or Multimedia Appendices included in this manuscript.

Study Design

The study design is summarized here, while additional methodological details and outcomes of the standard RCT have been reported in [16]. The protocol and statistical analysis plan can be accessed (Checklist 3, Template for Intervention Description and Replication intervention description) [17]. The bicentric (Memory Clinics Bern and Lucerne) RCT with parallel groups included 3 study arms (BBT, active control, and waitlist group). In total, we assessed 116 participants with SCD (n=89) or MCI (n=27). All participants received an Apple iPad and played with the BBT daily for 10 weeks (50 sessions, each 24 minutes, playing 3 games), including weekly in-clinic group sessions. Four sessions per week were played at home, and one session was played in the weekly group sessions (4‐6 participants). Participants were moreover allowed to play an additional bonus session per week (which results in max. 6 sessions/week). The intervention group started with the BBT immediately, the waitlist group started with a delay of 10 weeks, and the active control group first underwent 10 weeks of active control training (unspecific cognitive activity) before subsequently starting the BBT [16,17].

In the weekly group sessions, participants played the training session of the day with new games being introduced gradually. Two games were available immediately within the first week, with 2 new games being added every subsequent week. The in-person group sessions were led by neuropsychologists and research assistants and served the purpose of increasing adherence due to the social aspect and interactions, and as a possibility to discuss technical issues and BBT-related challenges experienced during the previous week. This was complemented by feedback from the game experience questionnaires (paper-pencil). At home, the participants were encouraged to play on their own and had the option to press the help button for immediate technical support whenever needed. The active control group followed the same intervention matched for duration and frequency, but watched documentaries (24 minutes per session, 4 times a week) instead of playing the BBT. Documentaries were accessed within the BBT app using the same devices later employed for the BBT intervention. In weekly on-site group sessions, active control participants discussed documentary content, resolved technical issues, completed paper-pencil feedback questionnaires, and engaged in noncognitively demanding games, such as slow-speed Bingo, to maintain engagement without specific cognitive training. These activities ensured comparable social interaction and attentional engagement across groups, isolating the specific effects of the cognitive training intervention.

The inclusion of a waitlist control group allowed for the evaluation of natural changes over time (eg, practice effects or cognitive changes unrelated to the intervention), while staggering the intervention optimized resource allocation. Ethically, providing the BBT to all participants was essential, as it was hypothesized to have positive effects on cognition.

Before and after the intervention, participants underwent a comprehensive neuropsychological assessment including the MoCA for general cognitive abilities, the Auditory Verbal Learning Test (AVLT) assessing episodic memory [20], verbal fluency, semantic memory (Graded Naming Test [21]), visuospatial skills (Rey-Osterrieth Complex Figure Test [22]), and short-term and working memory (digit span test forward and backward) [16].

Before each session, participants were asked to rate their current well-being and training motivation. After each session, they rated their play performance (7-point Likert scale and in-game questionnaires, Multimedia Appendix 1). After 10 weeks, participants reported on their “subjective improvement in cognition” and the likelihood of “recommending the BBT to a friend” (9-point Likert scale; Multimedia Appendix 1, Checklist 2). Furthermore, we assessed the “desired training duration” (Multimedia Appendix 1) and recorded the number of help button presses and possible side effects. Game experience (frustrating, difficult, entertaining, challenging, and motivating) and perceived game efficacy (vision, everyday activities, multitasking, hand-eye coordination, reaction time, thinking abilities, and memory) questionnaires were completed one week after game introduction using a 7-point Likert scale (Multimedia Appendix 1).

The BBT App

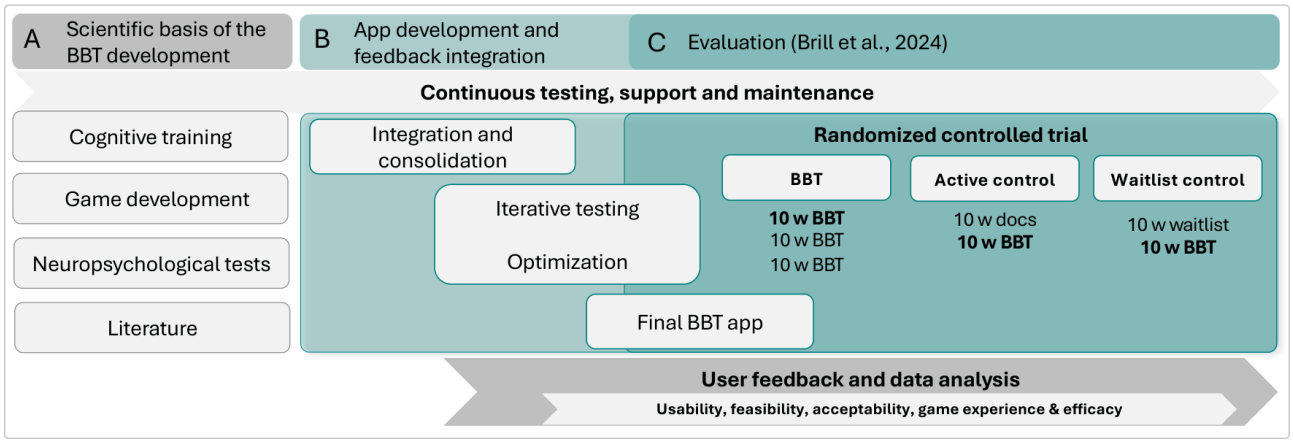
The BBT (Table 1 and Multimedia Appendix 2) targets cognitive functions affected early in the course of cognitive decline (episodic memory, spatial abilities, semantic memory, and working memory). The inclusion of games to train working memory is thought to increase the likelihood of transfer of training benefits to untrained domains [23]. Four adaptive games were designed for the identified cognitive domains, resulting

XSL•FO
RenderX

in 16 games. The app is tablet-based, and the games were played in a pseudorandomized order in each session, ensuring sufficient variability of trained domains and equal training durations of all games across the study population.

Table . Game descriptions of the 16 BBT[a] games per cognitive domain trained (episodic memory, spatial abilities, semantic memory, and working memory). Pictures for the Famous Faces game came from (copyright free) [24]; pictures for the "What's my name?" game were computer-generated faces from the "This person does not exist" website [25].

Domain and BBT game	Description
Episodic memory	
Shopping basket	Remember groceries presented on a belt. Inspired by [26].
Billboards	Remember the sequence of billboards. Inspired by [27].
What's my name?	Learn and remember face-name associations. Based on [28,29].
Artificial language learning	Learn Elvish vocabulary.
Semantic Memory	
Word grid	Find the name of a displayed object in a letter grid. Inspired by naming tasks (eg, [30]).
Pun game	Find a picture and a word that form a word pair.
Famous faces	Answer the question who the famous person in the picture is.
Wheel of Fortune	Participate in a game show and guess the correct word or phrase.
Spatial abilities	
Mental map	Move the animal to the correct position in a grid according to a reference object after movements along 3 axes.
Magic camera	Select the correct picture of a table that a camera would make. Inspired by [27].
Mansion	Navigate through a mansion and remember where you found the keys. Inspired by [31].
Wine cellar	Walk through a cellar and find your avatar after being shown the way. Based on [31].
Working memory	
Memory bears	Remember the sequence in which the bears were glowing and tap on them in reverse order. Based on the Corsi block backwards test [32].
Animal park	While indicating the orientation of several animals, their sequence and position have to be learned. Based on [33].
Safari	Take a picture of an animal according to the current n-back condition. Inspired by [34].
Quiz game	Answer quiz questions and remember the sequence of answers. Inspired by [28].



[a]BBT: Bern Brain Training.

Contributors and Development Background

The BBT was designed for a multicenter study [17]. The development started in 2019 with the first set of games finished by December 2020 and final versions by February 2022. A multidisciplinary panel with experience in neuropsychology and old age psychiatry, including neuropsychologists, psychologists, a game programmer, an occupational therapist, and a psychiatrist, selected and designed the games based on their experience and existing literature in regular meetings. The design was furthermore guided by input from experts in the field and participants, which is key to maximizing feasibility, usability, and acceptability [35]. For some games, cooperations allowed us to build on previous work. Pilot versions served to refine and optimize the gameplay experience and were presented to healthy older adults and to patients from the in-house memory training groups in Bern and Lucerne. In addition, feedback was given weekly by participants, leading to intermediate game versions. The feedback covered game experience in general, appropriateness of difficulty levels and adaptivity, usability (eg, speech recognition), and the presence of software bugs. This allowed us to integrate feedback from all potential end users and to improve the app continuously during an iterative process. The BBT was designed to allow translations to other languages with little effort. The development and study pipeline is depicted in Figure 1.

XSL•FO
RenderX

Figure 1. Development and evaluation of the Bern Brain Training (BBT). Development phase A: first phase of BBT development based on scientific evidence; development phase B: iterative optimization process of the BBT development, including feedback integration from public involvement. The app development was finalized during the first part of the randomized controlled trial; evaluation phase C: effectiveness was evaluated in three randomized groups (reported in [16]). Usability, feasibility, acceptability, and user experiences were investigated in a secondary analysis across the 3 treatment groups, as all groups played the BBT at different time points. The first group started with the BBT (BBT only), the second group started with active control training (10 weeks) and then moved on to the BBT (active control and BBT), and the third group started with the BBT after a waiting period of 10 weeks (waitlist control and BBT) [16]. BBT: Bern Brain Training.

App Development

The BBT app was developed for the iPad using the Unity game engine version 2021.3 (Unity Software Inc) and coded in C# using Visual Studio (Microsoft). Art and music assets used within the app have come from a variety of places, including the Unity Asset Store (Synty Studios). Pictures for the Famous Faces game came from [24] (copyright free); pictures for the What's my name? game were computer-generated faces from the This person doesn't exist website [25] (copyright free). Procreate (Savage Interactive), Photoshop (Adobe Inc.), and Blender (Blender Foundation) were used to create several in-app assets. To track adherence in real time, we used an API call to a Google Form, which updated information on which games were played on which devices. In case adherence was not met (less than 3 sessions per week), participants were contacted by the investigator via calls or reminder emails. To improve access to the data, as well as control certain features remotely, a secure API to an in-house server was developed to track and record data in real time from participants' devices.

Setup and Sessions

A password-protected intuitive interface was developed where a pseudonymous ID and start date can be entered, and a "Pod ID" for keeping track of groups of participants. Games are depicted as islands on a map-styled menu on the home screen, with the 3 games to be played in the current session being highlighted, while the other games are hidden in the mist (Figure S1 in Multimedia Appendix 2). The player selects an avatar at the start of the training, which travels on a boat to the selected game island and is included in visuals throughout the games.

Distribution of the games was predefined as a cyclical sequence to balance game distribution and reduce confounding effects on training outcomes from the order or timing of game rollout. Difficulty of the games adapted to individual participant performance. This adaptivity varied from game to game based on the challenges specific to each game as well as user feedback. In general, it would require 2 wins in a row to advance in difficulty, and one loss to fall back, thus resulting in an equilibrium of difficulty with a higher win ratio for motivation. On completing a session, the participants unlock a shared puzzle piece, which corresponds to their color within their pod. This enables them to get feedback and see their pod members completing games in a collaborative way.

Guest Account

Each iPad also included a guest account. This was designed to allow participants to allow friends and family members to experience the games without affecting the play time, scores, or difficulty levels of the main account. Guest accounts allow for all games available to the participant to be played in an unlocked fashion.

Assisted Help Features

From within the main menu, participants could tap a "Help" button, which sent an email to the instructors, who would then get in contact with the participants for support. This allows for easy and fast access to technical support or help with game instructions. A teleconferencing button opens the teleconferencing app Zoom (Zoom Communications, Inc) with a predefined meeting room for extra support. The Zoom feature was added specifically to deal with the challenges imposed by the COVID-19 pandemic.

In-Game Data Collection

In-game data collection can be broken down into several components: (1) Real-time adherence data includes a limited amount of data that is uploaded to a Google Form to tell us which games were being played on which devices. This is useful for tracking adherence. (2) Debug data was recorded to store limited data to aid in debugging issues with the devices and the app, which enabled us to provide quick and remote fixes and solutions. Debug data is stored locally on the device, as well as emailed in a limited capacity to the app developer. (3) Profile data tracked an overview of the user's progress. Profile data is used by the app to control sessions and difficulty levels of each game, and a snapshot of the profile is recorded at the end of

XSL•FO
RenderX

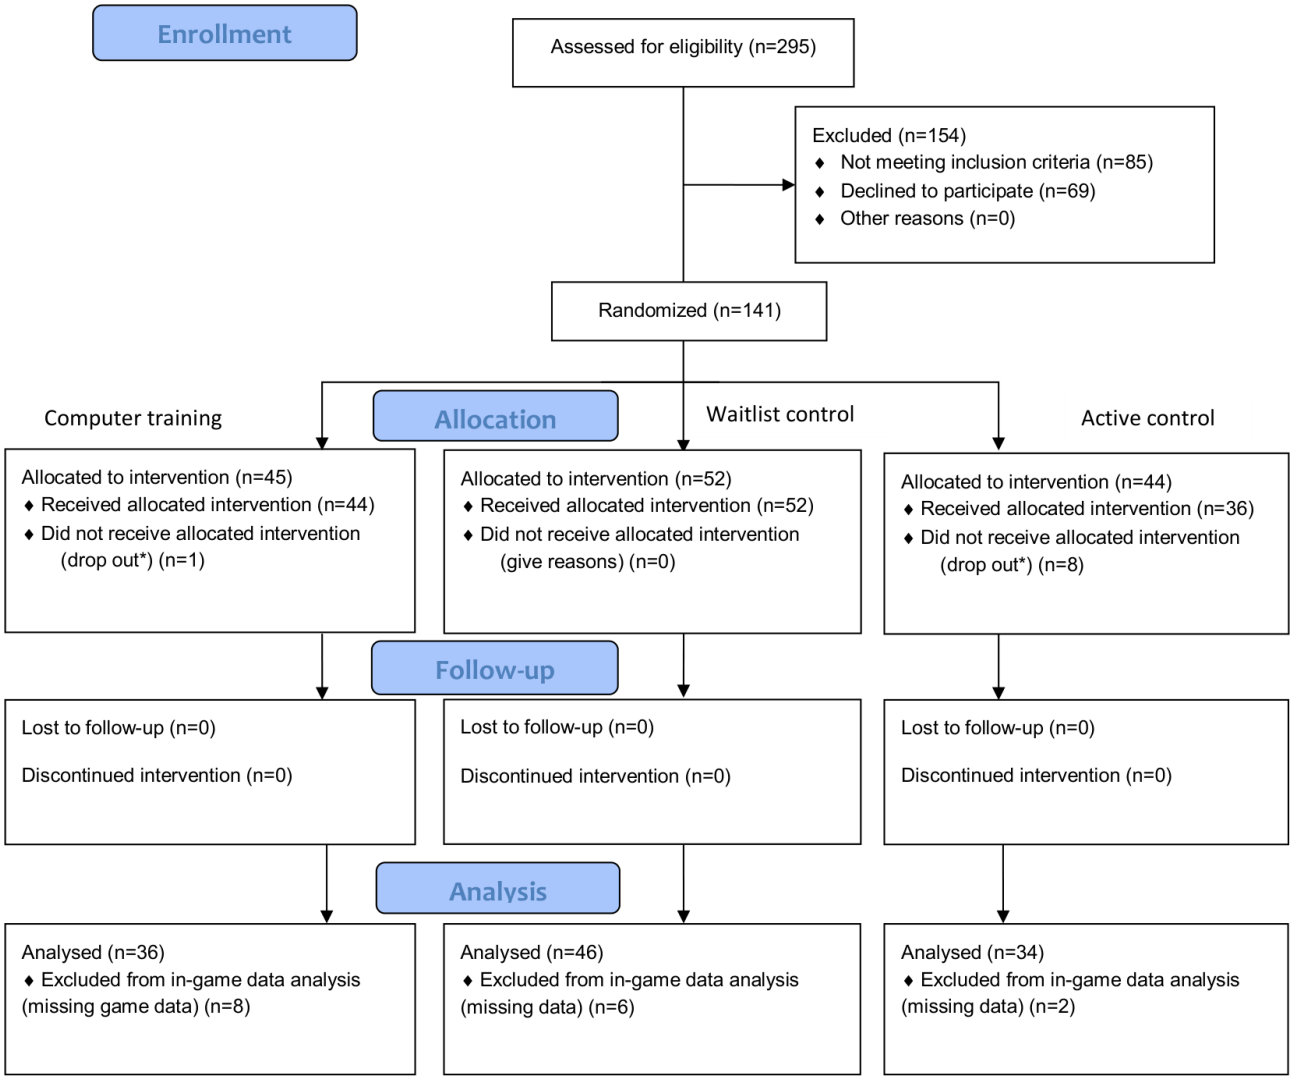
each round played in any game as a useful reference. (4) Unique game data is a game-specific data output file, which contains a unique set of rules and values, as well as the outcome of each round, so that conclusions can be drawn specific to each game's unique play style. Profile and unique game data are both stored physically on the device for retrieval at the end. To maintain control and flexibility of the app on each device remotely, a mobile device management tool was installed on each iPad. One major limitation is that iPads need to be collected for manual data removal at the end, and lost or damaged iPads could result in lost data.

Data Protection

Detailed performance data and debug logs are stored locally on the device and need to be manually extracted by plugging the tablet into a computer. A limited subset of adherence is stored online for the use of tracking whether patients are completing their tasks and to allow clinicians to follow up on missed sessions. A limited amount of debug data was emailed to a chosen email account to aid in bug fixes and support; however, this feature can be disabled. This ensures that important data is closed off from outside vectors, while basic information is still available to allow for limited support.

Data Analysis

The data were analyzed using the statistical program R Studio (Posit PBC) v2023.3.0.386. Descriptive statistics on demographic details, feasibility, and acceptability are reported. The primary interest was to analyze data across the three treatment groups, for which we performed one-way ANOVAs. As an exploratory analysis to examine differences between groups in in-game ratings over the course of training, we fitted separate linear mixed models for play performance, motivation, and well-being (7-point Likert scales), with group (BBT, waitlist, and active control), session number, and their interaction as fixed effects, and a random intercept for participant to account for repeated measurements. Models were estimated using restricted maximum likelihood, and *P* values for fixed effects were obtained using the Satterthwaite approximation for degrees of freedom. Further ANOVAs across all treatment groups were performed to elucidate the differences between the trained cognitive domains in terms of game experience (frustrating, difficult, entertaining, challenging, and motivating) and perceived game efficacy (vision, everyday activities, multitasking, hand-eye coordination, reaction time, thinking abilities, and memory) as dependent variables and the games as independent variables. Additional ANOVAs were performed to assess treatment group differences in game experience and perceived game efficacy. Tukey Honestly Significant Difference post hoc tests were performed as follow-up analyses. We furthermore investigated possible differences between SCD and MCI participants using *t* tests. To examine differences in game experience and perceived game efficacy ratings by sex, educational level, and socioeconomic status (SES), independent-samples *t* tests were conducted for each trained cognitive domain×rating combination. Sex (male vs female), education (median split into low vs high), and SES (median split into low vs high) were used as grouping variables. To control for multiple comparisons, Bonferroni-adjusted *P* values were calculated. Given that data were missing completely at random (MCAR, $P>.05$), we handled missing data using multiple imputation (m=20) via predictive mean matching, with group, session, and game included as auxiliary predictors. All estimates were pooled across the 20 imputed datasets following Rubin rules.



Results

Overview

In total, 132 datasets were available for analysis. Due to incomplete data resulting from technical issues (eg, data transmission errors, incomplete or faulty data storage), 16 datasets had to be excluded from further analysis (Figure 2). The technical issues did not impact training delivery and were backend-related and therefore did not interfere with players' game experience. Of the remaining 116 participants, 99 were tested in Bern and 17 in Lucerne. Groups did not differ in demographics (age, gender, and years of education) or depression ratings (all $P>.05$). SES was measured using the Swiss neighbor index of socioeconomic position (Swiss-SEP) 3.0 dataset from the Swiss National Cohort database. This postal code-based index is derived from the 2000 census and the 2012 - 2015 structural survey and is categorized into deciles. Table 2 depicts participants' ratings per study arm.

[g]GDSS: Geriatric Depression Scale Short.

[h]SES: Socioeconomic Status.

[i]MoCA: Montreal Cognitive Assessment.

Feasibility and Usability

Dropout was defined as discontinuation of the intervention. Once the BBT interval began, there were no dropouts in any of the three groups. We therefore did not have any participant-level missing data. As no participants dropped out once the BBT interval began, the analyzed sample is equivalent to the full randomized sample for the intervention period, rendering a separate intention-to-treat analysis unnecessary. However, during the control intervals before the BBT, 9 (6.82%) participants dropped out due to personal (n=5, 3.79%) and health-related (n=4, 3.03%) reasons [16]. Adherence to the training protocol was high across groups, with a mean of 5.10 (SD 0.69) out of 5 required and 6 possible sessions played per week and 9.18 (SD 1.05) weekly group sessions attended. Most common reasons for item-level missing data (game experience

XSL•FO
RenderX

and perceived game efficacy questionnaire) were due to not attending weekly group sessions or missing individual training sessions at home on grounds of ill health, holidays, and special occasions (Table 3). In-game item-level missing data (game performance, in-game questionnaires on daily motivation, well-being, and play performance; n=16) were related to technical issues. There were no significant (P<.05) group differences in adherence (Table 2). Out of the 6489 sessions registered in total, 598 (9%) ended prematurely (before the 24-minute cutoff), which was mainly due to environmental distractions according to participants' feedback in the weekly group sessions. A total of 61 help button presses (0.94% of all sessions) were documented, which were mainly initiated by participants to test the functionality rather than seeking actual assistance. Among the help requests that were related to specific issues, the majority pertained to nontraining-specific functionalities, such as the use of avatars, feedback mechanisms, or the guest account.

Table . Game experience and perceived game efficacy ratings across all three treatment groups undergoing BBT[a] (BBT only; waitlist control and BBT; active control and BBT)[b].

Domains and subdomains	Missing, n (%)	All games, mean (SD)	Working memory, mean (SD)	Episodic memory, mean (SD)	Spatial abilities, mean (SD)	Semantic memory, mean (SD)	*P* value	*F* test (*df*)	η^2_p[c]

[a]BBT: Bern Brain Training.

[b]Means, SDs per cognitive domain and across all domains (all games), and one-way ANOVAs in game experience and perceived game efficacy per cognitive domain (7-point Likert scale) are reported. Missing data (n=1005, 6.31%) refers to a total of N=15,916 item-level entries over all game experience and game efficacy ratings.

[c]η^2_p: Partial eta squared.

Acceptability

In-Game Ratings of Motivation, Well-Being, and Play Performance

In an exploratory analysis, we compared in-game ratings of the groups over the course of training in play performance, motivation, and well-being (Table S3 in Multimedia Appendix 3). At baseline, groups did not differ in self-rated play performance, well-being, or motivation. For play performance, participants in the BBT group showed a significant increase over sessions (b=.010, 95% CI 0.01-0.01; P<.001), while the waitlist group improved significantly less over time (b=-.010, 95% CI –0.01 to –0.00; P<.001). The active control group did not differ significantly from the BBT group (b=–.005, 95% CI –0.01 to 0.01; P=.09). For well-being, no significant session effect was observed in the BBT group (b=–.001, 95% CI –0.01 to 0.00; P=.14) and the waitlist group had a similar trajectory (b=.001, 95% CI –0.01 to 0.01; P=.66), while the active control group showed a significant decline relative to BBT (b=–.005, 95% CI –0.01 to –0.01; P=.001). For motivation, the BBT group also remained stable over sessions (b=–.001, 95% CI –0.01 to 0.01; P=.36), the waitlist group showed a significant increase compared to the BBT group (b=.003, 95% CI 0.01-0.01; P=.02), and the active control group showed a nonsignificant trend toward decline (b=–.003, 95% CI –0.01 to 0.00; P=.07).

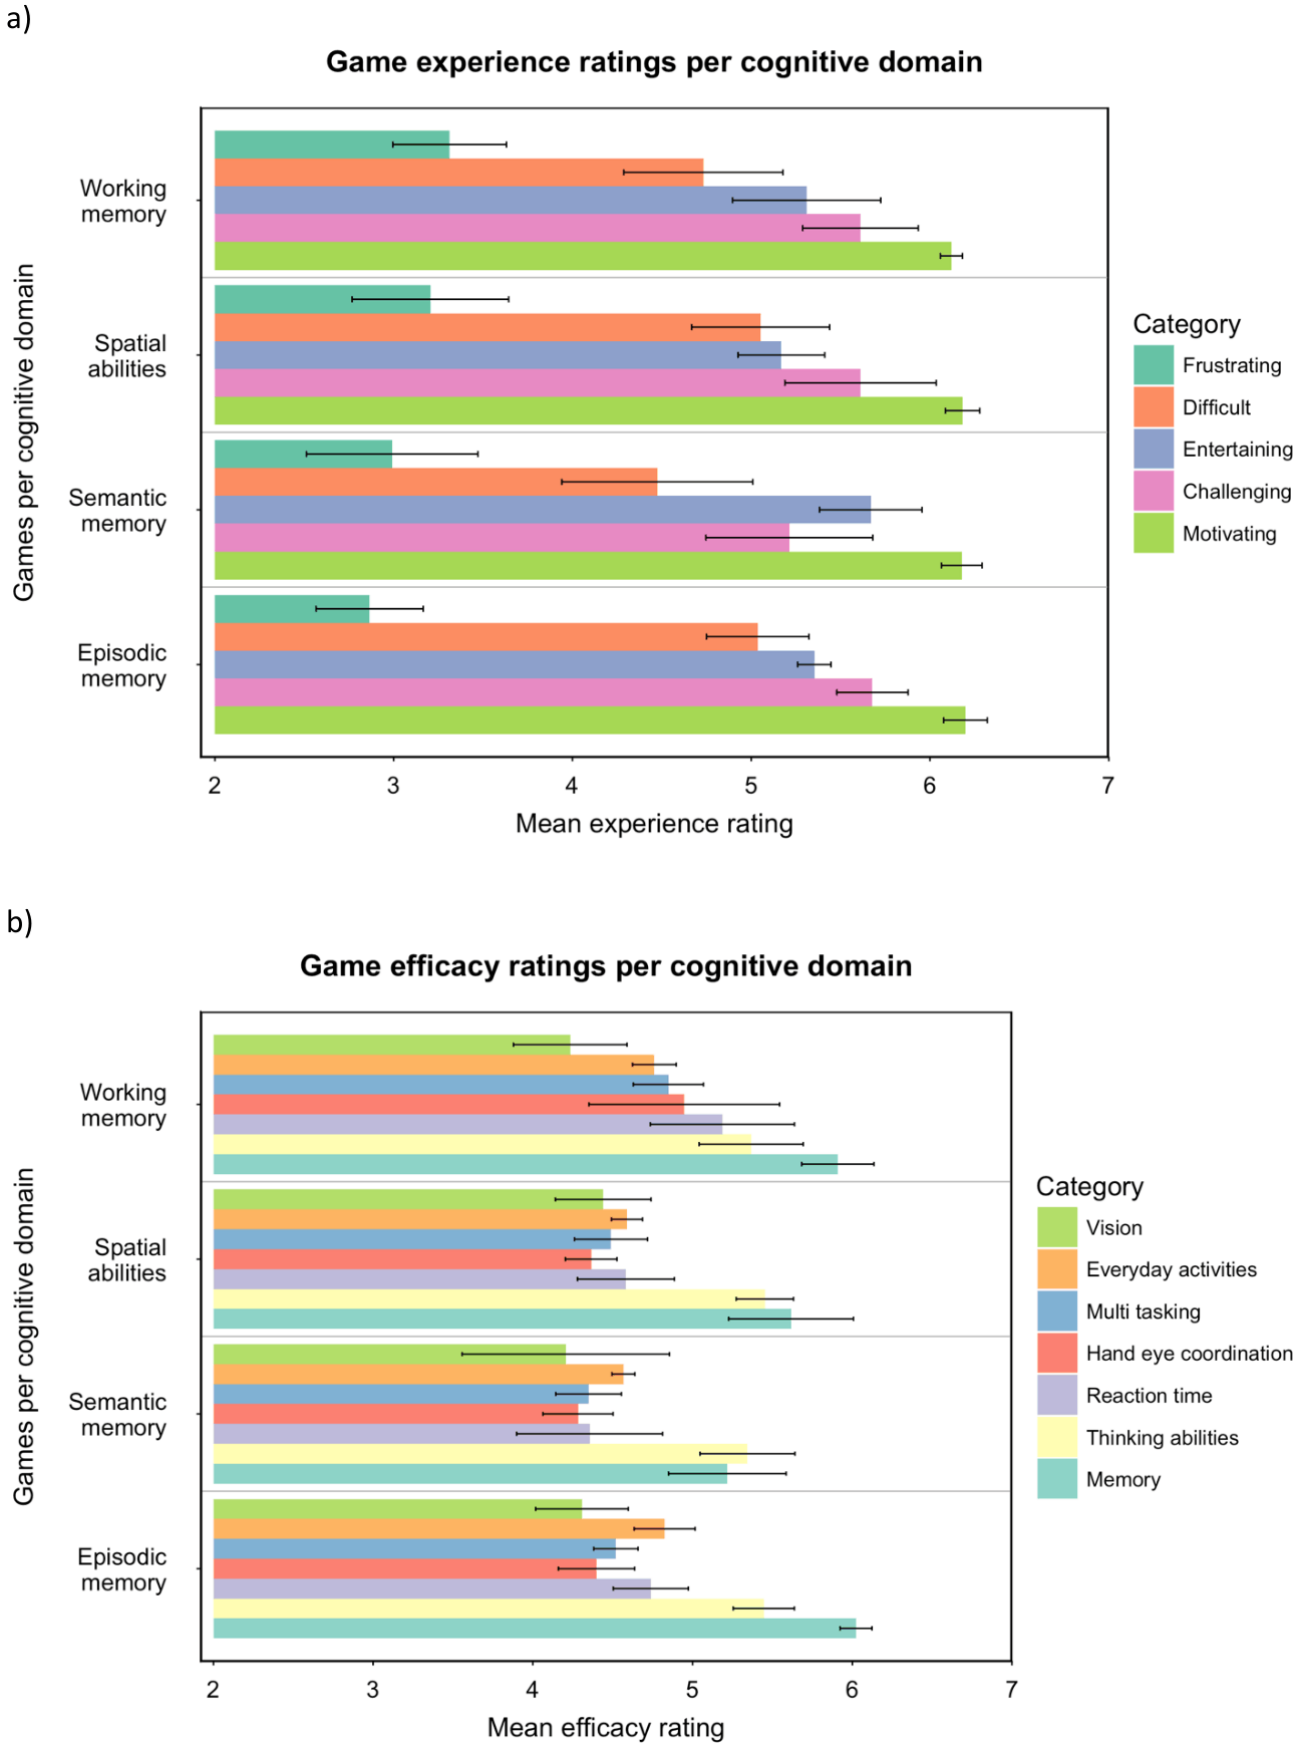
XSL•FO
RenderX

Questionnaire Ratings of Subjective Cognitive Improvement, Recommendation, Training Duration, and Side Effects

After 10 weeks of training, participants rated their subjective cognitive improvements at 4.86 (SD 1.64), and their likelihood of recommending the training to a friend was 6.82 (SD 1.68; 9-point Likert scales). The desired training duration was 28.9 minutes (SD 10.21), which exceeded the required 24-minute training duration. ANOVAs revealed no statistically significant differences between groups (Table 2). No side effects were reported.

Subanalysis of SCD and MCI

t test analyses between SCD and MCI participants showed no significant differences in measures regarding the intervention protocol and training compliance (attendance, adherence, recommendation, cognitive improvement, and ideal training duration). There was no significant difference in game-reported motivation before training (P=.58), well-being (P=.34), nor posttraining self-reported performance (P=.17). Analysis revealed no significant difference between SCD and MCI in terms of game experience and perceived game efficacy (for all ratings P>.05); therefore, the subsequent analyses do not distinguish between the 2 subpopulations.



Questionnaire Ratings of Game Experience and Perceived Game Efficacy

Missing data (n=1005 out of 15,916 item-level ratings, 6.3%) were handled using multiple imputation (m 20) via predictive mean matching, with group, session, and game included as auxiliary predictors. All estimates were pooled across the 20 imputed datasets following Rubin rules. On average, participants showed very high motivation across cognitive domains and training groups (mean 6.17, SD 0.95). ANOVAs revealed significant main effects in rating game experience as difficult ($F_{3,\ 301}$=5.52, η^2=0.03; P<.001), challenging ($F_{3,\ 301}$=7.32, η^2=0.03), and entertaining ($F_{3,\ 301}$=7.67, η^2=0.06; P<.001). Post hoc tests showed that semantic memory games were rated as significantly less difficult than spatial abilities (P=.003) and episodic memory (P<.001) games. Importantly, on average, none of the games was rated as excessively difficult or easy (mean 4.82, SD 1.33). In line with the difficulty levels, semantic memory games were rated as significantly less challenging than episodic (P<.001) and working memory games (P=.049), while being perceived as significantly more entertaining than spatial abilities games (P=.047). Frustration ratings were, on average, relatively low across all cognitive domains (mean 3.06, SD 1.80). All other post hoc tests did not show significant results (Table 3 and Figure 3A).

Perceived game efficacy (Table 3 and Figure 3B) indicated that games were perceived as most efficient in training memory (mean 5.69, SD 1.23) and thinking abilities (mean 5.38, SD 1.26). ANOVAs yielded significant main effects in training memory ($F_{3,\ 301}$=5.67, η^2=0.06; P=.001), reaction time ($F_{3,\ 301}$=5.91, η^2=0.04; P<.001), and hand-eye coordination ($F_{3,\ 301}$=4.17, η^2=0.03; P=.006). Post hoc tests revealed that, for perceived memory improvement, episodic memory games were rated as significantly more effective than semantic (P<.001), while working memory games outperformed semantic memory games (P=.008). For perceived reaction time improvement, working memory games were rated significantly more effective than semantic (P<.001) and spatial abilities games (P=.045). Regarding perceived improvement in hand-eye coordination, working memory games were regarded as more effective than semantic (P=.02), episodic (P<.001) memory games, and spatial abilities games (P=.005). All other post hoc tests did not show significant results. A comprehensive overview of each individual game is given in Table S2 in Multimedia Appendix 3. Groups did not differ in game efficacy ratings (Table S1 in Multimedia Appendix 3). Notably, however, the active control group experienced several training domains as less difficult, less challenging, and less effective than the other groups (Table S1 in Multimedia Appendix 3).

Subanalysis of Education, Sex, and SES

Independent samples *t* tests revealed no statistically significant differences between sex across any trained cognitive domain×rating combinations after Bonferroni correction ($P>.05$). Likewise, no significant differences were observed between participants with low versus high education levels nor between participants with low versus high SES.

Discussion

Overview

Remote CCTs provide a promising line of nonpharmacological treatment in cognitive decline [15,36]. We successfully developed the BBT, a tablet-based cognitive training app to train cognitive functions affected in SCD and MCI, through a user-centered co-design process and programmed by a professional game designer. The present findings originate from a secondary analysis of an RCT [17], in which the BBT was developed and initially evaluated. Our objectives were to (1) evaluate the feasibility, usability, and acceptability across the study population from a 10-week daily training program [16,17], and (2) to assess participants' perception of the app's effectiveness in improving cognitive performance. Feasibility was high, as reflected by strong adherence to both at-home training sessions and weekly group sessions. Participants demonstrated high motivation across cognitive domains and training groups, with no significant group differences in adherence. Usability was good, evidenced by the low number of help-button presses recorded across thousands of completed training sessions. Acceptability was also favorable, with participants reporting an entertaining game experience and low levels of frustration despite perceiving the BBT as challenging. The games were considered particularly effective for training "memory" and "thinking abilities." Finally, participants with SCD and MCI did not differ significantly in their ratings of game experience or perceived training efficacy.

Game Development and Design

Our design process was guided by expert input from relevant stakeholders (participants, patients, clinicians, and researchers) and programmed by a game designer. We put an emphasis on game diversity and individual adaptivity [12], while providing a rewarding, visually attractive, and demanding game environment [11,13]. The design and intervention environment, including ample time to familiarize with the app and the device, promotes adherence across an extended period of time [37], for which feasibility, support, and adaptivity are crucial [10,11]. Our results confirm our design efforts and show high feasibility, usability, and acceptability.

Feasibility and Usability

During the BBT interval, adherence was exceptionally high without dropouts and high attendance rates. This level of engagement is notable given that adherence to similar protocols and populations is often substantially lower: In the cognitive training element (max. n=144 sessions) of the large-scale Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) study [38], only 63% of participants (398/631) engaged at least once, 20% (126/631) completed at least half of the sessions, and merely 12% (76/631) completed the full training protocol. Further, in SCD populations, a web-based memory strategy program achieved an adherence rate of 50.6% (158/312) over 8 weeks [39], despite high satisfaction among completers (150/154, 97.4% of completers would recommend the training). Adherence in populations with MCI is inconsistently reported [15,40], but available meta-analytic evidence suggests that sustained engagement remains a key challenge across studies [41]. Against this backdrop, the near-complete adherence observed in the present study underscores the feasibility of the intervention and suggests that specific design features (eg, adaptive difficulty levels, weekly in-person meetings, large game selection, and appealing game design) may have been critical in supporting engagement. Moreover, older individuals and people with memory impairments may be more likely to adhere to CCT given heightened intrinsic motivation [11]. Technical support was provided via an integrated help button and in weekly in-clinic meetings. This socially stimulating group setting was further promoted by including social and multiplayer elements in the game design with the intent to enhance participant engagement and motivation [42]. Research suggests that incorporating social interaction into cognitive training programs for older adults can contribute to improved learning outcomes and promote cognitive health [43]. The importance of social interaction and continuous support is also underlined by the fact that the adherence rate was equally high in the active control group. The identical app framework was employed for the active control training, with the documentaries integrated into the same thematic landscape of virtual islands as the BBT games. Finally, the lack of observed differences between sex, education, and SES groups indicates that the BBT games provide a consistent experience across participants, suggesting their applicability across diverse user groups. This further suggests that the game design does not systematically advantage or disadvantage users based on sex, educational level, or SES. Such consistency is particularly important in the context of aging and cognitive decline, where equitable engagement across demographic groups is essential.

Acceptability

The BBT was perceived as challenging and at the same time entertaining. None of the games was experienced as excessively difficult or easy, and frustration levels were low. The games were perceived as being most effective in training memory and thinking abilities, with episodic memory and working memory games rated as most efficient candidates in driving participants' perception of efficacy.

Particularly noteworthy, when examining outcomes across varying degrees of cognitive impairment, no discernible distinctions were observed between individuals with SCD and those with MCI regarding game- and training-related measures, speaking for the versatile possibilities of implementation across this spectrum of cognitive impairment. The observed significant differences in well-being and self-perceived in-game performance can be attributed to the increased degree of cognitive impairment in the MCI group. However, we were able to uphold high levels of motivation and enjoyment across those subsamples, holding significant clinical relevance

XSL•FO
RenderX

concerning the acceptability of the BBT across a range of levels of cognitive impairment.

Interestingly, we found significant differences in perceived game efficacy and experience ratings in the active control group. Having spent ample time getting acclimated to the app interface and the electronic device during the 10-week active control training, they might have perceived the subsequent BBT games as comparatively less difficult and challenging and less efficacious in refining reaction time and vision. This observation is particularly relevant considering that older adults often contend with the initial phases of familiarizing themselves with the new devices and apps, which can be inherently challenging and appears to be beneficial for cognitive functions on its own [44]. Exploratory analyses of group differences in in-game ratings across the training course further supported these patterns and suggested that being on a waitlist or undergoing an active control training before the real intervention, compared to starting with the real intervention right away, might have differential effects on user experience. Regarding self-perceived play performance, both the intervention and active control groups improved over time, whereas the waitlist group showed a significantly smaller increase. Well-being remained stable across the intervention and waitlist groups but declined significantly in the active control group, possibly reflecting fatigue effects. Finally, motivation trajectories remained stable in the intervention and active control groups, with a significant increase observed in the waitlist group. Given that self-efficacy [45], motivation [46], and well-being [47] affect quality of life and cognitive outcomes in MCI, those findings highlight the importance of monitoring these aspects during remote cognitive training interventions.

Strengths and Limitations

We singled out several strengths and limitations with the potential for future improvements of the BBT. Strengths include: (1) High adherence rate in terms of number of dropouts, sessions played, and completed sessions. We believe that this is related to the professional game design and characteristics as well as social elements, which may be crucial for the successful implementation of long-term training programs. The remarkable levels of adherence underline the importance of design and game selection [48] and lead us seamlessly to the next point; (2) Stakeholder engagement within a multidisciplinary design process was crucial in identifying and addressing barriers to successful implementation of the BBT [35]; (3) Option for a low-cost and high-frequency cognitive intervention with a beneficial side-effect profile that could be covered by health insurances [49]; (4) Accessibility for underserved older populations is supported by the growing availability and acceptance of digital technologies among older adults [9]; and (5) Remote interventions reduce traveling time and inconveniences for mobility-impaired persons and caregivers.

Limitations include: (1) focusing on patients with SCD and MCI in the analysis precludes conclusions on feasibility and usability in more impaired populations such as the different stages of AD; (2) weekly in-clinic sessions constrained accessibility. However, it was very important during the developmental phase, as it allowed us to gather important information to further refine and debug the app; (3) though we engaged key stakeholders to provide feedback throughout the game development, feedback and integration phases were not structured enough to sufficiently assess the developmental process; (4) a social desirability bias might have led participants to answer questionnaires more benevolently. This is a known challenge associated with non-anonymized self-reports but has been suggested to be a minor issue in older adults [50]; and (5) we did not control for the time of day when participants completed their at-home sessions, which may have influenced attentional levels [51]. Future research could address this by standardizing session times or including time of day as a covariate. However, variability in participant chronotypes would still limit the generalizability and validity of any conclusions drawn from such analysis.

Outlook

This innovative study contributes significantly to the field by developing and evaluating a tablet-based cognitive training adapted to the needs of older adults with cognitive impairment. The participatory design process involving end users throughout development contributed to a successful implementation. The BBT was designed for cognitive training, but future developments could extend its functionalities. Monitoring in-game performance over a prolonged period and recurrent integrated cognitive tests could help identify early signs of cognitive decline and allow tracking cognitive changes over time [52]. Previous studies suggested that cognitive training might have far transfer effects on daily functioning and quality of life [4]. Combining different games, and therefore cognitive challenges, could mimic activities of daily living by creating a more immersive game experience and possibly increase far transfer effects on daily functioning [53]. While the BBT is designed in a real-life-like manner with immersive and interactive elements, it offers a bridge between cognitive training and real-world scenarios. We believe that 10 weeks of CCT is sufficient for establishing feasibility, acceptability, and usability, including capturing engagement and identifying technical challenges and barriers to sustained use. However, future studies should explore longer training durations, the effect of booster training periods, and transfer effects to establish the practical impact of CCT on daily functioning and quality of life. The integration of additional social elements such as multiplayer elements, chat rooms, or rank lists could further enhance participant engagement and motivation for those who appreciate competitive game features and player interactions. The COVID-19 pandemic has further highlighted the need for remote interventions, during which we integrated a Zoom-based option to also deliver the weekly sessions remotely [54]. Although this was ultimately not required, future studies should evaluate feasibility, usability, and acceptability using entirely remote and hybrid delivery models. Future iterations of the BBT app could moreover benefit from enhanced customization, such as incorporating personalized game selection based on individual needs and leverage AI to boost effectiveness and engagement [55]. The app could be adapted and extended to accommodate cognitively more impaired individuals with AD. The main challenge here is to maintain caregiver-independent training, for example by offering interactive tutorials, introducing games

XSL•FO
RenderX

in smaller steps, and reducing visual distractors [36,56]. Enriching the BBT with additional games to train attention and executive functions could moreover be useful for other psychiatric and neurologic patient populations with cognitive impairments.

Conclusion

In conclusion, we successfully developed the BBT app, a multidomain cognitive training designed to attenuate cognitive decline in individuals with SCD and MCI. Our findings demonstrate that user-centered, remotely delivered cognitive training can achieve sustained training adherence in individuals with SCD and MCI, a population that is often challenging to retain in long-term interventions [57]. This supports the potential integration of the BBT app into routine clinical practice, and its remote and home-based delivery may provide a scalable, cost-effective, and widely accessible tool to promote cognitive resilience, hereby enabling earlier and more continuous support for individuals with SCD and MCI. This is particularly relevant in settings where access to specialized cognitive services is limited. Addressing current limitations and expanding functionality, future research should work in close collaboration with key stakeholders to design additional games, including games to train attention and executive functions, and explore feasibility in more impaired populations (eg, different stages of AD) and extend it to different settings, such as the care-home setting.

Acknowledgments

We would like to thank the students who contributed to data collection, study management, recruiting and screening participants, and aiding in game development. We thank Jessica Peter and Katharina Henke for their expert input. We reserve a special expression of thanks for the study participants, whose dedication in allocating time for the study is truly appreciated.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: Literature search and systematization, Code generation, Code optimization, Proofreading and editing, Translation. The GenAI tools used were: ChatGPT-5-5, Claude Sonnet 5, Consensus. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

This research is funded by the Swiss National Science Foundation (Identifier: 32,003B_189240). The funder did not influence the design of the study, collection, analysis and interpretation of the data, or preparation of the manuscript. The article processing fee will be covered by institutional open-access funding provided by the University of Bern.

Data Availability

The data that support the findings of this study and the data dictionary are available from the corresponding author (AKB) on reasonable request.

Authors' Contributions

AKB, EB, MF, CK, and SK developed the app, provided clinical expertise, and contributed to the conception and design of the study. MF was responsible for game programming, maintenance, and technical support. SK is the principal investigator of the project, AKB is the co‐principal investigator responsible for the second study site in Lucerne. AKB, EB, AH, and CK collected the data. EB and AH analyzed the data under AKB’s supervision. All authors contributed to the drafting and revision of the manuscript.

Abstract

Background: Distinguishing autism spectrum disorder (ASD) from social communication disorder (SCD) is clinically challenging because both conditions present with overlapping social communication deficits. Standard caregiver-reported instruments capture surface-level behavioral similarities rather than underlying cognitive differences, motivating the development of digital gamified assessments that measure social cognitive processes directly.

Objective: This study developed and evaluated a 2-stage gamified digital pipeline: stage 1 (Buddy Plan, a self-report module) for high-sensitivity ASD screening, and stage 2 (Buddy Drill, story-based social-judgment scenarios), which was examined with a leakage-controlled analysis, for assessing whether ASD can be differentiated from SCD.

Methods: In this cross-sectional diagnostic accuracy study, 275 children and adolescents aged 6 - 18 years (mean 11.07, SD 3.13 years; 175/275, 63.6% male) were recruited by convenience sampling from 5 clinical and community sites in the Republic of Korea (May 2024 to February 2025) across 5 Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) groups: ASD (n=51), SCD (n=54), attention-deficit/hyperactivity disorder (n=23), high risk (n=52), and neurotypically developing (ND; n=95). Diagnoses were established by board-certified child psychiatrists. Participants completed 2 tablet-based modules: Buddy Plan (52 self-report items; stage 1) and Buddy Drill (153 story-based scenarios; stage 2). The primary outcome was diagnostic accuracy (area under the receiver operating characteristic curve [AUC], sensitivity, and specificity). Four machine learning algorithms were trained with nested cross-validation (5×5 folds). For stage 2, item selection and imputation were performed within each training fold. Explainability used Shapley Additive Explanations (SHAP). Significance was set at α=.05 (2-sided) with bootstrap 95% CIs.

Results: Group differences were tested by 1-way ANOVA. For stage 1 (ASD vs ND; n=146), random forest achieved a nested AUC of 0.912 (95% CI 0.856 - 0.953). At a threshold of 0.200, sensitivity was 96.1% (49/51; 95% CI 86.8% - 99.5%) and specificity was 58.9% (56/95; 95% CI 48.4% - 68.9%), with 2 false negatives. For stage 2 (ASD vs SCD; n=100), the fully nested pipeline yielded only chance-level discrimination: regularized logistic regression achieved a nested AUC of 0.62 (95% CI 0.51 - 0.74), and no feature configuration (self-report: 0.55, objective: 0.62, combined: 0.63) exceeded chance. SHAP identified 5 cross-algorithm stage 1 biomarkers with significant ASD-versus-ND differences (all P<.01) and no evidence of sex bias.

Conclusions: The gamified Buddy Plan module shows promise for high-sensitivity ASD screening. In contrast, once feature-selection leakage was removed with a fully nested pipeline, the Buddy Drill module did not robustly differentiate ASD from SCD, and the apparent advantage of objective features over self-report features seen in leaky analyses did not persist. Because the results derive from internal cross-validation in a single, predominantly male Korean cohort without external validation or IQ matching, they represent preliminary evidence of screening feasibility rather than validated clinical differentiation. Prospective, externally validated, IQ- and language-matched studies are required.

Introduction

Background

Autism spectrum disorder (ASD) affects approximately 1 in 36 children in the United States, with diagnosis frequently delayed beyond the age of 4 - 5 years despite the established benefits of early intervention [1,2]. A particularly salient clinical challenge lies in differentiating ASD from social communication disorder (SCD)—conditions that share core impairments in pragmatic communication, social reciprocity, and nonverbal communication but differ primarily in the presence of restricted and repetitive behaviors (RRBs) [3]. This diagnostic boundary has profound consequences: ASD and SCD require different intervention strategies, prognostic counseling, and service eligibility pathways, yet clinicians struggle to reliably distinguish these conditions [4]. The challenge is compounded by the fact that SCD was introduced in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) specifically to classify children with social communication deficits who lack the RRBs characteristic of ASD. However, high-functioning children with ASD whose RRBs are subtle or context-dependent may be misclassified as having SCD, leading to inappropriate intervention planning and delayed access to ASD-specific services.

Existing gold-standard instruments, such as the Social Responsiveness Scale-2 (SRS-2) and Vineland Adaptive Behavior Scales (VABS), rely on parent or caregiver report [5,6]. These instruments measure observable social behavior through a third-party lens that captures what an informant perceives about the child's social functioning. While psychometrically validated for broad screening, they assess surface-level behavioral phenotypes that appear similar in ASD and SCD [7]. When an observer rates a child's difficulty with understanding social cues, the outward manifestation may be identical in both conditions even though the underlying cognitive mechanisms differ.

Digital health technologies provide a mechanism for the direct assessment of internal social cognitive processes [8,9]. Gamified applications can embed psychometric measurement within engaging, narrative-driven interactive experiences [10]. Story-based social judgment tasks requiring interpretation of social cues, theory of mind (ToM) reasoning, and behavioral outcome prediction engage the same cognitive processes that are differentially impaired in ASD versus SCD [11,12]. Unlike observer ratings that capture behavioral endpoints, these performance-based tasks access the social information processing system, potentially revealing qualitative differences between conditions. Specifically, ToM deficits in ASD are thought to reflect an impairment in the ability to represent and reason about others' mental states, whereas SCD is characterized by more circumscribed difficulties in the pragmatic application of social communication skills with relatively preserved ToM capacity [11,12]. A digital assessment capable of probing these differential cognitive mechanisms could therefore provide the discriminative power that observer-rated instruments lack. In addition, a clinically practical screening tool must address 2 distinct questions sequentially: (1) "Does this child have clinically significant social communication difficulties?" and (2) "If so, is the pattern more consistent with ASD or SCD?" This sequential logic demands a 2-stage pipeline with different optimization targets at each stage.

However, translating digital behavioral data into reliable clinical decision support requires methodological transparency. The Consolidated Reporting Guidelines for Machine Learning Modeling Studies (CREMLS) emphasize multialgorithm comparison, calibration assessment, and transparent feature selection [13]. Machine learning (ML) approaches to ASD screening have shown promise, with several studies achieving area under the receiver operating characteristic curve (AUC) values above 0.85 for differentiating individuals with ASD from typically developing controls [14-16]. However, critical gaps persist. Despite recent advances, multialgorithm digital screening tools rarely quantify error propagation across sequential diagnostic stages. Furthermore, the comparative utility of subjective behavioral ratings versus objective, performance-based tasks for ASD-SCD differentiation remains underexplored within a unified digital platform. Existing models also frequently lack granular explainability, such as Shapley Additive Explanations (SHAP)–based feature attribution, across all stages of a clinical pipeline and often fail to rigorously control for demographic confounds like sex bias—a concern given that the male-skewed ASD prevalence is inadequately controlled in most studies [17].

This study aimed to address these gaps by developing and evaluating a 2-stage digital assessment pipeline using a gamified application with 2 complementary modules. For stage 1 (broad screening), we developed Buddy Plan, a gamified self-report module that captures subjective social competence ratings across multiple domains of social-communicative functioning. For stage 2 (differential diagnosis), we developed Buddy Drill, an objective story-based social judgment module grounded in ToM and social information processing frameworks, designed to probe the internal cognitive processes that may differentially distinguish ASD from SCD. To ensure methodological rigor and transparency, all classification analyses used nested cross-validation (5×5 stratified folds) for unbiased performance estimation; multialgorithm benchmarking across 4 ML classifiers (random forest [RF], support vector machine [SVM], gradient boosting [GB], and logistic regression [LR]); correlation-based, item response theory (IRT)–inspired psychometric item selection for stage 2 feature refinement; complete SHAP analysis for cross-algorithm explainability; calibration assessment via Brier scores; and sex-stratified sensitivity testing to evaluate potential demographic bias.

Methods

Study Design and Participants

This cross-sectional study enrolled 275 children aged 6 - 18 years (mean 11.07, SD 3.13 years; 175/275, 63.6% male) between May 2024 and February 2025 across 5 diagnostic groups: ASD (n=51), SCD (n=54), attention-deficit/hyperactivity disorder (ADHD; n=23), high risk (HR; n=52), and neurotypically developing (ND; n=95). Participants were recruited from 5 sites: Purme Foundation Nexon Children's Rehabilitation Hospital (Seoul), Incheon Medical Center (Incheon), Ewha Womans University Medical Center (Seoul), Pusan National University Yangsan Hospital, and Korea Brain Research Institute (Daegu). Clinical diagnoses followed DSM-5 criteria established by board-certified child psychiatrists (3 senior clinicians across 3 clinical recruitment sites). For each participant, the diagnosing clinician conducted a structured clinical interview with parents and direct behavioral observation of the child. Cases with an uncertain diagnosis were discussed in a multidisciplinary consensus conference attended by at least 2 clinicians; consensus was required before enrollment.

This was a cross-sectional, single-wave diagnostic accuracy study conducted and reported in accordance with the Journal Article Reporting Standards (JARS) for quantitative research and the guidelines for developing and reporting machine-learning predictive models in biomedical research [18].

Setting

Recruitment took place across 5 clinical and community sites in the Republic of Korea (3 hospital-based child psychiatry clinics, 1 university medical center, and 1 research institute) between May 2024 and February 2025.

Inclusion and Exclusion Criteria

The inclusion criteria were age 6-18 years; sufficient ability to complete a tablet-based assessment; and, for the clinical groups, a DSM-5 diagnosis confirmed by a board-certified child psychiatrist. The exclusion criteria were an uncorrected sensory or motor impairment precluding tablet use and inability to provide assent.

Sampling Procedures

Participants were enrolled using convenience (consecutive clinical-referral and community-volunteer) sampling; no probability-based sampling frame was used, which is acknowledged as a potential source of selection bias in the Limitations section.

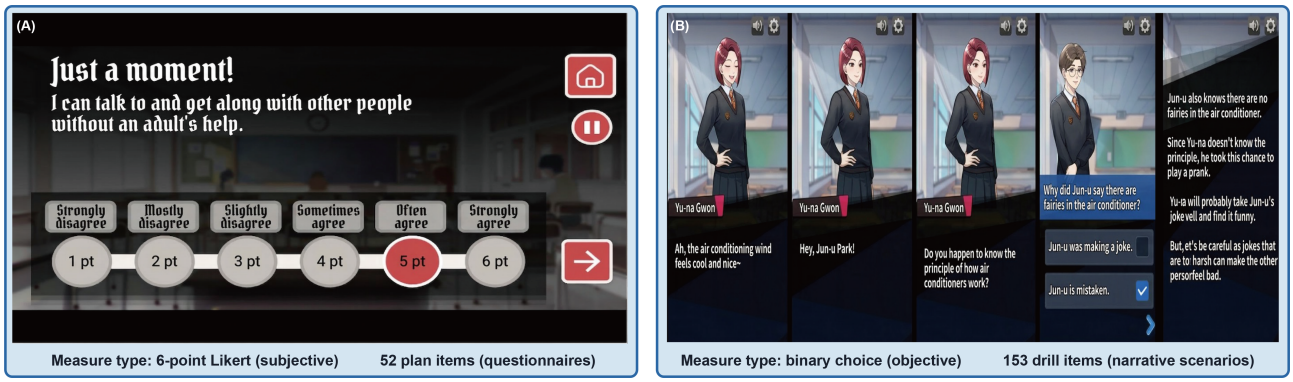
Sample Size, Power, and Precision

An a priori power analysis was not performed because the sample comprised all eligible participants accrued during the fixed recruitment window. Accordingly, precision is conveyed by bootstrap 95% CIs throughout, and the study is framed as providing preliminary, internally validated estimates rather than definitive effect sizes.

Measures and Covariates

The primary measures were the Buddy Plan and Buddy Drill digital modules, which are described below. Covariates comprised age; sex; and, where available, full-scale IQ (FSIQ), SRS-2, and VABS. A JARS-style participant flow diagram summarizing enrollment, module administration, and analytic inclusion at each stage is provided in Multimedia Appendix 1.

Ethical Considerations



The study protocol was reviewed and approved by the Institutional Review Boards (IRBs) of the following 4 institutions: Public Institutional Bioethics Committee (approval number: P01-202502-01-028), Incheon Medical Center (approval number: 115288 - 202408 HR-092-06), Ewha Womans University (approval number: ewha-202501-0001-02), and Pusan National University Yangsan Hospital (approval number: 10-2024-014). Written informed consent was obtained from all parents or legal guardians, and written assent was obtained from all child participants aged 7 years or older, in accordance with institutional policy. Participants received no financial compensation for study participation. All personally identifiable information was removed prior to analysis, and data were stored on encrypted, access-controlled institutional servers. All procedures were conducted in accordance with the Declaration of Helsinki. Children could withdraw from the assessment at any time without consequence, and research staff monitored for signs of fatigue or distress throughout the gamified assessment sessions. No individual participant is identifiable in any image, figure, or supplementary material in this manuscript. All figures present aggregated, deidentified data or schematic illustrations only, and no photographs or other potentially identifying images of participants are included.

Digital Assessment Platform

The gamified digital assessment was administered via tablet devices and consisted of 2 primary modules: Buddy Plan and Buddy Drill (Figure 1). The digital assessment modules, Buddy Plan and Buddy Drill, were developed by operationalizing core diagnostic features from established clinical instruments, including SRS-2 and VABS. To ensure a comprehensive digital phenotype, the content was mapped onto four critical domains of social-functional impairment: (1) situational awareness (recognition of social cues and environmental context), (2) communication (pragmatic language use and nonverbal communicative intent), (3) social motivation (the drive to initiate and maintain social engagement), and (4) restricted interests and behaviors (identification of rigid processing patterns, particularly in social reasoning scenarios).

XSL•FO
RenderX

Figure 1. Overview of the 2-module gamified digital assessment platform. (A) Buddy Plan (social competence rating module): a gamified self-report questionnaire comprising 52 items (P-items) in which the child rates social behaviors on a 6-point Likert scale. (B) Buddy Drill (story-based social judgment module): an objective, narrative-driven interactive assessment comprising 153 scenarios (D-items) grounded in theory of mind and social information processing frameworks. Each scenario presents a social situation requiring the child to interpret implicit social cues, engage in perspective-taking, and predict appropriate behavioral outcomes through a binary response (correct/incorrect).

Buddy Plan (Social Competence Rating Module)

The Buddy Plan module comprised 52 items (P-items) evaluating social behaviors, including social awareness, communicative intent, empathy, and social motivation. Items were presented as gamified self-report questions completed directly by the child participant on a tablet device, with a 6-point Likert response scale ranging from 1 (never/not like me) to 6 (always/very much like me). Reading-level appropriateness was ensured by keeping all items at a grade 3 reading level or below. A trained research assistant was present to provide item clarification for younger participants (aged 6‐8 years) if requested. This child self-report approach distinguishes Buddy Plan from parent-informant instruments such as SRS-2 and VABS, enabling direct capture of the child's subjective social experience rather than observer perception. However, self-report reliability is known to vary with age, cognitive ability, and insight capacity; younger children (6‐8 years) may have limited metacognitive awareness of their own social difficulties, while adolescents may demonstrate response bias related to social desirability [19]. Our study did not collect IQ or language proficiency data, which are potential confounders for self-report validity in this population. To ensure unidirectional interpretation—where higher scores consistently reflect greater social difficulty—20 of the 52 items were reverse-scored (calculated as 7 minus the original score). This module served as the primary feature set for stage 1 (broad screening). To provide a theoretically grounded interpretation of the ML results and facilitate clinically meaningful profiling across diagnostic groups, the 52 Buddy Plan items were organized into 5 theoretically derived subscales based on expert consensus classification. A panel of board-certified child psychiatrists and developmental psychologists independently categorized each item based on its target construct, drawing on established frameworks from the social cognition, social communication, and neurodevelopmental literature [3,4,11,12]. Items were assigned to subscales through iterative discussion until unanimous agreement was reached. This classification is theoretically motivated rather than empirically derived; no exploratory factor analysis or confirmatory factor analysis was performed to validate the 5-factor structure statistically. Accordingly, the subscale structure should be interpreted as a clinically informed organizational framework, and the factor solution may differ from data-driven approaches. Further details on the resulting 5-factor structure, which captures complementary dimensions of social-communicative functioning, are described in Multimedia Appendix 2.

Buddy Drill (Story-Based Social Judgment Module)

The Buddy Drill module was an objective, gamified assessment consisting of 153 narrative scenarios (D-items). Grounded in ToM and social information processing frameworks [11,20], this interactive story game evaluated the child's ability to interpret implicit social cues, engage in perspective-taking, and predict appropriate behavioral outcomes. Each scenario concluded with a binary choice (correct or incorrect), yielding an objective performance metric free from informant bias. This module served as the primary feature set for stage 2 (differential diagnosis). The Buddy Drill module was administered exclusively to children in clinical and HR groups (ASD, SCD, ADHD, and HR). Due to the sequential gatekeeping design, stage 2 focused exclusively on differentiating between clinical phenotypes within the social-communication deficit spectrum, where children with ND would have already been filtered out at stage 1. This design decision also reflected practical considerations: (1) the IRB mandated minimization of assessment burden for participants with ND, as the 153-scenario module requires 40‐60 additional minutes of testing, and (2) there was an anticipated ceiling effect in children with ND, inferred indirectly from the HR group's mean accuracy (D_mean=0.771). The HR group, while the least clinically affected group that received D-items, does not represent children with ND, and this inference therefore serves as a practical justification rather than an empirical demonstration. Future studies should administer Buddy Drill to participants with ND to establish full pipeline validity across all diagnostic groups.

Statistical Analyses

Missing data were minimal and are reported explicitly here. No participant had more than 5% missing Buddy Plan (P-item) responses, and overall P-item missingness was below 2% of all item responses. These few missing values were resolved by within-fold median imputation (applied within each cross-validation training fold to prevent data leakage), and with a missing fraction this small, multiple imputation was not

XSL•FO
RenderX

expected to materially alter estimates and was therefore not used. Across the clinical covariates that contained sporadic missingness (SRS-2 and VABS subscales; 0.7% of values), the Little missing completely at random (MCAR) test was nonsignificant (χ^2_9=5.9; *P*=.75), consistent with a MCAR mechanism. In contrast, Buddy Drill (D-item) and FSIQ data were missing by design rather than at random—the Buddy Drill module was not administered to the ND group (see the Buddy Drill section) and FSIQ was not collected for all participants—and this missingness was strongly nonrandom (Little MCAR test: χ^2_9=195.1; *P*<.001). Accordingly, D-item analyses were restricted to participants who completed the module, and no D-item imputation was performed. No outlier exclusions were applied, as all responses fell within the valid Likert range (1-6). Class imbalance between ASD (n=51) and ND (n=95) was addressed through class-weighted algorithms (class weight="balanced" for SVM and LR; balanced class weights for RF and GB) rather than synthetic oversampling, preserving the original multidimensional clinical phenotype distributions, which synthetic oversampling methods may distort in high-dimensional feature spaces. The 5×5 nested cross-validation design was selected to balance the bias-variance tradeoff in performance estimation: 5 outer folds provided sufficient held-out data per fold (approximately 29 samples), while 5 inner folds enabled robust hyperparameter selection within each training partition. To prevent optimistic bias from information leakage between tuning and evaluation, all models used nested cross-validation [21] (5×5 stratified folds). The outer loop provided unbiased generalization estimates on held-out data never used for hyperparameter selection, while the inner loop conducted exhaustive grid search (GridSearchCV) over predefined hyperparameter spaces. Feature standardization was applied within each outer training fold for algorithms requiring it (LR and SVM), preventing data leakage. Four algorithms were benchmarked: RF (324 combinations), GB (288 combinations), SVM (40 combinations), and LR (12 combinations). To ensure transparency in the classification models, we used SHAP [22] to quantify the contribution of each digital biomarker to individual predictions. For tree-based models (RF and GB), exact TreeSHAP was applied, computing feature-level contributions in polynomial time. For SVM, KernelSHAP with k-means summarization (k=50) of the background distribution was used. Both global importance (mean |SHAP|) and directional effects (beeswarm plots) were examined across all algorithms. Consensus biomarkers were defined as features ranking in the top 10 by SHAP across 3 or more algorithms. Given the unbalanced sex distribution (ASD: 43/51, 84% male; ND: 49/95, 52% male), the following three analyses tested for sex bias: (1) male-only subgroup analysis, (2) sex-inclusive models with sex as an additional (53rd) feature, and (3) SHAP-based quantification of sex's contribution to predictions. Differential item functioning (DIF) analysis by sex was not performed within the item selection framework owing to insufficient sample sizes within sex-by-diagnosis subgroups (female ASD: n=8; female SCD: n=6). DIF analysis is a priority for future studies with larger, sex-balanced cohorts to ensure that individual Buddy Plan and Buddy Drill items do not exhibit measurement bias by sex. An exploratory age-stratified analysis was conducted by dividing participants into younger (6 - 11 years; n=171) and older (12 - 18 years; n=104) subgroups. Stage 1 RF performance remained robust in both subgroups (younger AUC=0.896; older AUC=0.921), though the small subgroup sample sizes preclude definitive conclusions about age-specific performance. The age range of 6 - 18 years represents a substantial developmental span; age-normed scoring (adjusting item difficulty or subscale interpretation by developmental stage) was not implemented in our study but is recommended for future instrument development to account for maturational differences in social cognitive capacity across childhood and adolescence. Model calibration was assessed via calibration curves and Brier scores. Digital P-items were benchmarked against demographics only (age and sex) and a clinical gold standard (age, sex, SRS-2, and VABS). Cross-group generalization analysis applied the ASD-versus-ND–trained model to all 5 groups to assess dimensional sensitivity.

Principal Component Analysis–Based Dimensionality Reduction (Neurodevelopmental Scores)

To reduce potential redundancy across correlated behavioral features and extract latent cognitive phenotypes from the gamified assessments, we applied a principal component analysis (PCA)–based dimensionality reduction framework adapted from the E-score methodology described by Park et al [23]. This approach reduces redundancy across behavioral features by grouping correlated items and extracting composite scores that capture underlying neurodevelopmental dimensions. First, all 52 P-item scores were standardized into *z* scores, and outliers exceeding |2.5| SDs were capped at ±2.5 to prevent outlier dominance in PCA [23]. A global PCA was then applied to the feature correlation matrix to project all items onto a 2D principal component space. K-means clustering (k=3; selected via the elbow method) was applied to this 2D space to identify groups of items with similar covariance structures. Finally, within each cluster, a cluster-specific PCA was conducted, and the first principal component score (PC1) was extracted for each participant, yielding 3 composite "N-scores" (neurodevelopmental scores). These N-scores were evaluated for clinical validity through partial correlation analyses controlling for age and through group comparison analyses (ASD vs ND for P-item N-scores; ASD vs SCD for D-item N-scores). The classification performance of N-scores was compared against raw item scores using LR and RF with 10×5 repeated stratified cross-validation. A hybrid analysis further combined correlation-based selected D-items with P-item N-scores. Because the PCA-based N-score derivation and the item selection for these secondary analyses were performed on the full sample rather than within cross-validation folds, they are exploratory and, like the original stage 2 estimate, are subject to optimistic bias. They are not used to support the study's conclusions. The complete mathematical specification of this 5-step pipeline (equations 1-5)—including item-level *z*-score standardization, ±2.5 SD winsorization, eigendecomposition of the 52×52-item correlation matrix, k-means partitioning in the 2D loading space, and cluster-specific PC1 extraction—is provided in Multimedia Appendix 3.

Stage 1: Buddy Plan Screening (ASD vs ND)

Stage 1 classified ASD versus ND using all 52 P-items. Because stage 1 functions as a screening gate, where any false negative represents an irrecoverable error propagating through the pipeline, we optimized the classification threshold for ≥95% sensitivity, accepting reduced specificity to minimize missed ASD cases. The threshold was independently optimized within each outer fold's training partition and applied exclusively to that fold's held-out test data, ensuring no information leakage from cross-fold threshold selection. The reported sensitivity (96.1%) and specificity (58.9%) at a threshold of 0.200 reflect aggregated outer-fold performance at this threshold value. Error propagation was quantified by applying the trained stage 1 model to all 5 diagnostic groups (ASD, SCD, ADHD, HR, and ND) as a cross-group generalization analysis of dimensional sensitivity. The ADHD group (n=23) was not used in any primary classification analysis. It served exclusively in this cross-group generalization analysis to assess whether the ASD screening model appropriately differentiated ASD from a clinically relevant comparison group with overlapping behavioral features.

PCA-Based N-Score Analysis and Information Dilution Resolution

PCA-based clustering of the 52 P-items yielded 3 item clusters (19, 26, and 7 items; cumulative variance explained by PC1 and PC2: 78.8%), from which 3 N-scores were extracted. The second N-score (P_N2), derived from a 26-item cluster, demonstrated the largest effect size for ASD versus ND differentiation (Cohen d=2.03; t_{144}=12.04; P<.001). This large effect exceeds those observed with raw total scores (Cohen d=1.41 for P_sum), representing a 44% improvement in effect size through dimensionality reduction. P_N2 showed strong partial correlations (controlling for age) with SRS-2 total (r=0.458; P<.001), SRS-2 RRB (r=0.602; P<.001), and VABS-ABC (r=–0.552; P<.001), suggesting it captures a core social difficulty dimension with particular sensitivity to RRB features. Using only 3 N-scores, LR achieved an AUC of 0.910 for ASD versus ND classification—exceeding the 52-item LR AUC of 0.881 despite using 94% fewer features. Because this PCA-based extraction was performed on the full sample rather than within cross-validation folds, it is reported as an exploratory dimensionality-reduction result rather than a leakage-free performance estimate.

For ASD versus SCD differentiation, an exploratory hybrid approach combining selected D-items with P-item N-scores was also examined. Because both the N-score derivation and the D-item selection for this analysis were performed on the full sample, the resulting estimates are subject to the same feature-selection leakage identified for the primary stage 2 analysis and are reported only as exploratory. They should not be interpreted as leakage-free evidence of ASD-SCD differentiation.

Stage 2: Buddy Drill Differential Diagnosis (ASD vs SCD)

A correlation-based item selection procedure, inspired by IRT principles, identified maximally discriminating Buddy Drill scenarios. Because the sample size (n=100) was insufficient for formal IRT modeling via marginal maximum likelihood estimation—which typically requires 200 - 500 respondents per parameter for stable 2PL estimates [24]—a simplified approximation was used: the discrimination parameter *(a)* was estimated via point-biserial correlation with logistic scaling (×1.7), and the difficulty parameter *(b)* was estimated via probit transformation of accuracy. Unidimensionality was supported by a PC1/PC2 eigenvalue ratio of 2.33 (threshold: 2.0), though this is less conservative than the commonly cited 3.0 threshold, and 11.1% of item pairs exceeded the local independence criterion of |r|=0.20. Items were ranked by discrimination, and the top 50 were selected (IRT-50 set). An abbreviated 5-item set (IRT-5) was also evaluated for rapid screening feasibility. We acknowledge that this approach does not constitute formal IRT analysis; accordingly, we refer to it as "correlation-based item selection inspired by IRT" throughout this manuscript. In response to peer review and to eliminate feature-selection leakage, the entire item-ranking, selection, and median-imputation procedure was recomputed independently within each outer training fold of the nested cross-validation (a fully nested pipeline). The leakage-free estimates from this pipeline are those reported for stage 2. Estimates from the earlier version, in which selection was performed once on the full ASD-SCD sample, are identified as such and are not used to support the study's conclusions.

Results

Participant Characteristics

A total of 275 children aged 6-18 years (mean age 11.07, SD 3.13 years; 175/275, 63.6% male) were enrolled across 5 diagnostic groups (Table 1). One-way ANOVA revealed significant group differences across all continuous variables (all P<.001). The ASD group (n=51; mean age 12.00, SD 3.49 years; 43/51, 84% male) demonstrated the highest SRS-2 scores (mean 82.86, SD 15.38) and lowest VABS composite scores (mean 64.20, SD 11.60), indicating the most severe social communication impairment and adaptive functioning deficits. The SCD group (n=54; mean age 9.94, SD 2.84 years; 48/54, 89% male) showed moderately elevated SRS-2 scores (mean 72.47, SD 13.80) and low VABS scores (mean 68.13, SD 6.87). The ADHD group (n=23; mean age 10.00, SD 2.13 years; 18/23, 78% male) had a mean SRS-2 score of 67.64 (SD 18.15) and a mean VABS score of 70.32 (SD 8.63). The HR group (n=52; mean age 13.98, SD 2.66 years; 17/52, 33% male) had a mean SRS-2 score of 75.54 (SD 19.59) and a mean VABS score of 79.71 (SD 18.50). The ND group (n=95; mean age 9.86, SD 2.24 years; 49/95, 52% male) had the lowest SRS-2 scores (mean 41.97, SD 33.75) and highest VABS scores (mean 108.89, SD 16.50). Sex distribution differed significantly across groups (χ^2=53.92; P<.001; V=0.443), driven primarily by the lower male proportion in the HR group (17/52, 33%). On the Buddy Plan digital assessment, the ASD group reported the greatest overall social difficulty (P_mean=3.944, SD 0.478), followed by the HR group (P_mean=3.862, SD 0.569), SCD group (P_mean=3.772, SD 0.450), and ADHD group (P_mean=3.765, SD 0.351), with the ND group reporting the least difficulty

XSL•FO
RenderX

(P_mean=3.378, SD 0.304; $F_{4,270}$=19.63; P<.001; η^2=0.225). Across the Buddy Plan subscales, the largest group effect was observed for total score ($F_{4,270}$=33.04; P<.001; η^2=0.329), followed by F1 (social cognition and contextual understanding; $F_{4,270}$=30.11; P<.001; η^2=0.308) and F4 (repetitive/restricted interests and sensory rigidity; $F_{4,270}$=22.87; P<.001; η^2=0.253). The ASD-ND difference was the largest for F4 (delta=+1.391) and F1 (delta=+1.250), consistent with the DSM-5 diagnostic criteria. Of particular diagnostic relevance, the ASD-SCD comparison revealed near-zero differences in F2 (interaction skills and nonverbal communication; delta=−0.007) and F5 (self-expression and self-regulation; delta=−0.013), confirming that these 2 conditions present identically on observable interaction behaviors. The largest ASD-SCD difference was observed in F4 (repetitive/restricted interests and sensory rigidity; delta=+0.266), consistent with the DSM-5 criterion that RRBs primarily distinguish ASD from SCD. Convergent validity was supported by significant correlations between P_mean and SRS-2 (r=0.290; P<.001) and between P_mean and VABS (r=−0.376; P<.001). Regarding internal consistency, while most subscales showed acceptable to good reliability (Cronbach α range: 0.666-0.871), F5 (self-expression and self-regulation) demonstrated lower internal consistency (α=.508), below the conventional acceptability threshold. A post hoc sensitivity analysis excluding all F5 items from the stage 1 feature set yielded negligible performance change (RF AUC=0.905 vs 0.912 with full items), confirming the model's robustness to this subscale's variance (Table S1 in Multimedia Appendix 2).

Stage 1: Buddy Plan Screening

RF achieved the highest nested AUC of 0.912 (SD 0.054) with a precision-recall AUC of 0.869, F_1-score of 0.744, sensitivity of 0.627, and specificity of 0.968. SVM with a linear kernel yielded the second highest AUC of 0.885 (SD 0.097). GB achieved an AUC of 0.869 (SD 0.066) with a comparable F_1-score and specificity. LR had the lowest AUC of 0.826 (SD 0.093). All reported values reflect outer-fold predictions that were never used for hyperparameter tuning.

RF achieved the highest nested AUC (0.912, SD 0.054) with excellent specificity (0.968) at the default threshold of 0.500. However, sensitivity at the default threshold was 0.627, insufficient for a screening tool. We optimized the threshold to 0.200, yielding 96.1% sensitivity with 2 ASD false negatives (2/51) (Figure 2A and B). Model calibration assessment revealed that the RF model achieved a Brier score of 0.132 (stage 1), indicating good probabilistic accuracy. The calibration curve showed slight overconfidence in the mid-range probability zone (predicted probabilities of 0.3 - 0.6 were approximately 5 - 10 percentage points higher than observed frequencies), which is common in tree-based classifiers. For stage 2, the LR model achieved a Brier score of 0.207, reflecting moderate calibration consistent with the more challenging ASD-SCD discrimination. The stage 2 calibration curve demonstrated better calibration than stage 1 for the LR model, as LR inherently produces well-calibrated probabilities through its sigmoidal output function. For practical use, these calibration findings imply that if the model output is to serve as a risk score, mid-range stage 1 probabilities should be interpreted with mild caution given the observed overconfidence, and recalibration on the intended deployment population (eg, Platt scaling or isotonic regression) is advisable before threshold-based clinical decisions are made. Without any clinician involvement, digital P-items achieved a nested AUC of 0.912—an 18.6 percentage-point improvement over demographics alone (AUC=0.726) and 93% of the clinical gold-standard performance (AUC=0.976). The clinical gold standard required trained administrators to collect SRS-2 and VABS scores; the digital tool required none. The marginal degradation when combining clinical and digital features (0.976-0.969) reflected expected collinearity in a small sample with near-ceiling clinical performance. As illustrated in the receiver operating characteristic curves (Figure 2A), all 4 algorithms achieved AUC values exceeding 0.82, with RF demonstrating the most robust discrimination. The sensitivity-specificity tradeoff curve (Figure 2B) revealed that lowering the classification threshold from 0.500 to 0.200 shifted the operating point from high specificity (0.968) and low sensitivity (0.627) to the clinically preferred configuration of 96.1% sensitivity and 58.9% specificity, ensuring that virtually all ASD cases were captured for downstream differential diagnosis. Feature importance analysis (Figure 2D) confirmed convergence across Gini importance, permutation-based accuracy decrease, and linear coefficients, with items P07 (social attention), P11 (communicative initiative), and P12 (social engagement) consistently ranked among the top discriminative features. Validation benchmarking (Figure 2C and E) demonstrated that the digital P-item model substantially outperformed the demographics-only baseline and approached clinical gold-standard performance, indicating the potential of the gamified digital assessment to serve (future application requiring prospective external validation) as a first-line screening aid in settings where trained clinical administration is unavailable. We caution, however, that the stage 1 ASD-ND discrimination may partly reflect broad cognitive-developmental differences rather than social cognition specifically. FSIQ values were available only for a subset of clinical participants (ASD: 28/51; mean 66.3, SD 19.1; SCD: 50/54; mean 78.7, SD 17.4) and were not measured in any ND participant (0/95). Consequently, a direct ASD-ND IQ comparison and IQ-adjusted stage 1 analysis were not possible, and no ASD-ND IQ effect size has been reported. Normative FSIQ values imputed for the ND group were used only in an exploratory supplementary check and have not been treated as measured data. The stage 1 estimates should therefore be interpreted as a composite signal reflecting both social cognitive and broader cognitive-developmental differences, pending replication in IQ-matched cohorts.

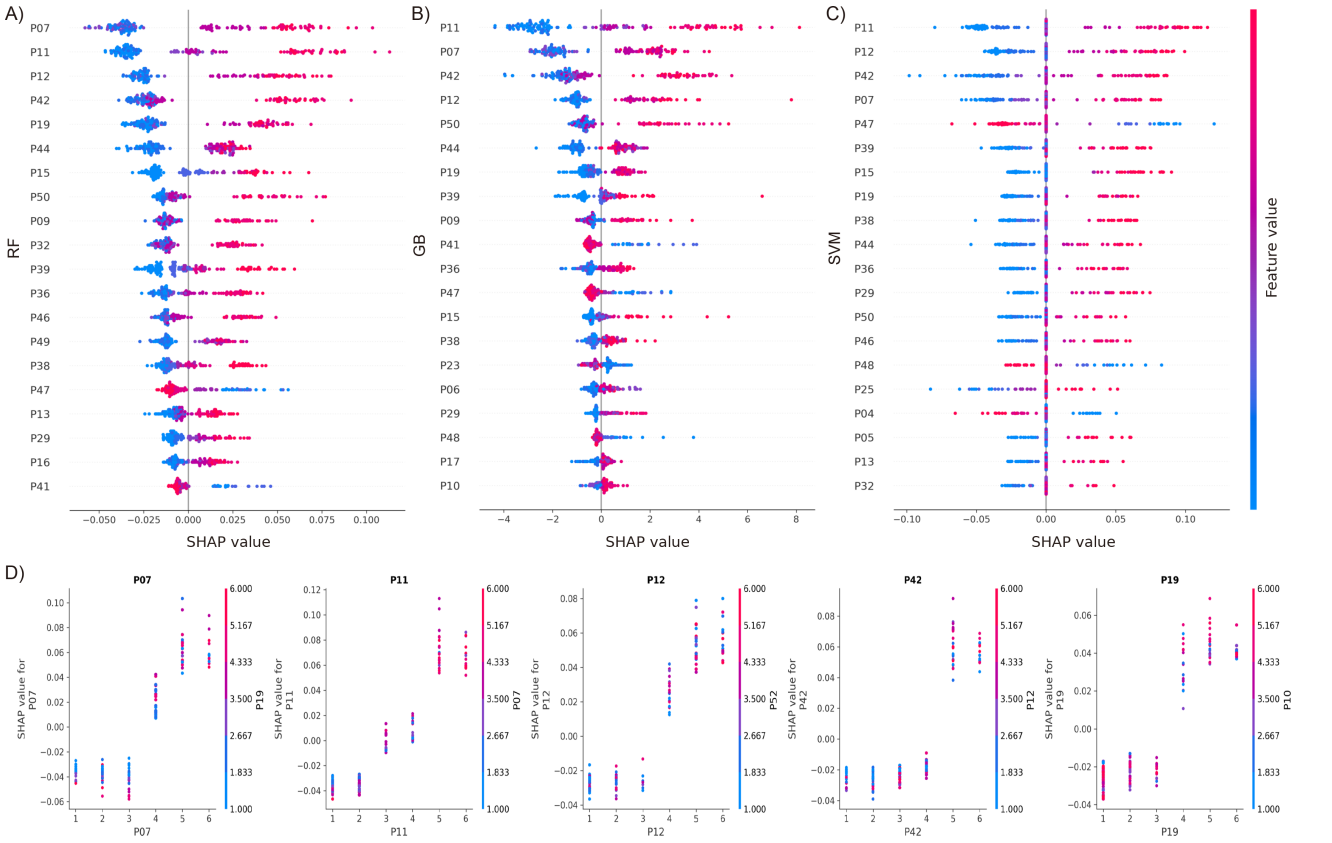

Figure 2. Stage 1 screening performance and threshold optimization for autism spectrum disorder (ASD) versus neurotypically developing (ND) classification (n=146). (A) Receiver operating characteristic (ROC) curves for 4 machine learning algorithms (random forest [RF], support vector machine [SVM], gradient boosting [GB], and logistic regression [LR]) with nested cross-validation area under the curve (AUC) values. RF achieved the highest AUC of 0.912 (SD 0.054). (B) Sensitivity-specificity tradeoff as a function of classification threshold, illustrating the optimized threshold of 0.200 that achieved 96% sensitivity (49/51) with 2 ASD false negatives (2/51). (C) Box plot of AUC distributions across algorithms comparing digital P-items, demographics-only baseline, and clinical gold standard models. (D) Feature importance rankings derived from Gini importance (RF), permutation importance (RF), and linear coefficients (LR). (E) ROC curves comparing feature set configurations: demographics only (AUC=0.726), digital P-items alone (AUC=0.912), clinical gold standard with Social Responsiveness Scale-2 and Vineland Adaptive Behavior Scales (AUC=0.976), and combined clinical plus digital features (AUC=0.969). ADHD: attention-deficit/hyperactivity disorder; HR: high risk; SCD: social communication disorder.

SHAP beeswarm plots (Figure 3A-C) revealed consistent cross-algorithm convergence among the top-ranked features. Across RF, GB, and SVM, items P07 (social attention), P11 (communicative initiative), P12 (social engagement), P42 (empathy and ToM), and P19 (social motivation) emerged as consensus biomarkers, each ranking within the top 10 features in at least 3 of the 4 algorithms (Table S3 in Multimedia Appendix 2). All 5 biomarkers exhibited monotonic positive SHAP directionality: higher social difficulty scores (red points) were associated with positive SHAP values, pushing predictions toward the ASD class, while lower difficulty scores (blue points) pushed predictions toward the ND class. This monotonic relationship was confirmed by the individual SHAP dependence plots (Figure 3D), which further revealed nonlinear dose-response patterns for certain biomarkers. To formally validate the discriminative contribution of consensus biomarkers, Mann-Whitney *U* tests were performed comparing SHAP value distributions between the ASD and ND groups for each of the 5 consensus biomarkers. All 5 biomarkers showed statistically significant between-group SHAP differences (P07: U=3842; P<.001; P11: U=3651; P<.001; P12: U=3498; P<.001; P42: U=3215; P<.001; P19: U=2987; P<.001; all Bonferroni-corrected P<.01), confirming group-level differences in feature contributions.

Figure 3. Shapley Additive Explanations (SHAP) explainability analysis for stage 1 digital biomarkers (autism spectrum disorder [ASD] versus neurotypically developing [ND]). (A-C) SHAP beeswarm plots for (A) random forest (RF), (B) gradient boosting (GB), and (C) support vector machine (SVM), displaying the top 15 buddy plan items ranked by mean absolute SHAP value. Each point represents a participant. The horizontal position indicates SHAP contribution to the ASD prediction (positive=toward ASD; negative=toward ND), and color encodes the feature value (red=high social difficulty; blue=low social difficulty). Five consensus biomarkers—P07 (social attention), P11 (communicative initiative), P12 (social engagement), P42 (empathy and theory of mind), and P19 (social motivation)—consistently ranked among the top features across all 3 algorithms, exhibiting monotonic positive directionality. (D) Individual SHAP dependence plots for each of the 5 consensus biomarkers showing the nonlinear relationship between item score and SHAP value. The vertical spread at each feature value reflects interaction effects with other features.

Stage 2: Buddy Drill Differential Diagnosis

In the originally reported analysis, in which correlation-based item selection had been performed on the full ASD-SCD sample before cross-validation, LR appeared to achieve a nested AUC of 0.767. This estimate was, however, inflated by feature-selection leakage. When item ranking, selection, and imputation were repeated entirely within each outer training fold (a fully nested pipeline), discrimination fell to chance across all algorithms: LR nested AUC of 0.62 (95% CI 0.51 - 0.74; sensitivity 0.61; specificity 0.71), SVM AUC of 0.61, RF AUC of 0.60, and GB AUC of 0.52, each with a 95% CI whose lower bound was at or near 0.50. Stage 2 therefore did not robustly differentiate ASD from SCD in this sample.

As a clinician-rated benchmark, a multivariable model of the observer scales did differentiate the 2 conditions: combining all SRS-2 and VABS subscales achieved a leakage-free nested AUC of 0.77 (95% CI 0.68 - 0.86), and the SRS-2 restricted/repetitive-behavior subscale showed the largest single group difference (ASD vs SCD Cohen *d*=0.84). By contrast, the corresponding digital restricted/repetitive-behavior proxy (Buddy Plan F4 items) did not differentiate the groups (nested AUC 0.55, 95% CI 0.44 - 0.66). Because the clinician-rated scales are not independent of the diagnostic process and require trained administration, they are reported only as a benchmark and not as a stand-alone or digital differentiator.

Under the fully nested pipeline, no feature configuration exceeded chance for ASD-SCD differentiation (Figure 4A): self-report P-items alone yielded a nested AUC of 0.55 (95% CI 0.44 - 0.67), objective D-items yielded an AUC of 0.62 (95% CI 0.51 - 0.74), and the combined P+D set yielded an AUC of 0.63 (95% CI 0.51 - 0.74). The combined set performed no worse than D-items alone. The “information dilution” effect reported previously—in which adding P-items appeared to degrade performance—therefore did not persist once selection leakage was removed and is now attributed to that leakage. Consistent with these results, no single SRS-2 or VABS subscale discriminated ASD from SCD (all AUC <0.65; Figure 4B), underscoring the genuine difficulty of this diagnostic boundary. An abbreviated 5-item variant, evaluated within the same fully nested framework, likewise remained at chance for ASD-SCD differentiation (nested AUC 0.60, 95% CI 0.49 - 0.70; Table 2) and is therefore not recommended as a rapid-screening tool for this purpose.

Figure 4. Stage 2 differential diagnosis performance and feature incompatibility analysis (autism spectrum disorder [ASD] versus social communication disorder [SCD]). The analysis comprised 100 participants (ASD: 51; SCD: 49). (A) Heatmap of nested cross-validation (CV) area under the receiver operating characteristic curve (AUC) values across 4 algorithms (logistic regression [LR], random forest [RF], gradient boosting [GB], and support vector machine [SVM]) and multiple feature set configurations, including Buddy Plan items only (P), psychometrically selected Buddy Drill items (D:IRT), full Buddy Drill items (D:All), and combined feature sets (P+D). Color gradient ranges from red (low AUC) to green (high AUC). (B) Comparative bar plots of individual Social Responsiveness Scale-2 (SRS-2) and Vineland Adaptive Behavior Scales (VABS) subscale AUC values for ASD versus SCD classification. (C) Horizontal bar chart comparing nested AUC values across feature set configurations for the best-performing algorithm. These panels reflect the originally reported analysis with full sample feature selection and are superseded by the fully nested, leakage-free estimates reported in the text (all AUC≈0.5 - 0.6). IRT: item response theory.

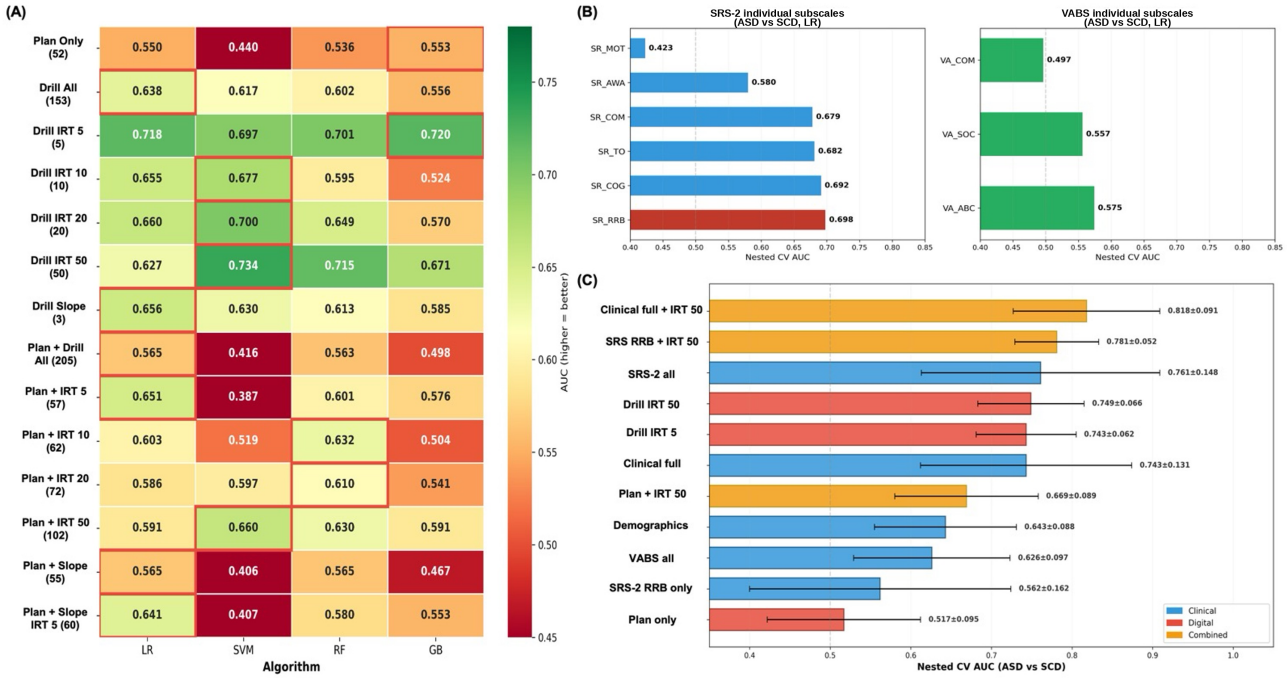

Table . Comparison of IRT[a]-50 and IRT-5 protocols[b] for stage 2 ASD[c] versus SCD[d] differential diagnosis (N=100; ASD: n=51, SCD: n=49).

Metric	IRT-50 (50 items)[e]	IRT-5 (5 items)[e]	Δ (IRT-5−IRT-50)
Nested AUC[f] (95% CI)	0.62 (0.51-0.74)	0.60 (0.49-0.70)	−0.02
Sensitivity[g], % (n/N)	61 (31/51)	57 (29/51)	−4 pp[h]
Specificity[i], % (n/N)	71 (35/49)	55 (27/49)	−16 pp
Concordance with IRT-50, % (n/N)	—[j]	85 (85/100)	—
Administration time[k]	Approximately 15 - 20 min	Approximately 2 - 3 min	Approximately 85% reduction

[a]IRT: item response theory.

[b]Both protocols performed at or near chance level for ASD versus SCD differentiation; the table is retained to document the abbreviated protocol comparison and not to support differential diagnostic use.

[c]ASD: autism spectrum disorder.

[d]SCD: social communication disorder.

[e]All values are from a single, fully nested, leakage-free 5×5 cross-validation pipeline in which item ranking, selection, and median imputation were performed within each outer training fold; the classifier was regularized logistic regression. Operating characteristics are reported at a .50 probability threshold.

[f]AUC: area under the receiver operating characteristic curve.

[g]Sensitivity denominator=51 (ASD).

[h]pp: percentage points.

[i]Specificity denominator=49 (SCD).

[j]Not applicable.

[k]Administration time estimates assume an average pace of 20-25 s per item.

Discussion

Principal Findings

Relative to the aims stated at the end of the Introduction, this study produced a clear dissociation between the 2 stages of the gamified pipeline. The Buddy Plan screening module distinguished children with ASD from their ND peers with high internal accuracy, supporting its promise as a screening aid. This result must nonetheless be interpreted cautiously because the 2 groups differed substantially in general cognitive ability that could not be equated in the present design. The Buddy Drill differentiation module, in contrast, did not reliably separate ASD from SCD once a fully nested analysis pipeline was applied, and the objective task performance, self-report rating, or their combination did not perform above chance. An apparent advantage of objective over self-report features and a related information-dilution pattern that had appeared in an earlier, nonnested analysis did not survive leakage-free reanalysis and are therefore not interpreted as genuine effects. Screening performance was stable across developmental age subgroups, and the explainability analysis highlighted candidate, model-derived features that require independent confirmation.

These findings help localize where the signal that distinguishes ASD from SCD resides. The 2 conditions are separated in DSM-5 primarily by RRBs [3], and, consistent with this, a clinician-rated restricted/repetitive-behavior scale showed a substantial group difference. Moreover, a multivariable clinician-rated model differentiated the conditions, whereas the gamified digital tasks did not: the objective social-judgment scenarios, self-report items, or digital restricted/repetitive-behavior proxy did not exceed chance. This dissociation suggests that the present gamified tasks index the social-communication difficulty shared by ASD and SCD rather than the restricted/repetitive-behavior dimension that separates them. A central design implication is that a digital differential diagnostic tool will likely need to measure RRBs and sensory features directly and sensitively—for example, through dedicated interactive tasks or caregiver-facing digital modules—rather than relying on social-judgment performance alone. The clinician-rated benchmark must be interpreted cautiously, because those measures are not independent of the diagnostic decision and require trained raters; it is presented to explain the digital null result, not as evidence that the present instrument differentiates the conditions.

For the screening stage, the decision threshold was set to favor sensitivity over specificity, a tradeoff that is appropriate for first-line screening, in which a missed case carries greater downstream cost than a false-positive referral that can be resolved by subsequent assessment [1,14]. Under this configuration, the self-report module approached the accuracy of a clinician-administered reference standard while requiring no clinician involvement, a property that is potentially attractive for resource-limited or nonspecialist settings [8,9]. This comparison should nonetheless be regarded as preliminary given the cognitive-ability imbalance between the groups. Because screening performance was also stable across developmental age subgroups, the module appears reasonably robust to maturational variation within the age range studied, although replication in independent, IQ-matched cohorts remains necessary before any screening use can be recommended.

The explainability analysis supported the face validity of the screening model without establishing a mechanism. A small set of items recurred as the most influential features across several algorithmically distinct classifiers, and the direction of their effects aligned with clinical expectation, including nonlinear patterns for an empathy and ToM item that are consistent with compensatory processes described in the autism literature [25,26]. Because SHAP can quantify each feature's contribution to model predictions but cannot demonstrate causal or mechanistic roles [22], these converging items are best regarded as candidate, model-derived markers that require independent, prospective confirmation rather than as validated clinical mechanisms.

The difficulty of the differentiation stage is consistent with the clinical and nosological overlap between the 2 conditions. ASD and SCD share the core domain of social-communication impairment and are separated in DSM-5 chiefly by the presence of RRBs [3], a domain that neither gamified module was designed to measure. Self-report ratings and social-judgment tasks that probe the shared social-communication phenotype may therefore index the common pathway [27] through which both conditions manifest, rather than the features that distinguish them. Consistent with this account, the between-group difference on directly observed interaction behavior in our sample was negligible, and observer-rated social measures alone are known to have limited power to separate these overlapping presentations [7]. We note that an earlier analysis had interpreted differences among feature sets as evidence of a construct-level information-dilution effect. Because that pattern did not survive leakage-free reanalysis, we no longer advance it and instead attribute the earlier impression to analytic bias rather than to a genuine property of the constructs.

Across all 4 algorithm classes, no feature configuration robustly separated ASD from SCD once selection leakage was removed, and individual clinician-rated subscales likewise failed to reach a useful level of accuracy for discriminating the 2 conditions. Together, these results indicate that the ASD-SCD boundary—defined in DSM-5 primarily by RRBs, which neither module directly measures—could not be resolved by the present gamified tasks in a sample of this size. The earlier impression that psychometric item selection was central to differential performance reflected optimistic bias introduced when items were selected on the full dataset rather than within cross-validation folds, and not a generalizable signal. Future work will require substantially larger, IQ- and language-matched samples; direct measurement of RRBs; and preregistered, fully nested analysis pipelines before differential diagnostic claims can be supported.

Methodologically, the contrast between our earlier and reanalyzed results is an instructive cautionary example for the digital-biomarker field. When correlation-based item selection and imputation were carried out on the full sample before cross-validation, the differentiation model appeared informative. When the identical steps were nested within each training fold,

XSL•FO
RenderX

the apparent advantage of objective features over self-report features disappeared, and all configurations reverted to chance. This is a well-characterized consequence of performing supervised feature selection outside the resampling loop, which permits information from held-out cases to influence model construction and inflates apparent performance, especially in small samples [21,28]. The episode underscores that feature selection, imputation, and any data-driven dimensionality reduction must be embedded within cross-validation and that preregistration of the analysis plan provides useful protection against such optimistic bias.

Buddy Drill was designed to probe social-cognitive processes, motivated by accounts in which ASD involves impaired mentalizing while SCD shows relatively preserved mentalizing with selective pragmatic deficits [11,12,29]. We had noted item-level accuracy differences on individual scenarios (eg, D099 and D075). However, because these item-level features were identified using the full sample rather than within cross-validation folds, they are considered exploratory and were not confirmed in the leakage-free analysis. We therefore have not interpreted them as validated differential biomarkers, and the ToM framing of Buddy Drill remains a hypothesis rather than a supported finding in these data.

From a clinical standpoint, these results temper expectations for gamified social-cognitive tasks as stand-alone differential diagnostic tools. Because the information that distinguishes ASD from SCD appears to lie in RRBs as characterized by trained clinicians [3], and because such ratings are neither independent of the diagnostic decision nor scalable without professional administration, they cannot substitute for an automated digital instrument. The practical corollary is that a useful digital differentiation tool would need to elicit RRBs and sensory features directly and sensitively, and would then require prospective, externally validated evaluation before any clinical role could be considered [30].

The variability of some algorithms across resampling folds further illustrates how fragile differential estimates can be at the present sample size, where a single classifier may appear either strong or uninformative depending on how the folds are partitioned. Such instability reinforces the importance of reporting nested, resampled estimates with CIs rather than single point values and the importance of interpreting abbreviated or reduced-item protocols with corresponding caution [21]. In our data, shortened item sets conferred no advantage for differentiation once leakage was removed, and we therefore do not recommend them for that purpose in the absence of substantially larger validation samples.

Comparison With Prior Work

Previous digital screening studies have primarily focused on ASD versus typically developing comparisons, reporting AUC values of 0.85 - 0.95 [14-16]. Our stage 1 result (AUC=0.912) is consistent with this range while adding nested cross-validation and SHAP explainability. The ASD-SCD differential comparison addressed in stage 2 has received less attention in the digital biomarker literature. To our knowledge, this is the first gamified assessment system to target this specific differential. We initially observed what appeared to be an information-dilution effect, but this did not survive a fully nested reanalysis and is now attributed to feature-selection leakage. We therefore do not advance it as a substantive finding. The more robust implication is methodological: in small digital-phenotyping samples, feature selection and dimensionality reduction must be nested within cross-validation, as emphasized in the ML literature [28], or estimates will be optimistically biased.

Our secondary analyses drew on a dimensionality-reduction framework previously applied to gamified emotional-cognitive indices in children [23], from which we derived composite "N-score" dimensions for the screening comparison and an exploratory hybrid model for differentiation. Because these composites and their accompanying item selection were derived on the full sample rather than within cross-validation folds, they are subject to the same optimistic bias identified for the primary differentiation analysis. We therefore report them only as hypothesis-generating and do not interpret them as validated evidence of differential diagnostic value. The dimensionality-reduction approach may nonetheless merit re-examination in adequately powered future studies that embed every data-driven step within the resampling procedure.

Limitations

This study has some limitations. First, several sample and measurement constraints limit interpretation. The Buddy Drill module was not administered to the ND group, and thus, stage 2 could be evaluated only for the ASD-versus-SCD contrast. Moreover, whether the objective items discriminate children with ASD from typically developing children remains untested. More importantly, cognitive ability was not comparable across groups and could not be adjusted for: FSIQ was measured only in subsets of the clinical groups and not in the neurotypical group, and thus, no measured ASD-ND IQ comparison or IQ-matched stage 1 analysis was possible. Stage 1 accuracy may partly reflect general cognitive-developmental differences rather than social cognition specifically, and language ability was likewise not assessed. In addition, Buddy Plan involves self-report, which raises validity concerns for younger and lower-ability children, and no test-retest reliability or measurement-invariance data were collected.

Second, analytic and generalizability constraints apply. The originally reported stage 2 estimate was inflated by feature-selection leakage. When item selection and imputation were nested within each training fold, discrimination fell to chance, and we therefore have reported stage 2 as a null result and have treated all secondary analyses that relied on full-sample selection or PCA (N-scores and hybrid models) as exploratory. The item-selection procedure was also only a correlation-based approximation of IRT rather than formal IRT modeling. All results were derived from internal cross-validation in a single, predominantly male, culturally homogeneous Korean sample without external validation, which limits generalizability. Moreover, because stage 2 did not exceed chance, it has no established clinical utility for ASD-SCD differentiation, and thus, predictive values based on the earlier (leaky) estimates are not reported.

XSL•FO
RenderX

Third, some interpretive and governance caveats remain. The Buddy Plan subscale structure was derived by expert consensus without factor-analytic validation, and one subscale showed low internal consistency. Thus, subscale-level interpretations are provisional. Likewise, the SHAP-based explainability analyses are associational rather than causal, and the highlighted features should be regarded as candidate markers requiring independent validation. Finally, 2 authors are affiliated with the developer of the assessment platform. Although the analyses were conducted independently at the Korea Brain Research Institute under a prespecified plan, no independent data-monitoring committee was involved, and the study was not preregistered. These factors warrant consideration when interpreting the findings.

Conclusions

The gamified Buddy Plan screening module distinguished children with ASD from their ND peers with high internal accuracy, supporting its promise as a first-line screening aid. However, this result is confounded by an unmatched cognitive-ability difference between the groups and therefore remains preliminary. The Buddy Drill differentiation module, by contrast, did not reliably distinguish ASD from SCD once feature-selection leakage was removed with a fully nested pipeline. Beyond the specific instrument, the study carries a broader message for the digital-biomarker field: in small clinical samples, feature selection and dimensionality reduction must be nested within cross-validation because procedures applied outside it can create apparent differential signals that do not generalize. Clinically, the observation that the differential signal between ASD and SCD resided in clinician-rated RRBs rather than in social-judgment task performance suggests that future digital differentiation tools should measure RRBs and sensory features directly. Prospective, externally validated studies with IQ- and language-matched, sex-balanced cohorts will be required before any clinical application, and no clinical deployment is warranted on the basis of the present data.

Acknowledgments

The authors thank the participating children and their families for their time and effort. We are grateful to the research staff and clinicians at Purme Foundation Nexon Children's Rehabilitation Hospital, Incheon Medical Center, Ewha Womans University Medical Center, Pusan National University Yangsan Hospital, and the Korea Brain Research Institute for their assistance with participant recruitment and data collection. Generative AI was not used in the original study design, data collection, statistical analysis, or interpretation. During preparation of the revised manuscript, the authors used Claude (Anthropic) to support language editing, the drafting of point-by-point responses to peer review, and the reanalysis code used to verify the cross-validation pipeline. The tool did not generate study data, design the study, or make analytic or interpretive decisions. All AI-assisted text and code were reviewed, verified, and approved by the authors, who take full responsibility for the integrity and content of the work. A complete generative AI use declaration prepared with the GAIDET (Generative AI Disclosure and Ethics Tool) framework is provided below.

In accordance with the GAIDET framework, the authors declare the following. Tool: Claude (Anthropic). Generative AI was not used for study conceptualization or design, participant recruitment or data collection, generation or fabrication of any data, selection of analyses, or interpretation of results. Generative AI was used, under full author supervision, for: (1) language editing and copyediting of author-written text; (2) drafting point-by-point responses to peer review; (3) assisting with the analysis and reanalysis code used to verify the nested cross-validation pipeline, with all code independently reviewed and reproduced by the authors; and (4) formatting and internal-consistency checks. No generative AI system is listed as an author or met authorship criteria. No confidential or identifiable participant data were entered into any AI system. All AI-assisted text and code were critically reviewed, verified, edited, and approved by the named authors, who take full responsibility for the integrity, accuracy, and originality of the entire manuscript.

Funding

This work was supported by the KBRI Basic Research Programs (26-BR-ISD-02), the National Center for Mental Health (MHER25C02), the AI-based Medical System Digital Transformation Support Program through the National IT Industry Promotion Agency (NIPA; R-20240329 - 024032) funded by the Ministry of Science and ICT, and the Startup Growth Technology Development Program (TIPS) through the Korea Technology and Information Promotion Agency for SMEs (TIPA; RS-2023 - 00303958) funded by the Ministry of SMEs and Startups.

Data Availability

The deidentified datasets generated and analyzed during this study are not publicly available owing to participant confidentiality requirements and institutional review board (IRB) restrictions on sharing clinical data from minors. However, to support transparency and independent verification, the following resources are available upon reasonable request: (1) the complete deidentified dataset, subject to execution of a data use agreement approved by the relevant IRB; (2) the full analysis code comprising the complete, end-to-end reproducible pipeline (Python scripts for data preprocessing and imputation, correlation-based item selection, nested cross-validation splits, complete hyperparameter grids, threshold selection, calibration, and Shapley Additive Explanations analyses), together with a fixed random seed and an environment specification to enable exact reproduction; and (3) the prespecified statistical analysis plan. Requests should be directed to the authors (MJ: minyoung@kbri.re.kr; SC: sungja_cho@neudive.com).

Conflicts of Interest

MJ, JR, EL, and SC are affiliated with Neudive Inc, the company that developed the Buddy Plan and Buddy Drill digital assessment modules used in this study, and this represents a potential conflict of interest. YS, SK, and JHK declare no conflicts of interest. To mitigate potential bias, the following governance procedures were implemented: (1) all data analyses and interpretations were performed by MJ at the Korea Brain Research Institute (KBRI), physically and administratively independent from Neudive Inc; (2) the statistical analysis plan, including all model hyperparameters, the cross-validation structure, and performance metrics, was documented prior to data access; (3) the analysis code was version-controlled and is available upon request for independent verification; and (4) Neudive Inc provided the digital assessment platform and contributed to data collection logistics but had no role in study design, statistical analysis, result interpretation, or the decision to submit the manuscript. Despite these measures, the absence of a formal independent data monitoring committee and the lack of study preregistration remain limitations. Prospective registration in a clinical trial or prediction model registry is planned for future validation studies.

Abstract

Background: Many existing digital cognitive assessments rely on isolated or abstract tasks, and primarily use accuracy-based outcome measures, despite recent advances in the field. Few have been culturally adapted to reflect the familiar daily-life experiences of Korean older adults. Integrating culturally meaningful scenarios with task-specific accuracy and reaction time (RT) measures may provide a more ecologically grounded approach to mild cognitive impairment (MCI) screening.

Objective: This study aimed to develop and preliminarily evaluate a tablet-based, scenario-based serious game for community-based MCI screening among Korean older adults.

Methods: In this cross-sectional diagnostic accuracy study, community-dwelling adults aged 60 - 84 years were recruited through convenience sampling from a senior welfare center in Daejeon, South Korea, between July 2024 and June 2025. Of 87 participants who underwent eligibility assessment, 67 participants were included in the analysis: 47 cognitively normal participants, and 20 participants with MCI. Clinical classification was determined according to Petersen criteria based on the Korean version of the Consortium to Establish a Registry for Alzheimer's Disease battery, second edition, structured clinical interviews, and clinician judgment blinded to the serious game results. The serious game initially comprised 5 culturally familiar and ecologically grounded daily-life tasks, from which task-specific accuracy and RT features were extracted. A reduced 4-task model informed by exploratory misclassification analysis served as the primary classification model and was evaluated using random forest classification with out-of-bag validation. A full 5-task model and a demographic-adjusted model were also evaluated. Convergent validity and perceived workload were assessed.

Results: The group with MCI was older (77.3 vs 74.5 y; *P*=.002) and had fewer years of education (9.4 vs 11.2 y; *P*=.04). The primary 4-task model achieved an overall accuracy of 82.1% (55/67), balanced accuracy of 80.1%, sensitivity of 75% (15/20), specificity of 85.1% (40/47), and an area under the receiver operating characteristic curve of 0.787 (95% CI 0.643 - 0.932). The demographic-adjusted model showed broadly comparable discrimination (area under the receiver operating characteristic curve 0.794, 95% CI 0.654 - 0.934). Accuracy and RT measures from the sale items task ranked among the most important predictors. Digital composite scores were significantly correlated with the Korean version of the Consortium to Establish a Registry for Alzheimer's Disease battery, second edition total score (*r*=.655 and *r*=.447; both *P*<.001). Perceived workload did not significantly differ between groups (*P*=.97).

Conclusions: This study provides preliminary evidence for the diagnostic utility and feasibility of a tablet-based serious game integrating culturally familiar daily-life scenarios with task-specific accuracy and RT measures, thereby capturing both performance accuracy and potential differences in processing efficiency. The automated format may offer a scalable and accessible screening option for community settings without specialized equipment. Independent, multisite, and longitudinal validation is required to establish its generalizability and predictive utility.

Introduction

Mild cognitive impairment (MCI) represents an intermediate clinical state between normative aging and dementia, characterized by cognitive decline that does not yet interfere substantially with daily functioning [1-3]. Individuals with MCI show an elevated risk of progressing to various dementia syndromes, although clinical trajectories remain heterogeneous [4-6]. The growing global burden of dementia, which is projected to exceed 130 million cases by 2050, highlights the importance of identifying cognitive vulnerability as early as possible [7]. Early detection enables timely monitoring, preventive intervention, and implementation of lifestyle strategies that may mitigate further decline [8,9]. In South Korea, nationwide prevalence estimates indicate that 20% to 30% of older adults meet criteria for MCI, underscoring the need for scalable screening approaches [10]. However, current diagnostic standards are often constrained by lengthy administration times, high costs, and the need for specialized personnel [11,12]. Furthermore, because early cognitive changes often mimic normal age-related decline [13], many individuals lack insight into their clinical status and fail to seek medical attention voluntarily [14]. This inherent difficulty in self-recognition, coupled with systemic barriers, underscores the need for accessible, cost-effective, and automated community-level screening tools.

Traditional neuropsychological assessments used for MCI screening vary widely in diagnostic performance [15,16]. The Mini-Mental State Examination (MMSE), although widely administered, shows low sensitivity for detecting MCI due to ceiling effects and limited assessment of attention and executive functioning [15,17,18]. The MoCA (Montreal Cognitive Assessment) demonstrates higher sensitivity (often 80% - 100%) but tends to show lower specificity and still requires trained examiners, which limits its scalability for routine community-based screening [15,17,19]. In South Korea, the Korean version of the Consortium to Establish a Registry for Alzheimer's Disease is widely used as a clinical reference battery because it provides well-established normative data within an internationally standardized assessment framework [20,21]. Its strong emphasis on memory assessment, reflecting its original development for Alzheimer disease, may reduce its sensitivity to nonamnestic presentations of MCI [22,23]. These limitations provide a rationale for digital approaches that can complement conventional screening. However, advances in digital approaches alone do not ensure that these tools are culturally appropriate or sufficiently sensitive to detect subtle behavioral changes associated with early cognitive decline.

Digital cognitive assessment has advanced substantially in recent years, with remote, unsupervised, and tablet-based tools demonstrating promising diagnostic performance for detecting MCI and dementia [24-27]. Serious game–based approaches have further extended digital assessment by embedding cognitive tasks within familiar everyday activities [28-31]. For example, recent scenario-based tools have assessed cognitive functioning through activities such as shopping in a virtual supermarket and other self-administered tasks modeled on everyday situations, supporting the feasibility of ecologically valid MCI screening [32-34]. However, these tools were developed and validated outside South Korea, and their language, scenarios, and interaction demands may not transfer directly to community-dwelling Korean older adults. Consistent with this, reviews of touchscreen cognitive tools have identified limited cultural and linguistic diversity in their development and validation, raising concerns about the generalizability of these tools across populations [35]. Culturally adapted assessment therefore requires more than translating existing tools; it involves designing task content, instructions, and interaction formats to reflect the everyday experiences of the intended population [36,37]. These limitations highlight the need for culturally adapted, scenario-based digital assessments developed and validated specifically for Korean older adults.

Culturally adapted design addresses one limitation of existing digital cognitive assessments; however, another limitation is their continued reliance on summary end point measures, such as overall accuracy, total completion time, or other aggregate scores [38,39]. Although these summary indices provide useful information regarding overall task performance, they may not fully capture subtle cognitive changes associated with early-stage MCI [40]. In contrast, a process-based approach to cognitive assessment offers an alternative framework by focusing on how cognitive tasks are performed rather than solely on their outcomes [38,39]. Within this framework, behavioral patterns observed during task performance provide clinically meaningful information beyond conventional end point scores [38,39]. Digital cognitive assessment is particularly well suited to process-based evaluation because it enables the automated capture of response-process data [41]. Such process-sensitive measures include reaction time (RT) and other behavioral indicators derived from task performance that are difficult to obtain using conventional paper-and-pencil assessments [41]. This perspective is consistent with information-processing and processing-speed theories of cognitive aging, which suggest that reduced processing efficiency associated with aging and early cognitive decline may be reflected in behavioral measures such as RT [42,43]. Among these process-sensitive behavioral indicators, the present study focused specifically on task-level RT, which may reflect processing efficiency while providing information complementary to conventional accuracy-based scores [44-48].

To address these remaining gaps, we developed a tablet-based, scenario-based serious game designed from the outset around the cultural and everyday experiences of community-dwelling Korean older adults. Drawing on a process-based assessment framework, the platform integrates culturally familiar daily-life scenarios with task-level accuracy and RT measures, a process-sensitive indicator of cognitive performance [38,41]. Task-level RT was included as a potential indicator of processing efficiency, complementing conventional accuracy-focused assessment [38,39]. This cross-sectional diagnostic accuracy study evaluated the preliminary diagnostic performance, convergent validity, and feasibility of this integrated approach. We further examined the contribution of task-level accuracy and RT measures to classifying older adults as having MCI or normal cognition.

Methods

Participants

Inclusion and Exclusion Criteria

Eligibility criteria included community-dwelling older adults aged 60 - 84 years who voluntarily participated and provided informed consent.

Exclusion criteria were the following: (1) a diagnosis of major neurocognitive disorder or inability to perform activities of daily living independently; (2) a history of major psychotic disorders (eg, schizophrenia) or current use of antipsychotic medications; (3) a history of significant head injury or neurological disorders; (4) uncorrectable hearing impairment or physical conditions that precluded tablet use; or (5) difficulty understanding the study aims and procedures. Additionally, participants scoring ≤19 on the MMSE, indicative of at least moderate neurocognitive impairment [49], were excluded to ensure that the sample targeted the MCI and cognitively normal (CN) range. However, no enrolled participant met this exclusion criterion.

Participants' Characteristics

This cross-sectional diagnostic accuracy study included community-dwelling adults aged 60 - 84 years from Daejeon, South Korea.

Sampling and Recruitment Procedure

Participants were recruited using convenience sampling from the Yuseong Senior Welfare Center in Daejeon, South Korea. The research team visited the center, explained this study to potential participants, and invited voluntary participation, resulting in a self-selected sample. A total of 89 individuals expressed interest in this study, of whom 2 individuals voluntarily withdrew during the scheduling process before formal screening. Consequently, 87 participants underwent eligibility assessment. Data collection was conducted from July 2024 to June 2025 in a quiet, partitioned consultation room within the facility to minimize environmental distractions and participant fatigue.

Ethical Considerations

This study was approved by the Institutional Review Board of Chungnam National University (202403-SB-038-01) and conducted in accordance with the Declaration of Helsinki. All participants received a detailed explanation of this study's purpose, procedures, potential risks, and their right to withdraw at any time without penalty, and provided written informed consent before participation. To protect privacy and confidentiality, all data were deidentified using unique identification numbers, and electronic files were stored in password-protected folders accessible only to the research team. Participants received a clinical report on their cognitive status and a participation fee of 50,000 KRW (a currency exchange rate of 1000 KRW=US $0.74 was applicable; approximately US $37) via bank transfer for the 2-hour session. The compensation was determined to be appropriate for the time commitment and did not constitute undue inducement. No identifiable personal information is included in this paper.

Sample Size, Power, and Precision

No a priori power analysis was conducted as this was a preliminary validation study focusing on feasibility and estimation precision rather than hypothesis testing. The target sample size was pragmatically set at approximately 60 - 70 participants based on recruitment feasibility and consistency with prior early-stage pilot and validation studies, which typically enroll small-to-moderate samples [50]. A total of 67 participants were included in the final analysis. To address precision, 95% CIs are reported for all primary diagnostic metrics, and findings are interpreted based on the precision of these estimates rather than reliance on *P* values alone. These considerations are consistent with recommendations for pilot and preliminary diagnostic accuracy studies [51,52].

Measures and Covariates

Overview

The primary measures in this study were performance indices derived from the serious game, which were used as features for diagnostic classification. Secondary measures included the second edition of the Korean version of the Consortium to Establish a Registry for Alzheimer's Disease (CERAD-K2) total score, which was calculated from selected core subtests according to the standardized scoring protocol and used exclusively for convergent validity analysis. The NASA Task Load Index (NASA-TLX) was used to assess perceived workload and usability of the digital tool. Age and education were included as covariates because baseline group differences were observed in these variables, and they were considered potential confounders in the interpretation of diagnostic performance.

Reference Standard

The CERAD-K2 battery was used as part of the clinical reference standard [53]. During the clinical interview, a brief *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition])–based prompt was used to document participants' self-reported cognitive difficulties across domains as supplementary clinical information. The final diagnosis of MCI vs CN was determined by a clinician based on a comprehensive assessment, including all CERAD-K2 subtest results and structured clinical rating procedures, with consideration of potential confounding factors (eg, affective disorders). Additional measures, including the MMSE (J3) and executive function tests (eg, Trail Making Test and Stroop Test; J9, J-ga), were used to inform clinical diagnosis, although they were not included in the CERAD-K2 total score. The clinician was blinded to the results of the serious game assessment during diagnostic determination.

Convergent Validity Measure

Separately, the CERAD-K2 total score (maximum score of 110) was derived from the sum of its 7 core components (J1, J2, and J4-J8) solely for the purpose of assessing the convergent validity of the digital tool. Following the standardized CERAD-K2 scoring protocol, J3 (MMSE) and executive function measures (Trail Making Test and Stroop; eg, J9 and J-ga) were excluded from the total score.

XSL•FO
RenderX

Serious Game Tasks

The serious-game screening tool comprised 5 ecologically valid tasks that probe early vulnerable neurocognitive functions in older adults. Accuracy and RT were recorded for each task to index both performance level and processing efficiency. Tasks were embedded in a continuous daily-life scenario that approximates instrumental activities of daily living in older adults. Their scenario roles and targeted cognitive domains are summarized in Table 1. Representative screenshots of the user interface for each task are provided in Figures S1-S5 in Multimedia Appendix 1. All 5 tasks were administered, and features from 4 tasks were ultimately retained for the machine learning (ML) classification model (see Results section for details on model refinement).

Each task was preceded by 1 practice trial to ensure rule comprehension. Accuracy was calculated as the raw number of correct responses (or partial score where applicable), and RT was measured in milliseconds.

Regarding sale items (memory), participants were presented with a list of 12 target items to memorize. The items consisted of high-frequency bisyllabic Korean words representing common market goods. In the recognition phase, participants had to identify the 12 target items from a pool containing 12 distractors (24 items in total). The performance metrics included accuracy (number of correctly identified items) and total completion time (from task onset to completion).

Regarding puzzle-solving (visuospatial), participants were asked to complete a puzzle consisting of 9 pieces. The metrics recorded were accuracy (success or failure) and total completion time (mean time from start to placing the last piece).

Regarding traffic signals (executive function and set-shifting), this task assessed cognitive flexibility using 20 trials with a 2-second time limit per trial. Stimuli consisted of 4 variations: 2 colors (green and red) and 2 postures (walking and standing). The task required participants to respond (“go” or “stop”) based on a changing rule (color rule vs shape rule). For example, under the “color rule,” participants had to follow the color regardless of the shape, whereas under the “shape rule,” they had to attend to the posture. Metrics included accuracy (number of correct responses) and mean RT (average latency of correct responses).

Regarding rice-barley (attention and inhibition), a localized auditory go or no-go task consisting of 100 trials was administered. Participants heard randomized voice stimuli of “rice” (ssal; go) or “barley” (bori; no-go) with a 1-second time limit. The ratio of go to no-go stimuli was 7:3 (70 rice and 30 barley) to induce response prepotency. Metrics included accuracy (number of correct responses) and mean RT (average latency for correct “go” trials).

Regarding spatial navigation (visuospatial memory), participants viewed a map with a designated path and were required to reproduce the path by connecting dots. The task consisted of 3 trials. While the practice trial presented the map in a standard orientation, the test trials required mental rotation, as the maps were rotated 90°, 180°, and 270°. Metrics included accuracy (partial scoring based on the number of correctly connected segments) and mean completion time (average time to complete the 3 trials).

Table . Task components of the serious game–based mild cognitive impairment screening tool. The tool consists of 5 ecologically grounded tasks designed to approximate instrumental activities of daily living and assess early neurocognitive changes. These tasks were used in a cross-sectional diagnostic study involving community-dwelling older adults (N=67) at the Yuseong Senior Welfare Center in Daejeon, South Korea, between July 2024 and June 2025. Scenario phases are numbered according to their sequence within the continuous daily-life storyline. Accuracy and reaction time were recorded for each task to assess performance level and processing efficiency. Five tasks were embedded in a continuous daily-life scenario approximating instrumental activities of daily living in older adults. Each task was preceded by 1 practice trial.

Scenario phase	Task name	Scenario role	Targeted domain
1 and 5	Sale items task	Checking a market flyer to encode discounted items (step 1) and later recognizing and purchasing those items at the market (step 5)	Multimodal (visual-verbal) memory
2	Puzzle-solving	Helping a grandchild complete a puzzle	Visual organization
3	Traffic signal	Crossing a broken traffic light on the way to the market	Executive function (interference control, set-shifting)
4	Rice-barley go/no-go	Participating in a local promotion (rice-barley; a Korean traditional hand game) at the market	Complex attention (sustained and selective attention, inhibitory control)
6	Spatial navigation	Finding the way back home	Spatio-temporal memory, route learning

Demographic Covariates

Age and education were included as demographic covariates because statistically significant group differences were observed in these variables. These variables were not prespecified predictors but were included to account for potential confounding in the interpretation of diagnostic performance. This approach is consistent with the common practice in diagnostic accuracy studies to adjust for demographic factors associated with cognitive performance [54,55].

Usability Assessment and Psychometric Evaluation

Usability was evaluated immediately after the digital protocol using the NASA-TLX [56], a self-report instrument widely used

XSL•FO
RenderX

to measure subjective mental workload. The assessment used items based on the 6 dimensions of NASA-TLX (mental demand, physical demand, temporal demand, performance, effort, and frustration) to evaluate the perceived workload and usability of the digital tool.

Procedure

Data Collection

All sessions were conducted individually in a quiet room. Following informed consent, participants first completed the MMSE for initial screening, the serious game assessment (approximately 20 min), and the usability questionnaire. After a 10-minute rest, the CERAD-K2 battery and clinical interviews were administered using paper-and-pencil procedures, with optional breaks provided to minimize fatigue.

Quality of Measurements

Assessments were administered by 2 master's-level trainees who received prior training in the standardized assessment procedures. All sessions were conducted under the supervision of a licensed clinical psychologist, who reviewed the assessment results and ensured consistency in administration and diagnostic decision-making.

Clinical Classification

Participants were classified into CN groups or groups with MCI according to Petersen's criteria. Objective cognitive impairment was defined as performance at least 1.5 SD below the age- and education-adjusted norms (≤−1.5 SD) in one or more cognitive domains. Subjective cognitive complaints were assessed during the clinical interview. Clinical diagnosis was based on a comprehensive assessment that included the CERAD-K2 neuropsychological battery and a structured clinical interview. All neuropsychological assessments and interviews were administered by 2 master's-level clinical psychology trainees. Final diagnoses were determined by a licensed clinical psychologist who supervised the process and reviewed all test and interview data.

Participants in the group with MCI did not exhibit significant impairment in activities of daily living. In addition to the prespecified exclusion criteria, a subset of participants was excluded after the clinical interview based on semistructured evaluation. Participants were excluded if the interview suggested that their cognitive complaints were primarily attributable to current depressive or anxiety symptoms (suspected affective etiology) or if functional impairment in activities of daily living exceeded the range typically associated with MCI, indicating possible major neurocognitive disorder. These decisions were made by a licensed clinical psychologist based on clinical judgment. This approach was intended to reduce potential confounding related to affective symptoms or functional impairment.

Data Diagnostics

Data Preprocessing

Before model construction, we preprocessed the data to ensure quality. Missing values resulting from technical errors or system malfunctions were excluded via listwise deletion; the number of affected observations ranged from 1 to 7 across behavioral features.

The wide range of RT values across features (approximately 270 to 296,000 ms) reflects differences in how RT was operationalized across tasks, not extreme values within any single task. The traffic signal and rice-barley RT represent mean per-trial response latencies, whereas sale items and spatial navigation RT represent total task completion times. All recorded RT values were retained, as no system errors were flagged during data logging.

All behavioral features (accuracy and RT for each of the 4 tasks; 8 features total) and demographic covariates (age and year of education) were then standardized to *z* scores (mean 0, SD 1) across the full analytic sample using the scale() function in R (R Foundation) because random forest (RF) splits are based on the rank order of observations; tree-based classifiers are invariant to monotonic transformations of individual predictors [57,58]; standardization does not alter the model's splitting behavior. We applied standardization for 2 practical reasons. First, the scale differences described above make unstandardized feature values difficult to compare in descriptive summaries and variable importance plots. Second, the digital composite scores (DCS1 and DCS2) are computed as Gini-weighted sums of feature values, and without standardization, features on larger absolute scales would dominate these composites. As standardization parameters (sample mean and SD) were computed from the full analytic sample before out-of-bag evaluation, this procedure is not strictly leakage-free. In practice, however, *z* scoring preserves the rank order on which RF splits depend, so out-of-bag predictions remain unaffected [58]. The m_{try} parameter was set to 3—the square root of the number of behavioral predictors—following the standard recommendation for classification [57].

ML Classification

We used the RF algorithm to classify individuals with MCI and CN. RF is an ensemble ML algorithm known to be particularly effective for datasets characterized by small sample sizes and class imbalance [57,59]. The CN-to-MCI ratio in our sample reflects the natural prevalence of MCI in older general populations, where early cognitive decline often goes undetected because of preserved activities of daily living [10]. Unlike traditional parametric models such as logistic regression, RF handles high-dimensional feature spaces and nonlinear interactions without making strict distributional assumptions while maintaining robustness against overfitting through its recursive partitioning and bagging mechanisms [59,60].

The RF model was optimized with 500 decision trees (ntree=500). To ensure optimal variance reduction and model stability, the number of features randomly sampled at each node split (mtry) was set to 3, which corresponds to the square root of the total number of behavioral predictors, a recommended standard heuristic for classification tasks [60].

Model performance and generalization error were strictly evaluated using the out-of-bag procedure, which serves as a rigorous internal validation mechanism [60]. Each tree of RF used 63.2% of the original data as a bootstrap sample for training

XSL•FO
RenderX

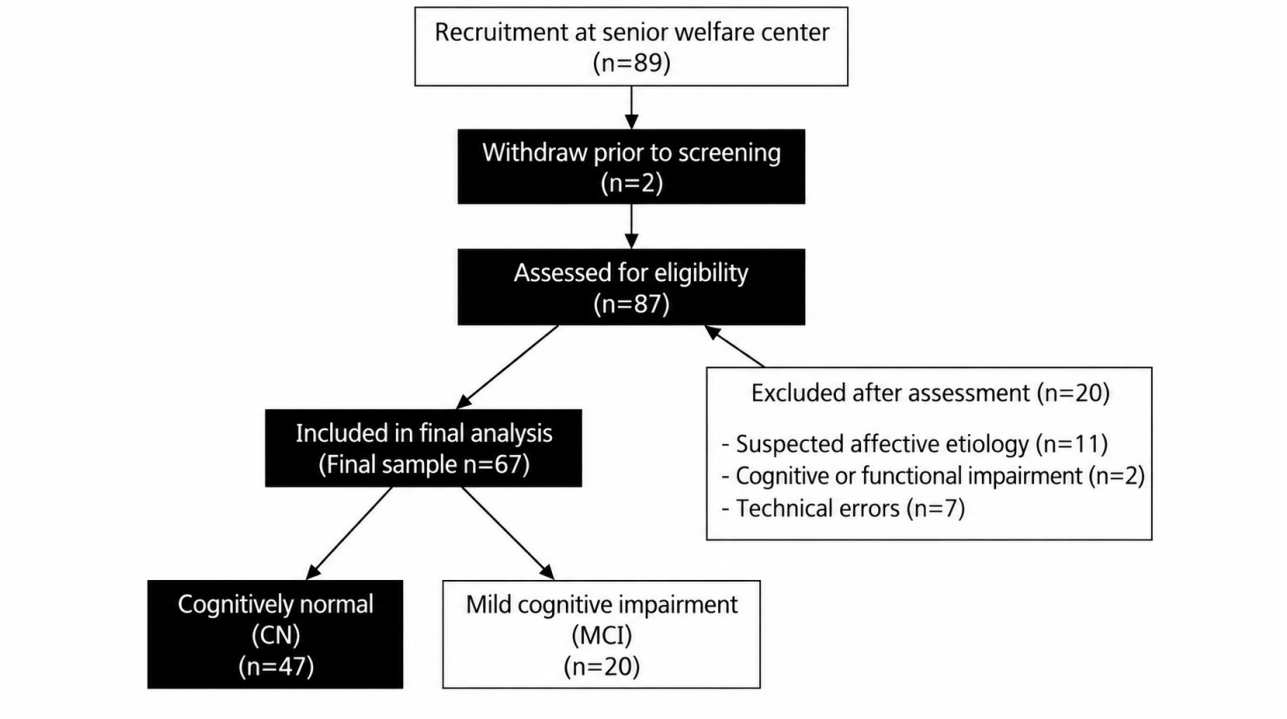
and set the remaining 36.8% of observations as an out-of-bag sample, which was excluded from the training of that specific tree. These out-of-bag samples then functioned as an independent validation set for each tree. By aggregating classification votes across the entire forest for each observation only when it was in an out-of-bag state, the model provides an unbiased estimate of generalization performance (eg, accuracy, sensitivity, specificity, and area under the receiver operating characteristic curve [AUC]). This approach effectively mitigates the risk of data leakage and provides a reliable assessment of diagnostic accuracy in studies where a separate hold-out test set is not feasible due to sample size constraints [60,61]. All statistical analyses were implemented using the *randomForest* package [61] in R (version 4.3.0) [62].

DCS

The primary outputs of the diagnostic model were DCS1 and DCS2, constructed to separately examine the contribution of accuracy-based performance and time-based processing efficiency. For both composites, feature weights were derived from a preliminary RF model trained on the present sample to maximize the contribution of task variables that best discriminated MCI from CN. DCS1 (accuracy-weighted) was calculated as a weighted sum of accuracy scores only, providing a composite analogous to traditional neuropsychological indices. In contrast, DCS2 (RT-included) incorporated both accuracy and RT features in a weighted sum to capture potential slowing and efficiency changes that may emerge in early cognitive decline even when accuracy remains relatively preserved.

Classification Performance and Convergent Validity

Model performance was assessed using accuracy, sensitivity, specificity, balanced accuracy, and the AUC. We estimated the 95% CI for the AUC using the DeLong method [63], implemented via the ci.auc() function in the *pROC* package in R; this approach derives the variance of the AUC nonparametrically from each observation's structural contribution to the overall estimate without assuming a specific score distribution. Feature importance values were extracted using the mean decrease in Gini impurity to examine the relative contribution of each task variable. Convergent validity was assessed by calculating the Pearson correlation coefficient between the digital tool performance and the final CERAD-K2 total score, with 95% CIs estimated using Fisher z transformation.



Results

Participant Flow

Recruitment and data collection were conducted from July 2024 to June 2025. A total of 89 individuals expressed interest in this study, of whom 2 withdrew before formal screening. Consequently, 87 participants underwent eligibility assessment. No participants were excluded at the screening stage based on the prespecified criteria. Following data collection, 20 participants were excluded from the final analysis due to suspected affective etiology (n=11), impairment exceeding the MCI range (n=2), or technical errors in data logging (n=7). This resulted in a final analytic sample of 67 (47 CN and 20 MCI) participants. A detailed participant flow diagram, including screening and exclusion reasons, is presented in Figure 1.

The diagram shows the recruitment, screening, withdrawal, exclusion, and final inclusion of community-dwelling older adults aged 60 - 84 years in Daejeon, South Korea, resulting in a final analytic sample of 67 (47 CN and 20 MCI) participants.

RenderX

Clinical Characteristics and Group Validation

The final analytic sample included 67 older adults, comprising 47 CN participants and 20 participants with MCI. Demographic and lifestyle characteristics of the groups are summarized in Table 2. Independent-samples *t* tests were used for continuous variables, and chi-square tests were used for categorical variables to compare baseline characteristics between groups.

Statistically significant differences were observed in age (*P*=.002) and education (*P*=.04). The group with MCI (77, SD 3 y) was significantly older and had fewer years of education (9, SD 4 y) than the CN group (74, SD 5, and 11, SD 2 y, respectively).

No significant differences were observed between groups in other demographic variables. The proportions of females were similar between groups (32/47, 68%, vs 14/20, 70%; *P*=.99), and no statistically significant differences were found in marital status (*P*=.65). However, no statistically significant difference was observed in driving status (*P*=.051), although a lower proportion of participants with MCI reported driving (6/20, 30%) compared with CN participants (28/47, 60%).

To characterize the clinical profiles of the groups and examine the validity of the classification, CERAD-K2 total scores were compared between groups. As expected, the CN group scored significantly higher than the group with MCI (*P*<.001; Table 2). This difference is consistent with the expected clinical distinction between the groups and supports the diagnostic classification based on the clinical reference standard.

Table . Participant characteristics and CERAD-K2[a] total score by group. This cross-sectional diagnostic study compared CN[b] older adults and those with MCI[c]. Participants were recruited from the Yuseong Senior Welfare Center in Daejeon, South Korea, between July 2024 and June 2025 (total N=67; 47 CN and 20 MCI). Independent samples *t* tests were used for continuous variables, and chi-square tests were used for categorical variables.

Variable	CN (n=47)	MCI (n=20)	*P* value
Demographics			
Age (y), mean (SD)	74 (5)	77 (3)	.002
Education (y), mean (SD)	11 (2)	9 (4)	.04
Female, n (%)	32 (68)	14 (70)	.99
Married, n (%)	43 (91)	18 (90)	.65
Currently driving, n (%)	28 (60)	6 (30)	.051
Clinical measures			
CERAD-K2 total score, mean (SD)	81.0 (9.0)	64.0 (8.0)	<.001

[b]CN: cognitively normal.

[c]MCI: mild cognitive impairment.

Classification Performance, Sensitivity Analysis, and Feature Importance

As a baseline analysis, we evaluated the full 5-task battery, including the puzzle-solving task. In this initial model, classification performance was 79.1% (53/67) accuracy, 70% (14/20) sensitivity, 83% (39/47) specificity, and an AUC of 0.861 (95% CI 0.757 - 0.964). These findings provide a reference for the diagnostic performance of the complete scenario-based assessment (Table 3).

Table . Confusion matrix for the full five-task model. This cross-sectional diagnostic study evaluated the classification performance of 3 models in distinguishing between CN[a] older adults and those with MCI[b]. Participants were recruited from the Yuseong Senior Welfare Center in Daejeon, South Korea, between July 2024 and June 2025 (N=67). Out-of-bag predictions for the full five-task model are presented here (see Tables 4 and 5 for the primary four-task and demographic-adjusted models, respectively).

	Observed CN, n	Observed MCI, n
Predicted CN	39	6
Predicted MCI	8	14

[a]CN: cognitively normal.

[b]MCI: mild cognitive impairment.

To explore potential sources of misclassification, we conducted an exploratory analysis of task-level performance patterns. This analysis indicated that the puzzle-solving task was associated with a higher proportion of false-negative classifications, with some participants with MCI showing relatively preserved performance on this task. Specifically, participants with MCI misclassified as CN showed higher accuracy (*P*=.06) and faster completion times (*P*=.01) than those correctly identified as MCI.

Based on these observations, we conducted a sensitivity analysis excluding the puzzle-solving task. In this reduced model, sensitivity increased to 75% (15/20), while overall accuracy

XSL•FO
RenderX

(55/67, 82.1%) and specificity (40/47, 85.1%) remained comparable. The AUC decreased to 0.787 (95% CI 0.643 - 0.932). The final RF model correctly identified 15 of 20 cases with MCI and 40 of 47 CN cases, as detailed in Table 4.

Table . Confusion matrix for the primary 4-task model. This cross-sectional diagnostic study involved community-dwelling older adults (N=67) recruited from the Yuseong Senior Welfare Center in Daejeon, South Korea, between July 2024 and June 2025.

	Observed CN[a], n	Observed MCI[b], n
Predicted CN	40	5
Predicted MCI	7	15

[a]CN: cognitively normal.

[b]MCI: mild cognitive impairment.

The analysis of feature importance, based on the mean decrease in Gini impurity, identified the variables that contributed most to the model's classification performance (Figures 2A and 2B). The most important feature for distinguishing MCI from CN was the sale items total score (X3_1), which reflects visual-verbal memory and decision-making. Following this, RT-related variables also contributed substantially to classification. The next most important features included sale items RT (X3_2), traffic signal overall RT (X2_2), and spatial navigation RT (X5_2). The prominence of RT-related features, particularly those associated with executive function and processing speed, suggests that variability in response speed may be relevant for distinguishing early cognitive decline.

Figure 2. Variable importance comparison between primary 4-task and demographic-adjusted models. Variable importance was ranked based on the mean decrease in Gini impurity. (A) Primary 4-task model using 8 digital behavioral features. (B) Demographic-adjusted model including age and education. Blue bars indicate behavioral features, whereas orange bars represent demographic covariates. The sale items total score (X3_1) was the highest-ranked feature across both models. This figure is based on a cross-sectional diagnostic study involving community-dwelling older adults recruited from the Yuseong Senior Welfare Center in Daejeon, South Korea, between July 2024 and June 2025.

Assessment of Demographic Covariates on Model Robustness

To evaluate the potential influence of demographic covariates, age and education were added as input features in a sensitivity analysis (Table 5). The AUC showed a modest increase from 0.787 (95% CI 0.643 - 0.932) to 0.794 (95% CI 0.654 - 0.934; Figure 3). The balanced accuracy of the primary 4-task model was 80.1%, showing minimal difference from the overall accuracy (55/67, 82.1%), which suggests that the model maintains consistent classification performance across groups. In the demographic-adjusted model, the balanced accuracy was 77.9%. This slight numerical shift indicates that while task-related features remain the primary drivers of diagnostic performance, demographic factors appeared to contribute incrementally to the model's classification. Other performance indices remained broadly comparable to those of the primary 4-task model, with a sensitivity of 75% (15/20) and specificity of 80.9% (38/47) in the demographic-adjusted model.

As shown in Figure 2, the overall pattern of variable importance appeared to remain similar after demographic adjustment. Specifically, the sale items task variables (X3_1 and X3_2) continued to rank among the top predictors in both the primary 4-task and demographic-adjusted models. Age also showed a

XSL•FO
RenderX

relatively notable contribution, ranking third in the importance hierarchy, although its inclusion did not appear to substantially change the overall diagnostic pattern. Education, by contrast, had a relatively low importance ranking, placing near the bottom of the feature set (9th; mean decrease Gini=1.7883). Taken together, these findings suggest that the model's classification performance was still mainly related to task performance, while the influence of demographic factors may have been limited (Table 6).

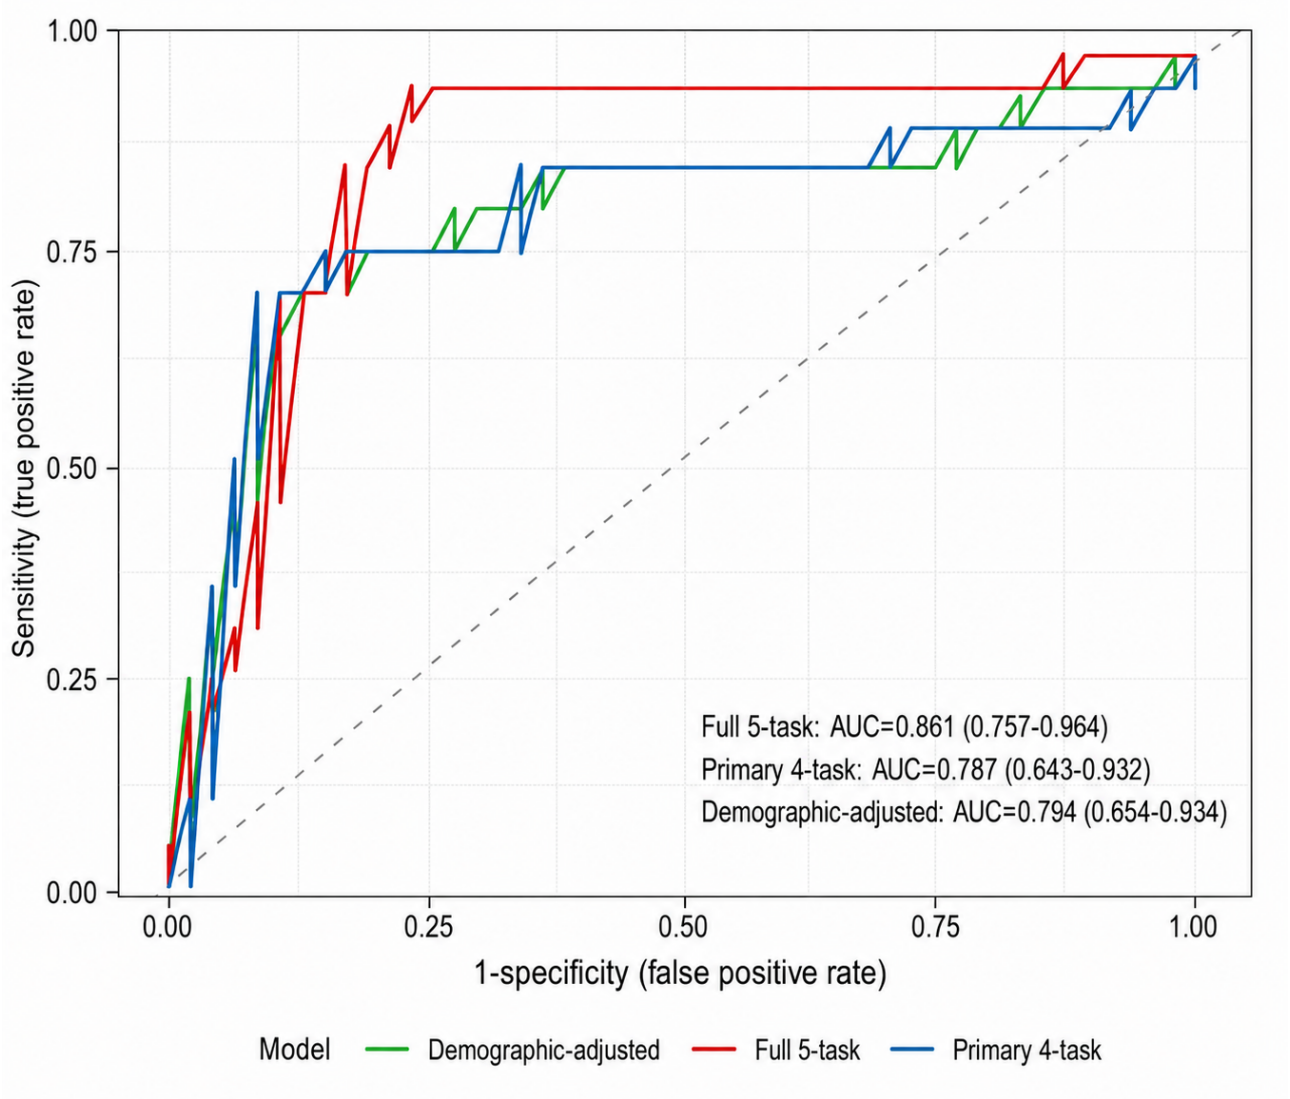

Table . Confusion matrix for the demographic-adjusted model. This cross-sectional diagnostic study involved community-dwelling older adults (N=67) recruited from the Yuseong Senior Welfare Center in Daejeon, South Korea, between July 2024 and June 2025.

	Observed CN[a], n	Observed MCI[b], n
Predicted CN	38	5
Predicted MCI	9	15

[a]CN: cognitively normal.

[b]MCI: mild cognitive impairment.

Figure 3. ROC curve comparison of the 3 predictive models for distinguishing between CN and MCI. This cross-sectional diagnostic study involved community-dwelling older adults (N=67) recruited from the Yuseong Senior Welfare Center in Daejeon, South Korea, between July 2024 and June 2025. The ROC curves illustrate the discriminative performance of 3 models for distinguishing CN individuals from those with MCI: the full 5-task model (red line, AUC=0.861), the primary 4-task model (blue line, AUC=0.787), and the demographic-adjusted model including age and education (green line, AUC=0.794). The comparison indicates comparable classification performance after adjustment for demographic covariates. AUC: area under the receiver operating characteristic curve; CN: cognitively normal; MCI: mild cognitive impairment; ROC: receiver operating characteristic.

Table . Comparison of classification performance across the 3 predictive models. This cross-sectional diagnostic study involved community-dwelling older adults (N=67) recruited from the Yuseong Senior Welfare Center in Daejeon, South Korea, between July 2024 and June 2025. The table compares the diagnostic performance of the primary 4-task model (excluding the puzzle-solving task) and the demographic-adjusted model (including age and education) for distinguishing cognitively normal individuals from those with mild cognitive impairment. Classification performance was evaluated based on out-of-bag predictions from random forest models. Balanced accuracy is reported to account for potential group imbalance.

Model	Accuracy, n/N (%)	Balanced accuracy, %	Sensitivity, n/N (%)	Specificity, n/N (%)
Full 5-task	53/67 (79.1)	76.5	14/20 (70.0)	39/47 (83.0)
Primary 4-task model	55/67 (82.1)	80.1	15/20 (75.0)	40/47 (85.1)
Demographic-adjusted model	53/67 (79.1)	77.9	15/20 (75.0)	38/47 (80.9)

Convergent Validity and Clinical Correlation

The convergent validity of the digital tool was assessed by calculating Pearson correlation coefficients between DCS1 and DCS2 and established clinical standards (CERAD-K2 total score and MMSE). The correlation analysis revealed that both DCS1 and DCS2 showed statistically significant, moderate relationships with the CERAD-K2 total score (DCS1: r=.655; DCS2: r=.447; both P<.001; Table 7). Similar trends were observed in comparisons with the MMSE, with DCS1 (r=.518, P<.001) showing a slightly stronger correlation than DCS2 (r=.442, P<.001). DCS1, which is based on accuracy scores, exhibited a slightly higher correlation with traditional clinical standards compared to DCS2, which integrates RT features. These moderate correlations are consistent with the ranges typically observed in digital screening tools and provide evidence for the convergent validity of the proposed scenario-based assessment.

Table . Pearson correlations between digital composite scores and clinical standards. Pearson correlations between digital composite scores and clinical reference measures in a cross-sectional diagnostic study involving community-dwelling older adults classified as cognitively normal status or as having mild cognitive impairment. Participants were recruited from the Yuseong Senior Welfare Center in Daejeon, South Korea, from July 2024 to June 2025.

Variable	CERAD-K2[a] total score, r (95% CI)	*P* value	MMSE[b], r (95% CI)	*P* value
DCS1[c]	0.655 (0.493-0.774)	<.001	0.518 (0.317-0.674)	<.001
DCS2	0.447 (0.232-0.621)	<.001	0.442 (0.226-0.617)	<.001

[b]MMSE: Mini-Mental State Examination.

[c]DCS: digital composite score.

Subjective Workload and Tool Feasibility

To assess the feasibility and user experience of the digital tool, perceived workload was evaluated using the NASA-TLX immediately following the task administration. Total workload scores did not differ between groups (P=.97), with similar mean ratings observed in the CN group (2.57, SD 0.71) and group with MCI (2.58, SD 0.58). These findings suggest that the scenario-based serious game was perceived as having a comparable cognitive demand across groups, indicating its feasibility for use among older adults in community settings.

Discussion

Principal Findings

This cross-sectional diagnostic accuracy study developed and evaluated a culturally adapted, tablet-based, scenario-based serious game for community-based MCI screening among Korean older adults, providing preliminary evidence of its feasibility and diagnostic utility. The final classification model demonstrated promising diagnostic performance, with an overall accuracy of 82.1% (55/67), a sensitivity of 75% (15/20), and a specificity of 85.1% (40/47). The robustness of the classification framework was further supported by a series of sensitivity analyses. Model performance remained relatively consistent despite variations in task composition and the inclusion of demographic covariates. In addition, the findings suggest the potential value of incorporating task-level RT as a process-sensitive behavioral indicator alongside conventional accuracy measures.

A notable finding emerged from the exploratory evaluation of the initial 5-task battery. Although the initial 5-task model achieved an accuracy of 79.1% (53/67), the puzzle-solving task was associated with a higher rate of false-negative classifications, particularly among participants with MCI. In a post hoc sensitivity analysis, excluding this task increased sensitivity from 70% (14/20) to 75% (15/20), while overall accuracy and specificity remained comparable. However, the AUC decreased from 0.861 to 0.787, indicating that improvements in threshold-dependent performance were accompanied by reduced overall discriminative ability. These findings underscore the potential value of task-level analysis in serious game design, suggesting that identifying tasks with limited discriminative value may inform future refinement of digital screening tools and strengthen process-based cognitive assessment.

Furthermore, we examined the potential confounding effects of demographic variables, a common concern in digital cognitive assessment [54,55]. In the demographic-adjusted model, the

XSL•FO
RenderX

inclusion of age and education as input features was associated with an AUC of 0.794 and an overall accuracy of 79.1% (53/67). Feature importance analysis consistently identified both the accuracy and RT measures from the sale items task as the most important predictors across both models. These findings suggest that task-specific accuracy and RT measures, particularly those derived from the sale items task, contributed more to model performance than the demographic variables included in the model.

Finally, the assessment of convergent validity and feasibility provides additional support for the clinical and practical utility of this tool. DCS1 and DCS2 showed statistically significant, moderate correlations with established clinical measures, including the CERAD-K2 total score and the MMSE. Moreover, the lack of significant group differences in NASA-TLX workload scores suggests that the game-based format imposed a comparable subjective workload on CN and participants with MCI. Taken together, these findings suggest that this culturally adapted, serious game–based approach may provide a scalable and user-friendly platform for community-based MCI screening and cognitive monitoring.

Interpretation of Accuracy and RT Markers

The diagnostic utility of the serious game–based tool may stem from its ability to capture both task accuracy and RT within cognitively meaningful tasks. Feature importance analysis identified accuracy (X3_1) in the sale items task as the strongest predictor, followed by the RT (X3_2) from the same task. These findings may have neuropsychological relevance, as the sale items task is designed to reflect visual-verbal episodic memory, a domain known to be affected early in amnestic MCI and the prodromal phase of Alzheimer disease [3,4].

The finding that both task-level accuracy and RT contributed to classification suggests that the tool captures not only successful task performance but also differences in processing efficiency associated with memory retrieval. In early-stage MCI, individuals may sometimes reach the correct answer but require more time and cognitive effort to do so [64]. By quantifying these subtle delays in responding within an ecologically relevant shopping scenario, the tool may help address some limitations of traditional accuracy-based assessments, which are susceptible to ceiling effects [18,38,39].

In contrast, the relatively low contribution of the puzzle-solving task in the initial 5-task model may offer insights into the cognitive profile of early-stage decline. This task primarily reflects visuoconstructional praxis, a domain that has been reported to remain relatively preserved during the early stages of MCI [65]. Consequently, the relatively preserved performance of some participants with MCI on this task, particularly those misclassified as CN, may have contributed to its limited discriminative power within the sample. These findings suggest that the tool may be particularly sensitive to episodic memory deficits, which represent one of the earliest cognitive changes observed in MCI [3,4,13]. More broadly, they indicate that refining the task battery based on the discriminative contribution of individual tasks may improve the diagnostic performance of serious game–based cognitive screening tools.

Comparison With Prior Work

When compared with widely used cognitive screening instruments, the diagnostic performance of the serious game–based tool appears broadly comparable. Traditional screening tools such as the MMSE often show modest sensitivity for MCI (around 60% - 65%), partly due to ceiling effects and limited coverage of executive or attentional domains [18,66]. The MoCA and CERAD-K2 total scores generally yield sensitivities of approximately 80% - 85% [67,68] and 79% - 84% [69,70], respectively. However, both require trained examiners, with the more comprehensive CERAD-K2 requiring longer administrations [16,53], which may limit their scalability for routine community screening. Within this context, the performance of the tool (accuracy 55/67, 82.1%; sensitivity 15/20, 75%; and specificity 40/47, 85.1%) appears broadly similar to these established approaches while relying on automated, tablet-based task performance measures that may help reduce examiner-related variability. Notably, the automated tool achieved this level of diagnostic performance within approximately 20 minutes, supporting its feasibility for use in both clinical and community settings.

Beyond traditional instruments, the landscape of digital MCI screening is increasingly shifting toward ecologically grounded and culturally adapted approaches that prioritize real-world functional markers over abstract performance metrics [24,31,35-37]. In this expanding field, the present results broadly align with performance ranges reported in contemporary digital and serious game–based MCI screening studies [26,32,71-74]. To place these findings in the context of current domestic digital screening tools, it is useful to compare the present results with those of the recently developed Seoul Cognitive Status Test (SCST) [75]. As reported in a recent clinical utility study involving a large outpatient cohort [75], the SCST demonstrated robust diagnostic validity in clinical settings. Notably, while the SCST achieved near-ceiling discriminative performance for dementia (AUC 0.980), distinguishing clinically normal individuals from those with MCI remained more challenging (AUC 0.854). Although the study populations differed, the comparable performance observed in the present study suggests that ecologically grounded serious game–based assessment may achieve clinically meaningful diagnostic performance in community settings. Furthermore, the tool achieved a specificity of 85.1% (40/47), providing a balanced diagnostic profile suitable for community-level screening. Maintaining this balance is important, as it may help mitigate the risk of excessive false positives that could otherwise strain health care referral systems [76,77].

A key strength of the tool lies in its integrated, scenario-based narrative structure. Unlike many existing digital platforms consisting of isolated mini-games or simple computerized versions of abstract tasks [26,71], the tool integrates multidomain assessment within a seamless daily-life simulation (eg, market shopping and navigating traffic), while capturing both accuracy and task-level RT. Furthermore, the tool was designed to facilitate real-world implementation and scalability for community-based screening. The tool demonstrated comparable diagnostic performance using a standard tablet interface without the need for specialized hardware (eg, high-end

XSL•FO
RenderX

VR sensors), which may limit the large-scale deployment of some contemporary high-tech systems [78,79].

Finally, a notable aspect of the tool is its culturally adapted design, developed specifically for community-dwelling Korean older adults. While many existing digital cognitive assessment tools rely on abstract or linguistically neutral tasks that may not fully reflect the sociocultural contexts of non-Western populations [35-37], the present serious game embeds cognitive tasks within familiar, culturally relevant scenarios, such as participating in traditional games. This approach may enhance ecological validity while potentially reducing cultural bias in the assessment process [31]. Such a design aligns with emerging global initiatives toward the indigenization of cognitive assessments, in which researchers are moving beyond literal translations to develop digital tools grounded in local sociocultural contexts [36,37,80]. Recent efforts, such as the CARE study [80], which developed game-based cognitive protocols for older adults in India, highlight the importance of incorporating indigenous perspectives. By integrating Korean-specific cognitive tasks, the tool reflects this broader movement toward culturally grounded digital assessment and may provide a useful framework for developing culturally adapted cognitive screening tools in other cultural settings.

Clinical and Ecological Implications

The integration of RT variables across multiple tasks suggests that time-based measures may provide clinically relevant information that complements traditional accuracy-based scores. Slower RT has been recognized as a potential behavioral indicator of age-related changes in processing efficiency [81-83], although such information is not routinely captured by memory-centered, accuracy-focused assessments such as the CERAD-K2 [15,23]. Within the present tool, RT indicators embedded in ecologically structured scenarios may capture aspects of processing inefficiency that are not fully reflected by accuracy measures alone. Incorporating both accuracy and RT measures may, therefore, contribute to a more differentiated characterization of cognitive performance in older adults, potentially supporting a more process-oriented understanding of cognitive aging.

The scenario-based design of this tool may offer a practical alternative to traditional cognitive assessment batteries, particularly in community settings. Conventional tests such as the CERAD-K2 rely on abstract tasks (eg, word list recall) that are not explicitly embedded in everyday contexts. In contrast, the present tool assesses cognition through familiar activities such as recalling sale items at a market, navigating traffic, and route finding. This ecological approach may help capture functional aspects of cognition that are relevant to independent living [84,85]. Specifically, these tasks are designed to align with instrumental activities of daily living, which are often among the first functional domains to be affected in the early stages of cognitive impairment [86]. By quantifying cognitive performance within these functional contexts, the tool may provide indicators of early cognitive changes relevant to independent living. Moreover, presenting these tasks within a continuous daily-life narrative may enhance user engagement and acceptability, supporting the feasibility of community-based screening [87,88].

Limitations

Despite the promising performance of the tool, several limitations should be acknowledged. First, although the sensitivity of 75% (15/20) is comparable to that of established clinical instruments, the corresponding false-negative rate of 25% (5/20) should be acknowledged. Therefore, the tool should be considered a complementary screening aid rather than a standalone diagnostic approach, particularly in community-based screening. Second, the generalizability of the findings is constrained by the sample characteristics. Participants were recruited through convenience sampling from a single center and demonstrated relatively higher educational attainment than the national average for Korean older adults [89], which may limit the generalizability of the findings to populations with different educational and sociodemographic backgrounds. Third, some participants required occasional assistance with navigation or device handling, suggesting that further interface refinement may be needed to support fully independent administration [90,91]. Nevertheless, the present version appeared feasible for supervised community-based administration. Fourth, although the RF classifier and out-of-bag procedure were used to estimate classification performance, the relatively small and imbalanced class distribution should be considered when interpreting the findings. Moreover, these performance estimates reflect internal rather than external validation. The post hoc exclusion of the puzzle-solving task was an exploratory refinement intended to identify potentially discriminative markers, and these findings require confirmation in an independent cohort. Finally, because this was a cross-sectional study, the present findings cannot address longitudinal predictive validity for dementia conversion or long-term cognitive trajectories [6,92].

Future Directions

Future research should validate this tool in independent, multisite cohorts. Such studies are needed to confirm the robustness and generalizability of the current findings beyond the internal out-of-bag validation used in the present study. Longitudinal follow-up studies will also be needed to determine whether the RT-based and scenario-based indicators identified here are predictive of cognitive decline over time, including conversion from MCI to dementia. In addition, broader validation across individuals with diverse educational backgrounds and varying levels of digital literacy will be important for assessing real-world scalability [93,94]. Further studies should also incorporate additional variability-based behavioral markers, such as trial-to-trial response-time variability, intraindividual SD, and error-pattern metrics, to better capture response inconsistency and subtle inefficiencies associated with early cognitive decline [95,96]. Finally, continued refinement of autonomous usability features, along with further exploration of adaptive task parameters, may help improve sensitivity to subtle early cognitive changes.

Conclusions

This study provides preliminary evidence supporting the diagnostic utility and feasibility of a tablet-based, scenario-based

XSL•FO
RenderX

serious game for community-based MCI screening. The key innovation of this study lies in integrating culturally familiar, ecologically meaningful daily-life scenarios with task-specific accuracy and RT measures. This approach captures both task performance accuracy and potential differences in processing efficiency within a continuous narrative context. Unlike conventional accuracy-focused screening instruments and digital tools composed of isolated or abstract tasks, this approach combines culturally adapted task design with task-specific RT measures that may provide information about processing efficiency in addition to conventional accuracy measures. These findings contribute to the growing field of digital cognitive assessment by demonstrating the potential value of culturally adapted and ecologically grounded serious games for MCI screening. From a practical perspective, the automated, tablet-based format may offer a scalable and accessible screening option for community settings without requiring specialized equipment. Nevertheless, independent, multisite studies with longitudinal follow-up are needed to establish the generalizability and long-term predictive utility of the tool.

Abstract

Background: Planning deficits are a common and functionally significant executive function difficulty in children with autism, affecting everyday activities such as organizing tasks, prioritizing goals, and monitoring progress. Traditional neuropsychological assessments often lack ecological validity and may not capture these skills in real-world contexts. Serious games offer promising alternatives by simulating everyday scenarios and enabling observation of planning behaviors during interactive tasks. However, most existing systems focus on training rather than theory-driven assessment, and are rarely evaluated for usability before deployment with children with autism.

Objective: This study aimed to design and evaluate ShopAutiPlan, a supermarket-based serious game intended to assess executive planning skills in children with ASD by conducting a formative expert evaluation before its use in clinical or research settings. The evaluation sought to identify usability strengths and limitations, ensuring that the system aligns with planning theory and accommodates the unique needs of autistic users.

Methods: A theory-driven design approach grounded in the Hayes-Roth cognitive model of planning was used to map planning subcomponents—including goal formulation, strategy generation, sequencing, execution, and monitoring—to in-game tasks and logged behavioral metrics. A cross-sectional, formative expert-based usability evaluation was conducted using inspection and think-aloud protocols. Six domain experts (2 psychologists, 2 human-computer interaction researchers, and 2 game developers) participated in individual evaluation sessions. Usability assessment was guided by ASD-specific usability heuristics, and experts completed the System Usability Scale (SUS). SUS scores were summarized using descriptive statistics, and qualitative feedback was analyzed through deductive coding mapped to heuristic categories.

Results: Across experts, 45 usability issues were identified, spanning cognitive accessibility, feedback clarity, realism, and technical performance. Severity ratings varied according to disciplinary perspectives: psychologists highlighted cognitive load, sensory accessibility, and task clarity, whereas developers focused on system responsiveness, interaction consistency, and technical reliability. The overall SUS score (mean 70.4, 95% CI 45.2 - 95.7) exceeded the standard benchmark of 68, supporting the acceptability of the system and complementing the qualitative findings from the heuristic evaluation. Recommendations from the evaluation informed iterative refinements to interface design, interaction flow, and task representation to enhance alignment between planning constructs and user experience.

Conclusions: To the best of our knowledge, this study introduces the first shopping-based serious game specifically designed to assess executive planning skills in children with autism. Unlike many existing autism-related serious games that primarily focus on intervention or training, ShopAutiPlan adopts a theory-driven assessment-oriented design grounded in a cognitive model of planning and supported by gameplay-based behavioral measures. By integrating cognitive theory, serious game design, and interdisciplinary usability evaluation, the study proposes a structured framework for developing ecologically valid digital assessment tools that may complement conventional neuropsychological approaches in autism research and clinical practice.

Introduction

Planning Deficits in Autism Spectrum Disorder

Autism spectrum disorder (ASD) is characterized by social communication difficulties, restricted interests, and repetitive behaviors [1]. Beyond these core features, impairments in executive functions are widely reported in autism, with planning deficits being among the most prominent and functionally impairing [2-5]. Planning involves goal setting, sequencing actions, strategy development, monitoring, and flexible adaptation to changing circumstances [2,3]. In children with ASD, planning difficulties manifest as problems with sequencing complex actions [6], time management [7], and adapting plans when situations change [8], which significantly affect daily functioning and independence [3,4,9]. While planning in ASD has traditionally been assessed using performance-based or scale-based neuropsychological tests [10], recent computerized approaches, including virtual reality and serious games, have demonstrated increased ecological validity and engagement [11]. However, standardized and theory-driven tools specifically designed to assess planning in ASD remain limited, highlighting a critical gap in current assessment practices.

Developing valid planning assessment tools requires interdisciplinary collaboration and a strong theoretical foundation to ensure scientific validity and usability for children with autism [12-16]. The cognitive model of planning [17] conceptualizes planning as a flexible and adaptive process, in which individuals dynamically shift between goals and actions in response to changing constraints. Originally demonstrated through the errand-planning task, this framework captures key real-world planning demands such as sequencing, goal trade-offs, and optimization [17]. As such, it provides a grounded basis for translating everyday planning behaviors into structured assessment tasks and interpretable performance metrics.

Developing Serious Games for Planning Skills Assessment

Serious games are interactive digital tools created for purposes beyond entertainment, offering engaging and ecologically valid environments where complex cognitive processes can be observed and objectively measured [18]. By presenting ill-structured, dynamic scenarios, serious games are especially well suited for assessing planning, an opportunistic cognitive process that requires flexible adaptation to changing conditions [17,19]. Serious games have been investigated as tools for assessing executive functions—including planning—particularly in populations with neurodevelopmental conditions like poststroke and mild cognitive impairment, as well as those with psychiatric conditions such as schizophrenia [20-23]. Notable examples include V-Store [24], which evaluates planning in a virtual grocery setting; the Multitasking in the City Test [25-28], which assesses adaptability in urban tasks; and the Nonimmersive Virtual Coffee Task [27], which measures sequencing and problem-solving in a task-oriented environment.

Specific recommendations for designing shopping-based serious games to evaluate executive functions have been proposed [28]. Shopping, a core instrumental activity of daily living [11], has been widely used in virtual supermarket simulations due to its strong engagement of planning, decision-making, and problem-solving processes [29]. A recent systematic review identified shopping as one of the most effective paradigms for assessing executive functions, as it requires strategizing, item comparison, budget management, and item tracking [11]. Systems such as the Adapted Four-Item Shopping Task [30], Virtual Action Planning–Supermarket [31], and VMall [32] capture detailed performance metrics and have demonstrated ecological validity and convergence with conventional assessments of planning. These shopping paradigms motivate the development of an autism-specific serious game that targets executive planning skills within an ecologically meaningful task context, with design considerations tailored to the needs of autistic users, enabling naturalistic assessment of planning behavior.

Expert Inspection Using ASD-Guided Heuristics

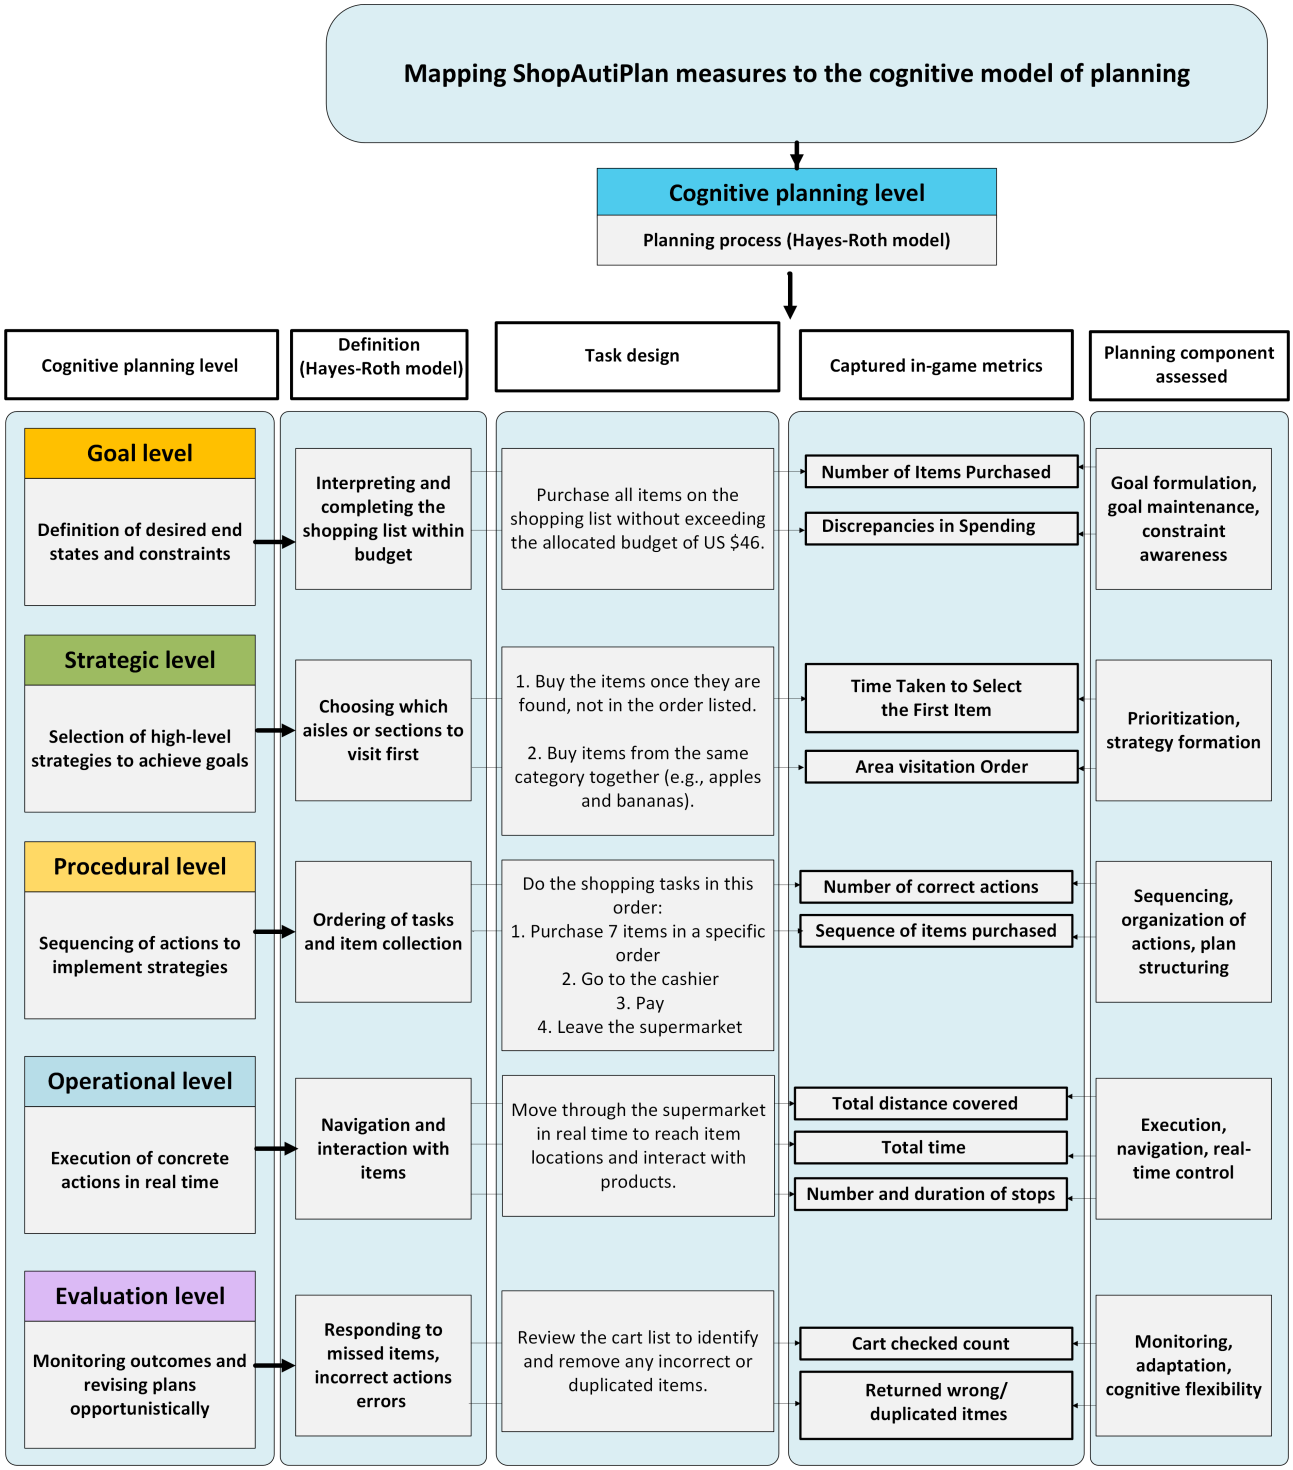
Assessing complex cognitive abilities such as planning requires both a strong theoretical foundation and rigorous usability evaluation prior to research or clinical deployment. Direct usability testing with children with autism, while essential, can be challenging due to cognitive, sensory, and communication differences, as well as anxiety in unfamiliar testing environments [33-37]. As a result, expert inspection methods are widely used in early-stage or ethically sensitive contexts to identify usability issues without direct user involvement [38-41]. Expert evaluation by specialists in cognitive psychology and human-computer interaction is particularly important for planning assessment tools, as it supports methodological rigor and accurate interpretation of performance metrics [42].

Expert inspection can be strengthened by think-aloud protocols, which encourage evaluators to articulate their reasoning during interaction and have been shown to improve the relevance and accuracy of identified issues [43,44-47]. Identified usability concerns can then be systematically mapped to established frameworks, such as Nielsen's heuristics [39], to support structured analysis and severity assessment [48-53]. However, when designing tools for children with autism, general heuristics alone may be insufficient. Autism-specific usability heuristics [54], which emphasize predictability, sensory regulation, and explicit guidance, provide critical additional perspectives. Combining general and ASD-tailored heuristics therefore enables a comprehensive expert-based usability evaluation that aligns standard human-computer interaction principles with autism-informed design requirements.

Objectives

The objective of this study was to introduce ShopAutiPlan, the first supermarket-based serious game specifically developed to assess executive planning skills in children with autism. The study aimed to ground the game in established planning theory and to guide its development through an interdisciplinary design framework integrating expertise from psychology, human-computer interaction, and game development to support cognitive validity and usability. Prior to involving the target population, the study further aimed to conduct a formative expert

XSL•FO
RenderX



evaluation using ASD-specific usability heuristics to inform design refinement for future empirical assessment.

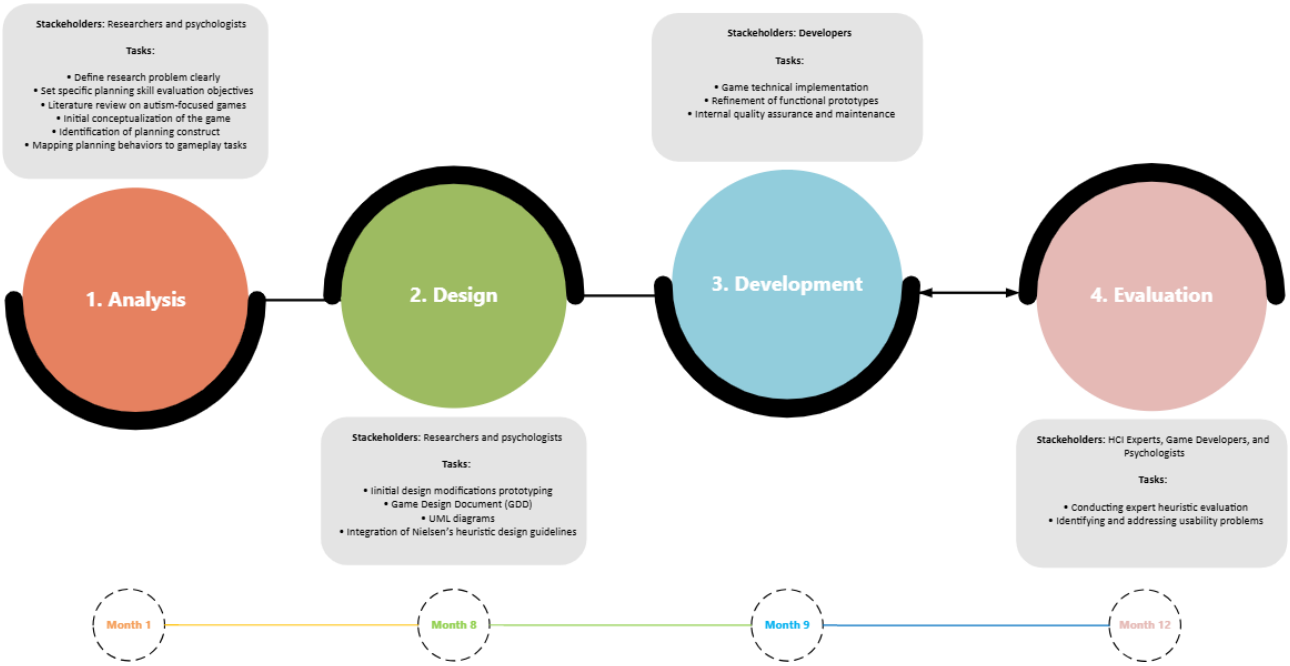
Methods

Cognitive Model of Planning

The assessment framework of ShopAutiPlan is grounded in the Hayes-Roth cognitive model of planning and was refined through expert input to establish a clear and theory-driven mapping between planning constructs, task design, and logged behavioral measures [17,55] (Figure 1). At the goal level, planning components such as goal formulation, maintenance, and constraint awareness are operationalized through the requirement to complete a predefined shopping list within a fixed budget. Experts confirmed that managing both item completion and budget constraints reflects real-world planning demands and aligns with the Hayes-Roth emphasis on coordinating multiple goals. Accordingly, measures such as correctly purchased items, budget violations, and spending discrepancies were retained as indicators of goal monitoring and constraint management.

Figure 1. ShopAutiPlan and the cognitive model of planning (Hayes-Roth) [17].

XSL•FO
RenderX



Strategic planning is operationalized through task design elements that allow children to freely determine the order in which items are collected and to group purchases by category or location. Experts specifically highlighted the importance of preserving this flexibility, noting that enforcing a fixed order would limit the expression of individual planning strategies. Measures such as order of aisle visitation and item grouping patterns were thus selected to capture prioritization and strategy formation, consistent with the opportunistic nature of planning described in the Hayes-Roth model. Procedural planning is instantiated through the requirement to execute a structured sequence of actions—item collection, checkout, payment, and exit—mirroring everyday shopping routines. Experts confirmed that this explicit action sequence supports assessment of plan execution and sequencing, leading to the inclusion of measures such as action order correctness, skipped steps, and redundant actions as indicators of procedural planning integrity.

At the operational level, real-time navigation and interaction with the supermarket environment reflect moment-to-moment planning adjustments. Experts noted that movement efficiency and pauses often signal hesitation or replanning, prompting the inclusion of measures such as total distance traveled, task duration, and stopping behavior to capture operational planning dynamics. Finally, evaluation and monitoring processes are explicitly embedded through tasks that require error detection and correction, such as reviewing the cart and removing incorrect or duplicated items. Experts identified these interactions as critical for assessing monitoring and adaptive control, reinforcing their inclusion as key indicators of cognitive flexibility and plan revision.

ShopAutiPlan Design and Development Process

The ShopAutiPlan development followed a 4-phase process—analysis, design, development, and evaluation (Figure 2) [56]—to support a systematic, multidisciplinary approach to assessing planning skills in children with autism. Development of the ShopAutiPlan spanned 12 months (February 2024 to January 2025), beginning with an *analysis phase* that included multiple collaborative sessions to define research objectives, review autism-focused serious game literature, and map in-game tasks and behavioral measures to the Hayes-Roth cognitive model of planning.

Figure 2. Game development and evaluation timeline. HCI: human-computer interaction; UML: Unified Modeling Language.

During the *design phase* (month 8), an interdisciplinary team of researchers, game designers, and psychologists collaboratively translated this framework into a functional prototype by mapping real-world shopping activities to game mechanics and performance measures, following established recommendations for theory-driven serious game development [57]. To support usability and accessibility from early development stages, the design was further guided by ASD-specific heuristics emphasizing predictability, sensory regulation, and explicit guidance [54] (as shown in Table 1). The design process was further refined through close collaboration with psychologists, who ensured that the game content was developmentally appropriate and cognitively accessible for the target population. Their input guided the simplification of task complexity, the reduction of sensory load, and the inclusion of clinically relevant planning scenarios. For example, they recommended removing time limits to create a more inclusive and comfortable environment that allows children with autism to complete tasks at their own pace. They also advised using calming and autism-friendly color schemes (eg, blue tones) and ensuring that each task explicitly measured planning ability—requiring the child to sequence actions such as selecting items, proceeding to the cashier, paying, and exiting the supermarket. In addition, they emphasized the importance of designing category-based item sequences (eg, purchasing 2 vegetables consecutively from the same section) to evaluate the child's ability to organize and plan efficiently. Psychologists further suggested analyzing pause locations and durations to determine whether children stop at task-relevant or irrelevant areas, as such data provides insight into attentional focus and

XSL•FO
RenderX

decision-making processes. These behavioral measures align with previous research and serve as key indicators during subsequent data analysis. Since the game was designed as an assessment tool rather than a training intervention, psychologists emphasized avoiding any explicit feedback or cues that indicate when an incorrect action is performed, ensuring that participants' behaviors reflect their natural planning and problem-solving strategies.

XSL•FO
RenderX

Table . Autism spectrum disorder–guided heuristics by Khowaja and Salim [54] as principal guidelines for designing ShopAutiPlan.

Heuristic ID	Guidelines	Examples
H1	Visibility of system status	• Ensure real-time feedback for player actions (eg, picking up items and adding them to the cart). • Implement a visual and audio cue as feedback when an item is placed in the cart, and the conveyor built at the checkout counter.
H2	Match between system and the real world	• Design the supermarket layout to resemble real-world store sections (eg, dairy, bakery, and frozen foods). • Use familiar icons and labels for store aisles, price tags, and checkout interfaces. • Ensure physics-based interactions, such as items falling if stacked improperly.
H3	User control and freedom	• Allow players to remove items from the cart if added by mistake. • Provide a clear way to exit the game or return to the main menu at any time.
H4	Consistency and standards	• Keep button and icon styles uniform throughout the system. • Standardized controls (eg, a button for picking up items, D-pad for navigation). • Ensure that similar interactions behave the same way (eg, all items are picked up and placed using the same method).
H5	Error prevention	• Provide confirmation pop-up messages before removing items from the cart. • Highlight incorrect actions (eg, placing the wrong item in the cart) with no checked sign feedback. • Preventing the game from progressing if mandatory tasks are incomplete (eg, exceeding the budget will let the cashier inform the player to return some items).
H6	Recognition rather than recall	• Always keep the shopping list visible instead of requiring players to memorize it. • Label checkout areas and food areas clearly so players don’t struggle to find them. • Provide quick-reference tooltips for game mechanics (eg, how to navigate using the buttons next to the icon, and how to interact with items).
H7	Flexibility and efficiency of use	• Offer multiple control schemes (eg, keyboard and gamepad).
H8	Aesthetic and minimalist design	• Keep the user interface clean, displaying only necessary information (eg, shopping list, cart summary, and remaining budget). • Ensure text and icons are legible with appropriate contrast. • Avoid excessive on-screen elements that clutter the interface.
H9	Help users recognize, diagnose, and recover from errors	• Display a message explaining why a certain action failed (eg, “Your purchase exceeds the actual budget”).

XSL•FO
RenderX

Heuristic ID	Guidelines	Examples
H10	Help and documentation	• Offer a brief tutorial to clarify game mechanics before the main gameplay begins for new players. • Ensure error messages are clear and provide solutions instead of generic failure alerts.
H11	[Personalization] of screen items	• Key gameplay settings such as budget, item count, time limits, gender, and camera perspective can be customized to match user needs or experimental requirements.
H12	User interface [screens] of the system	• Limit unnecessary animations or flashing elements to prevent sudden visual changes that may overwhelm users.
H13	[Responsiveness] of the system	• Immediate visual and auditory feedback after every action (eg, sound when adding to cart). No noticeable lag when moving or selecting. • Ensure smooth transitions between aisles without lag to maintain focus and reduce frustration.
H14	[Track] user activities, monitor performance, and repeat activity	• Record time stamps, distances, number of pauses, sequence of item selection, and errors. • The cart list allows players to review purchased items and monitor their progress.
H15	Use of [multimodalities] for communication	• When showing the shopping list, pair text with pictograms (eg, the word “apple” plus an image). • Instructions appear as text+image (eg, “Press A to Purchase” and “Press X to Delete”) as it is on the gamepad.

Game developers contributed to both functional and experiential elements, including the control scheme, navigation, and audiovisual feedback systems—such as sound cues for item selection and cart interactions. They also proposed using a third-person perspective to enhance engagement and offered recommendations for user interface elements like static icons and responsive feedback mechanisms. All design specifications, including both functional and nonfunctional requirements, were compiled into a comprehensive game design document, supported by Unified Modeling Language diagrams to visually map interactions and system behavior [57]. These deliverables were then handed over to the development team to guide the next implementation phase, as shown in Figures S1 and S2 in Multimedia Appendix 1.

In the subsequent development phase (month 9), developers collaborated closely with the researchers, holding regular technical review meetings to implement the game mechanics as defined in the game design document. Quality assurance protocols were enacted to rigorously test game stability, functionality, and performance, resolving technical issues promptly to maintain the project’s integrity and schedule. Finally, the evaluation phase (month 12) involved a cross-sectional, formative expert-based usability evaluation, engaging specialists in human-computer interaction, game development, and psychology, with data collected during single-session evaluations to identify usability issues and inform iterative design refinement. Structured evaluation sessions using expert inspection and think-aloud protocols were conducted to systematically identify and address usability concerns. Once the usability issues were identified, the feedback—along with expert recommendations—was compiled into a structured usability problem form and forwarded to the development team for refinement. This process enabled the team to implement targeted improvements based on expert feedback, ensuring the game was effectively optimized to assess planning skills in children with autism while maintaining a user-friendly and engaging experience.

Expert Evaluation

Sample of Study

For the usability evaluation, 6 experts were selected, each bringing specific expertise relevant to the assessment of the supermarket game. Typically, 5 to 8 evaluators are used in expert assessments as this range has been shown to identify approximately 75% or more of usability problems in an application or system [57]. The experts were chosen based on their backgrounds in human-computer interaction, game development, and autism. These areas of expertise were critical for ensuring a well-rounded evaluation of both the game’s design and its applicability to children with autism. The selected

XSL•FO
RenderX

specialists included 2 researchers, 2 psychologists, and 2 game developers (as shown in Table 2). The researchers focused on assessing the appropriateness of the game elements related to human-computer interaction and ASD, drawing from their academic and practical knowledge in these fields. The psychologists, with experience in executive function and ASD, evaluated the game's content to ensure that it was suitable for assessing planning skills in children with autism. The game developers brought their expertise in game mechanics and design, contributing to the evaluation of the overall user experience and ensuring that the game elements were engaging and accessible.

Table . Experts involved in the expert evaluation.

Expert ID	Professional role	Role	HCI[a]	Game development	ASD[b] into psychology	Working with ASD (yes/no)
R01	Researcher	Assessing the appropriate game elements related to HCI and ASD	7-10	—[c]	—	Yes
R02	Researcher	Assessing the appropriate game elements related to HCI and ASD	4-7	—	—	Yes
D01	Game developer	Assessing the appropriate game mechanics and design	—	7-10	—	No
D02	Game developer	Assessing the appropriate game mechanics and design	—	>10	—	No
P01	Psychologist	Assessing the appropriate game content related to EF[d] and ASD	—	—	>10	Yes
P02	Psychologist	Assessing the appropriate game content related to EF and ASD	—	—	7-10	Yes

[a]HCI: human-computer interaction.

[b]ASD: autism spectrum disorder.

[c]Not applicable.

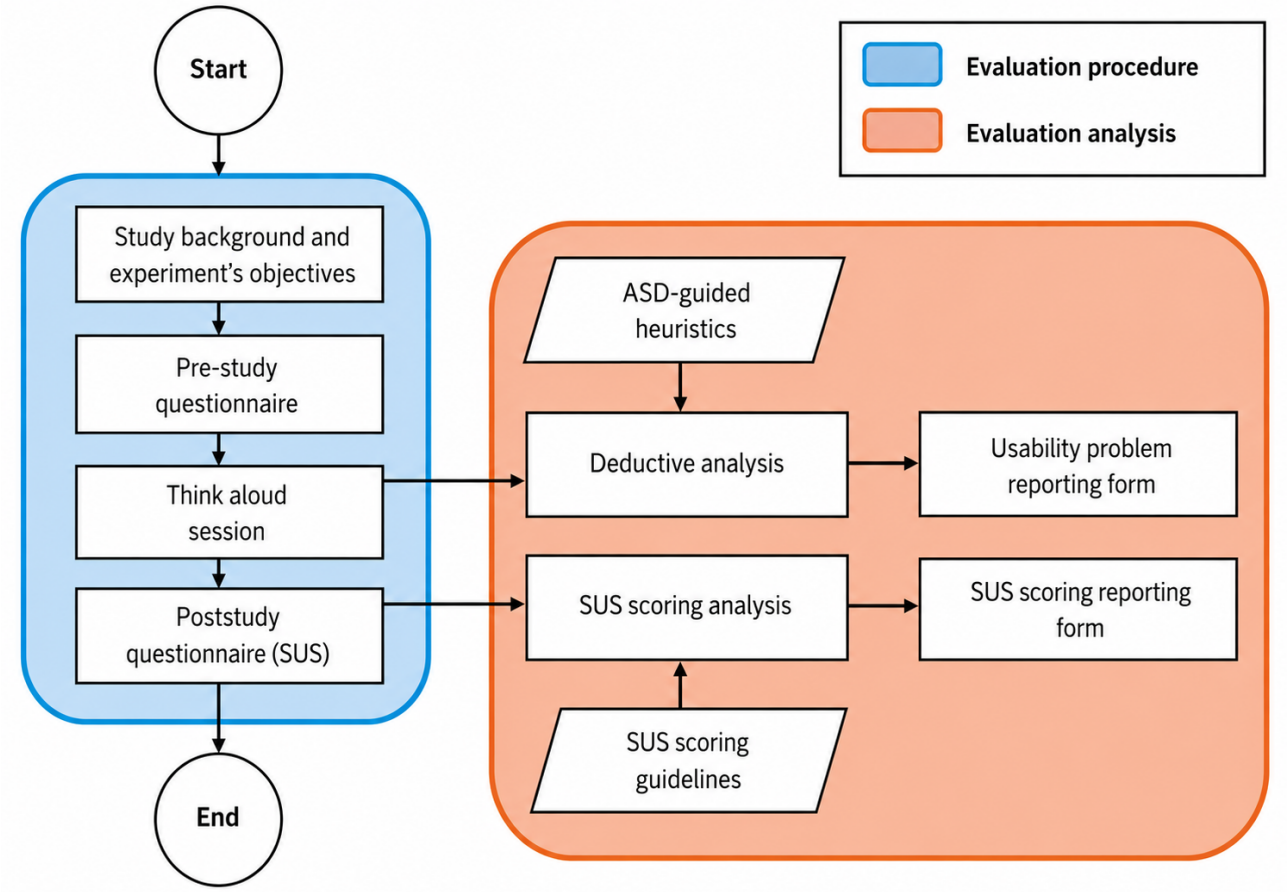
[d]EF: executive function.

Research Instrument

Prestudy Questionnaire

A prestudy questionnaire was administered to collect demographic information and professional background details from the experts involved in the expert evaluation. The questionnaire gathered essential data such as gender, professional role (eg, researcher, psychologist, and game developer), and the experts' years of experience working in their field. Additionally, participants were asked whether they had prior experience working with autistic individuals, as this may influence their perspective on the game's usability. The data collected from this questionnaire helped ensure that the evaluation included a diverse group of experts with relevant expertise, providing valuable insights into the game's usability.

System Usability Scale Reporting Form



System Usability Scale (SUS) is a widely recognized and reliable instrument for assessing the usability of software, websites, and other interactive systems [58]. The scale comprises 10 items, featuring a mix of positive and negative statements regarding system usability. Participants rate each item on a 5-point Likert scale ranging from "strongly disagree (1)" to "strongly agree (5)" (Table S1 in Multimedia Appendix 1). The principal advantages of SUS in our study are its simplicity, versatility, and well-established validity. Notably, SUS has been extensively validated across diverse studies and user contexts [59,60], contributing to its status as one of the most prevalent usability measurement tools in both research and industry.

Study Procedure

The formative usability evaluation of ShopAutiPlan was designed to systematically collect expert feedback prior to involving children in the experimental phase. As illustrated in Figure 3, the evaluation comprised a structured procedure and subsequent analysis. Each expert participated in an independent evaluation session [39], conducted at Hamad Bin Khalifa University, Qatar, in a quiet, well-lit research office. Sessions were carried out using a standardized hardware setup, including a Dell Inspiron 7500 laptop (Intel Core i7-1065G7@1.30 GHz, 32 GB RAM, Windows 10 Pro 22H2) with a 15.6 full HD (1920×1080) display, and a Logitech F710 wireless gamepad, while expert verbal feedback was audio-recorded for analysis.

XSL•FO
RenderX

Figure 3. Study procedure. ASD: autism spectrum disorder; SUS: System Usability Scale.

At the start of each evaluation session, experts were provided with an overview of the study background, objectives, and session flow. The investigator explained how the ShopAutiPlan was intended to assess executive planning skills and outlined the tasks to be performed. Prior to the evaluation, each expert completed a prestudy questionnaire capturing demographic information, professional background, and prior experience with autism.

During the think-aloud session, experts completed the same tasks planned for child participants. Each session began with a brief training phase in which experts practiced selecting 2 items, mirroring the tutorial designed for children. Experts then proceeded to the main task, which involved collecting 7 items, going to the cashier, completing payment, and exiting the supermarket. Throughout the session, experts were encouraged to verbalize their thoughts, identify usability issues, assign severity ratings, and suggest potential improvements. Following task completion, experts completed a poststudy questionnaire based on the SUS to provide quantitative support for the qualitative usability assessment.

Evaluation Analysis

Deductive Usability Analysis

To systematically identify usability issues within the game, all completed usability evaluation forms were compiled from each expert. Each form provided a concise description of the identified problems, along with severity ratings on a scale from 0 to 4—where 0 indicated "not a problem," 1 denoted a "cosmetic issue," and 4 represented a "usability catastrophe" [59,61]. In addition, each form included expert-recommended solutions corresponding to each usability problem. To facilitate structured analysis, all identified issues were mapped to specific ASD-guided heuristics based on Khowaja and Salim [54]. The aggregated list of problems was then communicated to the game development team, who subsequently implemented the necessary modifications to resolve the reported issues and improve the overall usability of the game.

SUS Scoring Analysis

SUS scores were calculated following the standard procedure [58]. For odd-numbered items, 1 was subtracted from the participant's rating, while for even-numbered items, the rating was subtracted from 5. The adjusted item scores were summed and multiplied by 2.5 to yield a total score ranging from 0 to 100. Scores above 68 are generally interpreted as indicating above-average usability, whereas lower scores suggest potential usability concerns. In line with prior studies [62,63], usability dimensions proposed by Kumar and Goundar [64] were further examined by mapping them to relevant SUS items as follows (see Table S1 in Multimedia Appendix 1):

1. Efficiency (items 5, 6, and 8): how quickly users can complete tasks once familiar with the interface.
2. Memorability (item 2): how easily users can regain proficiency after a period of inactivity.
3. Error minimization (item 6): focusing on the severity of user errors and the system's ability to support recovery.

XSL•FO
RenderX

4. User satisfaction (items 1, 4, and 9): assessing the overall pleasantness of interaction.
5. Learnability (items 3, 7, and 10): how easily users can perform basic tasks during initial use.

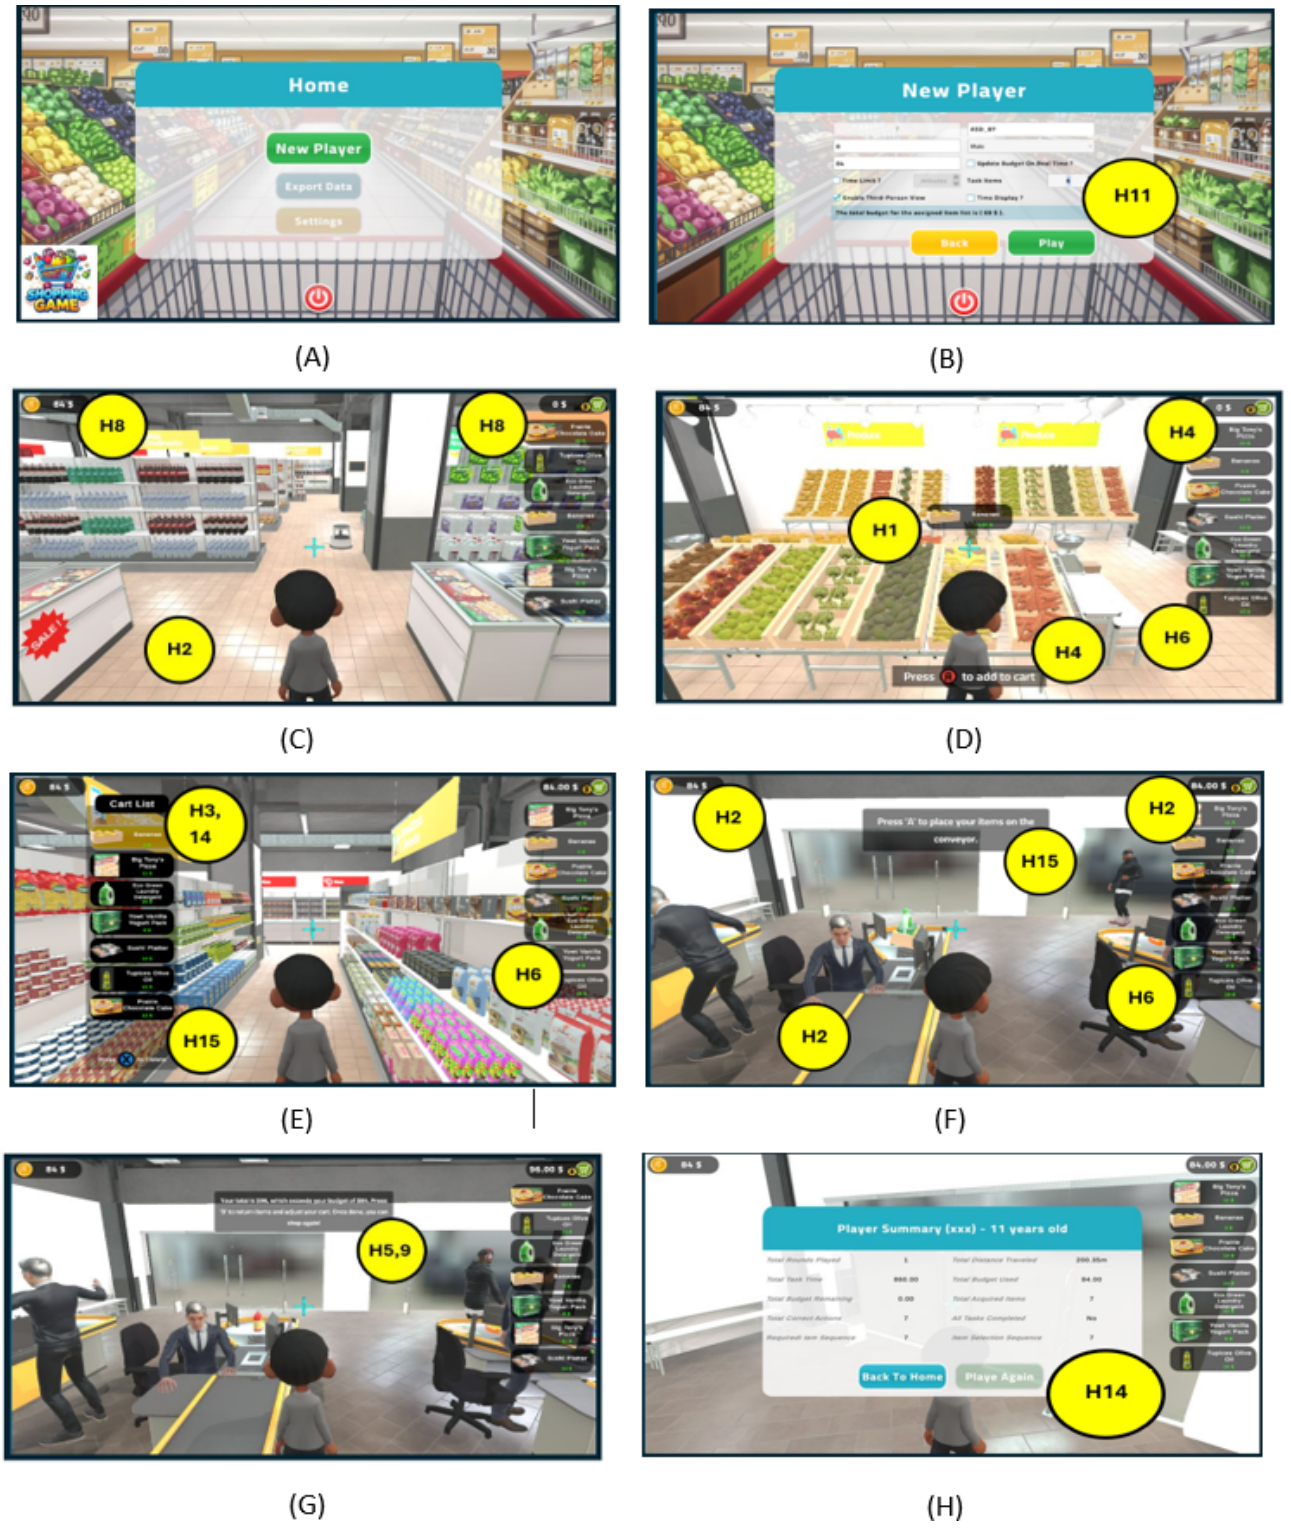
To contextualize the numeric SUS results, the scores were translated into qualitative descriptors of usability based on the scale proposed by Bangor et al [65].

Ethical Considerations

This study involved an expert-based usability evaluation only and did not include child participation or personal data collection; therefore, it was exempt from institutional review board (IRB) approval. All expert participants provided informed consent prior to participation, and no compensation was provided for this usability evaluation. Future empirical studies involving children with autism have received ethical approval from Hamad Bin Khalifa University (HBKU-IRB-2025 - 79) and will be conducted in accordance with institutional guidelines, including parental consent, child assent, risk mitigation procedures, and data anonymization. Although the study is noninvasive, several minimal risks are anticipated during gameplay, including cognitive fatigue, frustration, and potential sensory overstimulation. To mitigate these risks, sessions will be conducted individually in a quiet, low-distraction environment with adjustable lighting and audio levels. A short training phase will familiarize participants with the controls before the main task, and children will be allowed to pause or withdraw at any time. The session will be immediately stopped if signs of distress or fatigue are observed, and a trained researcher will monitor the child's comfort throughout without influencing task performance. To protect confidentiality, no identifying information was collected or stored within game logs; participants were assigned coded identifiers, and all behavioral and eye-tracking data were securely stored on password-protected institutional servers accessible only to the research team. No images of individual participants are included in the manuscript or supplementary materials. If any identifiable images are used in future studies, appropriate consent will be obtained and documented.

Results

The results acquired from the development process of the game, its assessment made by experts, and the usability testing are presented in the following subsections.



ShopAutiPlan: Initial Design

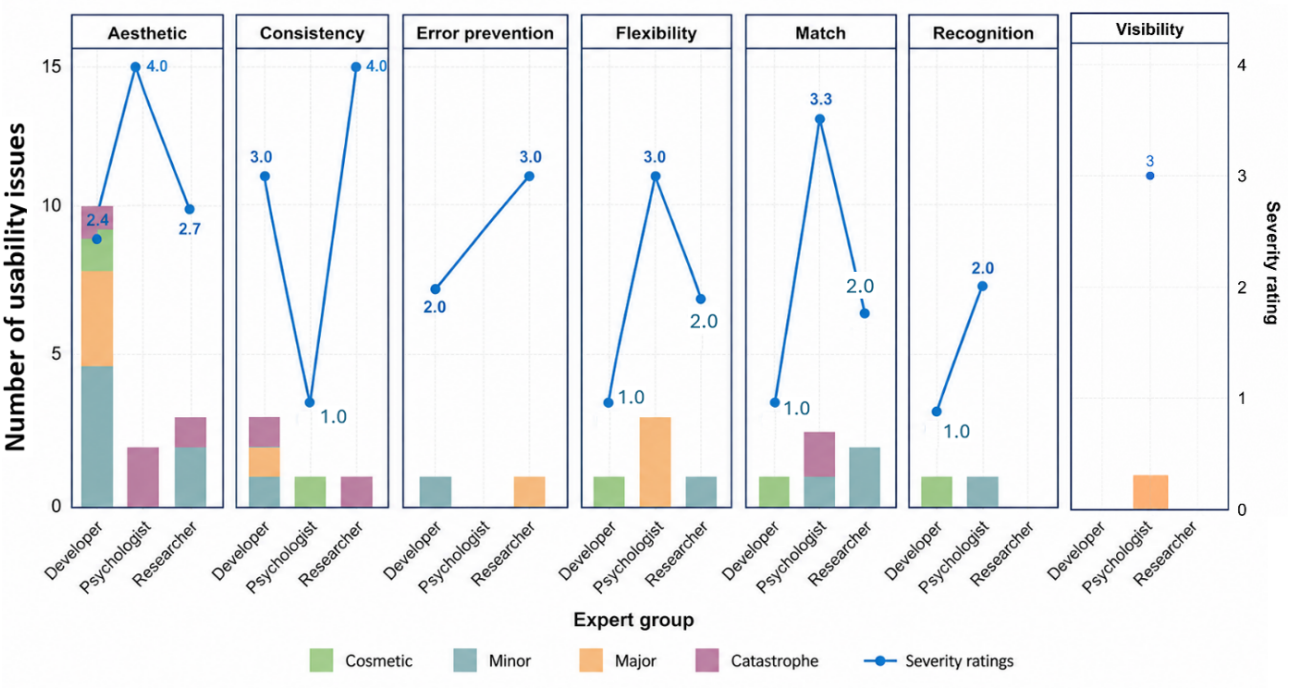
ShopAutiPlan uses a third-person perspective by default to simplify navigation within the virtual supermarket. Interaction is provided via an intuitive joypad to accommodate varying motor abilities and offer a more accessible alternative to keyboard-based input [66]. The interface was designed following ASD-informed guidelines (H1-H15) to maximize engagement while minimizing cognitive and sensory load [50]. Task difficulty is adjustable through parameters such as the number of items, available budget, and optional time constraints, supporting flexibility and personalization (H11). Visual design employs simple, cartoon-style graphics, clearly labeled product categories with prices, and a clutter-free layout (H8), while multimodal audiovisual feedback replaces text-heavy cues to support diverse sensory processing needs (H2 and H15) [67-73]. Personalization options, including avatar gender and optional first-person view, further align the game with individual preferences and experimental requirements [74,75].

ShopAutiPlan includes several functional windows to support interaction, personalization, and data collection, including a start window, player setup window, training window, main gameplay window, statistics window, and player list window. The start window allows language selection (Figure 4A), while the player creation window (Figure 4B) enables the researcher to configure participant information and task parameters such as budget, number of items, and optional time limits. Before gameplay, an optional training window introduces users to core mechanics through guided interaction, ensuring familiarity with controls and task structure prior to full gameplay (H10).

XSL•FO
RenderX

Figure 4. Overview of the ShopAutiPlan interface aligned with autism spectrum disorder–guided heuristics: (A) home screen, (B) new player setup and personalization options, (C) supermarket navigation, (D) item selection, (E) cart management and item return, (F) checkout interactions, (G) budget-exceeded error feedback, and (H) player summary interface. H: heuristic ID.

During gameplay, players interact with the main window, which presents a supermarket environment designed to resemble real-world shopping spaces, with organized aisles, 8 labeled product sections, price tags, and familiar product representations (Figure 4C). This design supports intuitive navigation and task comprehension (H2) while maintaining a minimalist, high-contrast layout to reduce visual clutter (H8). The shopping list and budget are persistently displayed (Figure 4D), reducing memory demands and supporting recognition rather than recall (H6). A cart list (Figure 4E) allows players to review and remove selected items, supporting user control and progress monitoring (H3 and H14). Item removal actions are reinforced through combined text-and-image prompts (eg, “Press X to Delete”), providing explicit guidance (H15). Interaction buttons remain consistent across contexts (Figure 4D), supporting consistency (H4). When approaching a product, immediate



XSL•FO
RenderX

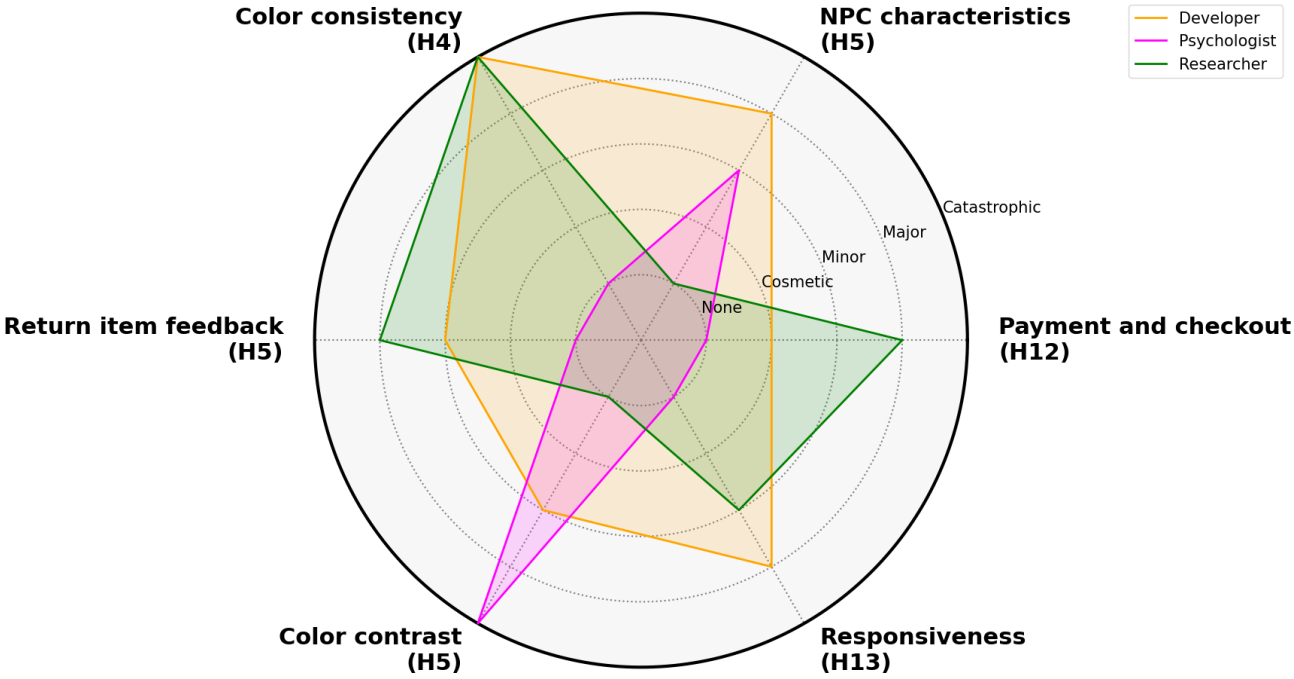
visual highlighting and item labels signal system response and available actions (H1). At checkout (Figure 4F,G), budget violations trigger explicit feedback that prevents task completion until constraints are resolved (H5). Corrective messages instruct players on how to adjust their cart (H9), while audiovisual cues confirm item scanning and budget updates (H2 and H15). Finally, the statistics window (Figure 4H) summarizes task performance and progress (H14) and enables researchers to export log-based measures for subsequent analysis.

Heuristic Deductive Evaluation

A total of 45 usability issues were identified through expert evaluation using ASD-specific heuristics [54], as summarized in Table S2 in Multimedia Appendix 1. Each issue was categorized by expert role, severity rating, and recommended solution, and deductively mapped to its corresponding heuristic to support both qualitative interpretation and quantitative analysis. Figure 5 illustrates the distribution and average severity of usability issues reported by developers, psychologists, and researchers across heuristics.

Figure 5. Number of usability problems and average severity ratings found in the ShopAutiPlan using 10 general heuristics.

The developer group identified the highest number of usability issues, with most concerns concentrated under H8, reflecting a focus on visual clarity and layout quality. Although numerous issues were reported, severity ratings were generally low to moderate, indicating refinement needs rather than critical interaction failures. For example, D02 noted insufficient lighting in the cart list (severity=2; Figure S3-e in Multimedia Appendix 1) and poor color contrast for shelf labels that reduced readability (severity=2; Figure S3-f in Multimedia Appendix 1). D01 also highlighted excessive white space leading to an unbalanced screen layout (severity=3; Figure S3-c in Multimedia Appendix 1). Additional issues were reported under H2 and H4, but these were similarly rated as minor to moderate, reinforcing developers' emphasis on aesthetic consistency and visual coherence.



The psychologist group reported fewer usability issues overall but consistently assigned higher severity ratings, reflecting a strong focus on cognitive load and developmental appropriateness. High-impact concerns were identified under H8, where even a small number of aesthetic issues were rated as highly disruptive (average severity=4.0), indicating that visual design problems may substantially affect engagement and cognitive effort (Figure S3-b in Multimedia Appendix 1). Psychologists also emphasized issues under H2, with P02 noting the absence of background supermarket announcements—an important real-world cue—which was rated as highly severe (severity=4) and recommended for improving realism and immersion. Additional concerns were raised under H1, where the lack of immediate feedback when selecting correct items was seen as potentially confusing; P01 recommended adding a visual confirmation (eg, a checkmark) to support clear system feedback (severity=3; Figure S3-e in Multimedia Appendix 1). Overall, the psychologist group's feedback underscored heightened sensitivity to design elements that may increase cognitive demand or disrupt intuitive understanding.

The researcher group provided a balanced evaluation, identifying a moderate number of usability issues across several heuristics, reflecting a systematic assessment of system behavior and user expectations. Key concerns were raised under H2 and H12, particularly regarding abrupt postpayment transitions (severity=4; Figure S3-d in Multimedia Appendix 1). Under H4, researchers identified a mismatch between physical gamepad button colors and on-screen representations (severity=4; Figure S3-a in Multimedia Appendix 1), which may hinder motor coordination in younger users. Additional issues were flagged under H5, where the absence of a confirmation prompt when returning items could lead to

XSL•FO
RenderX

unintended actions; R01 recommended adding a confirmation message to support error prevention (severity=3; Figure 6G).

Figure 6. Severity assessment of common usability issues across the expert group. H: heuristic ID.

The ASD-targeted heuristic analysis (Table 3) identified several high-impact issues directly related to children with autism's sensory and cognitive needs. Under H15, the absence of combined visual and auditory feedback during item selection was rated as a major concern (severity=3), as children with autism often rely on multisensory cues to interpret actions and maintain engagement. Issues under H12 highlighted that abrupt postpayment transitions were highly disruptive (severity=4; Figure S3-d in Multimedia Appendix 1), reflecting difficulties many children with autism experience with sudden interface changes; step-by-step visual transitions were recommended (eg, items moving into a bag followed by a brief status message) to preserve a stable mental model and reduce cognitive overload. Additional concerns under H14 emphasized the importance of clear progress tracking, as inconsistent ordering of purchased items made it difficult for children to monitor task completion (severity=3). High-severity issues were also identified under H11, where task difficulty was considered too demanding for younger children with autism (severity=4), underscoring the need for adjustable item counts to align challenge level with individual abilities (Figure S3-f in Multimedia Appendix 1). Finally, issues under H13 highlighted sensitivity to system responsiveness, as lag or rendering delays may disrupt attention and cause sensory discomfort, reinforcing the need for technical optimization to ensure smooth, stable performance.

XSL•FO
RenderX

Table . Examples of deductive usability analysis based on autism spectrum disorder–specific heuristics.

Heuristics	Expert ID[a]	Problem found	Recommendation	Severity rating
Use of [multimodalities] for communication [H15]	R01	No multimodal feedback when selecting the item.	Add multimodal feedback by incorporating both visual and sound effects.	3
User interface [H12]	R02	There is no bag after completing payment.	After successful payment, put all items in a bag and let the player hold it.	4
Tracking activity [H14]	P01	The order of purchased items is not the same as in the actual item list.	Ensure the order of purchased items matches the item list.	3
Personalization [H11]	P01	The game might be difficult for children with autism aged 7 - 10 years.	Task difficulty is adapted by adjusting functional cognitive and task parameters relevant to planning, including working memory load, number of constraints, and items sequencing complexity.	4
Responsiveness [H13]	D02	The game is heavy especially when the character turns right or left.	Changing from corei7 to more powerful computer is recommended.	4
Responsiveness [H13]	D02	Items are high polygon which demand more processing for the CPU.	Make only the front of items in 3D and use a simple colored box for the back to optimize performance.	4

[a]D: developer; P: psychologist; R: researcher.

Figure 6 illustrates areas of convergence and divergence across expert groups in the identification of critical usability issues. Substantial overlap in reported problems indicates strong consensus among developers, psychologists, and researchers on core usability challenges requiring attention. For example, H4 was consistently rated with high severity by developers and researchers, highlighting color consistency as a fundamental barrier to effective interaction across disciplines. A similar alignment was observed under H13, where developer experts assigned higher severity to responsiveness-related issues, reflecting awareness of how performance delays and rendering instability can disrupt interaction and engagement. In contrast, notable discrepancies emerged under H8, where psychologists rated color contrast issues as highly severe, while developers and researchers assigned lower severity, underscoring the influence of disciplinary perspective—particularly psychologists' heightened sensitivity to perceptual and cognitive impacts relevant to children with autism.

SUS for Usability Testing

Figures 7 and 8 present the results of the SUS evaluation across multiple expert reviewers. Figure 7 illustrates the SUS scores assigned by each expert, revealing an average score of 70.4 (95% CI 45.2 - 95.7), which exceeds the standard usability benchmark of 68 and indicates an overall acceptable level of usability for the serious game. While most experts rated the system at or above this benchmark, one outlier (D01), a developer, assigned a notably low score of 25%. In contrast, the highest rating of 87.5% was given by P02, a psychologist. Because the expert sample was small (n=6) and included a clear outlier score, the confidence interval around the mean SUS score was relatively wide (70.4, 95% CI 45.2 - 95.7), reflecting the statistical uncertainty associated with the estimate. SUS scores ranged from 25 to 87.5, which also reflects differences in disciplinary perspectives among the expert evaluators. Given these factors, the SUS results should be interpreted as exploratory and are reported primarily to complement the qualitative findings derived from the formative usability evaluation rather than as a definitive measure of system usability.

XSL•FO
RenderX

Figure 7. Usability evaluation results using System Usability Scale (SUS) scores per expert.

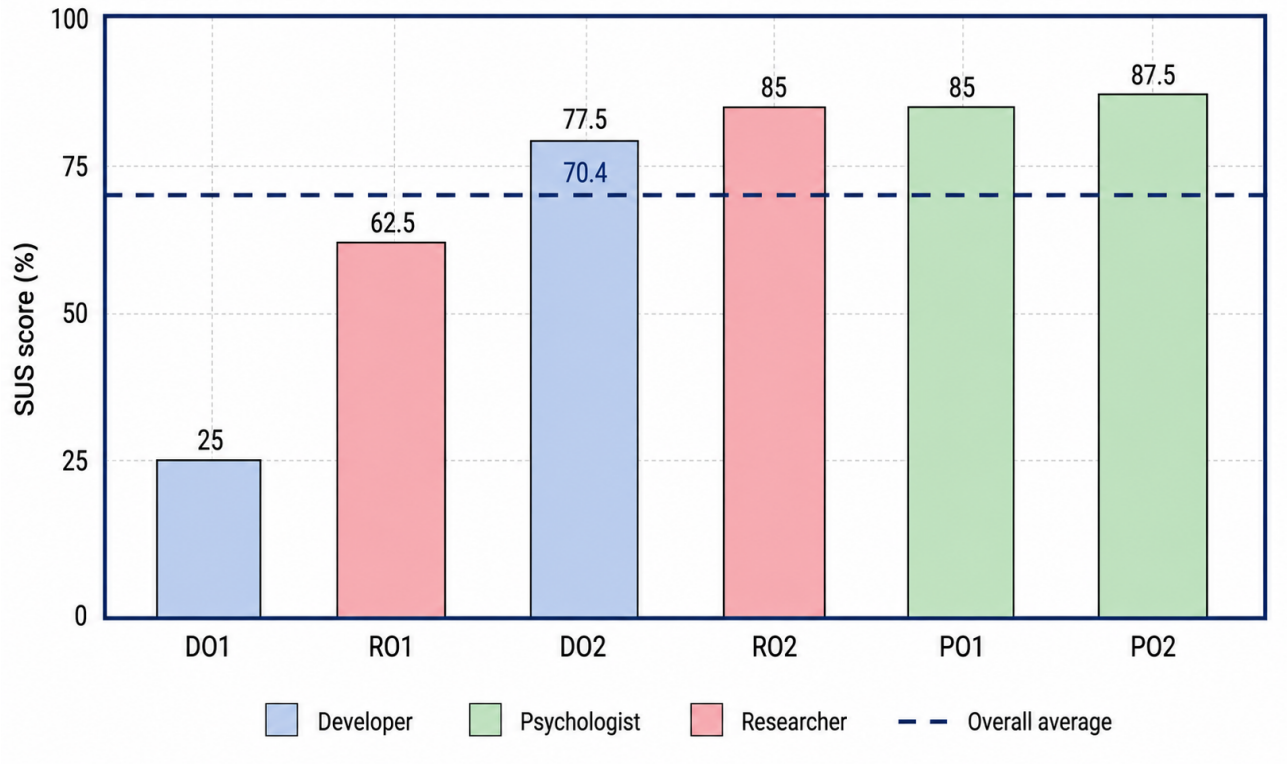


Figure 8. Average System Usability Scale (SUS) component scores.

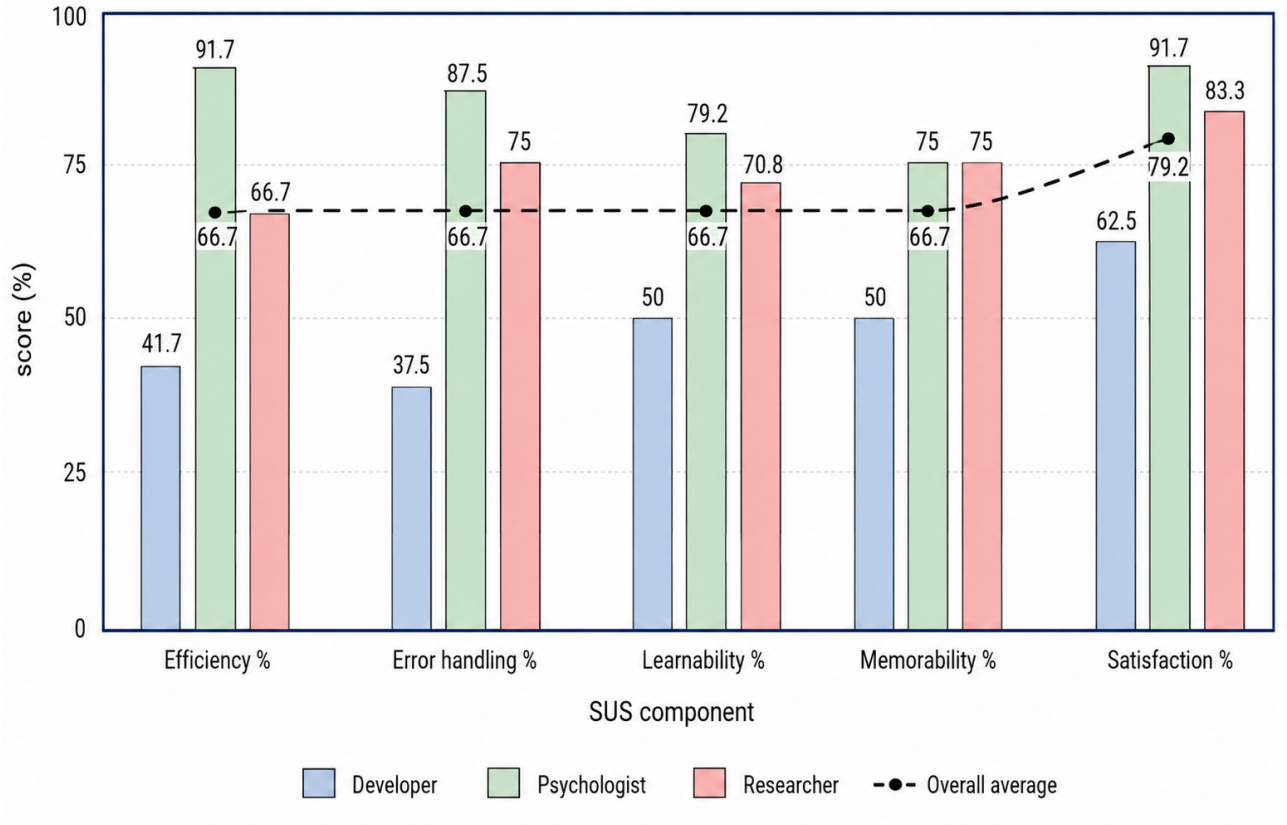

Figure 8 summarizes SUS component scores by expert group—developers, psychologists, and researchers—across 5 usability dimensions: efficiency, error handling, learnability, memorability, and satisfaction. Psychologists consistently reported higher ratings across all dimensions, with peak scores observed in efficiency (91.7%), error handling (87.5%), and satisfaction (91.7%). These ratings were accompanied by comments emphasizing usability clarity and sensory experience. For example, one psychologist (P02) described the environment as “very realistic,” noting that “it resembles a real supermarket.

XSL•FO
RenderX

I can even hear the ticking sound during the payment (sound is very nice!),” while another psychologist (P01) stated that “the helping message is very good when hovering on the item to help the child remember the button to select by A.” Developers assigned lower ratings across all usability dimensions, particularly for error handling (37.5%) and efficiency (41.7%). Developer feedback highlighted issues related to movement smoothness, spatial interaction, and system responsiveness. For instance, D01 noted that “the character entering inside the wall” and “the movement not being smooth” disrupted interaction flow. Additional concerns included camera behavior and collision handling, with D01 reporting that “collision and physics are not good,” as interactions with objects lacked realistic feedback.

Researchers’ scores generally fell between those of psychologists and developers. Although this group identified specific usability issues, satisfaction remained relatively high (83.3%). One researcher (R01) described the game as offering a “good user experience—smooth and easy to use,” while another (R02) commented that “the sound is good and not disturbing.” At the same time, usability limitations were noted, particularly regarding feedback after certain actions. For example, R01 marked down SUS Item 5, stating, “There’s no feedback after deleting an item from the basket, so users can’t easily confirm or correct errors.” Across all expert groups, satisfaction was the highest-rated usability dimension (mean 79.2%, 95% CI 54.7% - 103.7%), suggesting that the game is generally perceived as enjoyable. The remaining usability dimensions showed lower average scores (mean 66.7%, 95% CI 42.8% - 90.6%), indicating areas where the interface could be improved to better support task execution and error handling.

Discussion

The formative usability evaluation of ShopAutiPlan provides insight into the strengths and limitations of the current design for assessing executive planning skills in children with autism. This section discusses the key findings and their implications, situates the results in relation to prior work, and highlights the value of interdisciplinary expert evaluation. Limitations of this study are also addressed, alongside directions for future development and empirical validation.

Impact of Interdisciplinary Expertise on Usability Evaluation

This study underscores the importance of interdisciplinary collaboration in the formative evaluation of digital assessment tools for autism. By integrating expertise from psychology, human-computer interaction, and game development, usability issues were identified from complementary perspectives, spanning cognitive accessibility, interaction design, and technical performance [76]. Prior research similarly emphasizes that multidisciplinary involvement is essential for developing ecologically valid and usable digital systems for neurodiverse populations, as it facilitates alignment across clinical, educational, and technological priorities [76-78]. In particular, the study by Cox [78] highlights that involving a broad range of professionals—including psychologists, therapists, educators, and technical specialists—supports the development of comprehensive and contextually appropriate digital interventions for autism.

While this collaborative approach broadens the range of identified usability issues, it also requires careful negotiation of differing disciplinary priorities, such as balancing technical performance optimization with clinical and educational realism [79]. This dynamic is reflected in the observed variation in our SUS scores and severity ratings across developers, psychologists, and researchers, highlighting the influence of professional background on usability evaluation. For instance, developers identified the greatest number of issues, particularly related to aesthetic consistency and system behavior, whereas psychologists assigned higher severity to issues affecting cognitive clarity and accessibility. Researchers generally provided more moderate ratings, focusing on interaction flow and system-level coherence. While such variability may reflect discipline-specific preferences and is therefore a potential limitation of expert-driven evaluation [45], it also represents a key strength. Bringing together diverse expert perspectives enables a balanced evaluation of usability concerns and supports informed refinements aligned with both assessment goals and system performance [80].

Although expert inspection provides valuable formative feedback, it cannot replace empirical usability testing with the intended users, particularly in neurodevelopmental populations [80]. Heuristic evaluation is primarily designed to identify interface issues and guide early-stage design refinements; however, it does not capture actual user performance, interaction behaviors, or experiential responses [80,81]. For technologies developed for children with autism, user-centered validation is especially critical, as real-world interaction patterns, sensory processing, and engagement behaviors may differ substantially from expert expectations [61,82]. Empirical studies involving autistic participants further highlight that stakeholders may interpret system features differently, which has direct implications for usability and engagement [82]. For instance, in Ghanouni et al [82], parents recommended additional motivational elements such as music and reward mechanics, whereas autistic youth preferred reduced auditory stimulation to maintain comfort and realism; similarly, parents favored numerical scoring feedback, while autistic participants preferred qualitative responses (eg, “excellent”). Systematic reviews indicate that expert-based inspection and user-based testing capture complementary aspects of usability, and combining these approaches yields a more comprehensive evaluation of system effectiveness [81].

Accordingly, this study should be interpreted as a formative, predeployment evaluation, designed to identify and minimize major usability barriers prior to involving child participants. Future research will incorporate controlled usability testing and empirical validation with autistic users, enabling assessment of authentic interaction behaviors and ensuring that the serious game accurately reflects real-world planning performance.

Usability Refinements, Psychometric Factors, and Measurement Validity

In assessment-oriented serious games, it is important to distinguish usability issues that affect user experience from

XSL•FO
RenderX

those that influence the validity of measured constructs [61]. Although the expert evaluation of ShopAutiPlan focused on usability, several interface-related issues—such as delayed feedback, unclear action confirmations, and inconsistent visual cues—were identified as potential sources of interaction-induced variance that could affect planning-related behavioral measures, including task duration and error rates. In this context, learnability and error handling emerged as critical aspects of expert feedback, particularly for younger children and users with autism. Experts in this study noted that excessive task complexity (eg, requiring 7 items instead of 5) may increase extraneous cognitive load and obscure planning-related behaviors through frustration or disengagement. Gradually scaling task complexity was therefore identified as important for preserving assessment validity by ensuring that observed behaviors reflect strategic organization rather than overload-induced errors [83].

Many of the proposed refinements serve a dual purpose: enhancing overall usability while minimizing non-planning-related delays and unintended errors that could confound behavioral interpretation. By improving system responsiveness, interaction latency is reduced, ensuring that timing-based measures—such as time to first item selection, number of pauses, and pause duration—more accurately reflect strategic initiation and deliberation rather than delays caused by the interface [54,61]. Enhancements in visual clarity, including increased contrast [84] and improved readability [85] of shelf labels, facilitate anticipatory navigation and advance organization of actions, allowing the sequence of item purchases, aisle visitation order, and total distance traversed to represent strategic sequencing and spatial planning rather than challenges in visual search [84,85].

Similarly, clearer action cues during interaction, such as prompts for selecting, deleting, or reviewing items, reduce hesitation arising from interface uncertainty, enabling measures such as cart-review frequency and corrective action latency to reflect monitoring and error-detection processes rather than recall of control mappings. Consistent with prior research, explicit visual and auditory confirmations further support error awareness and action verification in children with autism, fostering self-correction and sustained goal-directed behavior [86]. Finally, maintaining continuous visibility of the shopping list and budget stabilizes goal tracking, ensuring that outcomes such as item omissions, duplicate purchases, and budget violations correspond to genuine breakdowns in goal maintenance and constraint management, rather than limitations in memory or interface comprehension [21,87].

Beyond interface design, several psychometric factors may further influence performance independently of executive planning ability, particularly in studies involving children with autism [88-90]. Motor demands represent key validity threats, as performance improvements may arise from increasing familiarity with game controls rather than planning competence [88]. To address this, future studies will incorporate a standardized training phase involving a simplified task with minimal planning requirements, allowing participants to become familiar with the control scheme. In addition, background information on prior gaming and shopping experience will be collected to support exclusion criteria or analytical control [90-93]. Navigation strategies constitute another potential confound, as individual differences in spatial exploration may affect metrics such as path efficiency or task time without directly reflecting planning processes [89]. To disentangle navigation behavior from planning-related cognition, future studies will employ eye-tracking to differentiate visual search and decision-making from movement-based navigation during gameplay [94,95].

Sensory Sensitivities and Dominant Usability Issues

Sensory sensitivities emerged as a dominant theme in the expert evaluation and strongly shaped usability priorities for an autism-focused serious game. In this context, aesthetic and minimalist design (H8) was the most frequently violated heuristic across all expert groups and received the highest severity ratings from psychologists. Reported issues primarily involved visual clutter, insufficient color contrast, and suboptimal lighting. Psychologists emphasized these concerns because children with autism are particularly sensitive to sensory input and often experience difficulty filtering irrelevant visual information [96,97]. Prior research indicates that visually simple, high-contrast interfaces can reduce cognitive load and support sustained attention and task engagement in neurodiverse users [98], whereas excessive visual complexity may increase anxiety, distraction, or disengagement [99]. From a clinical and usability perspective, violations of minimalist design principles therefore represent significant barriers to accessibility and comfort rather than minor aesthetic shortcomings [100]. In response, sensory-related usability issues were prioritized during the second iteration of development and addressed through targeted refinements to color use, contrast, and overall visual load.

Closely related to these sensory considerations, realism emerged as the second most frequently violated heuristic. Experts identified usability gaps such as the absence of ambient supermarket sounds and unrealistic postpurchase behaviors (eg, the avatar not visibly handling items or bagging groceries). These observations align with prior work emphasizing the importance of ecological validity for engagement and task relevance in serious games [101,102]. Psychologists within this study noted that more realistic environmental cues could enhance immersion and help align the game experience with everyday shopping contexts [28]. However, emerging evidence suggests that realism in autism-focused digital environments must be approached cautiously. For instance, the study by Haskins et al [103] demonstrated that in naturalistic, multisensory virtual environments, behavioral differences in autism became more pronounced under increased perceptual load, indicating that realistic sensory contexts can amplify attentional demands and influence performance independently of the targeted cognitive construct. This finding highlights that realism may simultaneously enhance engagement while increasing sensory demands. Accordingly, realism in autism-oriented serious games should be treated as a calibrated design decision rather than an unconditional benefit, balancing authenticity with sensory accessibility to support comfortable, sustained interaction [104].

XSL•FO
RenderX

Usability vs Technical Optimization

While the primary focus of the evaluation centered on usability issues as mapped to the ASD-guided heuristics, it became evident that performance factors—such as responsiveness, framerate drops, glitches, and inconsistent character movement—were also frequently highlighted, particularly by developers. These technical shortcomings significantly disrupted the fluidity of gameplay and contributed to lower scores in areas such as efficiency and error handling, mirroring findings in Bevan [105] that underscore the inseparable nature of usability and technical performance in interactive systems. Previous research indicates that technical instability and interruptions can negatively impact user engagement and task completion, with amplified effects for users with autism who may be especially sensitive to erratic system feedback or unexpected disruptions [106]. Unlike general usability heuristics, which often overlook system-level performance aspects, the ASD-guided heuristics explicitly emphasize the importance of responsiveness that is critical for autistic users who may be highly sensitive to unexpected feedback or system delays [61]. Addressing such technical shortcomings was therefore essential to ensuring a seamless and accessible experience [54]. In response to these findings, the game was migrated to a higher-performance platform to achieve smoother operation and more stable performance in subsequent evaluations.

Comparison With Prior Work

Although existing shopping-based serious games have shown promise in evaluating planning skills, several important limitations remain. First, none of the current shopping serious games have been applied to assess planning in children with autism. Most existing tools have been developed for other populations, such as individuals recovering from stroke, those with mild cognitive impairment, and adults with psychiatric conditions including schizophrenia [20-23]. These systems demonstrate that shopping tasks are well suited for capturing planning behaviors such as sequencing, goal management, and constraint handling. However, they are not designed for neurodevelopmental populations and often overlook developmental, sensory, and cognitive considerations that are critical when working with children on the autism spectrum. In contrast, ShopAutiPlan was specifically designed for children with autism, with interface simplicity, sensory-sensitive visual design, and age-appropriate task structure explicitly incorporated to support this population while preserving the ecological validity of the shopping task.

A smaller body of work has applied shopping-based serious games to children with autism, but these systems have been used exclusively for training or rehabilitation rather than assessment [107-111]. These studies typically focus on improving daily living skills, money handling, or shopping competence through repeated practice and pre-post intervention designs. However, because their primary goal is skill acquisition, outcome measures are generally limited to learning gains or task success rates, rather than fine-grained behavioral indicators of planning. In contrast, ShopAutiPlan was designed as an assessment-oriented serious game, where planning behaviors are captured during natural task execution using log-based measures, enabling objective evaluation of planning efficiency, sequencing, and decision-making.

Across both autism and nonautism studies, serious game development has primarily emphasized design and engagement considerations, including immersive environments [112], enhanced user interaction [113], and strategies to increase enjoyment and motivation [114]. While these approaches improve usability and user acceptance, they do not, on their own, ensure that in-game behaviors can be meaningfully interpreted as valid indicators of executive planning processes [115]. Moreover, although some shopping-based serious games report planning-related measures—such as task duration, errors, or navigation efficiency—many studies provide limited methodological detail regarding how these measures are derived, theoretically justified, or validated [20-23]. They lack standardized frameworks to guide the development of serious games for executive function assessment, particularly frameworks that integrate theoretical models of planning with psychometric rigor and usability principles. Our ShopAutiPlan integrates a theoretical model of planning [17] to guide task design and metric selection and combines this with a predeployment expert evaluation, enabling transparent design decisions, systematic identification of usability issues, and clearer interpretation of planning-related behaviors.

Limitations and Future Work

This study is not without limitations. Most notably, the evaluation was limited to expert-based formative assessments and did not involve direct participation from children with autism—the game's intended end users. As such, the findings may not fully capture the real-world usability challenges, sensory sensitivities, or interaction patterns specific to this population. In addition, the SUS results were derived from a small expert sample and included a clear outlier; therefore, SUS scores are reported with appropriate caution and are intended to complement the formative evaluation rather than to provide standalone conclusions. Some usability issues identified during the evaluation were related to technical performance and hardware limitations, such as delayed responsiveness or reduced frame rates on lower-specification systems. Developer experts specifically recommended deploying the game on standardized and sufficiently powerful hardware to ensure stable performance during assessment sessions. These constraints, however, mark only the first stage of a broader research project aimed at validating ShopAutiPlan as an assessment tool for executive planning in ASD.

Building on the expert feedback reported, all experimental sessions will be conducted on identical or equivalently configured systems, using the same operating system, graphics settings, and input devices. Hardware specifications (eg, processor, memory, and graphics capability) and performance parameters will be explicitly documented and reported in future studies. Initial pilot usability testing will be conducted with neurotypical children to confirm technical stability and interaction reliability, followed by an empirical study involving both ASD and typically developing cohorts to establish the game's discrimination (between-groups) validity. Finally, construct and convergent validity will be examined by

XSL•FO
RenderX

correlating in-game performance metrics with established clinical measures of planning (eg, BRIEF-2 [*Behavior Rating Inventory of Executive Function*, Second Edition] and Key Search and Zoo Map subtests of BADS-C [Behavioral Assessment of the Dysexecutive Syndrome for Children]). By systematically addressing usability, technical consistency, discrimination validity, and convergent validity, the overall project aims to deliver a robust and ecologically grounded instrument for assessing executive planning in autism research and practice.

Conclusions

This is the first study to describe the design and formative usability evaluation of "ShopAutiPlan," a supermarket-based serious game developed specifically to assess planning skills in children with autism. ShopAutiPlan was created using a theory-driven, interdisciplinary approach that mapped real-world shopping tasks to planning processes within an ecologically valid assessment context. Unlike existing serious games that focus primarily on training or engagement, this work emphasizes assessment-oriented design and interpretable performance metrics. A predeployment expert evaluation combining ASD-guided heuristics, SUS, and think-aloud protocols identified critical usability issues, informing targeted refinements before end-user testing. These findings provide a good foundation for subsequent empirical validation and support an iterative, evidence-based serious game development process.

Acknowledgments

The authors would like to express their sincere gratitude to the 6 domain experts who participated in the formative evaluation of ShopAutiPlan. Their valuable insights from the fields of psychology, human-computer interaction, and game design were instrumental in refining the game's design, usability, and accessibility.

Funding

The authors declared no financial support was received for this work.

Conflicts of Interest

Abstract

Background: Traditional neuropsychological assessments often lack ecological validity and have limited sensitivity for detecting executive dysfunction (ED) in daily life. Although grounded in standardized tasks, they do not represent the complexity of real-world contexts. Serious games (SGs) have emerged as a promising approach by simulating ecologically valid environments involving dynamic, emotional, and socially embedded interactions.

Objective: This study aimed to (1) describe the development of a clinically oriented SG for assessing executive functioning in ecologically valid scenarios, and (2) evaluate its usability in clinical and healthy populations.

Methods: We conducted a cross-sectional usability study using a theory-driven SG set in a restaurant environment, developed through an iterative process based on neuropsychological theory and expert input. Participants assumed the role of a waiter and completed tasks targeting multiple executive domains (eg, planning, working memory, decision-making, contextual control, social cognition, prospective memory, and multitasking), with embedded emotional and social cues. A total of 181 participants (43 with traumatic brain injury [TBI], 49 post–COVID-19, and 89 healthy controls), aged 21 to 66 years, were recruited through convenience sampling from clinical and community settings. ED was classified based on standardized neuropsychological assessment and clinical consensus involving neurologists and neuropsychologists. Usability and perceived difficulty were assessed using the System Usability Scale and Perceived Difficulty Scale. Group differences were analyzed using Kruskal-Wallis tests with post hoc comparisons, and generalized linear and ordinal logistic regression models adjusted for age, sex, and education (α=.05).

Results: A novel SG designed to support the assessment of executive functioning provides a more ecologically valid context than traditional neuropsychological tests. Usability was rated as good across groups, with mean System Usability Scale scores

XSL•FO
RenderX

of 73.9 (SD 17.6) in TBI, 76.5 (SD 14.5) in post–COVID-19, and 81.7 (SD 13.5) in controls. Significant differences were observed across groups (χ^2_2=9.18, *P*=.01), with lower usability in TBI compared to controls. Participants with ED (n=59) showed lower usability (mean difference −8.6, 95% CI −13.2 to −4.0; *P*<.001) and higher perceived difficulty (mean difference 1.3, 95% CI 0.5 - 2.1; *P*<.001), though these differences were no longer significant after adjusting for age and education. Age was associated with lower usability (β=−.27, 95% CI −0.45 to −0.09; *P*=.003) and higher difficulty (odds ratio 1.04, 95% CI 1.02 - 1.07; *P*<.001), while higher education was associated with better usability (β=.79, 95% CI 0.04 - 1.54; *P*=.04).

Conclusions: This study presents a novel SG integrating emotionally and socially embedded tasks to assess executive functioning in ecologically valid contexts, extending prior work through the inclusion of clinical populations and real-world demands. Findings indicate good usability and underscore the influence of demographic factors. This approach enhances the ecological relevance of neuropsychological assessment and supports its application in clinical and digital health settings. Further research should evaluate diagnostic accuracy, reliability, and real-world implementation.

Introduction

Executive Dysfunction and Its Assessment

Executive functions (EFs) arise from the interaction of multiple cognitive domains and are defined as the cognitive abilities necessary for goal setting, efficient execution of actions, and flexible modification of behavior to adapt to changing contexts [1,2]. Executive dysfunction (ED), a disruption of these abilities, is a frequent consequence of brain-related disorders, including traumatic brain injury (TBI), dementia, and schizophrenia and, more recently, has been recognized as a sequel of COVID-19 [3]. ED is a major contributor to psychosocial disability in these patients, affecting their ability to perform cognitively demanding activities such as employment and social participation [4-6]. This loss of functional independence has been directly linked to increased health care costs, with a linear relationship observed between the severity of ED and the economic burden associated with these disorders [7,8].

Early recognition of ED is essential to identify patients' difficulties and facilitate timely access to social and health services. However, current assessment methods demonstrate limited ecological validity and low sensitivity, often failing to detect executive difficulties that manifest in daily life [9], limiting timely access to necessary health care services and psychosocial support. Although a wide range of traditional methods exist, including paper-and-pencil tests and naturalistic observations, expert clinicians frequently identify ED in patients who perform adequately on standard evaluations [10,11]. There is consensus that traditional clinical assessments have lower sensitivity compared to expert clinical judgment [12]. In fact, standard evaluations fail to detect ED in up to 58% of individuals with TBI [13], likely due to their inability to reflect real-world cognitive demands. This detection gap has been attributed to several factors: (1) conventional tests often do not assess critical domains of executive functioning necessary for everyday life, such as contextual adaptation integrating cognitive and emotional information, prospective memory, and multitasking within social contexts; (2) they rely on highly structured tasks; and (3) they measure performance through a limited number of discrete or categorical variables (eg, correct responses, errors, and overall task completion time) [12,14,15].

Serious Games for EF Assessment

Information and communication technologies have enabled the development of novel, computer-based tools—notably serious games (SGs)—to enhance the sensitivity and ecological validity of ED assessments. SGs are interactive digital applications designed with purposes beyond entertainment, including assessment, education, or rehabilitation in health contexts [16,17]. SG-based evaluations facilitate the assessment of EF within simulated real-life contexts through unstructured tasks, allowing the inclusion of EF domains that are not typically evaluated [14]. These tools are easy to implement in clinical settings, require only standard, low-cost technology (eg, computers or tablets), are simple for health care personnel to administer, are well tolerated by patients, and are applicable across a broad spectrum of brain disorders. Recent studies have increasingly explored the use of SG for cognitive assessment and rehabilitation, highlighting their potential to enhance ecological validity and user engagement [14,18,19]. However, much of this research has been conducted in nonclinical populations or small samples [20,21]. Although SGs have been proposed as a way to enhance ecological validity by simulating real-world contexts, it is important to keep in consideration that it may also increase cognitive load, which can influence user performance and experience [22,23].

Additionally, performance can be assessed through multiple indicators, including continuous measures that are often overlooked by conventional neuropsychological tests. Furthermore, advanced analytical approaches, such as machine learning models, provide a powerful framework for extracting clinically meaningful insights from these complex, multidimensional data [24].

Importance of Usability Studies in SGs for Cognitive Assessment

Beyond diagnostic sensitivity, the clinical applicability of SGs also depends on their usability, particularly for individuals with cognitive impairments. Usability can be defined as the degree to which a product can be used effectively, efficiently, and

XSL•FO
RenderX

satisfactorily by specific users in a particular context [16,25]. In neuropsychological applications, this includes learnability, ease of navigation, user control, and satisfaction with game features. Poor usability may overload cognitive resources, hinder learning, and reduce motivation to engage with the task [26-28]. Although usability studies have been conducted for SGs [20,25,29,30], most have involved small samples or participants who do not represent the intended clinical population [21,31,32]. Given that SG users may belong to nongaming populations with heterogeneous cognitive profiles, it is critical to assess usability in the specific clinical groups for whom these tools are designed [30]. Although some studies have examined usability aspects, these have often been limited to specific populations or have not incorporated complex, socially and emotionally embedded scenarios that reflect real-world executive demands [21,33]. As a result, there remains a need for clinically oriented SG that combines ecological validity with systematic usability evaluation in populations affected by ED.

Objectives

The objective of this study was to introduce a new SG developed to assess EFs in adults. The aims of this study were (1) to describe the development of a clinically oriented SG designed to assess ED in ecologically valid contexts and (2) to evaluate its usability in clinical and healthy populations using standardized measures of usability and perceived difficulty.

Methods

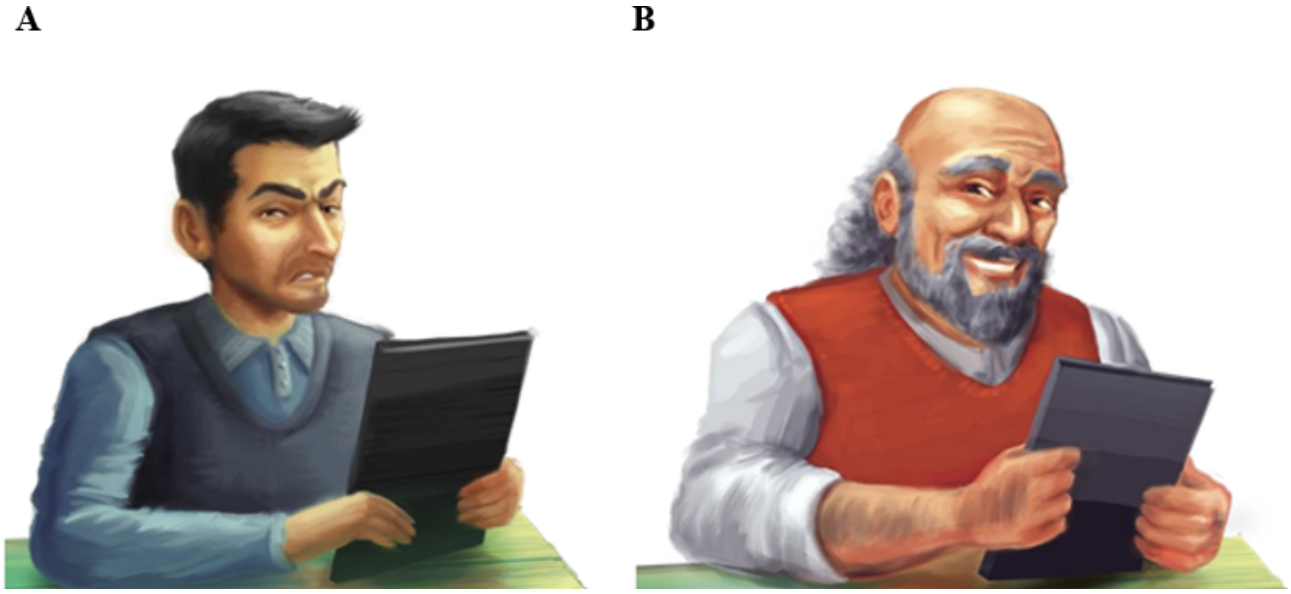
SG Development

Our team developed a novel computer-based tool for the assessment of EF through an SG. The development process followed an iterative, theory-driven design, incorporating input from expert clinicians and cognitive scientists. Expert judges, comprising national and international neuroscientists, neurologists, and neuropsychologists, participated in a structured validation process. They contributed to the selection of the EF domains to be assessed, the design of the SG's central metaphor, a restaurant setting in which the player assumes the role of a waiter, and the specification of the tasks designed to evaluate core executive processes. This "waiter scenario" was intentionally chosen to simulate cognitively demanding situations grounded in everyday life, particularly those requiring rapid decision-making, emotional regulation, and cognitive flexibility—capacities often compromised in individuals with ED. Working as a waiter involves managing multiple concurrent events (eg, taking orders, responding to customer feedback, and coordinating with kitchen staff), all within a socially and emotionally dynamic environment. These conditions create an ideal context for embedding emotionally salient and contextually rich cues that reflect the complexity of real-life cognitive demands. Special attention was given to enhancing ecological validity and contextual realism. For example, the game's graphic design emphasized clearly identifiable facial expressions to support emotional recognition and contextual control during gameplay. Tasks integrate context-dependent problem-solving, emotionally charged stimuli, and simultaneous goal management, components that, according to recent theoretical frameworks [14], are essential for assessing ED in ecologically valid settings.

Expert Consensus

The SG was designed to operationalize 9 key EF domains, selected based on expert consensus and their relevance to real-life functioning. Table 1 presents each cognitive domain, its conceptual definition, and how it is operationalized within the gameplay. The in-game tasks were crafted to embed these domains in naturalistic interactions, ensuring ecological validity by incorporating emotionally salient cues, simultaneous task demands, and context-rich decision-making scenarios. This structure allows for the assessment of ED as it emerges in realistic, socially embedded environments, rather than through artificial, isolated tasks.

To empirically evaluate the alignment between expert ratings and the SG's proposed indicators of ED, the Cohen κ coefficient [34-36] was used. This statistic is suitable for assessing interrater agreement in categorical or ordinal data across multiple evaluators. Content validity was supported by high levels of expert agreement, with at least 60%—and in most cases over 80%—of experts rating each proposed domain and corresponding task metric as appropriate for assessing ED.



Following the review of these domains, experts also evaluated a set of 6 character illustrations designed to portray basic emotional expressions (sadness, disgust, anger, happiness, neutral, and surprise). These visual stimuli were used to assess emotional recognition and the player's capacity to adapt behavior according to social signals, a core component of contextual control and social cognition. Special care was taken to ensure that facial expressions were visually distinct and ecologically valid, providing reliable cues for real-time emotional appraisal and decision-making. Figure 1 depicts the examples of customer characters expressing anger and happiness.

XSL•FO
RenderX

Table . Definition of cognitive domains and their operationalization within a clinically oriented serious game designed to assess executive dysfunction.

Cognitive domain	Conceptual definition	Operationalization definition
Time-based prospective memory	Ability to remember to perform a postponed action after a predetermined time interval	Remember to play music every time it is switched off. Indication is given that music should always be playing in the restaurant
Event-based prospective memory	Ability to remember to perform an action in response to an environmental cue	Execution of a task when a predefined condition occurs within the game context
Working memory	Limited-capacity system for temporary storage and manipulation of information	Retention and short-term recall of information required to complete tasks
Planning	Ability to set goals and organize intermediate steps	All actions or strategies performed by the participant to achieve a specific goal
Decision-making	Ability to evaluate potential outcomes of different actions	Choice between alternative actions with distinct positive, neutral, or negative consequences
Cognitive flexibility	Ability to adapt behavior to changing demands	Behavioral adjustment in response to novel or changing game conditions
Contextual control	Ability to regulate behavior based on contextual emotional or nonverbal cues	Adaptation of responses to customers' petitions or facial expressions
Social cognition	Ability to understand others' intentions and social norms	Conventional behavior aligned with social expectations during interactions
Multitasking	Ability to manage multiple tasks simultaneously or sequentially	Concurrent or alternating the execution of multiple in-game tasks

Figure 1. Illustration of customer characters used in the serious game, displaying 2 emotional expressions, (A) Anger and (B) Happiness to simulate socially and emotionally relevant interactions.

Development of the SG

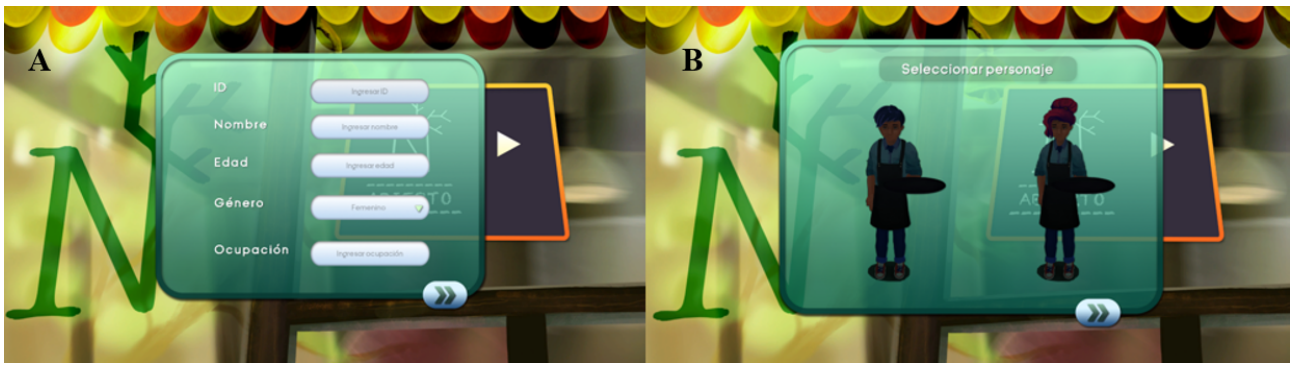
Game Tracking

The SG was implemented on a standard laptop using a mouse for navigation. All player interactions were dynamically tracked through an integrated recording system, which captured performance metrics throughout the restaurant environment (including tables, kitchen, and service zones). Each action was logged along with contextual parameters such as the emotional state of customers, concurrent tasks, and environmental demands. States were defined by sequences of actions, with metrics such as execution times, decision choices, errors, and the simultaneous state of all tables recorded in real time. This dynamic recording generated a substantial volume of data, organized into a JSON file structure. This format enabled both macrolevel and microlevel analyses, including reaction times, error rates, and the reconstruction of player behavior across the full temporal sequence of gameplay. In the present publication, we focus on the development of the SG and its usability evaluation; performance data and gameplay metrics involving both healthy and clinical populations will be presented in future studies.

Gameplay Procedure and Structure

The SG is intended to be administered in the context of a neuropsychological evaluation, under the supervision of a health professional. The game's setting is situated within the context

XSL•FO
RenderX



of a restaurant, wherein the player assumes the role of a waiter (Figure 2 for the SG environment).

Figure 2. Serious game environment representing a restaurant setting used to simulate ecologically valid scenarios for the assessment of executive functioning.

Initially, participants are required to provide their full name (which is used to personalize interactions with customers during the game), age, and sex (female, male, or other). The following step involves the selection of an avatar from a pair of possible options. Figure 3 shows the home screen and avatar selection.

Figure 3. (A) Home screen and (B) avatar selection interface of the serious game, allowing users to choose their in-game character before gameplay.

The game begins with a tutorial phase in which a character (the chef) gives instructions and shows the steps necessary to achieve the proposed objectives (see Figure 4). The purpose of this phase is to familiarize the person with the virtual environment and the tasks to be performed when the evaluation begins.

XSL•FO
RenderX

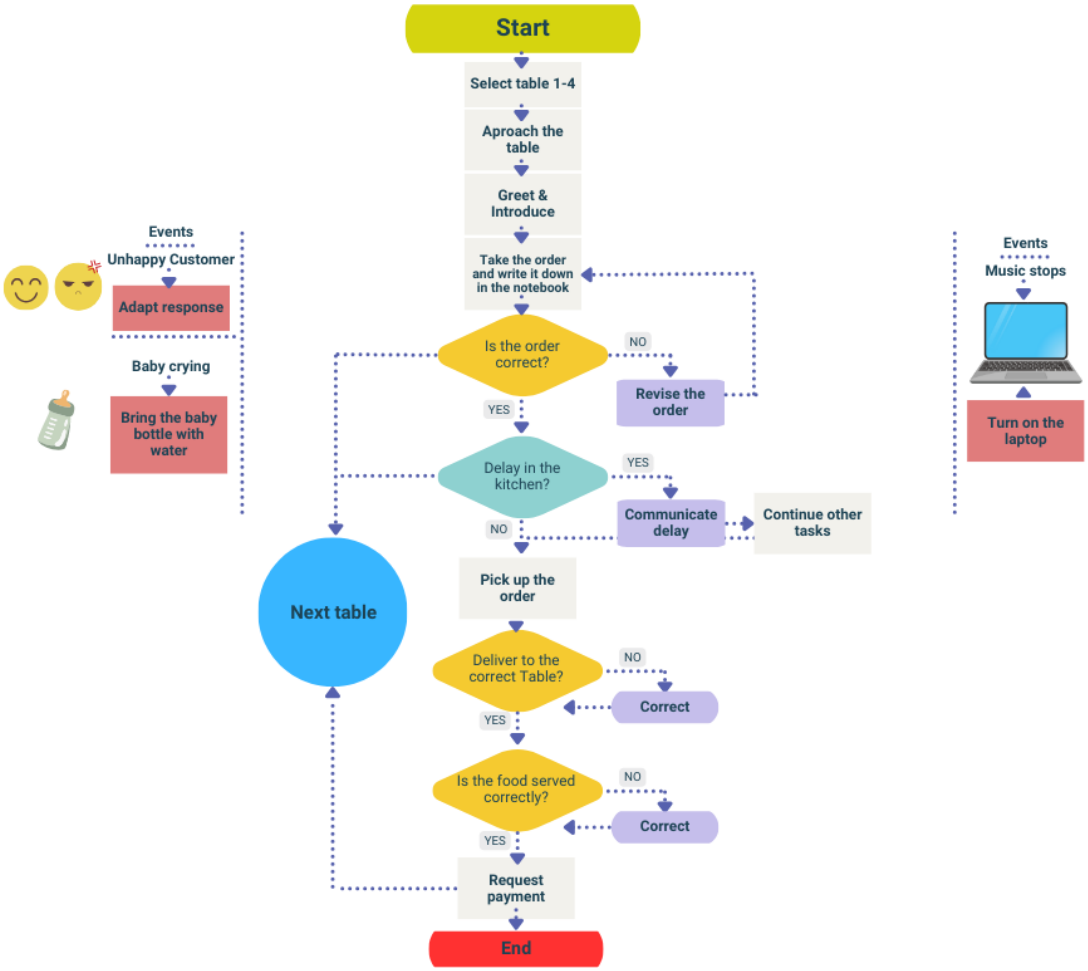


Figure 4. Initial tutorial of the serious game. In this phase, players are introduced to the game mechanics and instructions.

The SG is designed to integrate ecologically valid elements by simulating real-life challenges within emotionally and socially dynamic environments. As such, it provides a unique opportunity to assess EF with high contextual relevance, particularly in populations whose deficits are often undetected by conventional methods. Figure 5 shows the flow of the core gameplay loop.

XSL•FO
RenderX

Figure 5. Illustration of the structure and flow of the core gameplay loop. It includes multiple simultaneous and context-sensitive interactions, such as responding to customer emotions, handling multitasking under time constraints, and managing delays or order issues, all representative of real-life executive functioning demands. This flowchart highlights how key executive domains (eg, planning, decision-making, multitasking, and contextual control) are embedded into the gameplay.

The creation and design process of the SG resulted in a clinically oriented tool intended to assess the previously described EF domains in a manner that approximates real-world contexts. Table 2 shows the examples of tasks associated with each cognitive function.

XSL•FO
RenderX

Table . Cognitive skills assessed across different tasks within the serious game (SG) designed to evaluate executive dysfunction.

Cognitive function assessed	Task	SG
Contextual control	Table with 1 customer: the customer's order is delayed and he starts to get angry. The player must choose an appropriate response to the customer's emotional state, which can either increase his anger or calm him down.	
Prospective memory	Remember to play music every time it is switched off. The player is informed at the beginning that music should always be playing in the restaurant, making this a time-based prospective memory challenge.	
Working memory	Table with 4 customers: In total, they order 3 different meals and 3 different beverages, with repetition of one meal and one beverage (working memory load: 6 items).	
Cognitive flexibility	Table with 4 customers: one of the customers, after ordering and at the moment the dish is delivered, decides to change his order. The player is required to adapt to the change and select an appropriate course of action.	
Planning	All actions or tasks performed by the assessed participant to achieve a goal. The trajectory followed by the subject—from the kitchen to each table—is evaluated to assess planning efficiency.	
Decision-making	All situations in which the person being assessed has to choose between 2 or more actions, which will have different consequences (positive, neutral, or negative).	
Social cognition	Ability to respond in a conventional manner to social norms. Each time the waiter starts interacting with a new customer, he/she will have the option to introduce him/herself or skip this step and take the order directly. Additional dilemmas include whether or not to return found money from one of the tables.	
Multitasking	Simultaneous performance of multiple tasks during gameplay, including distractions such as a crying baby.	

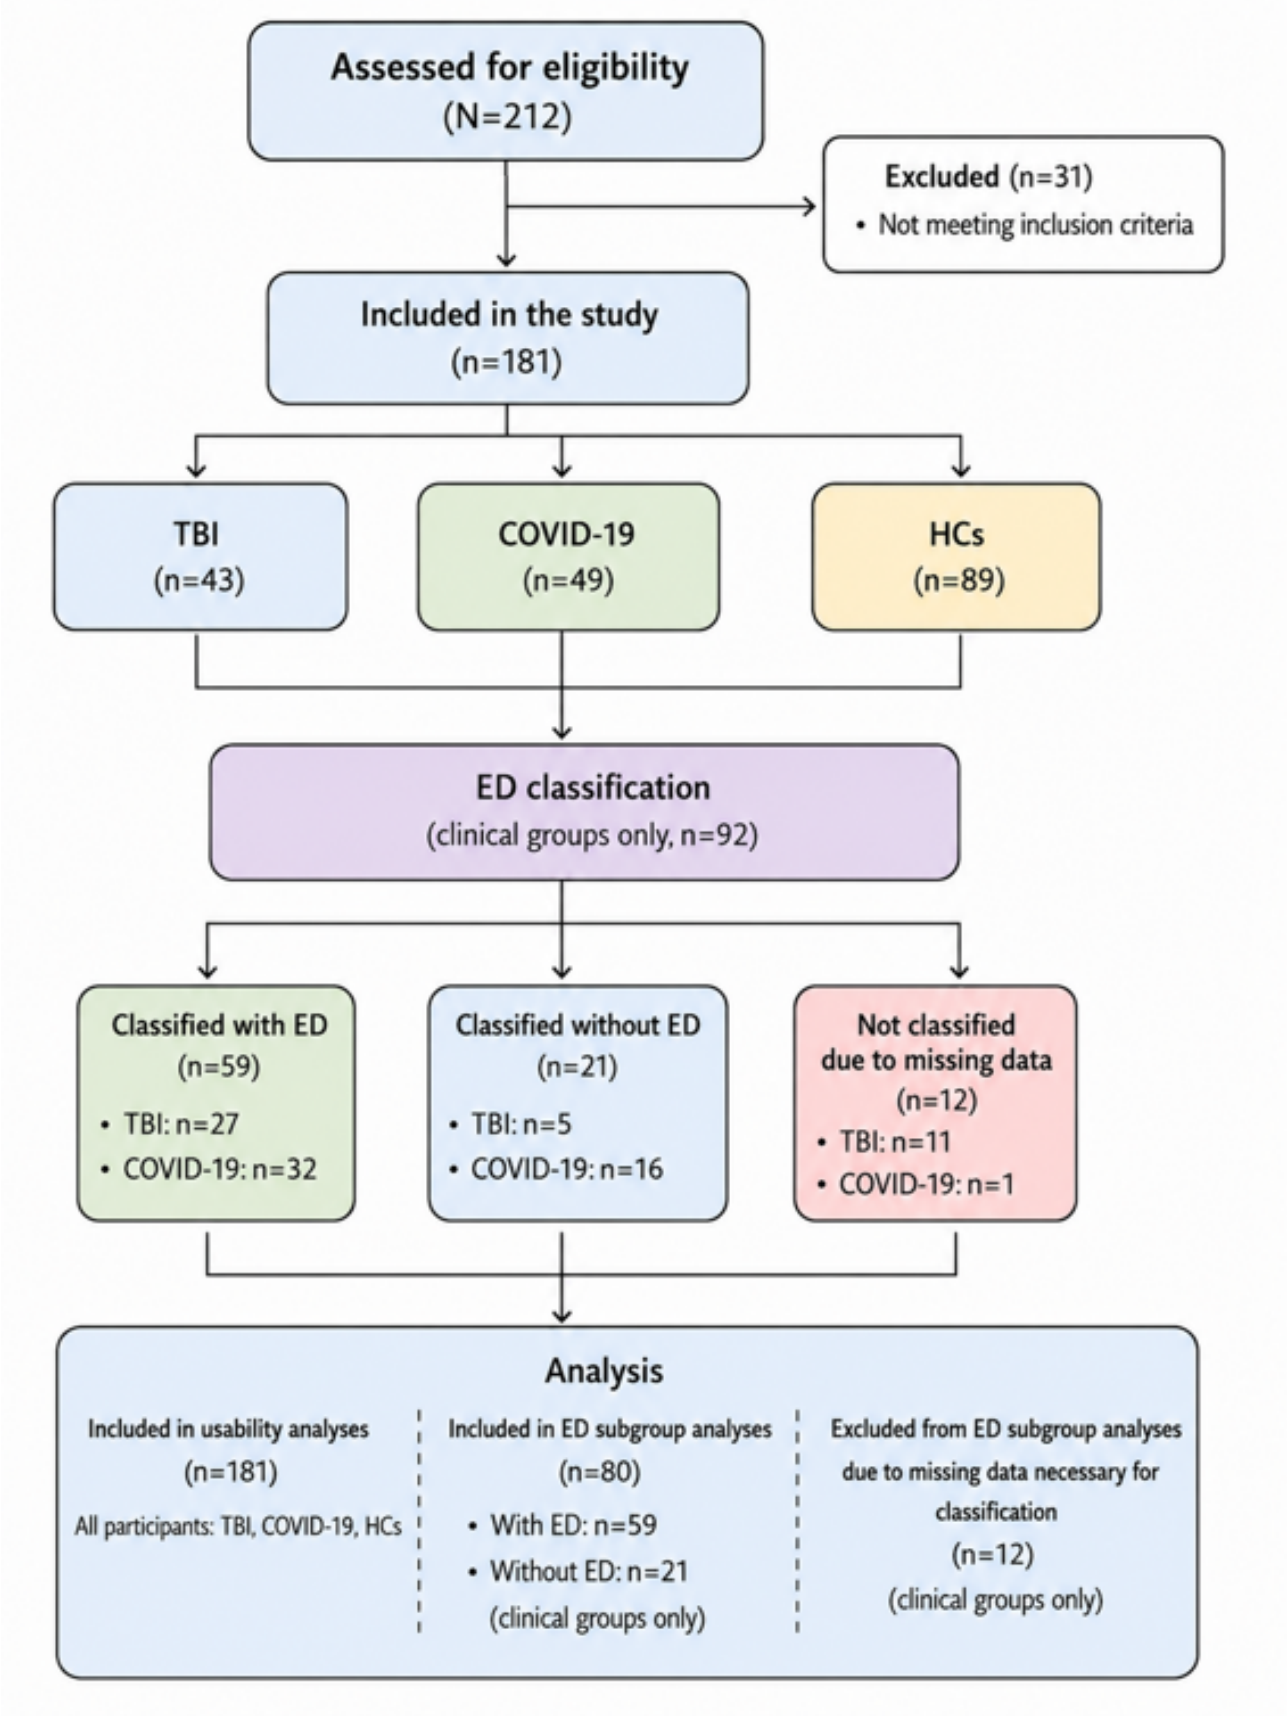
Usability Study

Study Design

This study follows a cross-sectional observational design, with clinical and nonclinical participants, aimed at evaluating the usability of a clinically oriented SG developed to assess ED in ecologically valid contexts.

Setting

The study was conducted in 3 clinical settings in Santiago, Chile (Hospital del Salvador, Hospital Clínico de la Universidad de Chile, and Mutual de Seguridad). Data collection took place between August 2023 and February 2025, including participant recruitment, neuropsychological evaluation, and SG administration. All assessments were performed in controlled environments under the supervision of trained health professionals.



Sampling Procedures

Participants were recruited through convenience sampling. Clinical participants were identified principally via referrals from health care professionals in collaborating institutions, while healthy controls (HCs) were recruited through community outreach and institutional participant registries. Initial eligibility screening was conducted via telephone, followed by in-person confirmation (Figure 6).

No monetary compensation was provided. Participants were offered a snack during a break in the evaluation session and received feedback on their neuropsychological assessment scores. It was clearly explained that these results represented psychometric findings only and did not constitute a formal clinical report.

XSL•FO
RenderX

Figure 6. Participant flow diagram of the study. The diagram illustrates recruitment, group allocation (traumatic brain injury [TBI], COVID-19, and healthy controls [HCs]), executive dysfunction (ED) classification within clinical groups, and inclusion in the analyses. A total of 181 participants were included (43 with TBI, 49 with COVID-19, and 89 HCs). ED classification was conducted in clinical groups only (n=92), with 12 participants excluded from subgroup analyses due to missing data.

XSL•FO
RenderX

Participant Characteristics

Inclusion and Exclusion Criteria

The sample included individuals aged 21 to 66 years, comprising both clinical populations (TBI and post–COVID-19) and HCs. Eligibility criteria were defined as follows:

Participants were required to (1) have completed at least 6 years of education, (2) be able to agree to participate in the study and sign the informed consent form, and (3) be able to perform cognitive tasks for at least 20 minutes. People were not recruited if they had severe cognitive impairment (assessed via neuropsychological testing), sensory impairments not compensated by assistive technology, motor impairment of the dominant hand, speech impairment interfering with assessment, or disabling systemic disease preventing a definitive diagnosis of ED.

Clinical Group

Inclusion criteria included (1) COVID-19 infection requiring hospitalization (at least 3 mo ago) with self-report of at least one neurological sign (COVID group) or TBI that has required emergency department consultation or hospitalization after the TBI (TBI group) and (2) clinical history suggestive of ED according to the Dysexecutive Questionnaire [37] or reported by the clinical staff (not explained by another cause such as perceptual, motor, or other cognitive disorders). Exclusion criteria included a history of premorbid intellectual disability that has limited access to formal education.

HC Group

Inclusion criteria included (1) being a resident of the community and able to live independently, (2) performance in normal ranges in the Frontal Assessment Battery (Chilean version) [38], and (3) clinical consensus following neuropsychological evaluation, excluding the presence of ED. Exclusion criteria included (1) a history of major neurological and/or psychiatric disease, alcohol, or drug abuse, (2) the current use of certain psychotropic drugs, or (3) current depressive or anxiety disorder.

Measures and Covariates

Demographic variables, including age, sex, and years of education, were recorded and included as covariates in the statistical analyses. All participants were evaluated by a clinical neuropsychologist who collected qualitative clinical data.

Neuropsychological measures included assessments of general cognitive functioning using the Montreal Cognitive Assessment [39]; attention and working memory using the Digit Span test (forward and backward) [40] and the d2-R Test of attention [41]; processing speed using the Trail Making Test Part A; and executive functioning using the Trail Making Test Part B [42], Frontal Assessment Battery [38], Tower of London Test [43], and the Dysexecutive Questionnaire [37] administrated to the participant and a reliable proxy. Finally, daily functioning abilities were evaluated using the Technology–Activities of Daily Living Questionnaire [44], administered both to the participant and the proxy.

The primary outcomes of interest were usability and perceived difficulty, assessed using the System Usability Scale (SUS) [45] and the Perceived Difficulty Scale (DP13-CL) [46], respectively.

- SUS: The SUS is one of the most widely used questionnaires to test usability [32]. It evaluates the effectiveness, efficiency, and satisfaction of participants' interaction with a system by means of 10 items answered with a Likert scale ranging from 1 ("strongly disagree") to 5 ("strongly agree"). Sample items include: *I think I would use this system frequently*, *I find this system unnecessarily complex*, and *I think the system was easy to use*, among others.
- DP13-CL (Adaptation of the DP-15 Scale): This scale was specifically designed to assess perceived difficulty in the SG. Respondents rate their difficulties on a numerical scale, where level 1 denotes "no difficulty" ("extremely easy") and level 13 represents "maximum difficulty" ("extremely difficult").

ED Classification

Clinical consensus regarding ED was established through multidisciplinary case discussions involving neurologists and neuropsychologists, after the completion of each participant's neuropsychological evaluation. ED was operationally defined based on a combination of standardized neuropsychological test performance and expert clinical consensus, which served as the reference standard for group classification.

Participants were classified into 3 categories: no ED, mild ED, or moderate to severe ED, based on the integration of standardized test performance, deviations from normative values, and functional impact. In cases of disagreement, consensus was reached through discussion among clinicians. For the purposes of the present analyses, participants classified as mild or moderate to severe were grouped as presenting ED.

Importantly, ED classification was independent of the clinical group, such that participants within the TBI and COVID-19 groups could be classified as with ED (27 participants with TBI and 32 participants with COVID-19) or without ED (5 participants with TBI and 16 with COVID-19) based on the consensus procedure.

It is worth noting that 12 out of 92 participants within the clinical groups (11 with TBI and 1 with COVID-19), representing approximately 13% of the clinical sample, could not be classified regarding the presence or absence of ED due to missing clinical or informant data required for consensus-based classification. Consequently, these participants were excluded from analyses that required ED classification. No imputation procedures were applied, as the missing data affected only the classification variable and not the primary usability outcomes.

Sample Size, Power, and Precision

The study sample size (N=181) was determined based on feasibility considerations, including participant availability within the recruitment period and resources for comprehensive neuropsychological assessment. While no formal a priori sample size calculation was conducted given the primary focus on

XSL•FO
RenderX

usability evaluation rather than hypothesis testing, a post hoc power analysis confirmed the robustness of our comparative findings. Specifically, for our main contrast regarding perceived usability between clinical patients with ED (n=59) and HC (n=89), the analysis indicated an adequate effect size (Cohen *d*=0.588), yielding a statistical power of 93.5% (1–β=.935) to detect meaningful differences in SUS scores at an α level of .05. Furthermore, to address estimation precision, 95% CIs were computed and reported for all key usability metrics and point estimates.

Statistical Analysis

Descriptive statistics were computed for all variables. Group differences in continuous variables were assessed using nonparametric tests (Kruskal-Wallis and Mann-Whitney tests), while categorical variables were analyzed using chi-square tests. To indicate the precision of our estimates, 95% CIs were calculated for the main group comparisons. Sociodemographic variables were used as covariates when corresponding.

To control for potential confounders, linear models were used to analyze SUS scores, including group and sex as fixed factors and age and education as covariates. Ordinal logistic regression models were applied to analyze perceived difficulty (DP13-CL), using the same covariates.

All statistical analyses were conducted using Jamovi software (The Jamovi Project), with statistical significance set at $P<.05$.

Ethical Considerations

This study was approved by the Ethics Committee of Hospital Clínico de la Universidad de Chile (approval number OAIC 1300/22), covering research activities conducted at Hospital Clínico de la Universidad de Chile and Hospital del Salvador, and by the Ethics Committee of Mutual de Seguridad (approval number 20CV-140571). The study was conducted in accordance with the ethical principles of the Declaration of Helsinki and applicable national regulations governing research involving human participants. Participants were recruited and assessed at Hospital Clínico de la Universidad de Chile, Hospital del Salvador, and Mutual de Seguridad. Written informed consent was obtained from all participants prior to study participation. No financial compensation was provided. However, participants were offered a light refreshment during the assessment session and received individualized feedback on their neuropsychological assessment results.

All data were anonymized prior to analysis to ensure participant confidentiality, using coded identifiers. Data were securely stored using REDCap electronic data capture tools hosted at the Faculty of Medicine, Universidad de Chile [47], and were accessible only to authorized members of the research team. No identifiable participant data or images are included in this paper or supplementary materials.

Results

Perceived Usability and Difficulty

A total of 212 participants were assessed for eligibility in the usability study, of whom 181 were included in the final analyses. The final sample consisted of 43 participants with TBI, 49 participants with COVID-19, and 89 HCs. Table 3 presents the demographic characteristics of the sample, including age, years of education, sex distribution, and the mean scores on the neuropsychological tests and questionnaires administered during the assessment.

The analysis of total scores on the SUS and DP13-CL is presented in Table 3. The item-level breakdown of the SUS is shown in Figure 7. According to the classification proposed by Bangor et al [48], SUS scores indicated good usability across all groups. A Kruskal-Wallis test revealed significant differences between groups ($\chi^2_2=9.18$, $P=.01$). Post hoc pairwise comparisons showed that the TBI group rated usability significantly lower than the HC group ($P=.02$). No significant differences were found between the TBI and COVID groups ($P=.93$) or between the COVID and HC groups ($P=.06$).

For the DP13-CL, the overall mean score across all participants was 5.61 (SD 2.36), corresponding to an average difficulty rating between “easy” and “neither easy nor difficult.” Reported scores ranged from 1 (“extremely easy”) to 12 (“very difficult” to “extremely difficult”), with a total sample size of 181. Group-level analysis revealed that the COVID group reported the highest perceived difficulty (mean 6.43, SD 2.29), followed by the TBI group (mean 5.79, SD 2.61) and the HC group (mean 5.08, SD 2.14). A Kruskal-Wallis test indicated significant differences among the 3 groups ($\chi^2_2=11.6$, $P=.003$). Post hoc pairwise comparisons showed a significant difference between the COVID and HC groups ($P=.001$), while no significant differences were observed between the TBI and COVID groups ($P=.63$) or between the TBI and HC groups ($P=.23$).

Table . Demographic characteristics of the clinical group and healthy controls (HC)[a].

Characteristic	TBI[b] (n=43), mean (SD; range)	COVID (n=49), mean (SD; range)	HC (n=89), mean (SD; range)	Median (IQR)	*P* value
Age	48.4 (11.0)	48.7 (10.9)	42.9 (13.6)	48.0 (21.0-66.0)	.04
Education	12.3 (3.3)	14.3 (3.1)	17.2 (2.8)	16.0 (6.00-26.0)	<.001
Sex (male/female)	24/18	18/31	25/64	—[c]	.006
MoCA[d]	24.0 (4.6)	24.4 (3.8)	27.2 (2.2)	26.0 (13.0-30.0)	<.001
FAB[e]	14.5 (2.6)	15.3 (2.4)	17.0 (1.0)	16.0 (7.00-18.0)	<.001
GREFEX[f]	1.97 (1.56)	1.59 (1.89)	0.25 (0.53)	0 (0-7)	<.001
SUS[g]	73.9 (17.6; 68.5 - 79.3)	76.5 (14.5; 72.3 - 80.7)	81.7 (13.5; 78.9 - 84.5)	80.0 (12.5-100)	.01
DP13-CL[h]	5.79 (2.61; 5.0 - 6.6)	6.43 (2.29; 5.8 - 7.1)	5.08 (2.14; 4.6 - 5.5)	6.00 (1-12)	.003

[a]Continuous variables were compared using the Kruskal-Wallis test, and sex was compared using the chi-square test. MoCA and FAB scores are reported to reflect general and frontal cognitive functioning, respectively. GREFEX indicates symptom reports related to the behavioral dysexecutive syndrome, with the presence of three or more symptoms suggesting the presence of this syndrome. Seven participants from the TBI group and 2 from the HC group did not have GREFEX data due to difficulties coordinating interviews with their respective informants.

[b]TBI: traumatic brain injury.

Figure 7. Spider plot representing the mean scores for each item of the System Usability Scale (SUS) across groups. The plot displays the mean score (range 1 - 5) for each of the 10 SUS items: (1) "I think that I would like to use this system frequently," (2) "I found the system unnecessarily complex," (3) "I thought the system was easy to use," (4) "I think that I would need the support of a technical person to be able to use this system," (5) "I found the various functions in this system were well integrated," (6) "I thought there was too much inconsistency in this system," (7) "I would imagine that most people would learn to use this system very quickly," (8) "I found the system very cumbersome to use," (9) "I felt very confident using the system," (10) "I needed to learn a lot of things before I could get going with this system." HC: healthy control; TBI: traumatic brain injury.

When analyses were restricted to participants with ED from the COVID and TBI groups (n=59), they exhibited significantly lower SUS scores (mean 73.1, SD 16.2; P<.001) and higher perceived difficulty (mean 6.34, SD 2.32), compared to HCs (SUS: mean 81.7, SD 13.5; DP13-CL: mean 5.08, SD 2.14; Table 4).

Given the observed group differences in age and education, additional analyses were conducted to control for these demographic variables. A general linear model was used to analyze SUS scores, with group and sex as fixed factors and age and years of education entered as covariates. The model was significant ($F_{7,171}$=4.32, P<.001, R^2=0.150). However, no significant main effects of group (P=.51) or sex (P=.86) were observed, and the group × sex interaction was not significant (P=.28). Notably, age was negatively associated with SUS scores (β=–.272, P=.003), while education was positively associated (β=.794, P=.04). These findings suggest that the initial group differences observed in unadjusted analyses were largely explained by individual differences in age and education.

To explore whether the same pattern was held for perceived difficulty (DP13-CL), an ordinal logistic regression (proportional odds model) was conducted using group and sex as fixed factors, with age and education as covariates. The model was significant (χ^2_7=34.4, P<.001, R^2=0.044). As in the SUS analysis, group (P=.08), sex (P=.59), and the group × sex interaction (P=.31) were not significant. However, age was positively associated with perceived difficulty (odds ratio 1.04, 95% CI 1.02-1.07, P<.001), indicating that older participants reported higher difficulty. Years of education showed a trend-level negative association with perceived difficulty (odds ratio 0.91, 95% CI .83-1.00, P=.05), suggesting that higher educational attainment was associated with lower perceived difficulty.

Table . System Usability Scale (SUS) and Perceived Difficulty Scale (DP13-CL) scores across groups[a].

Type of scale	ED[b] (n=59), mean (SD; 95% CI)	HC[c] (n=89), mean (SD; 95% CI)	*P* value
SUS	73.1 (16.2; 68.9 - 77.3)	81.7 (13.5; 78.8 - 84.5)	<.001
DP13-CL	6.34 (2.32; 5.73 - 6.94)	5.08 (2.14; 4.63 - 5.53)	<.001

[a]Mann-Whitney different means with *P*<.001.

[b]ED: executive dysfunction.

[c]HC: healthy control.

Discussion

Principal Findings

The present study had two aims: (1) to describe the development of a clinically oriented SG designed to assess ED in ecologically valid contexts and (2) to evaluate its usability in clinical and healthy populations. Overall, usability was rated as good across groups, and perceived difficulty fell within a moderate range. Participants with ED reported lower usability and higher perceived difficulty compared to HCs, although these differences were attenuated after adjusting for age and education. Age and educational level were significantly associated with usability and perceived difficulty, indicating that user characteristics influence interaction with the tool.

Interpretation

Differences in perceived usability and difficulty in older and less educated participants are consistent with prior findings indicating that age affects usability perceptions, in which task difficulty may be over- or underestimated regardless of objective performance [49]. Regarding education, it is noteworthy that participants with lower educational backgrounds were mainly from the TBI group, which also showed more pronounced ED. Previous studies have documented the relationship between lower education and greater executive deficits in TBI [50], suggesting that usability differences may partly reflect underlying executive impairment, while also highlighting the role of demographic factors in shaping user experience [49]. The relatively narrow confidence intervals observed for these estimates suggest an acceptable level of precision [51], although some variability remains, particularly in subgroup analyses. Future studies are needed to determine the extent to which demographic factors influence the diagnostic accuracy of the SG.

As highlighted by Martínez-Pernía et al [14], traditional tools lack ecological validity, whereas SGs can more accurately simulate the demands of everyday life. A key advantage of the current SG lies in its ability to recreate realistic, dynamic, and socially embedded situations relevant to everyday functioning. Participants with ED, across both the post–COVID-19 and TBI groups, showed lower usability ratings and higher perceived difficulty compared to HCs. These group differences are consistent with previous literature, suggesting that individuals with ED experience greater difficulties when interacting with complex and dynamic environments [14]. Such contexts often involve emotionally salient and embodied interactions (ie, the integration of cognitive, emotional, physiological, and bodily responses during real-world social interactions) [14,52,53], which are crucial for effective executive functioning in daily life. However, these features may also increase task complexity and cognitive load [22]. Importantly, ecological validity does not necessarily imply lower task demands or greater usability; rather, more realistic scenarios may inherently increase cognitive load [14,22,23]. Therefore, the observed differences may reflect both the sensitivity of the task to executive impairments and the increased complexity associated with these context-rich environments, and its utility for diagnostic accuracy remains to be established. These findings should be interpreted in light of the adjusted analyses, in which group differences were attenuated after controlling for age and education. Accordingly, the results are better understood as reflecting the interaction between user characteristics and task demands within realistic assessment contexts, rather than as evidence of differential sensitivity to ED.

Unlike earlier usability studies that relied exclusively on healthy participants (eg, [16,27,28]), the inclusion of clinical groups in this study provides important evidence for the feasibility and acceptability of the SG in its intended population, thereby enhancing its translational relevance. Although usability testing can yield meaningful insights with relatively small samples, larger sample sizes increase confidence in the identification of usability issues. As Faulkner [54] noted, “more test users means greater confidence that the problems that need to be fixed will be found” (p. 382).

Implications

SGs have emerged as promising tools for cognitive assessment, with the potential to address limitations of traditional neuropsychological measures by providing more engaging, dynamic, and ecologically valid contexts [14,18,19,21]. The present findings support the feasibility of this approach in clinical populations, demonstrating that a complex, ecologically valid SG can be used with acceptable usability across diverse groups. Importantly, the influence of age and education on usability highlights the need to consider demographic factors in the design, interpretation, and implementation of SG-based assessments. Future studies should explore the development of adjusted norms, stratification strategies, or interface adaptations to ensure accessibility and appropriate interpretation across populations [18,55].

Although the present study focused on development and usability rather than diagnostic validity, the platform offers a promising foundation for future validation work [14,18,19]. Subsequent research should evaluate its sensitivity and specificity by comparing gameplay-derived performance with gold-standard neuropsychological measures and clinical

XSL•FO
RenderX

consensus classifications of ED. Given its digital and interactive nature, the SG also has potential for broader applications, including screening, longitudinal monitoring, and integration into stepped-care models [56]. However, its use was evaluated in a supervised clinical context, and further research is needed to establish its feasibility, reliability, and interpretability in unsupervised or real-world settings.

Limitations

This study has several limitations that should be considered when interpreting the findings. First, usability was assessed using self-reported measures, which may be subject to response biases and do not fully capture actual user behavior or task engagement [57,58]. Although the platform records detailed behavioral data (eg, action sequences, timing, and errors), these were not analyzed in the present study, which focused on development and initial usability, and therefore represent an important direction for future research. Second, the study did not evaluate the diagnostic validity of the SG; therefore, no conclusions can be drawn regarding its ability to detect ED or differentiate between clinical conditions. Third, the observed influence of age and education highlights potential variability in user experience, which may limit the generalizability of the findings across populations with different demographic characteristics. Finally, the SG was evaluated within a supervised clinical context, and its feasibility, reliability, and user interaction patterns in unsupervised or real-world settings remain to be established and should be examined in future studies. Nonetheless, a major strength of this study is the development of a novel SG for the assessment of ED, as well as the reporting of usability and perceived difficulty data in both healthy participants and individuals with ED from different etiologies.

Conclusion

The SG showed good usability and represents a promising platform for future validation studies. Its design supports the development of more contextually grounded approaches to the assessment of executive functioning and provides the initial evidence of feasibility in clinical populations. These findings contribute to the growing use of interactive, context-rich digital tools in neuropsychological assessment, addressing longstanding limitations of traditional methods in capturing everyday cognitive functioning. As digital health technologies continue to evolve, ensuring usability and accessibility will be critical for successful clinical implementation. Future research should incorporate objective behavioral metrics derived from gameplay, alongside self-report measures, to achieve a more comprehensive characterization of user interaction and performance. Further work is also needed to establish diagnostic accuracy and clinical reliability and to integrate such tools into routine neuropsychological assessment.

Acknowledgments

The authors would like to acknowledge the support of the Centro de Investigación Clínica Avanzada (CICA) and Mutual de Seguridad for their collaboration and institutional support throughout this project. Their commitment and collaboration were essential to the successful completion of this research. David Martínez-Pernía is a co-corresponding author of this paper (email: david.martinez@uai.cl). The authors declare the use of generative AI in the preparation of this manuscript. According to the GAIDeT taxonomy (2025), generative AI tools were used for proofreading and editing purposes only. The tool used was ChatGPT (OpenAI, GPT-4). Its use was limited to supporting grammar, clarity, and language refinement in English. The generative AI tool was not used to generate scientific content, design the study, perform data analysis, or interpret the findings. All scientific content, study design, and conclusions reflect the original intellectual contribution of the authors, who take full responsibility for the integrity and accuracy of the manuscript. Abstract

Background: With rapid urbanization, the proliferation of densely arranged buildings and increasingly homogeneous architectural designs has made disorientation and navigation difficulties more common, especially for older adults. Meanwhile, advances in virtual reality technology now allow researchers to create highly immersive navigation games, offering opportunities for assessing cognitive abilities and examining how environmental factors shape navigation behavior.

Objective: This study aimed to design a virtual reality–based navigation game capable of assessing cognitive abilities through navigation behavior and quantitatively examining how environmental configurations influence navigation patterns in different age groups.

Methods: We designed a virtual goal–directed navigation game and recruited 2 groups, younger adults (n=18) and older adults (n=21), to complete identical wayfinding tasks. Before the formal experiment, participants completed cognitive assessments and received training. To characterize navigational behavior, k-means clustering was applied to classify navigation states and extract behaviorally meaningful navigation measurements, which were then examined for correlations with cognitive test scores. To quantify the effects of environmental structure, space syntax analysis was conducted to calculate line-based and grid-based experienced metrics for each participant, and their associations with navigation performance were examined. Additionally, between-group differences in navigation performance and experienced metrics were evaluated across age groups.

Results: Our results revealed that navigation behavior performance, particularly navigation efficiency, was significantly influenced by cognitive abilities and was strongly associated with several cognitive tests: the Montreal Cognitive Assessment (r=0.495, P=.04), Trail Making Test Part A (r=−0.761, P=.001), and the Mental Rotation Test (r=0.848, P<.001). In terms of environmental influences, experienced axial integration (EAI) and experienced visual integration (EVI) demonstrated significant age-related differences: EAI (z=–2.43, P=.01) and EVI (t=2.48, P=.02). Moreover, navigation efficiency exhibited distinct age-specific correlations with experienced metrics: among older adults, navigation efficiency was negatively associated with EVI (r=–0.48, P=.04), and young adults showed negative correlation between navigation efficiency and EAI (r=–0.64, P=.005).

Conclusions: Our findings demonstrate that k-means clustering provides an effective approach for classifying navigation states and extracting quantitative behavioral indicators for assessing cognitive abilities. In addition, the environment-based experienced metrics derived from space syntax analysis revealed distinct age-related navigation patterns, highlighting how spatial configuration shapes wayfinding behavior across age groups. These results establish an important foundation for future applications in clinical cognitive assessment and rehabilitation, as well as the design of age-friendly urban environments.

Introduction

With rapid urbanization, the proliferation of densely packed buildings with homogeneous architectural designs has increased the likelihood of disorientation and navigation difficulties. Irregular street networks and the frequent modification of road layouts further disrupt the formation of cognitive maps and hinder spatial orientation [1]. Spatial navigation, the ability to determine an appropriate route and purposefully move toward a specific destination, has increasingly become a considerable challenge, particularly for older adults [2,3].

Significant declines in navigation ability have been recognized as one of the earliest indicators of mild cognitive impairment and Alzheimer disease [4,5]. Individuals experiencing navigation difficulties tend to confine themselves to familiar environments, resulting in critical limitations on their ability to engage in daily activities [5]. Neuroscientific evidence underscores the vulnerability of the entorhinal cortex, a crucial region involved in spatial navigation, to neurodegenerative processes [6]. Grid cells within the entorhinal cortex, which are essential for spatial representation and path integration, exhibit notable functional impairments as individuals age. These age-related deficits in grid cell activity may disrupt the formation of stable cognitive maps, leading to difficulties in orientation, route planning, and wayfinding [7]. Early and rapid identification of navigation impairments is of critical importance.

Evidence from previous studies has indicated that behavioral performance in navigation tasks is influenced by both extrinsic factors (eg, spatial properties of the environment, visual accessibility of the landscape) [8,9] and intrinsic factors (eg, age, cognitive abilities) [10,11]. These factors jointly determine how individuals gather and interpret spatial information, select navigation strategies, and execute wayfinding decisions. Extensive research has demonstrated that environmental cues [12], such as the configuration of landmarks [8], locations [13], and paths [14,15], play a critical role in guiding navigation behavior as well as the neural processes underlying spatial orientation [16,17]. Importantly, age-related differences in the use of environmental cues are well documented [18]. Older adults tend to rely more on associating specific directional responses with particular landmark stimuli [19]; when geometric cues conflict with landmark cues, they are more likely to maintain the landmark-response association [20]. This reliance reflects an egocentric navigation strategy, in which spatial relations are encoded from a body-centered perspective, and actions are guided by subject-to-object associations [18,21,22]. In contrast, younger adults more effectively integrate both geometric and landmark cues, showing greater flexibility in switching between allocentric (map-based) and egocentric (route-based) frames of reference [18].

Although many studies have explored how modifying environmental elements affects navigation behavior, a consistent and intuitive way to characterize spatial properties across different settings is lacking. Space syntax, a well-established framework for quantifying spatial configuration [23], offers a powerful solution. It has been widely applied in urban design [24], path planning [25], and wayfinding research [26]. Within this framework, axial map analysis (AMA) [13] characterizes spatial structure through line-based representations, whereas visibility graph analysis (VGA) [9,27,28] captures grid-based visibility relationships. Key parameters, including integration, depth, and connectivity, reflect how accessible, shallow, or interconnected different spatial segments are. Prior research has demonstrated the value of these metrics for predicting exploration and wayfinding behavior. Among them, integration is particularly important, as it indicates how accessible a location can be reached from all others and is considered a key determinant of navigation difficulty [29]. Moreover, experienced integration has been shown to indicate the extent to which individuals concentrate their movement within globally integrated regions [13]. Spending more time in highly integrated areas enables individuals to form more accurate cognitive maps [14], resulting in higher experienced integration. Building on this theoretical foundation, we further introduce a series of experienced metrics derived from both axial and visual analyses to quantify the environmental structures that influence participants' actual navigation behavior.

Recent advancements in virtual reality (VR) technology have enabled the creation of highly immersive virtual environments (VEs) that closely replicate the real world with high fidelity [30,31] and have been widely applied in the field of spatial navigation. Researchers can precisely control environmental variables such as landmark distribution, path complexity, spatial layout, and visual cues in immersive VEs [32], making it possible to investigate navigation behavior under the influence of different factors. Moreover, VR technology allows for the collection of a wide range of behavioral data, such as completion time, movement trajectories, error rates, and specific behavioral reactions at given moments [33]. By constructing immersive VEs and a task framework, researchers have developed a variety of experimental paradigms designed for specific navigation tasks, including the Virtual Floor Maze Test [34], Morris Water Maze task [35], and object-location memory task [7,36]. Efficient VR-based navigation tasks are regarded as valuable tools for assessing and enhancing spatial navigation [34].

In recent years, navigation tasks have increasingly been gamified [37,38], with successful applications reported in both the health care domain and geographic science research. For example, the mobile game Sea Hero Quest has been widely used for large-scale assessment of human navigation ability [39], providing detailed analyses of navigation performance across age groups and cultural backgrounds [12,40-42]. In parallel, gamification approaches combined with location-based services have demonstrated effectiveness in improving users' understanding of urban maps, orientation, and wayfinding skills in real-world city environments [43,44]. The introduction of serious games (SGs) has enhanced the engagement of navigation tasks while preserving scientific validity. By incorporating clearly defined goals, standardized task structures, and meaningful feedback within immersive environments, SG-based VR navigation paradigms provide effective platforms for assessment, training, and rehabilitation [45].

In this study, we intentionally integrated structured navigation tasks into a goal-oriented game framework. We developed a goal-oriented VR-based navigation game, aimed at effectively

XSL•FO
RenderX

assessing individual cognitive abilities and exploring how environmental configurations influence navigation behavior. Specifically, the objectives were to (1) evaluate the feasibility and reliability of the VR navigation game as a cognitive assessment tool; (2) compare navigation behaviors between younger and older adults; and (3) examine how key environmental factors shape navigation performance across age groups. These findings are expected to provide methodological support for cognitive assessment and training, as well as empirical evidence to inform spatial planning in aging cities.

We hypothesized that navigation behavior would be closely associated with cognitive abilities, such that individuals with higher cognitive capacity would demonstrate more efficient wayfinding performance. We further expected that younger and older adults would exhibit distinct navigation patterns, reflecting age-related differences in cognitive processes and strategy use. Finally, we anticipated that quantitatively measured environmental configuration would exert effects on navigation efficiency, and that these effects would differ significantly between age groups.

Methods

Ethical Considerations

This research involved human participants. Approval of all ethical and experimental procedures and protocols was granted by the Ethics Committee of Beihang University (BM20230063). Strict privacy protection measures were applied, and all data were anonymized with no personally identifiable information included. Prior to participation, all individuals were fully informed about the study procedures, potential risks, and their right to withdraw at any time without penalty. All participants provided written informed consent and were compensated at a rate of 100 CNY (approximately US $14) per hour.

Considering that older adults constitute a potentially vulnerable population, additional safeguards were implemented for the older adult group. These included the presence of at least one qualified health professional to provide immediate medical support, repeated verbal reports to monitor fatigue, dizziness, and overall comfort, and the option for participants to terminate the experiment immediately upon experiencing any discomfort.

Participants

The study was conducted with 21 healthy older adults (14 males and 7 females) aged 65 to 80 years (mean age 71.79 , SD 4.57 years) and 18 healthy younger adults (10 males and 8 females) aged 21 to 33 years (mean age 26.50, SD 2.99 years). All participants had no history of neurological or psychiatric disorders. Older participants were recruited from the community and were at least 65 years old and able to complete daily activities independently. One older participant with a history of cerebral hemorrhage was excluded prior to the study, and another withdrew due to intolerance to VR-induced dizziness. Younger participants were recruited through public advertisements posted on the university campus. Individuals who expressed interest were screened using the same inclusion criteria applied to all participants, including normal or corrected-to-normal vision, no history of neurological or psychiatric disorders, and no prior diagnosis of cognitive impairment. Additionally, individual information, encompassing age, gender, education, and prior VR experience, was systematically gathered from each participant.

System Configuration

The virtual navigation game used in this study was developed with Unity 2019.4 (Unity Technologies) and deployed via the HTC VIVE Pro head-mounted display. The visual scene was rendered at 90 Hz and presented at a single-eye resolution of 1440×1600 pixels (2880×1600 binocular) with a 110° field of view, providing an immersive experience. For the experimental setup, the head-mounted display was connected to a high-performance desktop PC via a wired connection using the standard VIVE link box to ensure low latency and stable rendering. The system was equipped with an Intel Core i7-9700K CPU, an NVIDIA GeForce RTX 2070 GPU, 32 GB of RAM, and the Windows 10 operating system, enabling smooth rendering and reliable behavioral data acquisition.

The VE was designed as a simplified yet ecologically valid urban block (200 vm×150 vm, virtual meters), featuring residential buildings, street networks, greenery, and small parks. The intentional integration of these elements provided sufficient spatial complexity to elicit meaningful wayfinding behavior while minimizing potential discomfort or anxiety associated with navigation in a VE [46].

Given that older participants may experience limitations in sustained physical walking, we adopted a hybrid navigation control scheme combining the handheld controller and natural facing direction [47]. The VIVE controller features an ergonomic design with a circular touchpad. To minimize operational complexity, participants were instructed to press the touchpad to move forward in the direction they were facing, and releasing it stopped movement immediately. Horizontal body rotation was mapped one-to-one to virtual orientation, allowing participants to turn naturally without additional button input. Throughout the experiment, all participants were instructed to avoid movement in the physical space and to navigate using the controller and body rotation only. Most participants completed the game while standing, whereas three older participants, due to advanced age, performed the experiment while seated in a swivel chair that allowed 360° physical rotation. This simplified control scheme reduced cognitive and motor demands while ensuring consistent interaction across participants.

Experimental Procedure

The experiment consisted of three phases: (1) neuropsychological assessment, (2) pretraining, and (3) formal experiment. The neuropsychological assessment phase aimed to evaluate the cognitive abilities of older participants using standardized measures of general cognitive skills and empirically validated tests. During the pretraining phase, participants were instructed to navigate freely within the VE for 15 minutes. Navigation proficiency was considered achieved when participants demonstrated the ability to independently and fluently operate the controller and navigate to designated target locations, qualifying them to proceed to the formal experimental

XSL•FO
RenderX

phase. In the formal experimental phase, participants were required to sequentially navigate to multiple target locations, with spatiotemporal data recorded at fixed intervals throughout the navigation process. Older participants completed all 3 phases, while younger participants, who were healthy university students with presumed normal cognitive function, only participated in phases 2 and 3.

Before the formal navigation tasks, general cognitive functioning was quantified using the Mini-Mental State Examination (MMSE) [48,49] and the Montreal Cognitive Assessment (MoCA) [50]. Specifically, the MMSE administered in this study was the standardized Chinese adaptation based on the international MMSE framework, which has been validated through prior pilot testing and is widely used in studies involving Chinese populations [48,49,51]. The MoCA Full Chinese (Beijing) Version 7.1 was the official Beijing version published on the MoCA website [52]. MoCA scores were adjusted according to participants' education level, with one additional point added for individuals with 12 years of formal education or fewer. Nonverbal memory was further assessed using the delayed recall condition of the Rey-Osterrieth Complex Figure Test, while visuospatial functioning was evaluated through the Copy condition of the Rey-Osterrieth Complex Figure (ROCF-C) test [53]. To examine executive function and working memory, Part A of the Trail Making Test (TMTA) was administered [54]. Additionally, spatial rotation ability was assessed using a standardized Mental Rotation Test (MRT) [55]. These assessments provided a comprehensive cognitive profile for each participant prior to engagement in the virtual navigation experiment.

During the pre-experimental phase, identically shaped but differently colored target objects were placed at various locations within the VE (Figure 1). Participants were instructed to memorize the spatial locations corresponding to each colored object. The specific verbal instructions can be found in Multimedia Appendix 1. During the formal experimental phase, 5 target locations previously encountered during the training phase were used (Figure 2C). Target locations were presented in a fixed sequential order, allowing for consistent route comparisons across participants. Each trial began with a fixation cross (1000 ms), followed by the target cue (2000 ms), another fixation cross (1000 ms), and then participants were required to navigate to the designated target location (Figure 2A). Upon reaching the target, the current trial was concluded, and the next trial was automatically initiated. This sequence continued until all tasks were completed. Participants were instructed to navigate as quickly and accurately as possible (Figure 2B), and a congratulatory animation was displayed after each trial to prevent boredom.

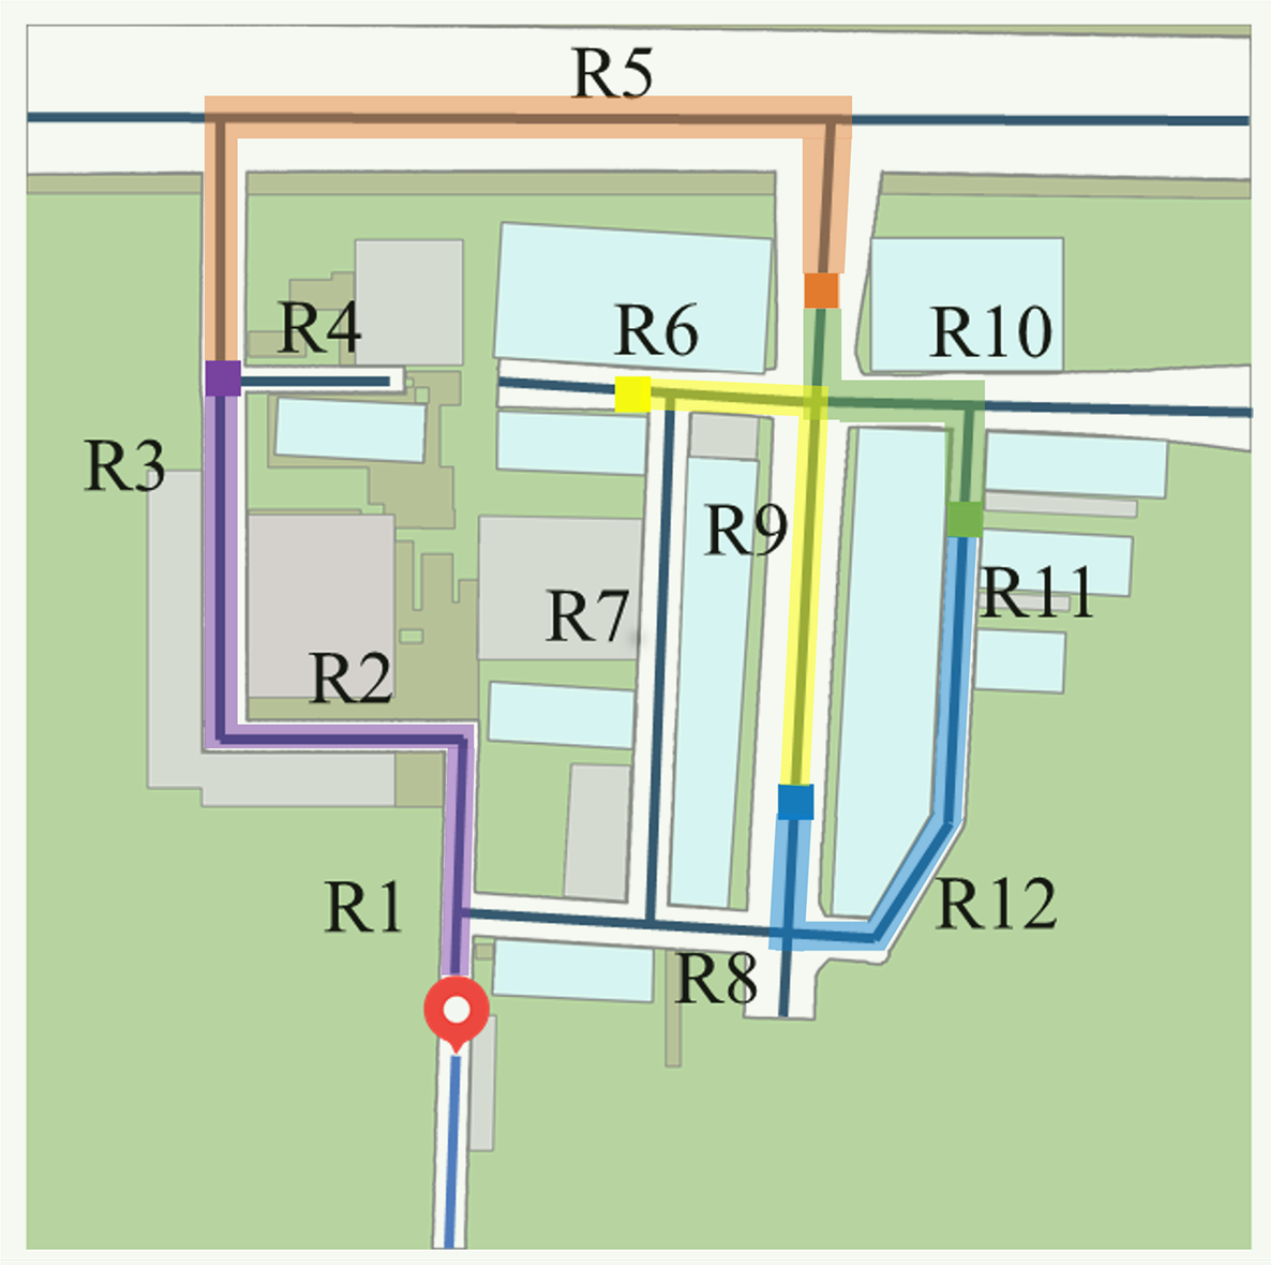
(B) Photograph of an older participant during the experiment. (C) Layout of the virtual city environment, including the shortest route planned to all target locations.

Environmental Structure Analysis

Space Syntax



Space Syntax provides a robust and systematic framework for examining the spatial arrangement of environments and the interrelationships between spaces. This methodology has been extensively applied to explore how spatial configurations affect human behavior [26,56,57], particularly how individuals encode, represent, and retrieve spatial information during navigation. In this study, both AMA and the VGA of the VE were carried out using the DepthmapX software (Space Syntax Laboratory).

Axial Map Analysis

The axial map provides a graphical representation of spatial structure, where streets within an urban environment are abstracted as axial lines, defined as the minimal set of longest straight lines of sight from a given location [23,58]. These lines collectively cover the entire space, capturing all possible movement paths. Based on the 2D layout of the VE street network, we constructed an axial map with a total of 12 axial lines delineated (Figure 3). For analytical purposes, key metrics such as axial integration, axial connectivity, and axial mean depth were calculated to characterize the accessibility and flow potential of individual environmental segments.

XSL•FO
RenderX

Figure 3. The axial map constructed from the 2D layout of the virtual environment street network.

Visibility Graph Analysis

VGA provides an analytical approach for quantifying the spatial characteristics of an environment by assessing the extent to which any given point within the space is visible from any other point [59]. In this study, the structural layout of the VE was first modeled using AutoCAD. Subsequently, a 1 m×1 m grid was generated in DepthmapX to perform the analysis. This process enables the computation of key spatial metrics at each node, including visual integration, visual connectivity, and visual mean depth.

Measurement

Metrics Setting

A set of behavioral and environment-based metrics was calculated in the virtual navigation game to evaluate the effectiveness of the game in assessing cognitive abilities and to examine age-related differences in navigation performance and sensitivity to environmental features. Spatiotemporal data were recorded for each participant at a fixed sampling frequency. Based on these data, the navigation behavioral metrics and environment-based navigation metrics were defined as follows.

Wayfinding, Transition, and Moving States

During navigation, we continuously recorded each participant's spatial position (xi,yi) at timestamp ti . For each recorded point i (excluding the starting and ending points), the instantaneous speed was computed as the average of the velocity estimates derived from two adjacent time intervals.

$$vi=((xi-xi-1)2+(yi-yi-1)2ti-ti-1+(xi+1-xi)2+(yi+1-yi)2ti+1-ti)/2$$

The instantaneous speed series for each participant was then classified into 3 distinct categories using the k-means clustering algorithm, yielding low, medium, and high speed clusters. These clusters corresponded to meaningful navigation states:

XSL•FO
RenderX

Wayfinding (low speed: searching, hesitation, or reorientation), Transition (medium speed: directional adjustment or preparatory acceleration), and Moving (high speed: continuous, goal-directed locomotion). This classification allowed us to segment the entire trajectory into functionally interpretable behavioral states.

Navigation Efficiency

Navigation efficiency is defined as the ratio of effective navigation time (moving time and transition time) to the total duration of the navigation game (navigation time).

$$\text{Navigation efficiency} = (\text{Moving time} + \text{Transition time}) \text{Navigation time}$$

This metric serves as an indicator of the capability to navigate effectively within the environment. Higher values reflect a more streamlined and goal-oriented navigation process, characterized by reduced time spent on behaviors such as hesitation, reorientation, or uncertainty. By quantifying navigation efficiency, we can evaluate the extent to which individuals construct accurate cognitive maps and adopt effective spatial strategies during navigation tasks.

Experienced Axial Metrics

Axial analysis is derived from a representation of the environment using the fewest and longest lines of sight, which capture key structural characteristics of an urban street network. In this study, we used the axial values computed from the axial map shown in Figure 3. Three axial measures were considered: axial integration, which quantifies the accessibility of an axial line from the rest of the system; axial connectivity, which denotes the number of axial lines directly linked to a given line; and axial mean depth, which represents the arithmetic mean of the topological depths from each axial line to all others. To examine how participants' navigation behavior was shaped by the underlying street configuration, we computed the average value of each metric along the participant's trajectory, resulting in 3 experienced axial metrics: experienced axial integration (EAI), experienced axial connectivity (EAC), and experienced mean axial depth (EMAD).

$$EAI = 1n\sum i=1nIA(xi,yi)$$

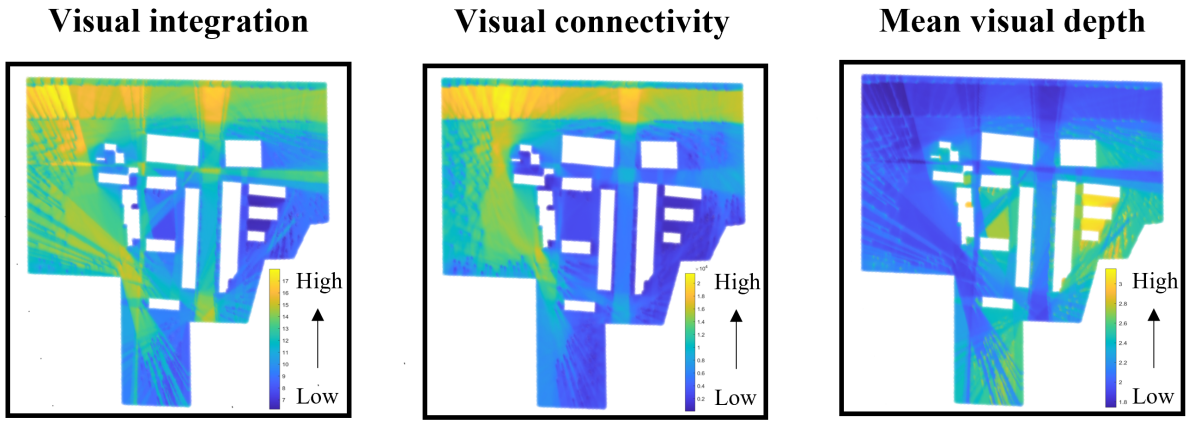
$$EAC = 1n\sum i=1nCA(xi,yi)$$

$$EMAD = 1n\sum i=1nDA(xi,yi)$$

The point (xi,yi) denotes the coordinates of the participant at sample *i*, and IA, CA, and DA represent the integration, connectivity, and mean depth values of the axial line associated with that position. The variable n indicates the total number of sampled points along the participant's trajectory.

Experienced Visual Metrics

VGA represents an environment as a grid-based visibility network, enabling the quantification of visual relationships between locations. The visual integration, visual connectivity, and visual mean depth values used in this study were derived from the VGA map shown in Figure 4. To examine how participants' navigation behavior was influenced by visually accessible spatial properties, we computed the average value of each VGA metric along the participant's trajectory, yielding experienced visual integration (EVI), experienced visual connectivity, and experienced visual mean depth.



$$EVI = 1n\sum i=1nIv(xi,yi)$$

$$EVC = 1n\sum i=1nCv(xi,yi)$$

$$EVMD = 1n\sum i=1nDv(xi,yi)$$

Iv, Cv, and Dv represent visual integration, visual connectivity, and visual mean depth values associated with participants' position (xi,yi) in the VGA grid.

Figure 4. The visualization of the virtual urban spatial structure using visibility graph analysis.

Statistical Analysis

Data from the experiment were processed using custom scripts developed in MATLAB, and all statistical analyses were performed using SPSS (IBM Corp). The normality of each variable was assessed through visual inspection of histograms and the Shapiro–Wilk test. Spearman's rank correlation analyses were conducted to examine the associations between navigation-related behavioral measures and cognitive test scores. To evaluate age-related differences, independent-samples *t* tests were applied to variables that met normality assumptions, whereas the Mann-Whitney *U* test was used for variables that were not normally distributed. In addition, correlations between navigation efficiency and the various experienced spatial metrics were examined using Pearson correlations for normally distributed variables and Spearman rank correlations for nonnormally distributed variables.

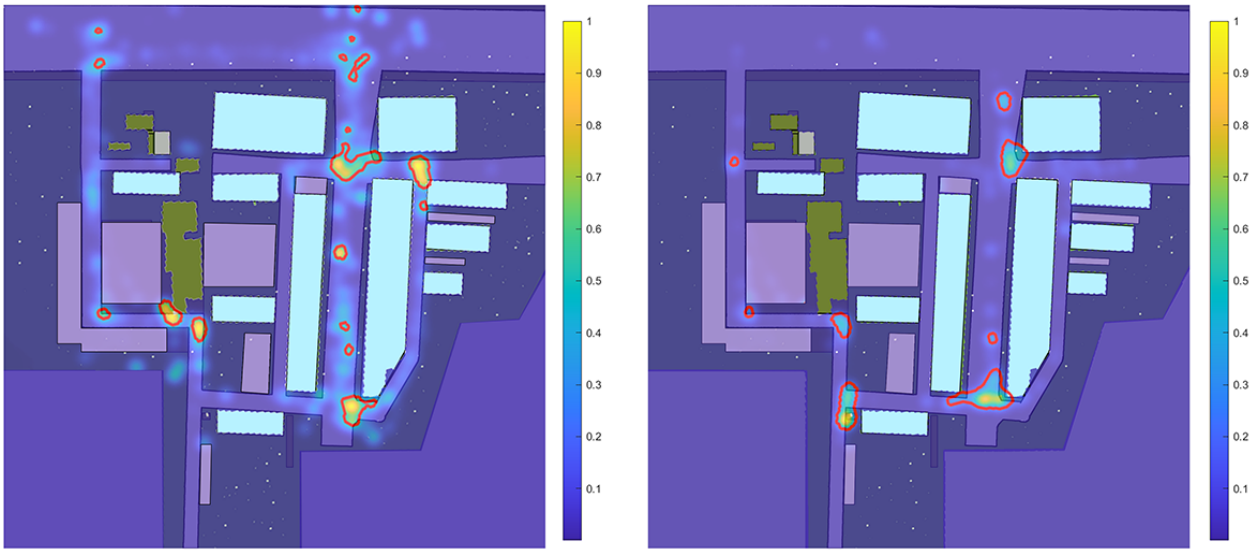
Results

Participants

All 19 older participants and 18 young participants successfully completed the experiment without experiencing severe motion sickness. Table 1 summarizes the cognitive characteristics of the older group, including the means and SDs for various cognitive assessment scales. Notably, none of the participants had prior experience with VR technology, which reduced potential biases associated with equipment familiarity.



After clustering the data, points labeled as wayfinding state exhibited clear spatial concentration and age-related differences (Figure 5). This spatial density map visualizes wayfinding patterns, offering an intuitive overview of participants' spatial behavior based on spatiotemporal features. The red-outlined areas indicate the top 1% of regions with the highest density values, highlighting zones of intensified wayfinding activity within the VE.

The Correlation Between Navigation Behavior and Cognitive Abilities in Older Participants

Spearman rank correlation analysis was conducted to examine the relationships between navigation behavior metrics and cognitive assessment scores (Table 2). No significant correlations were observed between either distance or error and any of the cognitive scales. However, temporal-based navigation parameters performed well. Navigation time was significantly associated with both TMTA (r=0.503, P=.047) and the MRT (r=−0.526, P=.03). Wayfinding time showed strong correlations with several cognitive measures, including TMTA (r=0.716, P=.002), MoCA (r=−0.549, P=.02), ROCF-C (r=−0.588, P=.01), MMSE (r=−0.458, P=.046) and MRT (r=−0.751, P<.001). Additionally, navigation efficiency demonstrated significant associations with MoCA (r=0.495, P=.04) and ROCF-C (r=0.658, P=.003) scores, and particularly strong correlations with TMTA (r=−0.761, P=.001) and MRT (r=0.848, P<.001). These findings confirmed that cognitive abilities play a crucial role in influencing navigation efficiency, including navigation time and wayfinding time.

Analysis of Age-Related Decline in Wayfinding Ability

The Mann-Whitney *U* test was used to assess differences in navigation performance between age groups (Figure 6). Compared to young participants, older adults, who exhibited significantly lower cognitive ability, demonstrated significantly longer navigation time (z=−4.771, P<.001) and wayfinding times (z=−4.315, P<.001), as well as reduced navigation efficiency (z=−4.285, P<.001).

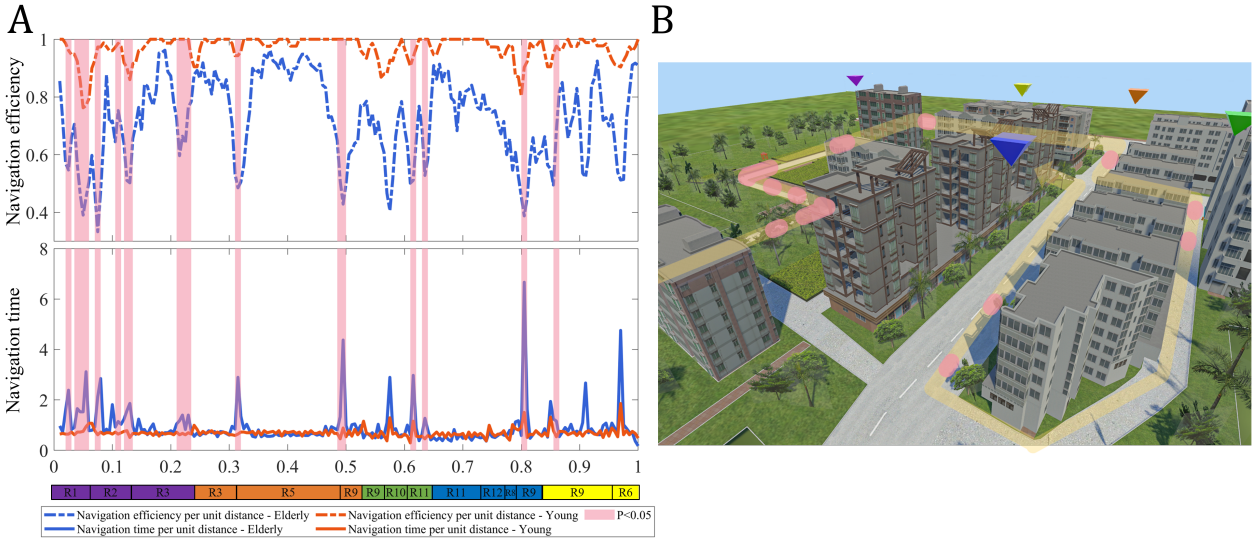

Figure 6. Box plots illustrating differences in navigation performance between older and younger participants.

The above metrics reflect participants' overall wayfinding performance. However, navigation behavior is not solely influenced by internal factors such as cognitive ability. It also varies depending on the location of participants within the VE. Figure 7A illustrates differences in the navigation process across age groups during the formal experiment. To investigate this, participants' spatial positions are mapped onto the shortest navigation routes (excluding trials involving route errors), and the time spent per unit distance is calculated for each individual. Based on these data, we plot curves of navigation time and navigation efficiency for each age group. Furthermore, a permutation test is conducted on navigation efficiency within each unit distance between older and young adults. The shaded regions on Figure 7B correspond to areas where significant differences are observed (P<.05) in Figure 7A, revealing spatial zones where age-related differences in navigation behavior are most pronounced. These results highlight age-related differences in spatial behavior and reinforce the utility of these behavioral metrics as sensitive indicators of cognitive function.

XSL•FO
RenderX

Figure 7. Comparison of the navigation process between older and younger participants during the formal experiment. (A) The x-axis represents the normalized value along the shortest distance across 5 consecutive trials, and the y-axis shows both navigation time and navigation efficiency. The colored bar at the bottom corresponds to the target color for each trial, and the labels R1, R2, ... indicate the axial lines that constitute the shortest navigation route for that trial. (B) Pink-shaded areas indicate route segments where significant differences in navigation efficiency were found between older and younger participants, as determined by permutation testing (P<.05).

Effects of Environmental Structure on Navigation Behavior in Different Age Groups

The influence of environmental characteristics on navigation performance is analyzed from the perspective of spatial configuration using both AMA and VGA. Between-group comparisons revealed significant age-related differences in several experienced spatial measures. Older adults showed higher EAI (z=–2.43, P=.01) and EVI (t=2.48, P=.02), whereas young adults exhibited higher EMAD (z=–2.13, P=.03) and EMVD (t=–2.49, P=.02). No significant group differences were found for experienced axial connectivity and experienced visual connectivity.

Correlation analyses further revealed distinct age-specific associations between navigation efficiency and experienced metrics. Among older adults, navigation efficiency showed a significant negative correlation with EVI (r=–0.48, P=.04) and a positive correlation with EMVD (r=0.49, P=.03). In contrast, young adults demonstrated strong associations with axial properties, with navigation efficiency negatively correlated with EAI (r=–0.64, P=.005) and positively correlated with EMAD (r=.72, P<0.001). Young adults also exhibited a significant positive relationship between navigation efficiency and EMVD (r=0.57, P=.01).

Discussion

Summary and Explanation of Findings

This study investigated how cognitive abilities and environmental structure jointly shape navigational performance in a virtual navigation game across different age groups. Consistent with prior research, our findings demonstrate that performance in navigation games, particularly navigation efficiency, is strongly influenced by individual cognitive capacity, as well as the spatial configuration of the environment. These results underscore the relevance of navigation behavior as an indicator of cognitive status and highlight the potential of VR-based navigation tasks as effective tools for cognitive assessment. Moreover, the insights gained from this work also provide valuable guidance for future urban design and navigation-game development.

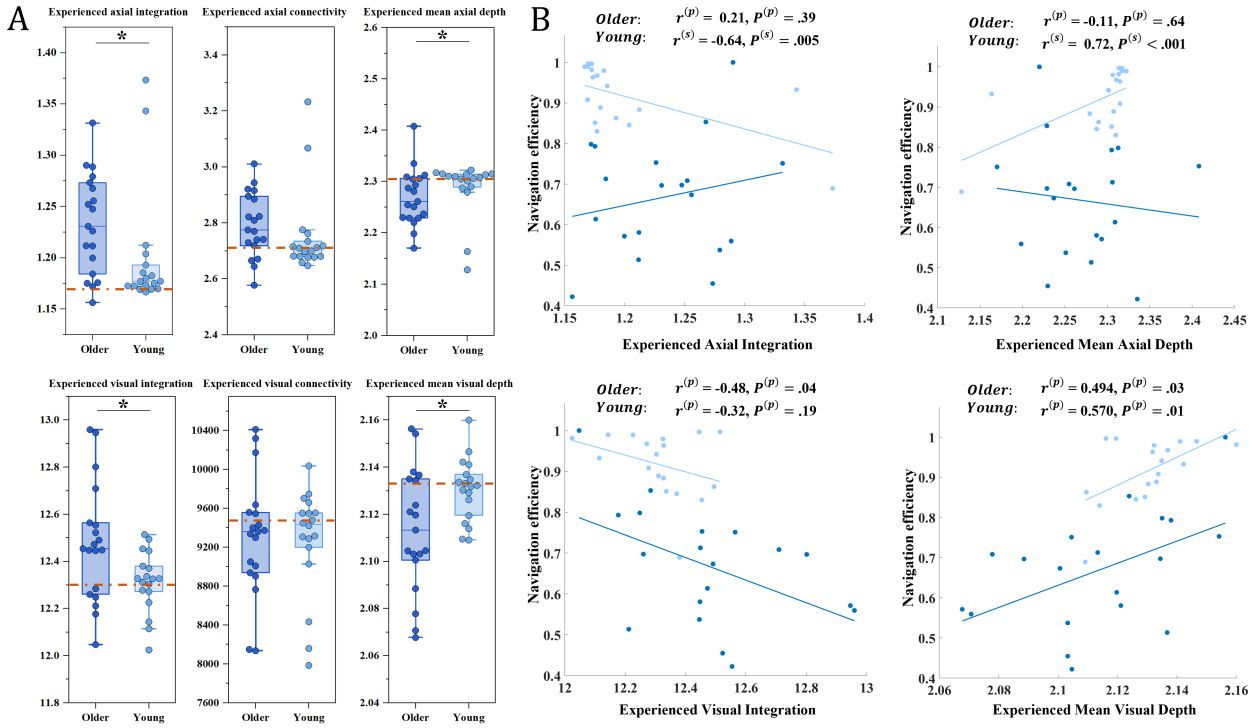
The behavioral metrics used in this study, including traversal distance, number of errors, and navigation time, are widely used in human navigation research [34,60]. Spatiotemporal representation has long been essential for analyzing navigation behavior, and the present study extends conventional approaches by classifying participants' navigation states using an individualized method. Navigation tasks are generally considered to consist of 2 main components [61]: locomotion and wayfinding. Locomotion refers to the physical execution of movement in the space, whereas wayfinding is involved in determining and planning a route to a desired destination [62]. Traditional approaches typically distinguish these components using fixed absolute speed thresholds [47,63]. To account for individual differences in navigation ability, we applied k-means clustering to each participant's instantaneous speed distribution to derive personalized relative speed thresholds. k-Means is a classical clustering algorithm that iteratively assigns data points to the nearest cluster center [64]. To assess the reliability of this classification, clustering solutions with different numbers of clusters (k) were evaluated across all younger and older participants using the sum of squared errors (SSE) [65] and the silhouette coefficient [66] (Figure S3 in Multimedia Appendix 2). The SSE quantifies within-cluster variance by measuring the squared distance between each data point and its assigned cluster center, whereas the silhouette coefficient provides a complementary assessment of clustering quality by comparing consistency within clusters with separation between other clusters [67]. When k=3, the SSE curve showed a clear inflection point, indicating a markedly diminished rate of decrease in within-cluster variance. Meanwhile, the silhouette coefficient remained relatively high and exhibited more stable variance, suggesting an optimal balance between cluster cohesion and

XSL•FO
RenderX

separation. In addition to these statistical indicators, the three clusters aligned well with meaningful navigation states observed in participants' movement patterns (Figure S2 in Multimedia Appendix 3): (1) low-speed hesitation or searching, (2) medium-speed transitional adjustments, and (3) high-speed goal-directed movement. Taken together, both the quantitative metrics and the behavioral interpretability support the individualized clustering approach, which enabled the effective categorization of each sampled time point into low-, medium-, or high-speed states, thereby identifying regions within the environment where participants associated with wayfinding, transition, or continuous movement.

Effective spatial navigation relies on the integration of multiple abilities, including visual perception, spatial orientation, learning, and memory [68]. Wayfinding encompasses all of the ways in which people orient themselves in physical space and navigate from place to place. As anticipated, wayfinding ability, as a cognitive element of the navigation process [69], is effectively captured by parameters such as wayfinding time and navigation efficiency, both of which are shown to be sensitive indicators of cognitive capacity in the current study. As summarized in Table 2, cognitive scales including the MMSE, MoCA, ROCF-C, TMTA, and MRT exhibited robust correlations with these navigation metrics. Among these, the MoCA and MMSE are widely used for comprehensive cognitive assessment; the TMTA primarily reflects executive functioning; ROCF-C performance is sensitive to visuoconstructive and geometric processing abilities; and the MRT assesses mental rotation capacity. These cognitive functions collectively support navigation by contributing to processes such as initial route planning, continuous movement control, reorientation, and decision-making. SG-based VR navigation tasks elicit continuous, ecologically relevant behavior under dynamic task constraints, enabling the simultaneous assessment of multiple cognitive functions within an integrated behavioral context. Quantifying wayfinding performance provides an indirect yet meaningful reflection of an individual's cognitive functioning [34]. Longer wayfinding times and lower navigation efficiency were associated with poorer cognitive performance in our older participants. Taken together, these findings highlight the potential of well-designed navigation games to serve as effective tools for cognitive assessment [70].

Human navigation in outdoor environments involves a series of distinctive behaviors, such as retracing steps, hesitation, and reorientation [71]. These behaviors become particularly evident in complex spatial settings where individuals must process environmental cues and make directional decisions. Wayfinding time serves as a key indicator for revealing navigation uncertainty, effectively pinpointing locations where external environmental factors impact individuals' sense of directional uncertainty (Figure 4). We observe that prolonged wayfinding times were predominantly concentrated in the turning areas of the path and the starting or ending locations of each trial. These highlighted areas in the figure represent regions where participants are more likely to encounter decision-making bottlenecks, experiencing uncertainty in selecting the correct path [72]. Furthermore, integrating the analysis in Figure 6, we find significant differences in navigation performance between older and younger participants in certain regions.



Synthesizing findings from previous research, we propose that these results may be explained by age-related differences in navigation strategy preferences. Human navigation relies on 2 primary strategies: allocentric (survey-based) and egocentric (route-based). Younger adults tend to rely more on the allocentric strategy [18] and show greater flexibility in switching between allocentric and egocentric frames of reference [73]. However, aging is associated with a decline in allocentric navigation abilities, accompanied by a preferential shift toward egocentric strategies [18,21,22], which may contribute to less efficient route planning and increased reliance on familiar or visually accessible paths. These strategy differences align closely with the behavioral patterns observed in our study. Young participants adopted a more proactive and goal-directed approach: they typically scanned the environment at the beginning of each trial, extracted relevant spatial cues, and formed a planned route before moving. In contrast, older participants showed a stimulus-response navigation pattern [74,75], making decisions only upon arriving at intersections rather than planning ahead. This led to hesitation at nearly every decision point (Figure 6B), reflecting greater reliance on immediate cues and reduced anticipation of upcoming turns. Consequently, participants spent more time searching for landmarks or other environmental cues, leading to decreased navigation performance [76,77]. Such behaviors are consistent with age-related declines in spatial working memory and executive function [78], which limit their ability to efficiently integrate spatial cues.

To explore how environmental structure influences navigation across age groups, we used line-based (AMA) and grid-based (VGA) analytic approaches. Both methods quantify spatial configuration and offer complementary perspectives on how spatial structure shapes navigation behavior. Within this framework, integration serves as a core space syntax metric capturing the degree to which a path is connected to its surrounding environment [13,29]. In this study, experienced integration reflects the actual spatial integration values of the segments that participants traversed, thereby characterizing the dynamic interplay between environmental structure and navigational behavior. Older adults exhibited significantly higher EAI and EVI than young adults, suggesting a tendency to navigate toward more integrated areas rather than taking shorter or more direct routes. Prior studies have shown that spending more time in highly integrated areas facilitates the formation of accurate cognitive maps [13]. With aging, older adults require more time to form cognitive maps and encode spatial information [79], which may partly explain their tendency to remain within highly integrated axial regions during navigation. From another perspective, although integration is the normalization form of mean depth [25], the two measures capture different aspects of spatial structure. Mean depth quantifies the average topological steps from a location to all others, with higher values indicating deeper and harder-to-reach positions. Older adults showed lower EMAD and EMVD values, suggesting a tendency to remain within relatively shallower, more accessible areas.

XSL•FO
RenderX

In our navigation game, all participants were instructed to reach the target location as quickly as possible. By comparing each group's experienced metrics with those of the shortest path (Figure 8A), we found that the experienced metrics of younger participants closely matched the optimal path. This pattern is consistent with behavioral observations showing that young participants, driven by the goal of rapid completion, tended to select more direct and efficient routes. Correlation analyses further support these environment-mediated navigation patterns. Among young adults, EAI was negatively correlated with navigation efficiency, indicating that more movement through globally integrated axial lines was associated with increased wayfinding behaviors (eg, hesitation, pausing, reorientation), thereby reducing overall efficiency. For older adults, EVI showed a significant negative correlation with navigation efficiency, suggesting that more extensive traversal within visually integrated regions corresponded to heightened hesitation or searching behaviors. The results for EMAD and EMVD exhibited similar trends: achieving higher navigation efficiency and shorter routes requires participants to strategically decide whether to traverse spatially advantageous or disadvantageous areas. Younger adults tended to accept navigating through deeper or less accessible regions to optimize route efficiency [56], whereas older adults were more likely to remain within visually accessible areas, even when these were not part of the shortest path.

Figure 8. Experienced metrics across age groups and their associations with navigation efficiency. (A) Group differences in 6 experienced spatial metrics, experienced axial integration (EAI), experienced axial connectivity, experienced mean axial depth (EMAD), experienced visual integration (EVI), experienced visual connectivity, and experienced visual mean depth (EVMD) are shown for older adults (dark blue) and young adults (light blue). The brown dashed line represents the experienced metric obtained from the shortest path. (B) Correlations between navigation efficiency and 4 key experienced metrics (EAI, EMAD, EVI, and EVMD) are presented separately for older adults (dark blue) and young adults (light blue). Pearson correlations are denoted by (p) and Spearman correlations by (s).

This subjective tendency in navigational behavior indicates that participants do not passively respond only to environmental structure; rather, their navigational choices also reflect intentional, strategy-driven preferences [13]. Such findings point to a bidirectional relationship between spatial configuration and navigation behavior, where environmental structure shapes movement patterns, and individuals' strategic preferences, in turn, influence the parts of the environment they traverse. Understanding whether environmental properties or individual behavior play the dominant role in guiding navigation will require further empirical investigation.

Additionally, our findings extend this literature by demonstrating age-specific patterns in the relationship between experienced metrics and navigation efficiency. Navigation efficiency in younger adults was strongly associated with line-based (AMA) metrics such as EAI and EMAD, whereas older adults showed stronger associations with grid-based (VGA) metrics, such as EVI and EMVD. These differences can be meaningfully interpreted through the lens of allocentric and egocentric navigation strategies. Younger adults tend to rely more on allocentric representations, enabling them to rapidly extract structural information from the environment, integrate axial connectivity, and flexibly switch between global structure and local visual information. This cognitive flexibility allows them to traverse deeper or less accessible areas. In contrast, aging is associated with an increased reliance on egocentric navigation. Older adults become more dependent on the visual field and immediate cues, which aligns with their stronger correlation between navigation efficiency and visual-based experienced metrics (EVI and EMVD). Their tendency to remain within visually accessible, highly integrated regions suggests that they

XSL•FO
RenderX

prioritize environments that offer clear visual guidance and reduced cognitive demands [14].

Together, space syntax highlights the fundamental role of spatial configuration in shaping navigation behavior, and our findings further show that its influence varies with age, ultimately affecting navigation performance. These insights have important implications not only for developing more effective cognitive assessment tools but also for designing age-friendly urban environments that support safe, efficient, and accessible navigation. Strengthening the coordination and integration of street space is essential for urban street-design guidelines and road-network optimization [80]. Through axial and grid-based analyses, space syntax provides a powerful framework for identifying high integration. Such information can guide the placement of landmarks, directional signage, and other environmental cues that facilitate cognitive map formation and enhance navigability for diverse user groups. Moreover, because spatial integration is closely tied to navigation difficulty [29], purposeful modulation of integration levels can help calibrate the cognitive demands of navigation tasks. From an SG perspective, the majority of participants verbally reported a high level of immersion and task engagement, suggesting that the SG-based framework effectively supported sustained interaction with the spatial environment. By integrating principles of spatial configuration into an immersive VR navigation game, this approach may provide promising opportunities for the development of gamified tools for cognitive assessment, training, and rehabilitation, particularly for individuals with spatial or cognitive impairments.

Limitations and Future Work

This research highlights the critical role of cognitive abilities and spatial configuration in shaping navigation behavior. However, several limitations should be acknowledged. First, the participant sample may not fully represent the broader population. The young participants were primarily between 20 and 30 years of age, whereas the older group ranged from 65 to 85 years, leaving a substantial gap between ages 30 and 65 years, which was not included. This omission limits the generalizability of the findings, as individuals in midlife may exhibit distinct navigation patterns and cognitive characteristics that were not captured in the current analysis [72]. Second, the individualized k-means clustering approach adopted in this study is particularly suited to navigation games characterized by relatively stable movement speeds. It may be less appropriate for tasks involving pronounced, irregular, or continuous speed transitions, in which clear and interpretable cluster boundaries are difficult to establish. Moreover, although a 3-cluster solution showed good behavioral interpretability within the current navigation game, the generalizability of this clustering scheme to other navigation games or more complex real-world environments remains to be validated in future studies. Third, discrepancies between virtual and real-world navigation are unavoidable [76]. The absence of environmental features such as directional signs, combined with the lack of natural physical movement, may influence how spatial information is encoded, updated, and retrieved [81]. Finally, the study did not explicitly account for the influence of demographic factors such as gender, educational background, or geographic and cultural experience. Ignoring these variables could obscure important individual differences and interactions relevant to wayfinding performance.

Future research should aim to address these limitations by recruiting a more demographically diverse participant sample, including middle-aged individuals, and by designing VEs with greater ecological validity. Incorporating navigation methods that more closely approximate natural physical movement may yield richer behavioral data and uncover additional nuances in navigational performance. Additionally, systematically examining the role of experienced metrics could provide deeper insights into urban design, spatial planning, and navigation-aid development in both virtual and real-world contexts. From a rehabilitation perspective, the game demonstrates promising potential for virtual navigation tasks as a controlled and adaptable platform for personalized cognitive assessment and training. Further research could investigate the incorporation of adaptive task difficulty and longitudinal monitoring into VR-based rehabilitation, thereby supporting the maintenance or recovery of spatial and cognitive functions.

Conclusions

This study provides quantitative evidence for how environmental configuration and cognitive abilities jointly shape navigational behavior in VEs. By applying an individualized k-means clustering approach, we extracted key behavioral indicators, such as wayfinding time and navigation efficiency, that proved sensitive to cognitive decline. This method offers a more personalized and potentially more effective framework for assessing cognitive function through navigation tasks. Through spatial analysis, we further identified age-specific regions of wayfinding difficulty and quantified the extent to which environmental structure influences navigation behavior. These findings reveal distinct navigation patterns between younger and older adults and underscore the value of integrating behavioral analytics with spatial-syntax metrics. Overall, the results lay an important foundation for future applications in clinical cognitive assessment and rehabilitation, as well as in the development of age-friendly urban environments.

Abstract

Background: The relationship between video game experience and cognitive plasticity remains a central focus of research, particularly given its potential applications in clinical rehabilitation. Although both first-person shooter (FPS) and multiplayer online battle arena (MOBA) games have been shown to enhance cognitive functions, the specific associations between the cognitive effects of different game genres and brain network structure remain unclear.

Objective: This study aimed to examine whether long-term experience with FPS and MOBA games is associated with genre-specific patterns of cortical thickness covariation across brain regions.

Methods: A total of 116 male participants (mean age 21.2, SD 1.9 y) were recruited via online advertisements for this cross-sectional study. On the basis of strict inclusion criteria (gaming experience >5 years, gaming frequency >5 hours per week, and ranking within the top 15%), participants were categorized into FPS players (n=39, 33.6%) and MOBA players (n=40, 34.5%). An additional group of healthy controls (n=37, 31.9%) with no gaming experience in the past 2 years was also included. High-resolution structural magnetic resonance imaging data were acquired using a 3-T scanner. Individualized differential structural covariance networks were constructed based on the cortical thickness values extracted from 68 brain regions using the Desikan-Killiany atlas. Statistical analysis included one-way ANOVA to identify significant structural covariance edges (SCEs), network-based statistic prediction analysis for weekly gaming hours, and support vector machine analysis for group classification.

Results: One-way ANOVA identified 30 significant SCEs across the 3 groups (P<.001, false discovery rate corrected). Post hoc analysis (P<.02, Bonferroni corrected) revealed that, compared to the MOBA and control groups, the FPS group exhibited 2 dominant networks: a temporo-fronto-parietal network anchored in auditory regions and a visuo-sensorimotor network. Both gaming groups showed enhanced SCEs in visual-attentional networks compared to the control group. The network-based statistic–predict analysis demonstrated that structural covariance matrices could effectively predict weekly gaming hours in FPS players (r=0.34, 95% CI 0.26 - 0.42). The positive edges primarily formed a temporo-fronto-parietal-occipital network, whereas the negative edges were centered on the entorhinal cortex. The support vector machine classifier successfully differentiated FPS players from controls (area under the curve=82.95%) and from MOBA players (area under the curve=72.37%).

Conclusions: Long-term FPS and MOBA gaming experiences are associated with different brain structural network architectures. The uniqueness of FPS gaming lies in the extensive structural covariance between the primary auditory cortex and regions supporting visual attention and sensorimotor processing, which may reflect higher demands on cognitive skills. This suggests potential utility in auditory-visual rehabilitation and provides a theoretical basis for the assessment and selection of professional electronic sports players. However, the negative edges involving the entorhinal cortex in FPS players indicate that an overreliance on response learning strategies may come at the expense of the spatial memory system. Consequently, caution is warranted when applying such games to ameliorate age-related memory decline.

Introduction

The relationship between video games and human cognitive plasticity has been a focal point of research over the past decades [1]. As electronic sports (esports) became an official event in the Olympic Games, video games, recognized as particularly captivating within the esports domain, gained popularity. Action video games (AVGs), a common subtype of video games [2], involve the rapid perception of high-load targets and the execution of actions under time pressure, as well as flexible switching between focused and divided attention to enhance attentional control [3]. These components of AVGs may enhance cognitive functions such as perception [4], attention [5,6], memory [7], and executive control [8], which are known to decline with aging and in neurodegenerative diseases [9,10]. Recent studies further suggest that video games can positively influence brain health and mental well-being [11,12]. Therefore, exploring the potential of AVGs to improve these cognitive functions could provide valuable insights for developing nonpharmacological intervention strategies aimed at mitigating age-related or neurodegenerative cognitive decline.

Traditional AVGs typically refer to first-person shooter (FPS) games. However, with the evolution of video games, certain video games that were not traditionally classified as AVGs now incorporate elements typically associated with AVGs. This includes the multiplayer online battle arena (MOBA) genre, which is sometimes referred to as action real-time strategy (RTS) games [1,3]. FPS games are characterized by players engaging in combat using firearms or other weapons within a first-person perspective environment, either individually or as part of a team. These games impose higher sensorimotor demands on players, requiring enhanced hand-eye coordination and rapid responses [13]. Players must quickly locate enemy positions, make swift decisions, aim accurately, and ultimately eliminate targets [14]. In MOBA games, players operate from a third-person perspective as part of a team. They must comprehend the characteristics of each character and collaboratively devise appropriate strategies to destroy the opposing team's headquarters, which places higher demands on cognitive abilities, such as working memory and short-term memory [15].

Previous studies indicated that extensive experience with AVGs enhanced players' performance on auditory tasks [16,17]. Specifically, for high-level FPS players, shorter auditory latency was associated with improved game performance [18]. Thus, acoustic information likely played an essential role for FPS players. Additionally, an electroencephalography study revealed that FPS players produced greater interactions than controls between auditory and visual networks and between auditory and attention networks, whereas MOBA players showed greater functional interactions than controls between visual and attention networks only [19]. Therefore, based on existing research [16-19], we hypothesized that the structural differences underlying auditory attention and other cognitive abilities may differ between long-term MOBA players and FPS players. To investigate this potential divergence in depth, selecting an appropriate neuroimaging technique is crucial. Although electroencephalography exhibits high temporal resolution, its spatial localization remains relatively limited [20]. While magnetoencephalography provides superior spatiotemporal resolution, its widespread application is constrained by prohibitive equipment and acquisition costs [21]. Furthermore, functional magnetic resonance imaging (MRI) data are prone to instability arising from factors such as head motion [22] and physiological noise [23]. In contrast, structural MRI, primarily used to acquire anatomical information of the brain, offers more stable image quality and relatively lower acquisition costs and is frequently used to assess alterations in structural brain connectivity [24]. Consequently, this study aimed to investigate, from an anatomical perspective, whether different types of video games exert distinct cognitive effects.

The phenomenon of structural covariance refers to the pattern in which structural differences in one brain region covary with differences in other regions, influenced by genetic, behavioral, and cognitive factors [25]. Initially, this approach was used to investigate cortical thickness (CT) across developmental stages and associated changes across multiple regions [26]. CT is defined as the distance between the pial surface and the white matter (WM), reflecting the thickness of the cortical gray matter (GM). In healthy adults, greater CT is generally associated with better cognitive abilities, such as auditory attention, visuospatial attention, and reward learning [27-30]. Studies have found that structural connectivity often mirrors patterns of functional connectivity [31], suggesting that regions exhibiting morphological covariance belong to the same functional networks [32,33], and this correspondence is related to human cognition [34], potentially continuing to be reshaped throughout the lifespan [35,36]. Therefore, compared to approaches that primarily reflect short-term functional connectivity between brain regions, structural covariance networks can reflect characteristics of brain connectivity over longer time scales [37].

Early structural covariance networks were constructed by calculating statistical correlations between regions based on morphological measurements across groups of subjects [38]. However, this approach lacked individual brain morphological information, limiting its application in studying individual variability in brain structure. A recent study has proposed a network template perturbation method for constructing a single structural covariance network using regional GM volume information [39]. This individualized structural covariance network analysis calculates the Pearson correlation coefficient between GM volumes across regions and constructs a reference structural covariance network from a group of healthy controls. A perturbed structural covariance network is then created by

XSL•FO
RenderX

adding a patient to the control group. Therefore, the strength of this approach lies in its individual-level construction, which incorporates reference group information and explicitly reflects the degree of morphological variation in each patient's brain regions relative to the reference group. Individualized differential structural covariance network (IDSCN) analysis has been successfully applied in multiple cross-sectional studies across different age groups and disease conditions, ranging from cognitive impairment in preterm children [40] and posttraumatic stress disorder in young-to-middle-aged adults [41] to Alzheimer disease in older adults [42]. Several longitudinal studies have demonstrated that long-term video game training induces changes in brain structure [43-46]. However, traditional methods, such as voxel-based morphometry and surface-based morphometry, primarily assess changes in individual brain regions and fail to capture correlational relationships among multiple regions. Therefore, the IDSCN approach, which combines similarity to functional connectivity with stability over extended time scales, may provide valuable insights into brain structural differences between FPS and MOBA players from a structural connectivity perspective. There are 2 commonly used measures in IDSCN, that is, GM volume and CT. As a product of surface area and CT, GM volume cannot distinguish the relative contributions of these variables [47].

Therefore, we chose CT as the morphological measure for constructing the IDSCN in this study. Unlike GM volume, CT does not require the inclusion of total intracranial volume as a covariate [48,49]. The NBS-Predict provides a distinct methodological advantage for identifying subnetworks of connectivity strength that are associated with behavioral measures [50]. We therefore applied the NBS-Predict to predict weekly gaming hours separately for the FPS and MOBA groups based on their respective structural covariance matrices. Furthermore, similar to a previous study [51], to assess the extent to which IDSCN analysis can differentiate between FPS and MOBA players, as well as between video game players and the control group, we used support vector machines (SVMs) to establish classification models for the comparisons between each pair of groups. Building on previous research [6,16,19], we hypothesized that significant differences in CT covariation exist among the FPS, MOBA, and control groups. Specifically, we anticipate that the auditory regions in the FPS group will exhibit stronger CT covariation with other brain regions compared to those in both the MOBA and control groups.

Methods

Inclusion and Exclusion Criteria

In accordance with a previous study [51], we defined gaming group players based on skill and time commitment. For gaming skill criteria, we referenced rankings published in November 2023 [52]. Inclusion criteria for the FPS group were (1) ≥5 years of experience in PC-based FPS, ≥5 hours per week of gameplay in the last 6 months, and ranked within the top 15% of all players; and (2) no MOBA experience or no MOBA gameplay within the last 2 years. Inclusion criteria for the MOBA group were (1) ≥5 years of experience in PC-based MOBA, ≥5 hours per week of gameplay in the last 6 months, and ranked within the top 15% of all players, and (2) no FPS experience or no FPS gameplay within the last 2 years. Inclusion criteria for the control group were no MOBA or FPS experience, no gameplay within the last 2 years, and no gaming experience in the last 6 months.

Exclusion criteria included visual or auditory impairments, metallic implants or electronic devices in the head, neurological or psychological disorders, alcohol or drug abuse, smoking, and claustrophobia.

Participant Characteristics

Consistent with previous research [53], it was challenging to recruit a sufficient number of high-level female players; therefore, all participants in this study were men. All participants were right-handed undergraduates or postgraduates.

Sampling Procedures

Participants were recruited through online advertisements posted at Shanghai University of Sport. As part of the initial screening process, potential candidates completed a comprehensive questionnaire designed to verify the predefined inclusion and exclusion criteria. This questionnaire also gathered genre-specific information from the MOBA and FPS groups, including their competitive rankings and average weekly gaming hours over the previous 6 months. The next step involved collecting high-resolution brain structural images on participants who met the experimental criteria.

Sample Size, Power, and Precision

Sample size determination was informed by prior cross-sectional neuroimaging studies investigating video game genres [54,55]. To ensure adequate statistical power and robust effect sizes, we established a minimum target of 35 participants per group. A total of 116 participants were successfully recruited, including 39 (33.6%) FPS players, 40 (34.5%) MOBA players, and 37 (31.9%) healthy controls.

Measures and Covariates

The primary measures in this study were individualized structural covariance edges (SCEs) constructed based on CT across 68 brain regions. Potential covariates, including age and years of education, were prespecified for inclusion in the statistical models if significant between-group differences were observed during demographic comparisons. Additionally, weekly gaming hours were collected as a behavioral measure for the predictive analysis.

Data Collection and Instrumentation

Structural images were acquired using a 3-T Siemens Prisma MRI scanner with a 64-channel phased-array head coil and using a magnetization-prepared rapid gradient echo sequence (repetition time=2300 ms, echo time=2.98 ms, inversion time=450 ms, field of view=256 mm, flip angle=9°, voxel size=1×1×1 mm^3, and 176 contiguous slices). The duration of the structural acquisition scan was 5 minutes.

Calculation of CT

High-resolution brain structural images were converted from DICOM to NIFTI format using MRIconvert (version 2.1.0;

XSL•FO
RenderX

Lewis Center for Neuroimaging), followed by a quality check of each participant's anatomical images to confirm the absence of significant artifacts. Anatomical images for each participant were realigned to the anterior commissure–posterior commissure plane using the Statistical Parametric Mapping (SPM12) software package [56] within the MATLAB 2020b environment [57], ensuring a consistent origin at the anterior commissure [58]. Subsequently, the Computational Anatomy Toolbox (CAT12.8.1 [59]) based on SPM12 was used to preprocess the MRI anatomical images of the 3 groups and to compute the CT. The specific steps included (1) standardization was conducted using Diffeomorphic Anatomical Registration using Exponentiated Lie algebra [60], followed by segmentation of the images into GM, WM, and cerebrospinal fluid; (2) calculation of CT: CT was calculated as the distance between the inner and outer surfaces of the GM [61]; (3) images were smoothed with a 15 mm FWHM Gaussian kernel; and (4) each hemisphere was segmented into 34 cortical regions using the Desikan-Killiany atlas [62], and the CT for all 68 brain regions across participants was extracted to construct the IDSCN.

Data Diagnostics

The mean CT of all participants was within 3 SDs of the group mean. All participants met the image quality criterion of grade C or above, and therefore, no data were excluded from further analysis.

Construction of IDSCN

The construction process of the IDSCN was as follows [39]:

1. Construction of the reference structural covariance network (rSCN): All participants in the control group were used to construct the rSCN. Each edge in the network was derived from the Pearson correlation coefficient (r) calculated for the CT between each pair of brain regions. Thus, the rSCN can be represented as r_n.
2. Construction of the perturbed network: By adding gamer k into the control group, a new structural covariance network (SCN) is constructed using n+1 participants, which can be represented as the perturbed network r_{n+1}.
3. Construction of the individualized SCN: The difference between the perturbed network and the reference network is calculated as $\Delta r_n = r_{n+1} - r_n$. In this manner, an individualized SCN is generated for each participant in the FPS and MOBA groups.
4. The weight of each edge in the IDSCN was calculated: Using the Desikan-Killiany atlas, a total of 4624 edges were obtained across 68 brain regions. The weight of each edge can be calculated as follows (equation 1):

$$(1) Z = \Delta SCN(1 - rSCN2)/(n-1)$$

The edges in the IDSCN represent how the inclusion of gamer k altered the covariance of pairs of brain regions in CT compared to the reference group.

SCEs and Statistical Analysis

We used the Gretna toolbox [63] to conduct a one-way ANOVA based on the z scores of 4624 edges across the 3 groups. Multiple comparisons were controlled by applying a false discovery rate correction using the mafdr function, which implements the Benjamini-Hochberg procedure, at a threshold of $P<.001$ [64]. Significant edge differences for all participants were extracted, and post hoc comparisons were performed using Bonferroni correction in IBM SPSS Statistics (version 26.0; $P<.05/3=.02$) [65]. The results were visualized using BrainNet Viewer [66]. To further enhance the robustness of the results, we conducted an additional nonparametric permutation test (10,000 permutations) using network-based statistics (NBS) on the 4624 edges among the 3 groups [67], with the α level set at .05 and the F threshold corresponding to the minimum significant F value derived from the parametric tests. The demographic information was tested for normality using the Shapiro-Wilk test in SPSS (version 26.0). Age and years of education were analyzed using the Kruskal-Wallis H test, while weekly gaming hours were assessed using the Mann-Whitney U test for independent samples. The distribution of gaming levels between the FPS group and the MOBA group was analyzed using the 2-sample Wilcoxon rank-sum test.

NBS-Predict

The analysis predicting weekly gaming hours based on structural covariance matrices was conducted in accordance with the official NBS-Predict guidelines [50]. The significance threshold for the suprathreshold edge selection algorithm was set at $P<.01$, with 10,000 permutations used for statistical testing in correlation mode. Input features were scaled using MinMaxScaler, hyperparameter optimization was conducted via a grid search algorithm, and the number of optimization steps was set to 5.

Support Vector Machine Analysis

In machine learning, SVM represents a class of supervised learning models and serves as a classic binary classification tool [68]. The construction of the SVM is consistent with a previous study [51]. We used SVM to assess the stability of connectivity differences between groups. The SVM analysis was conducted using the fitsvm function in MATLAB 2023a [57]. All differential edges in the FPS and MOBA groups were considered as feature values, with mutual information used as the feature selection algorithm [69], ranking feature values based on their importance. Leave-one-out cross-validation is a special case of k-fold cross-validation, where the number of folds equals the number of participants. It is particularly suitable for use when the dataset is small, and there is no need to randomly split the dataset into training and testing sets [70]. Therefore, we used a linear kernel SVM classifier and used the leave-one-out cross-validation strategy to evaluate its performance. The evaluation metrics included area under the curve (AUC), accuracy, sensitivity, and specificity [71]. Furthermore, SVM analysis was conducted on all differential edges between the FPS and the control groups, as well as between the MOBA and control groups. The visualization of the SVM results was performed using GraphPad Prism 9.5 [72].

Ethical Considerations

This study involving human participants was reviewed and approved by the Ethics Committee of Shanghai University of Sport (approval 102772024RT028). All procedures were conducted in accordance with the Declaration of Helsinki, as

XSL•FO
RenderX

well as relevant local legislation and institutional requirements. Written informed consent was obtained from all participants prior to their involvement, explicitly including provisions that allow for the secondary analysis of the collected research data without the requirement for further consent. Participants were informed that their participation was voluntary and their right to withdraw from the study at any time without penalty or the need to provide a reason. To ensure privacy and confidentiality, all data were anonymized. Furthermore, we confirm that no individual participant can be identified in any figures, tables, or supplementary materials presented in this manuscript. Upon completion of the experimental procedures, each participant received compensation of Chinese Yuan 35 (US $5) for their time and participation.

Results

Descriptive Data

This study included 116 male participants, divided into 3 groups, aged 18 to 26 (mean 21.2, SD 1.9) years. The demographic and game information of the 3 groups is presented in Table 1. In the FPS group, 90% (35/39) of the players played *Counter-Strike 2*, and 26% (10/39) played *Apex Legends*, with 15% (6/39) playing both games. The MOBA group included 98% (39/40) *League of Legends* players and 2% (1/40) *Dota 2* players. No significant differences were found in age or years of education among the study groups. We also observed no significant differences in the weekly gaming hours or rank distribution between MOBA and FPS groups.

Table . Demographic and game information.

Item	FPS[a] (n=39)	MOBA[b] (n=40)	Control (n=37)	*P* value
Age (y), median (IQR)	21 (19.5 - 21)[c]	21 (20 - 23)	22 (19 - 23)	.18[d]
Education (y), median (IQR)	14 (13 - 14)	14 (13 - 16)	13 (12 - 16)	.15[d]
Weekly gaming hours, median (IQR)	21 (11 - 34)	18 (10 - 25)	N/A[e]	.18[f]
Rank (top percentage of all players), % (n/N)				
<1%	41 (16/39)[g]	52.5 (21/40)	N/A	.08[h]
1% - 5%	25.6 (10/39)	32.5 (13/40)	N/A	N/A

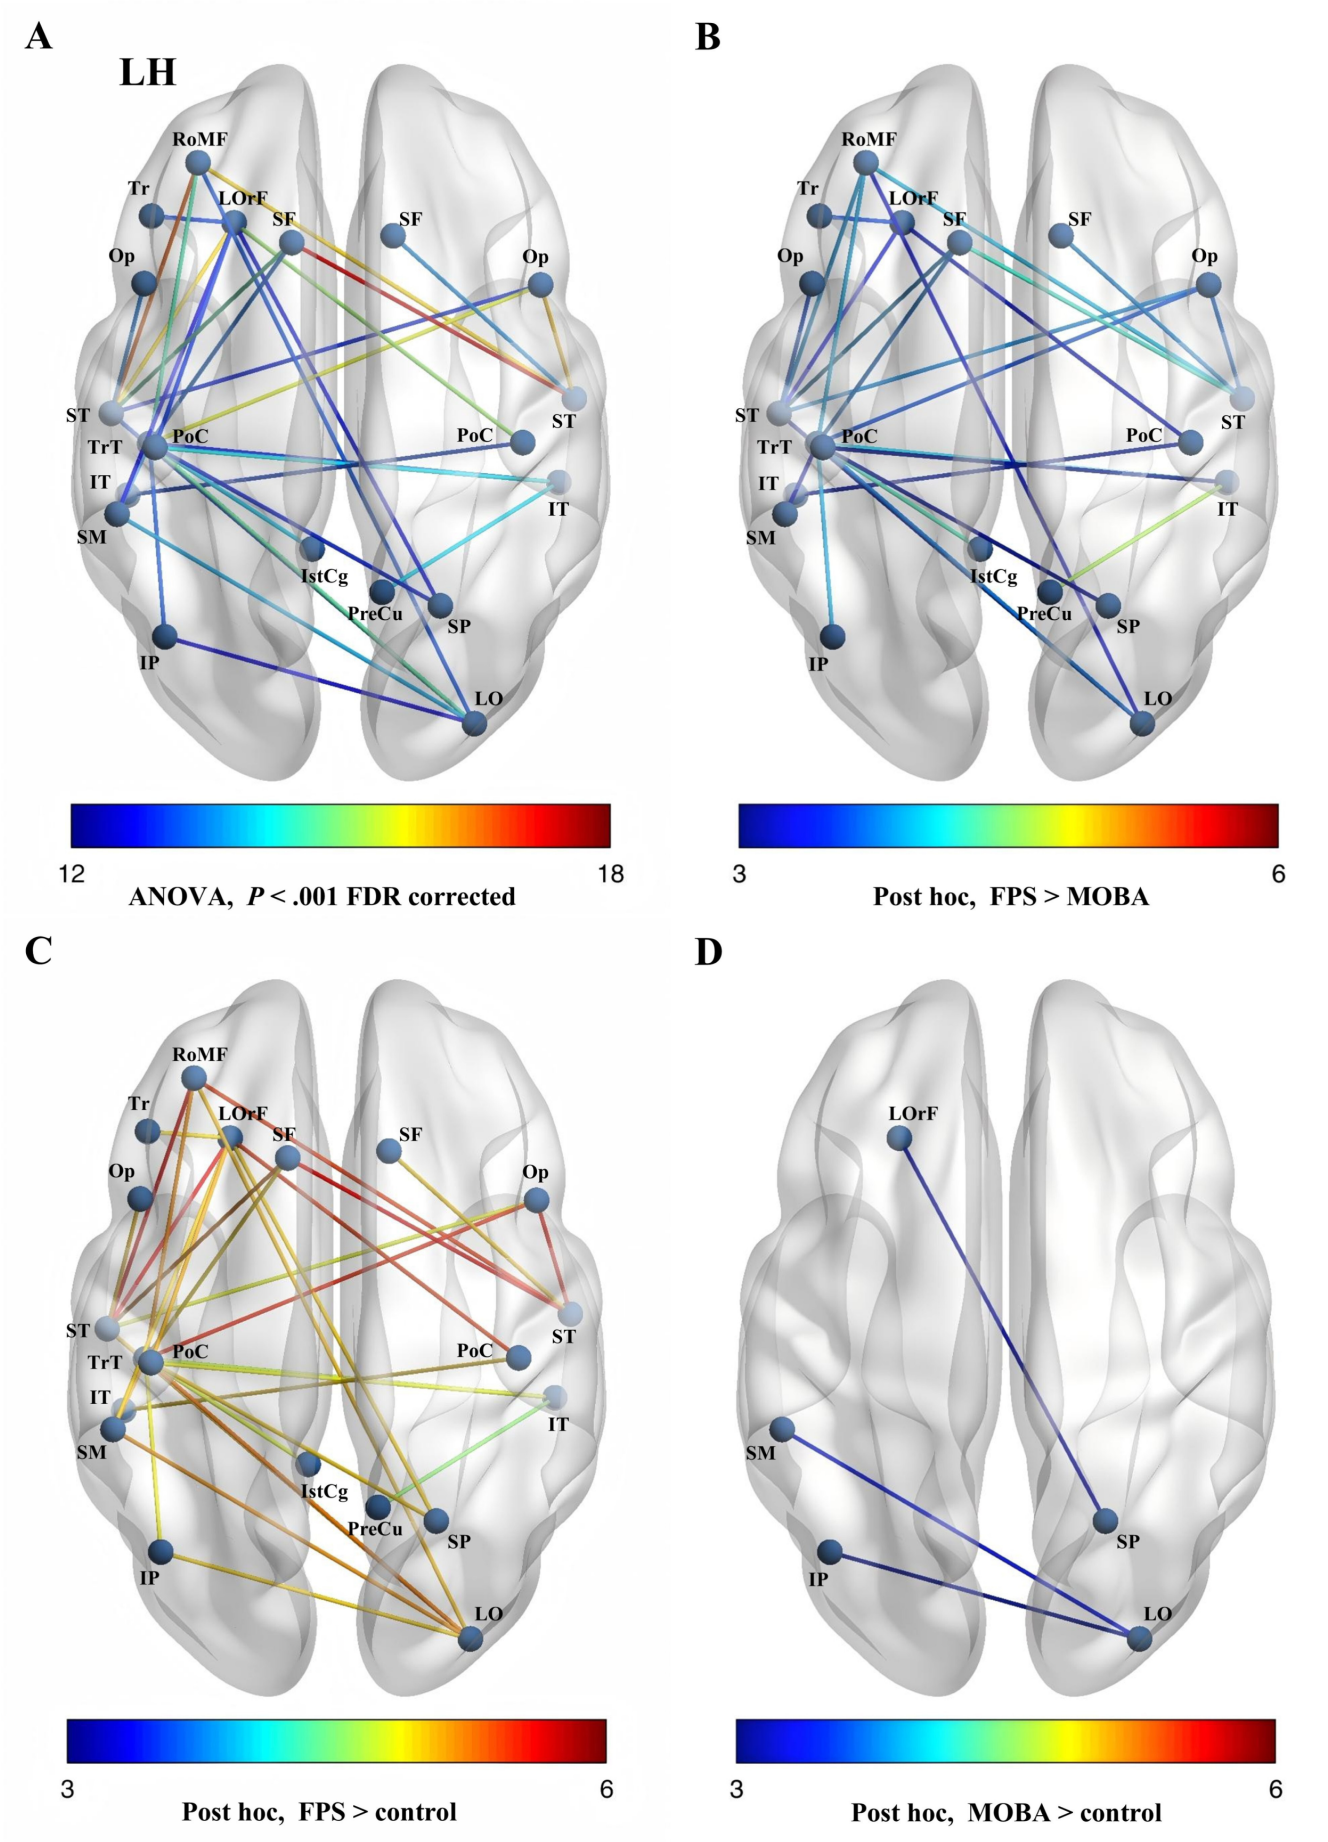
[h]*P* value was obtained by the Wilcoxon rank-sum test.



SCE Results

The results of the one-way ANOVA for SCEs among the 3 groups are presented in Figure 1A and Table 2. A total of 30 SCEs were observed across the whole brain at the significant threshold of $P<.001$ (false discovery rate corrected). A consistent result was also obtained using an NBS analysis with 10,000 permutations (Multimedia Appendix 1).

Post hoc analysis indicated that compared to the MOBA and control groups, the FPS group displayed 2 dominant networks. These consisted of a temporo-fronto-parietal network anchored in auditory regions, specifically the superior and transverse temporal gyri, and a visuo-sensorimotor network involving the inferior temporal gyrus and postcentral gyrus (Figure 1B and C and Table 3).

Additionally, both gaming groups exhibited significantly enhanced connectivity within visual-attentional networks relative to the control group (Figures 1C and 1D and Table 3).

All the significant SCEs mentioned earlier were treated as feature values using the MI algorithm for importance ranking, with lower values for greater significance of the feature in distinguishing between each pair of groups. Detailed results are presented in Multimedia Appendix 2.

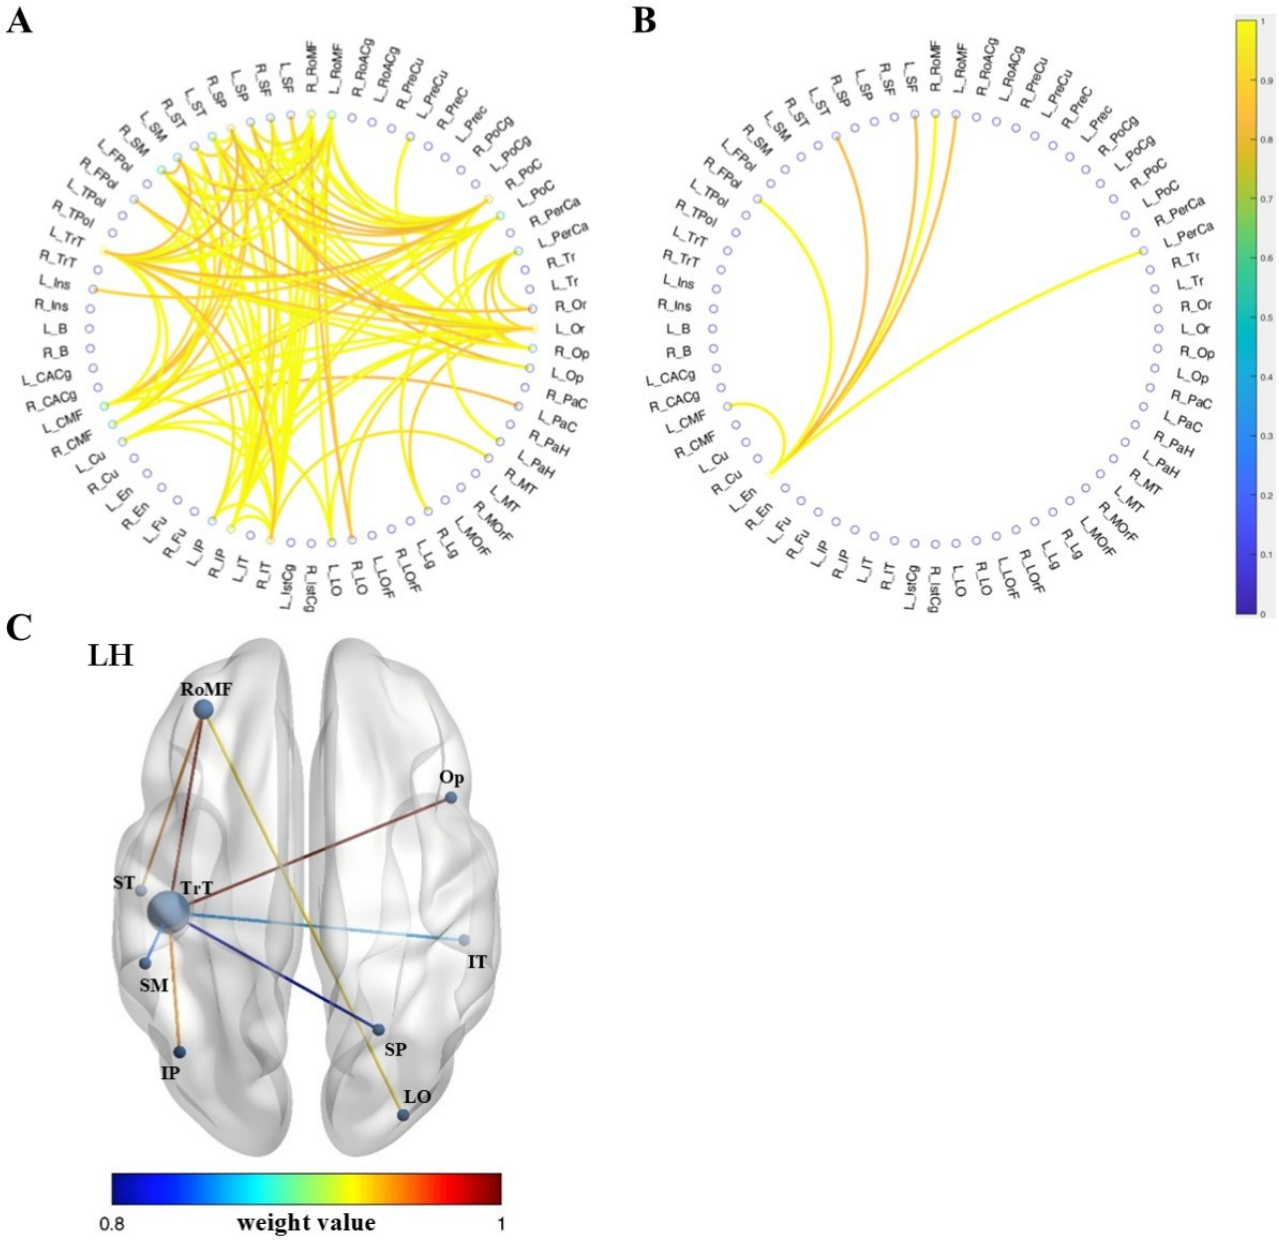
NBS-Predict Results



The weekly gaming time of the FPS group was predicted using the NBS-Predict based on individual structural covariance matrices. The predicted weekly gaming time showed a significant correlation with the actual values, with a Pearson correlation coefficient (*r*) of 0.34 (95% CI 0.26 - 0.42). Within the linear regression model, we identified 100 positive edges and 7 negative edges (connecting 34 brain regions) with weight values >0.8 (Table 4 and Figure 2), where higher edge weights indicate greater contribution to the model. The positive edges constituted a connected network centered on the auditory-related transverse temporal gyrus and extending into frontal, parietal, and occipital lobes, involving regions such as the inferior temporal gyrus, superior temporal gyrus, pars orbitalis, rostral middle frontal gyrus, superior parietal gyrus, inferior parietal gyrus, and postcentral gyrus (Figure 2A). The negative edges primarily reflected connections between the entorhinal cortex and several frontal regions (eg, rostral middle frontal, caudal middle frontal, and frontal pole), the pericalcarine cortex, and the superior temporal cortex (Figure 2B). Furthermore, this pattern of positive edges showed substantial overlap with the differential network of the FPS group relative to the MOBA group (Figure 1B), with overlapping connections illustrated in

XSL•FO
RenderX

Figure 2C. Additionally, a validation analysis was performed by increasing the weight threshold to 0.9, which revealed that the identified significant connections remained highly consistent with those obtained under the 0.8 threshold (Table 4 and Multimedia Appendix 3 and Multimedia Appendix 4).

No significant predictive effect was observed when using the structural covariance matrices of the MOBA group to predict their weekly gaming time.

Figure 2. Using linear regression within the NBS-Predict framework, weekly gaming hours in the first-person shooter group (FPS) were predicted from the structural covariance matrix, showing a Pearson correlation of 0.34 (95% CI 0.26 - 0.42) between predicted and actual weekly gaming hours. Panel A shows 100 positive edges under a weight threshold of 0.8. Panel B illustrates the 7 negative edges under the same threshold. Panel C presents the structural covariance edges in which the positive edges overlap with those identified in Figure 1B (ie, the differential edges representing FPS>MOBA). Nodes and edges are depicted by size and color according to the nodal degree and weight, respectively. SVM Results on Testing Set

The classification results showed that the FPS group could be differentiated from the MOBA group based on high AUC (72.37%), accuracy (70.89%), sensitivity (85%), and specificity (56.41%). The AUC, accuracy, sensitivity, and specificity were 82.95%, 73.68%, 64.10%, and 83.78%, respectively, for the classification between the FPS and control groups. The AUC, accuracy, sensitivity, and specificity were 74.26%, 67.53%, 57.50%, and 78.38%, respectively, for the classification between the MOBA and control groups (Figure 3).

Discussion

Principal Findings

This study aimed to examine whether long-term FPS and MOBA gaming experience is associated with the covariation of CT across brain regions, thereby elucidating the potential corresponding cognitive functions. Our results corroborated the initial hypotheses, revealing that compared to the MOBA and control groups, FPS players exhibited differences in CT covariation between the auditory cortex and the frontal, occipital, and parietal regions. These networks, involved in auditory processing, visual perception, attentional control, cognitive flexibility, and sensorimotor integration, also demonstrated predictive value for weekly gaming hours. Compared to the control group, MOBA players showed differences in CT covariation between the lateral occipital cortex and the inferior parietal and supramarginal regions, as well as between the superior parietal and the lateral orbitofrontal cortex. Furthermore, significant connectivity edges differentiating the FPS and MOBA groups were used as input features for an SVM classifier, and the results indicated that these structural signatures effectively discriminated between the 2 player groups.

Comparison With Prior Work

Previous research has found that long-term experience with RTS games can enhance WM connectivity in the occipito-parietal regions [8], and such structural changes may further drive functional reorganization in frontoparietal and parieto-occipital brain regions [73]. Classical video game genres

XSL•FO
RenderX

primarily include FPS, MOBA, and RTS. Early studies have demonstrated the benefits of video games for visual attention [5,74]. In this study, we observed covariation within frontal-parietal-occipital regions among MOBA and FPS players, which may reflect the influence of shared cognitive demands associated with these game genres. Two review articles on the cognitive benefits of video game training have suggested that not all video games elicit the same cognitive effects [3,75]. Consistent with this perspective, our findings revealed that FPS players exhibited more extensive covariation patterns across auditory, visual, and sensorimotor networks. This may indicate that compared with MOBA players, whose covariation patterns were primarily confined to visual-attentional networks, FPS gameplay imposes more comprehensive cognitive demands on players.

Longitudinal intervention studies investigating video game training have reported increases in GM volume in the superior temporal cortex [45] and the dorsolateral prefrontal cortex [76]. The superior and transverse temporal gyri are key anatomical substrates for auditory processing [77,78], whereas prefrontal regions are primarily associated with cognitive flexibility [79]. These findings are consistent with the temporal-prefrontal covariance patterns observed in our study. This correspondence suggests that FPS players may rely on dynamic interactions between auditory processing networks and attentional control networks [19].

Visual stimuli, a core element of AVGs, produce stronger visual motion effects in first-person perspectives compared to third-person perspectives [80]. A cross-sectional study found that AVG experience might lead to improvements in attention observed in both the visual and auditory domains [17], and AVG training has been shown to improve phonemic decoding and visual attention in children with developmental dyslexia [81]. Long-term FPS intervention could increase GM volume in visual regions such as the middle occipital gyrus [45]. Notably, alterations in occipital networks have been linked to neurodegenerative conditions such as Lewy body dementia [10]. Moreover, auditory-perceptual game-based training has been shown to improve cognitive performance in older adults, an effect that depends on the integrity of occipito-temporal WM connections [82]. Thus, the observed auditory-visual covariance, which positively correlates with weekly gaming hours in FPS players, implies that FPS-like gaming paradigms may offer a promising approach to maintaining brain health and mitigating age-related cognitive decline.

Research has shown that long-term FPS interventions may increase CT of the sensorimotor regions [44]. The superior parietal and inferior parietal regions were associated with the execution control of visually related motor responses [83]. Moreover, the superior parietal cortex also serves as a critical region for hand movements [84]. In an auditory-motor integration task, the superior temporal and supramarginal regions were co-activated in pianists [85] who shared certain common features with AVG players in frequent hand movements. The joint engagement of superior temporal and inferior parietal cortices functions to modulate motor responses to auditory stimuli in relation to visual stimuli [86]. FPS games have been examined in motor skill research due to their distinct kinematic characteristics [13,14]. Furthermore, these games are rich in auditory cues. For example, players often rely on enemy footsteps to localize opponents and execute rapid sequences of actions to eliminate them. The observed SCEs between auditory and sensorimotor networks may imply an association with integrated audio-motor processing.

We found that the negative SCEs between the entorhinal cortex and the frontal regions as well as the superior temporal gyrus in FPS players could effectively predict weekly gaming hours. This is a noteworthy phenomenon that may be linked to negative cognitive effects associated with FPS gaming. West et al [43] found that spatial navigation strategies can increase GM volume in the entorhinal cortex. In contrast, the use of in-game GPS guidance in FPS games—directing players to subsequent locations or events—may encourage greater reliance on response learning strategies, thereby indirectly contributing to reductions in hippocampal and entorhinal regions involved in spatial navigation. Additionally, the observed negative edge between the entorhinal cortex and superior temporal gyrus resembles the reduced hippocampal-superior temporal functional connectivity reported by Benady-Chorney et al [87] in AVG players, which may further indicate potential memory impairment. With advancing age, humans tend to shift toward response learning strategies [88], and FPS gaming may exacerbate such aging-related cognitive risks. Therefore, future game design should aim to balance elements related to response learning and spatial navigation strategies to safeguard the memory system.

Limitations

This study has several limitations. First, the cross-sectional design precludes causal conclusions about the relationship between game type and brain structure. It is also possible that inherent brain structure specificity leads players to perform better in FPS games rather than MOBA games. Second, although we observed covariation of CT between the auditory cortex and several other regions in FPS players, no auditory tasks were designed and conducted, which limits our ability to directly correlate auditory behavior with structural network changes. Future research should use a longitudinal intervention design, coupled with task-based functional MRI, to explore the effects of FPS and MOBA games on players' auditory attention. Finally, while IDSCN has been shown to resemble functional networks in several studies [31-33] and offers substantial advantages by overcoming the limitations of group-level structural covariance analysis through individual-level assessments, it serves only as an indirect marker of neuroplasticity. Its biological basis remains incompletely understood, and interpretation should be approached with caution.

Conclusions

This study characterizes the distinct structural network architectures associated with long-term FPS and MOBA gaming. The findings indicate that while both genres engage visual-attentional networks, FPS gaming is uniquely associated with extensive structural covariance between the primary auditory cortex and regions governing visual attention, sensorimotor processing, and multisensory integration. These distinct patterns likely reflect the broader cognitive demands of FPS gaming, supporting the potential utility of FPS-based

XSL•FO
RenderX

paradigms in auditory and visual rehabilitation [89-92]. Additionally, the identified structural features offer a theoretical foundation for the assessment and selection of professional esports players. However, the observed negative edges involving the entorhinal cortex warrant caution. This may indicate that the heavy reliance on response learning strategies in FPS gaming comes at the expense of spatial navigation systems dependent on the entorhinal cortex. This potential trade-off is particularly relevant for designing game-based interventions aimed at mitigating age-related cognitive decline. Given the cross-sectional nature of this study, these structural associations cannot confirm causality. Future research should prioritize longitudinal designs combined with auditory behavioral tasks to verify whether these gaming habits actively induce neuroplasticity or reflect preexisting traits and to further elucidate the balance between cognitive benefits and potential risks to the spatial memory system.

Acknowledgments

The authors acknowledge the support of the participants involved in this study. The authors also thank the Brain Imaging Center of Shanghai University of Sport, which provided assistance with data collection and training activities. The authors used DeepSeek R1 for spelling and grammar checks of the manuscript. The authors declare the use of generative artificial intelligence (Gen-AI) in the research and writing process. According to the Generative Artificial Intelligence Delegation Taxonomy (GAIDeT; 2025), the following tasks were delegated to Gen-AI tools under full human supervision and translation. The Gen-AI tool used was DeepSeek R1. Responsibility for the final manuscript lies entirely with the authors. Gen-AI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Cognitive impairment is a core and enduring deficit in schizophrenia, severely affecting social functioning and quality of life. Traditional assessments such as the MATRICS Consensus Cognitive Battery face limitations in validity and engagement. Virtual reality (VR) serious games may offer an immersive alternative, and machine learning (ML) can uncover complex behavioral patterns. However, integrating VR-based assessment with ML for discriminating stable-phase schizophrenia remains unexplored.

Objective: This prospective cohort study aimed to examine whether a VR serious game (“Fruit Pioneer”) can effectively assess cognitive function in stable schizophrenia, verify its correlation with the standard Brief Cognitive Assessment Tool for Schizophrenia (B-CATS), and test the discriminative capacity using ML models. We hypothesize that (1) patients with schizophrenia will show poorer VR game performance than healthy controls (HCs), (2) VR metrics will correlate with B-CATS scores, and (3) ML models will help classify patients with schizophrenia and HCs using VR data.

Methods: A total of 42 patients with stable schizophrenia and 65 HCs (aged 18-40 years) were enrolled. Exclusion criteria included color blindness, visual impairment, substance abuse, and comorbid chronic physical diseases. Finally, 39 patients with schizophrenia and 64 HCs were included. Materials included the VR serious game “Fruit Pioneer,” B-CATS (Digital Symbol Substitution Test, Trail Making Test Part A, Trail Making Test Part B, and Animal Fluency), Simulator Sickness Questionnaire, and Game Experience Questionnaire. Data were collected via standardized VR gameplay and paper-based assessments. Logistic regression and a support vector machine (SVM) model were built using VR metrics.

Results: Patients with schizophrenia performed worse on all B-CATS subtests (all $P<.001$). They also showed lower VR total scores (median 467, IQR 376-544 vs median 683, IQR 616-753; $P<.001$), longer reaction times (median 1.11, IQR 0.995-1.23 vs median 1.03, IQR 0.96-1.1; $P=.006$), lower gaze hit rates (median 0.515, IQR 0.442-0.554 vs median 0.552, IQR 0.497-0.592; $P=.01$), and higher bomb penalty scores (median 150, IQR 95-170 vs median 108, IQR 85-131; $P=.002$). In the schizophrenia group, VR metrics correlated with B-CATS results, whereas this relationship was minimal in HCs. Classification performance of the SVM (average area under the curve [AUC]=0.874, 95% CI 0.860-0.888) was comparable to logistic regression (average AUC=0.854, 95% CI 0.838-0.870).

XSL•FO
RenderX

Conclusions: This study demonstrates the innovative integration of a VR serious game with ML to assess cognitive function in stable schizophrenia. Unlike prior VR studies focused mainly on validation, our approach combines behavioral metrics with an SVM model, achieving effective classification. The findings support the potential of a scalable digital assessment correlated with standard tests. In clinical practice, this system may serve as an engaging alternative to traditional methods, facilitating long-term cognitive monitoring and personalized rehabilitation strategies.

KEYWORDS

B-CATS; cognitive function; schizophrenia; serious game; virtual reality

Introduction

Problem

Schizophrenia imposes significant economic and psychological burdens on patients, their families, and society [1]. Cognitive dysfunction, a core feature affecting the majority of patients, impairs attention, memory, executive function, and processing speed [2,3], thereby severely compromising social functioning and quality of life. This underscores the critical need for accurate assessment tools. Traditional cognitive assessments, for example, the MATRICS Consensus Cognitive Battery, however, face major limitations [4]. They are time-intensive and require specialized training, leading to low clinical use; their artificial tasks lack validity and fail to reflect real-world functioning. Additionally, they are prone to subjectivity (unable to capture fine-grained behavioral metrics), and their passive nature often results in low patient motivation and compliance [5,6]. The Brief Cognitive Assessment Tool for Schizophrenia (B-CATS) improves time-efficiency but remains a laboratory-based assessment [7]. While it evaluates key domains such as processing speed, attention, executive function, and semantic memory, it still lacks validity and the capacity for dynamic behavioral capture.

Review of Relevant Scholarship

Emerging technologies such as virtual reality (VR) and serious games offer potential solutions. VR creates immersive and standardized environments that can enhance engagement through reward mechanisms, which is particularly crucial for patients with anhedonia [8-10]. Furthermore, it enables the automated, objective capture of high-resolution behavioral data, such as gaze latency and movement precision [11]. Empirical studies support the use of VR in effectively assessing and differentiating cognitive impairments in psychiatric populations. A VR navigation task study demonstrated that patients with schizophrenia exhibited significant impairments in allocentric, egocentric, visual, and verbal memory tasks compared to bipolar disorder patients and healthy controls (HCs) [12]. Another study used interactive VR to assess verbal memory, processing speed, attention, working memory, and planning skills in 40 patients with mood or psychotic disorders [13]. Serious games, which are being increasingly adopted in mental health research and clinical practice, integrate cognitive assessment into structured virtual activities and foster engagement that aligns with core therapeutic goals [14].

Considering VR assessments generate complex and high-dimensional data, machine learning (ML) has been recommended as a core analytical component [15,16]. Support vector machines (SVMs), as a famous ML model, can identify subtle, nonlinear patterns and support individualized cognitive profiling for this heterogeneous disorder [17]. Compared with the traditional logistic regression analysis, SVM handles high-dimensional data well and mitigates overfitting with limited samples [18]. Recent studies have also validated that SVM models using VR data can achieve superior classification accuracy [19].

Hypothesis, Aims, and Objectives

This study adapts our previously developed VR serious game "Fruit Pioneer" [20], aiming to investigate the efficacy of this serious game system in assessing cognitive dysfunction in patients with stable schizophrenia. Specifically, it seeks to evaluate the system's validity through correlation analysis with the B-CATS and to leverage ML to validate its discriminative capacity in differentiating patients from HCs. By integrating the validity of VR, the engagement of serious games, and the pattern recognition capabilities of ML, this study may provide a scalable and clinically relevant cognitive assessment tool. We hypothesize that (1) patients will exhibit poorer overall performance on the VR serious game compared to HCs; (2) metrics from the VR serious game will show potential correlations with B-CATS scores in the patient group; and (3) ML models will classify patients and HCs based on the VR game metrics.

Methods

Inclusion and Exclusion

This study was a prospective cohort study conducted in patients with stable schizophrenia and HCs at the Mental Health Center of West China Hospital, Sichuan University, from May to December 2023. Participants were diagnosed with stable-phase schizophrenia according to the *Diagnostic and Statistical Manual of Mental Disorders,Fifth Edition* (*DSM-5*). The stable phase was defined as a period satisfying two key criteria: (1) no acute exacerbation of positive symptoms within the past 3 months and (2) maintenance on a stable dosage of antipsychotic medication for at least 1 month. Inclusion criteria for the schizophrenia group included (1) age 18-40 years, (2) inpatients in the stable phase of schizophrenia, and (3) signed written informed consent. Exclusion criteria for the schizophrenia group included (1) color blindness, (2) visual impairment requiring glasses for correction, (3) substance abuse (including alcohol dependence), and (4) comorbid chronic physical diseases. Inclusion criteria for the HCs group were (1) age 18-40 years,

XSL•FO
RenderX

(2) healthy individuals with no personal or family history of psychiatric disorders (confirmed via self-report and brief structured interview), and (3) signed written informed consent. Exclusion criteria for HCs were consistent with the schizophrenia group.

"Fruit Pioneer" Serious Game Procedures

We have developed the VR serious game "Fruit Pioneer" [20], aiming to provide an immersive, distraction-minimized environment to enhance assessment engagement. The game adopts a first-person perspective, featuring key elements including a swinging panda, a real-time scoreboard, and multiple circular fruit-shooting nozzles (Figure S1 in Multimedia Appendix 1). To minimize external distractions, participants wore VR headsets and earphones that delivered dynamic game sounds (eg, fruit-slicing feedback and background music). Handheld interactive devices were visualized as 2 long swords in the virtual environment, enabling intuitive operation.

To eliminate potential learning effects that may confound cognitive performance outcomes, no practice session was conducted prior to the formal assessment; instead, trained researchers provided participants with a standardized verbal explanation of the game rules, including fruit/bomb identification, scoring criteria, controller operation, and movement boundaries within the designated physical area. Following the rule explanation, the formal 5-minute game session was initiated, during which fruits (banana, apple, watermelon, orange, and pineapple) and black spherical bombs were randomly launched from the 8 nozzles at varying speeds (Figure S1 in Multimedia Appendix 1), and participants could move their head and body freely within the designated physical area to adjust their field of view and swing the haptic controllers to slice fruits for points while avoiding bombs.

A predefined scoring system has been implemented in this framework to distinguish cognitive task difficulty. Specifically, watermelon (+1 point/piece) has the largest volume, highest visual salience, and lowest difficulty, requiring minimal attentional allocation for perception and slicing; banana (+2 points/piece) has moderate volume and irregular shape, with intermediate visual salience and difficulty that demands moderate attentional effort for tracking and slicing; apple, orange, and pineapple (+3 points/piece each) have small volume and similar round shapes, resulting in the lowest visual salience and highest difficulty, and their low salience and similar appearance increase perceptual challenge, requiring participants to strategically allocate attention and prioritize low-salience targets—tasks relying on executive function and sustained attention, which are impaired in schizophrenia. Bombs served as penalty targets (–5 points/piece) to assess inhibitory control (a core component of executive function), as the design requires participants to suppress prepotent slicing responses to task-irrelevant stimuli (bombs). The game automatically terminated after 5 minutes, with all behavioral data recorded in real time by the system, and a professional psychiatric nurse was present throughout the gameplay to guide participants, ensure the smooth execution of the assessment, and promptly address any adverse events (eg, anxiety and dizziness).

A total of 9 core metrics were extracted from the game to assess participants' cognitive functions:

1. Game score: reflects overall operation performance, including points from all sliced fruits and deductions from sliced bombs; the total score is the sum of all items. Formula: total game score = Σ(score of each sliced fruit) – Σ(penalty score of each sliced bomb). Watermelon score = quantity of sliced watermelons × (+1 point/piece) Banana score = quantity of sliced bananas × (+2 points/piece) Apple score = quantity of sliced apples × (+3 points/piece) Orange score = quantity of sliced oranges × (+3 points/piece) Pineapple score = quantity of sliced pineapples × (+3 points/piece) Bomb penalty score = quantity of sliced bombs × (+5 points/piece)
2. Average reaction time for hits: measures the mean duration from target (fruit/bomb) appearance to successful interaction, reflecting integrated attentional and executive function capabilities involving working memory processing efficiency. Formula: average reaction time for hits = total reaction time of all successful hits/number of successful hits; reaction time for a single hit = time of target appearance (system record) – time of successful slicing (system record).
3. Average time from gaze to hit: captures the mean latency between visual fixation on a target and execution of the corresponding action, directly associated with decision-making speed and cognitive control within executive functions. Formula: average time from gaze to hit = total time from gaze to hit of all successful hits/number of successful hits; time from gaze to hit = time of successful slicing – time of initial visual fixation on the target (tracked by VR eye-tracking module).
4. Gaze hit rate: represents the proportion of successful operations under visual fixation, quantifying the accuracy of goal-directed behavior and the efficacy of executive responses. Formula: gaze hit rate = (number of successful hits with prior visual fixation/total number of targets fixated on) × 100%.
5. Nongaze hit rate: indicates the proportion of successful operations without prior visual fixation, supplementing the assessment of automated and intuitive executive responses. Formula: nongaze hit rate = (number of successful hits without prior visual fixation/total number of targets fixated on) × 100%.
6. Shortest time from gaze to hit: identifies the fastest response latency, signaling peak performance of attention and executive function under optimal conditions. Formula: shortest time from gaze to hit = minimum value among the time from gaze to hit of all successful hits.
7. Longest time from gaze to hit: reveals the slowest response latency, exposing potential deficits in cognitive flexibility or task-switching efficiency. Formula: longest time from gaze to hit = maximum value among the time from gaze to hit of all successful hits.
8. Bomb score: quantifies inhibitory control—a core component of executive function—by measuring suppression of responses to irrelevant stimuli. Formula: bomb score = number of bombs hit × penalty score per bomb. Note: penalty score per bomb is predefined as 5

XSL•FO
RenderX

points; a higher bomb score indicates poorer inhibitory control, as it reflects more frequent inappropriate responses to irrelevant stimuli (bombs).

9. Number of continuous hits: tracks consecutive successful operations, reflecting sustained attention, working memory updating, and executive coordination. Formula: number of continuous hits = number of consecutive successful fruit slicing operations (even 2 consecutive successful slicing operations are counted as valid continuous hits). Note: "Continuous" is defined as successful fruit slicing without interruptions (slicing bombs or missing fruits), and this continuous slicing process is automatically recorded by the system.

Cognitive Assessment by B-CATS

B-CATS is used in this study for objective cognitive function assessment across 4 dimensions: Digital Symbol Substitution Test (DSST), Trail Making Test Part A (TMTA), Trail Making Test Part B (TMTB), and Animal Fluency (AF; Table S4 in Multimedia Appendix 1) [21]. In the DSST, participants received a sheet displaying 9 symbols, each matched with digits 1-9 at the top, with additional rows of symbols below. Within a 120-second time frame, participants were required to correctly match each symbol to its respective digit. The total number of correct matches determined the score. Out of 120 symbols on the sheet, the first 10 served as examples, so the highest possible score was 110. The DSST quantitatively assessed participants' core cognitive domains, including processing speed, attentional control, and visual working memory. For TMTA, participants sequentially connected numbered circles (1-2-3-...) in ascending order while maintaining continuous pen contact. Errors were corrected by redirecting to the last correct position. TMTA assesses visual scanning speed, sustained attention, and psychomotor processing speed. For TMTB, participants alternately connected numbered and lettered circles (1-A-2-B-3-...) in ascending alphanumeric sequence under continuous pen-tracking requirements, with errors similarly corrected. TMTB evaluates executive function, task-switching ability, and inhibitory control (specifically requiring suppression of prepotent numeric sequencing). In the AF task, participants generated unique animal names within a 60-second interval, with the score representing the total count of valid distinct responses. AF assesses three core domains: (1) semantic memory (access to categorical knowledge mediated by anterior temporal lobes), (2) lexical access efficiency (rapid word retrieval supported by left inferior frontal gyrus), and (3) strategic retrieval processes (executive-guided clustering/switching strategies involving dorsolateral prefrontal cortex). Performance thus reflects integrated frontotemporal network functions with significant executive control contributions.

Simulator Sickness Questionnaire

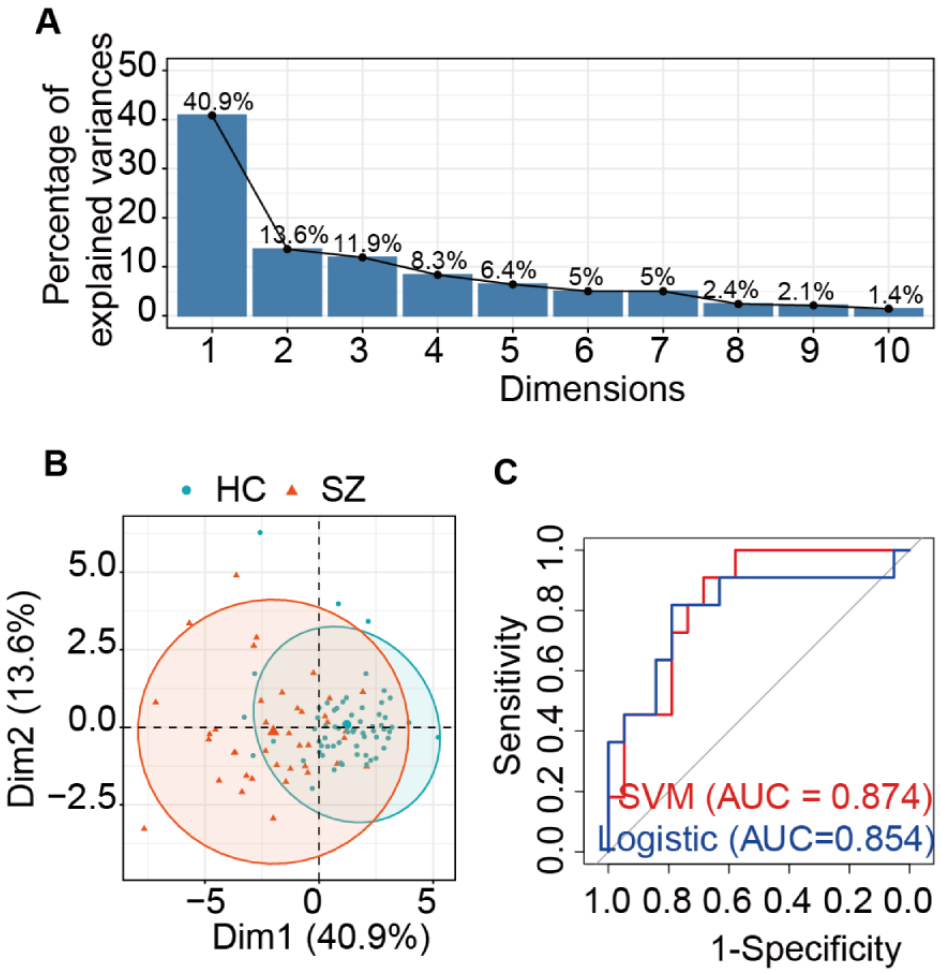
The Simulator Sickness Questionnaire (SSQ), a widely-used tool in VR research, evaluates discomfort symptoms that participants may experience post engagement with VR environments (Table S5 in Multimedia Appendix 1). The SSQ assesses 16 different symptoms across 3 dimensions: oculomotor issues, disorientation, and nausea. In our study, the scoring procedure for the SSQ followed the recommendations by Bouchard et al [22]: the total nonweighted score (ie, SSQ-total raw) was calculated by simply summing all 16 items of the SSQ once [23].

Game Experience Questionnaire Core Module

The Game Experience Questionnaire Core Module (GEQ-Core Module), designed by IJsselsteijn et al [24], encompasses essential aspects necessary for assessing the gaming experience (Table S6 in Multimedia Appendix 1) [25]. It includes 33 items across 7 dimensions: competence, sensory and imaginative immersion, flow, challenge, positive affect, negative affect, and tension/annoyance. The questionnaire uses a 5-point Likert scale for responses, ranging from 0 (not at all) to 1 (slightly), 2 (moderately),3 (highly), and 4 (extremely). By calculating the average scores for each dimension, differences in participants' experiences across various aspects can be evaluated.

Analytic Strategy

A total of 103 participants were included for the final analyses, and no missing data existed. All analyses were performed according to a prespecified statistical analysis plan. Statistical comparisons used a 2-tailed significance test with a 95% confidence level. All analyses were conducted using a complete case analysis. All statistical analyses were performed using R software (version 4.2.3; R Foundation for Statistical Computing).



For continuous variables (eg, B-CATS subtest scores, VR game metrics, SSQ, and GEQ-Core Module scores), the Shapiro-Wilk test was first used to verify data normality: if the data were normally distributed, the independent samples 2-tailed *t* test was used for intergroup comparisons; if not normally distributed, the Mann-Whitney *U* test (nonparametric test) was applied. The chi-square test was used for statistical inference of categorical data (eg, gender distribution between groups).

To identify the most discriminative VR metrics for classifying patients with schizophrenia and HCs, we performed principal component analysis (PCA). All 15 standardized VR game metrics (game score, banana score, apple score, watermelon score, orange score, pineapple score, bomb score, average reaction time for hits, average time from gaze to hit, gaze hit rate, nongaze hit rate, shortest time from gaze to hit, longest time from gaze to hit, bomb penalty score, and number of continuous hits) were included in the PCA. This technique transforms the correlated original variables into a set of uncorrelated principal components (PCs), which are ordered by the amount of variance they explain. To determine the number of key PCs to retain for subsequent analysis, we examined the scree plot (Figure 1A) and the cumulative proportion of explained variance. The scree plot showed a clear "elbow" after the first few components, indicating a point of diminishing returns in variance explained by subsequent components. We retained the first 7 PCs ("nongaze hit rate," "gaze hit rate," "orange score" "apple score," "pineapple score," "watermelon score," and "bomb score"), which collectively explained over 80% of the total variance in the dataset, ensuring a substantial reduction in dimensionality while preserving most of the original information. To address potential bias from unbalanced group distribution or data leakage, we used stratified random sampling

XSL•FO
RenderX

(via the createDataPartition function in the caret package) to split the full dataset into a 70% training set and 30% testing set in each iteration (total 50 iterations). For model training, a radial kernel SVM was trained on the training set with probability estimates enabled to generate continuous prediction scores for receiver operating characteristic analysis, and a binomial logistic regression model was trained on the same training set to predict binary group membership. For performance evaluation and robustness check, model performance was evaluated on the independent testing set for each iteration using accuracy, precision, recall (sensitivity), specificity, and F_1-score. Receiver operating characteristic curves and area under the curve (AUC) were calculated to quantify discriminative ability. The entire process was repeated 50 times with independent stratified random splits to account for random variation, mean values of all metrics (±variability) were reported to reflect stable model performance, and 90% CIs for AUC values were additionally calculated to assess the reliability of discriminative ability estimates.

Figure 1. Principal component analysis and receiver operating characteristic curves for support vector machine (SVM) and logistic regression machine models. (A) Scree plot of principal component analysis. (B) Principal component analysis score plot of samples. (C) Receiver operating characteristic curves for classification models. AUC: area under the curve.

Ethical Considerations

This study was conducted in strict accordance with the ethical principles of the Declaration of Helsinki and approved by the Medical Research Ethics Committee of Sichuan University (reference number 2023-1926). Safety was ensured by an on-site psychiatric nurse monitoring for adverse events (eg, anxiety and dizziness) with authority to terminate assessments if needed.

All participants provided written informed consent after detailed verbal explanations of study objectives, procedures, potential risks, benefits, and the right to withdraw without penalty. HCs received additional clarification about voluntary participation. Original consent forms are securely archived. Ethics approval explicitly permits future secondary data analysis without reconsent. All data were anonymized. Personally identifiable information was stored separately in password-encrypted systems with restricted access; paper records were kept in locked cabinets. Only authorized researchers accessed deidentified data. No identifiable information appears in publications. Data retention complies with institutional regulations. No form of compensation was provided to participants for their participation in this study. This publication and its supplementary materials do not contain any images, videos, or other materials that may identify individual participants.

Results

Participant Flow and Recruitment

A total of 107 participants were initially enrolled, consisting of 42 patients with schizophrenia and 65 HCs. Overall, 103/107 (96.26%) participants completed the study. For the schizophrenia group, 3 out of the 42 initially enrolled patients were excluded: 2 due to inability to complete TMTB (unfamiliar with English alphabetical order) and 1 due to a negative total score in the VR serious game (indicating misunderstanding of game rules). For the HCs group, 1 out of the 65 initially enrolled controls was excluded due to technical equipment failure that prevented data recording. After applying post–data-collection exclusion criteria, 39 patients with schizophrenia and 64 HCs were included in the final analytic sample. No missing data were observed in the final analytic sample (Figure 2).

The schizophrenia group was older than the HCs group (patients with schizophrenia: median 25, IQR 19-29 years; HCs: median 20, IQR 20-21 years; P<.001). No significant between-group differences were observed in gender distribution (χ^2_1=0.072; P=.79) or educational background (χ^2_1=1.196; P=.27), indicating that the groups were balanced in these demographic variables (Table 1).

Figure 2. Flowchart of the data selection process with reasons for exclusion of participants specified. In the stable-phase schizophrenia group, 3 participants were excluded from the final analysis: 2 were unable to complete the questionnaire, and 1 had a negative score in the virtual reality (VR) serious game, resulting in 39 participants analyzed. In the HC group, 1 participant was excluded due to technical equipment failure that caused data to be missing, leaving 64 participants for final analysis.

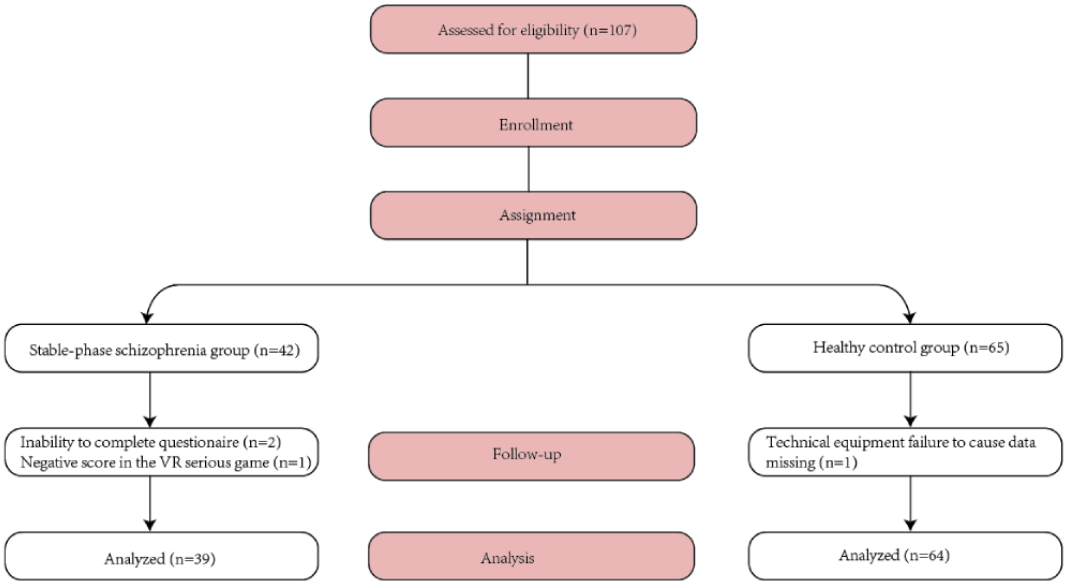

Table 1. Demographic characteristics of stable patients with schizophrenia (SZs) and healthy controls (HCs) in a cross-sectional study of virtual reality serious game–based cognitive function assessment.

B-CATS Outcomes of Patients With Schizophrenia and HCs

The DSST scores and AF scores followed a normal distribution (P>.05), while the TMTA and TMTB scores did not conform to a normal distribution (P<.01). Therefore, with age as a covariate, an independent *t* test was used to compare the DSST and AF scores, and the Mann-Whitney *U* test was used to compare the TMTA and TMTB scores between the 2 groups. Significant differences were observed between patients with schizophrenia and HCs across B-CATS results. The schizophrenia group exhibited lower performance on DSST

XSL•FO
RenderX

(P<.001), TMTA (P<.001), TMTB (P<.001), and AF (P<.001) compared to the HCs group (Table 2).

Performance of VR Serious Game Between Patients With Schizophrenia and HCs

Patients with schizophrenia achieved lower scores for various fruits but higher penalty points for bombs in the VR serious game compared to HCs (P<.001; Table 3). Furthermore, patients with schizophrenia exhibited longer average reaction time for hits (P<.001) and average time from gaze to hit (P<.001) compared to HCs. Also, patients with schizophrenia had a lower gaze hit rate compared to HCs (P=.01). However, no discernible differences were observed between patients with schizophrenia and HCs in terms of nongaze hit rate, nongaze/gaze hit rate, shortest time from gaze to hit, longest time from gaze to hit, and the number of continuous hits. In the schizophrenia group, significant correlations were observed between the B-CATS and total game score (P=.04), average reaction time for hits (P=.02), continuous hits (P=.03), as well as shortest time from gaze to hit (P=.02; Table S2 in Multimedia Appendix 1).

Table 3. Comparison of virtual reality serious game performance between patients with schizophrenia (SZs) and healthy controls (HCs) in a cross-sectional study.

Variables	HCs	SZs	Test statistic	*P* value
Game score (points)				
Total score, median (IQR)	683 (616-753)	467 (376-544)	2255.5[a] (101)	<.001
Banana score, mean (SD)	70.7 (11.5)	53.0 (13.6)	6.766[b] (101)	<.001
Apple score, mean (SD)	197 (27.8)	150 (35.8)	7.013[b] (101)	<.001
Watermelon score, median (IQR)	102 (93.8-107)	84 (76-93.5)	2137.5[a] (101)	<.001
Orange score, mean (SD)	182 (29.1)	138 (34.5)	6.625[b] (101)	<.001
Pineapple score, mean (SD)	240 (36.3)	180 (40.8)	7.596[b] (101)	<.001
Bomb penalty score, median (IQR)	108 (85-131)	150 (95-170)	797.5[a] (101)	.002
Average reaction time for hits (seconds), median (IQR)	1.03 (0.96-1.1)	1.11 (0.995-1.23)	845.5[a] (101)	.006
Average time from gaze to hit (seconds), median (IQR)	0.43 (0.389-0.468)	0.481 (0.417-0.599)	807.5[a] (101)	.003

Results of SSQ and GEQ-Core Module

While no statistically significant differences were found between the patients with schizophrenia and HCs in the dimensions of competence, immersion, flow, and challenge, notable distinctions emerged between the symptom group and the HC group in their scores for positive and negative affect, as well as tension (Table S3 in Multimedia Appendix 1). The HCs group scored higher in positive affect, and the schizophrenia group scored higher in negative affect (P=.03 and P=.02, respectively). Tension was significantly higher in the schizophrenia group compared to the HCs group (P=.045). Regarding SSQ scores, although the difference between the schizophrenia group and the HCs group did not reach the conventional threshold for statistical significance (P=.06), this value represents a borderline trend that merits cautious interpretation. Specifically, the numerical pattern of SSQ scores suggested a potential directional difference between the 2 groups, which may have been masked by the relatively small sample size of this study.

ML Model Classification Results

Based on PCA analysis, 7 features were included in ML analyses, including “nongaze hit rate,” “gaze hit rate,” “orange score,” “apple score,” “pineapple score,” “watermelon score,” and “bomb score”. SVM had a slightly higher AUC value compared with logistic regression machine (LRM) models (AUC—SVM: 0.874, 95% CI 0.860-0.889; LRM: 0.854, 95% CI 0.838-0.870; Figure 1). Both SVM and LRM models effectively classified patients with schizophrenia and HCs, with SVM achieving 0.801 accuracy, 0.765 precision, 0.710 F_1-score, and LRM showing 0.794 accuracy, 0.734 precision, 717 F_1-score.

Discussion

Principal Findings

Our study demonstrated that the VR serious game could differentiate cognitive function between patients with schizophrenia and HCs. Furthermore, VR-derived metrics showed potential correlations with B-CATS measures, highlighting the potential use of VR-based serious games for capturing valid cognitive functioning.

Interpretation

Patients with schizophrenia exhibit significant cognitive impairment, including attention deficits and executive function deficits. Attention deficits manifest as difficulties in sustaining attention on task objectives, particularly evident in multitasking contexts [26]. According to stimulus-driven theories of visual processing within the current VR serious game, external stimuli can directly generate perceptual experiences corresponding to the stimulus properties [27]. Constrained by the physiological limitations of the visual system, the capacity for processing external stimuli at any given moment is finite [28]. This limitation manifests in the domain of stimulus size, where larger objects inherently exert stronger visual stimulation intensity compared to smaller objects [29]. Within the VR serious game, when multiple fruits appear simultaneously, larger fruits deliver higher visual stimulus intensity, while smaller fruits deliver lower visual stimulus intensity [20]. Therefore, smaller fruits are assigned higher point values, while larger fruits receive lower scores in the current VR games. This score system would help distinguish patients with attention deficits. This aligns with their poorer performance evaluated by B-CATS. Compared to HCs, patients with schizophrenia also exhibited prolonged response latencies across VR tasks, which correspond to impairments observed in the DSST and TMT subtests of the B-CATS.

Inhibitory control constitutes a core component of executive function [30], primarily serving to suppress prepotent responses [31]. Critically, patients with schizophrenia experiencing heightened excitement face an elevated risk of impulsive/aggressive behaviors, posing potential threats to the environment, themselves, and others [32]. During the VR game, these patients may exhibit undirected behavioral actions, consequently resulting in poor game performance [20]. Furthermore, these behaviors may precipitate hyperarousal and elevated mood states [31]. Therefore, within this VR game framework, bombs were incorporated as inhibitory stimuli. Accidental detonation of these bombs triggers deduction of accumulated points according to a predefined scoring protocol, thereby operationalizing the inhibitory mechanism [20]. This finding aligns with impaired inhibition measured by the TMT-B, wherein suppressing prepotent numerical sequencing tendencies is essential.

Similarity of Results

Patients with schizophrenia exhibited lower scores in positive emotions and higher scores in negative emotions and tension in our study, aligning with prior research indicating a tendency for individuals with schizophrenia to anticipate negative emotions more than HCs [33,34]. Martin et al [35] conducted a study involving 16 patients with schizophrenia and 30 HCs using a task paradigm with real-life social interaction, which similarly found heightened anticipation of negative emotions among patients with schizophrenia compared to HCs. Furthermore, there were no differences in SSQ scores between the schizophrenia group and the HCs group, indicating comparable susceptibility to simulator sickness symptoms between patients with schizophrenia and HCs. This implies that patients with schizophrenia's adaptability in VR environments may mirror that of nonclinical populations.

Our current VR serious game helped differentiate the patients with schizophrenia from the HCs using ML. This aligned with a previous study on VR assessment of cognitive function in patients with schizophrenia [36]. The authors stated that the VR cognitive training system distinguished patients with schizophrenia in the stable phase stage and HCs with high accuracy (88.89%), sensitivity (88.89%), and specificity (88.89%) [36]. While the classification accuracy of SVM models remained moderate in the study, this limitation does not negate the core value of ML integration. Rather than evaluating ML by accuracy alone, its indispensable contribution lies in 3 key aspects that address the shortcomings of traditional analytical methods. First, SVM excels at processing high-dimensional, multimodal VR-derived data (eg, gaze latency and movement precision) that the traditional LRM method cannot fully interpret. Conventional approaches only detect linear

XSL•FO
RenderX

relationships between variables, but ML identifies hidden nonlinear interactions and prioritizes key cognitive markers (eg, bomb score for inhibitory control deficits). Second, from a clinical perspective, SVM provides individualized cognitive profiles that the traditional B-CATS tool cannot deliver. Even with moderate accuracy, the models generate targeted deficit profiles for each patient, guiding personalized rehabilitation planning. Third, this limited performance reflects objective constraints rather than SVM ineffectiveness, including the moderate sample size, inherent heterogeneity of schizophrenia, and incomplete coverage of cognitive domains by existing VR metrics.

Implications

This study provides preliminary evidence supporting the potential use of VR serious games as an adjunctive tool for cognitive assessment in stable schizophrenia. Our findings suggest that the "Fruit Pioneer" game might address key limitations of traditional testing by offering a more engaging format that captures nuanced behavioral data. This may, in future applications, improve patient acceptance and facilitate more frequent monitoring in clinical or research settings. Methodologically, this work contributes a scalable digital assessment framework. The integration of game mechanics with ML for pattern recognition represents a promising step toward automated, objective cognitive profiling. However, the translational clinical implications remain to be fully established. Future work must prioritize independent validation in larger, age-matched cohorts and longitudinal designs to determine the tool's reliability and sensitivity to change.

Limitations

This study has several limitations. First, the ML models were developed and evaluated using repeated stratified sampling within the same cohort. While this internal validation approach helps mitigate overfitting, it does not constitute a true external validation. The generalizability of the SVM and logistic regression models to entirely new, independent populations of patients with schizophrenia and HCs remains to be demonstrated. Future studies with multicenter designs and independent validation cohorts are necessary to confirm the robustness and clinical transportability of these models. A second major limitation is the significant age difference between the schizophrenia and HCs groups, with HCs being notably younger. Although ANCOVA results indicated that age did not fully account for the observed group differences in VR metrics, age is closely linked to cognitive performance and familiarity with VR technology [37], which may have influenced our findings. In future studies, we will strictly recruit age-matched participants (±3 years) to eliminate this confounding factor and further validate the specificity of VR metrics for schizophrenia-related cognitive impairment. Third, the potential for learning effects with repeated use was not addressed in this cross-sectional design. While we omitted a practice session to minimize confounding effects on the initial assessment, repeated exposure to the "Fruit Pioneer" game in a longitudinal or periodic monitoring context could introduce performance improvements unrelated to cognitive change, thereby confounding the interpretation of scores over time. This is an important consideration for the tool's application in long-term monitoring. Another limitation is the relatively small sample size of this study, which may affect the stability and generalizability of our ML models. Future multicenter studies with larger cohorts are needed to confirm our findings. Additionally, we did not collect longitudinal data, so the ability of VR metrics to track changes in cognitive function over time remains unclear.

Conclusion

This study explored the application of the VR serious game "Fruit Pioneer" in the cognitive assessment of patients with stable schizophrenia. Methodologically, our study is innovative in its synergistic use of a purpose-built serious game for multidomain cognitive profiling and ML for pattern recognition and classification. This integrated approach differs from existing studies by not only demonstrating correlation with B-CATS but also providing a data-driven discriminative model. This work may contribute to the field by establishing a scalable digital assessment correlated with standard cognitive tests. Regarding real-world implications, the immersive nature of the VR serious game makes it a promising tool for practical clinical settings. It could serve as a potentially more acceptable method for routine cognitive screening and long-term monitoring in schizophrenia, thereby facilitating earlier identification of cognitive deficits and informing personalized rehabilitation strategies. Future research should further validate and optimize the ML models with larger, multicenter samples, explore the longitudinal use of the game for tracking cognitive change, and investigate its applicability across diverse clinical subgroups.

Acknowledgments

We thank the staff of the Mental Health Center of West China Hospital and all the participants for their assistance.

The authors declare the use of generative AI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to generative artificial intelligence (GenAI) tools under full human supervision: code optimization. The GenAI tool used was: DeepSeek. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Conflicts of Interest

The authors declare no financial competing interests. The authors developed the VR serious game system “Fruit Pioneer,” evaluated in this study, for academic research purposes. This constitutes a nonfinancial competing interest and has been fully disclosed. The authors confirm that this involvement did not influence the study design, data collection, analysis, or interpretation.

Abstract

Background: Digital health technologies increasingly use tablet-based cognitive assessments for children, yet interaction design choices can substantially influence cognitive load and measurement validity. Although cognitive load has been extensively studied in educational settings, its impact on patient-facing digital assessment tools for pediatric populations remains underexplored.

Objective: This study examined how the interaction format influences cognitive load and measurement validity in a tablet-based Stroop task for children, comparing text-based with color-based response selection to determine which format better supports valid attention assessment.

Methods: Using a within-subject design, 127 typically developing children (n=55, 43.3%, girls; n=72, 56.7%, boys) aged 6-12 (mean 9.15, SD 1.56) years were recruited via convenience sampling from local communities in the Republic of Korea. Participants completed both a text-based and a color-based Stroop task on a tablet. Cognitive load was indexed using prefrontal functional near-infrared spectroscopy (fNIRS), measuring functional connectivity (FC) and global network efficiency. Behavioral outcome measures included accuracy, reaction time, and the composite efficiency score. Clinical validity was assessed by correlating task performance with parent-reported attention problems using a standardized behavioral rating scale. General cognitive ability was controlled using a standardized intelligence measure. Condition differences were analyzed using paired-sample *t* tests (α=.05), clinical associations using Pearson correlations with Fisher *r*-to-*z* transformation, and predictor contributions using random forest regression.

Results: In the paired-sample *t* tests, the color-based format yielded significantly higher accuracy (0.91 vs 0.86; mean difference 0.05, 95% CI 0.03-0.08; t_{126}=3.81, Cohen *d*=0.34, *P*<.001), faster reaction times (1183 vs 1269 ms; mean difference −85.4 ms, 95% CI −107.2 to −63.5; t_{126}=−7.72, Cohen *d*=–0.69, *P*<.001), and superior composite performance (t_{126}=6.81, Cohen *d*=0.62, *P*<.001). Pearson correlations revealed that color-based performance was significantly associated with parent-reported attention problems (*r*=−0.20, 95% CI −0.37 to −0.03; *P*=.03), whereas text-based performance was not (*r*=−0.05, 95% CI −0.23 to 0.12;' *P*=.56); the Fisher *r*-to-*z* test indicated this difference was not statistically significant (*z*=1.54, *P*=.12). fNIRS-derived neural indices (ΔFC, global efficiency) did not differ significantly between conditions (*P*>.05). Random forest analyses indicated that after controlling for age and general cognitive ability, individual variations in prefrontal efficiency accounted for 40% to 44% of residual performance variance.

Conclusions: This study provides some of the first empirical evidence that the interaction format substantially influences task demands and measurement validity in pediatric digital assessments, extending cognitive load theory into digital health assessment design. Color-based response formats that minimize extraneous semantic processing yield superior performance and stronger clinical validity compared to text-based formats. These findings suggest that prioritizing response modalities aligned with children's developmental capabilities may improve the clinical utility of digital attention assessments.

Introduction

Digital health technologies have rapidly expanded in recent years [1], especially in mental health applications that offer both assessment and intervention capabilities [2-4]. One of the advantages driving this growth is accessibility: digital health tools can be accessed on demand through widely available consumer devices, such as tablets and smartphones [5,6]. However, this accessibility also presents a challenge. Because these tools are often designed for self-guided use on personal devices, sustained user engagement becomes critical for their effectiveness [7,8]. Without adequate engagement, users may discontinue assessments prematurely or fail to complete intervention protocols, undermining potential clinical benefits [9,10]. Consequently, strategies such as gamification, which incorporate game-like elements to enhance motivation and sustain participation [11], have emerged as important approaches in digital health applications [12]. Within this framework, specific design decisions, such as interaction formats, are important considerations, yet empirical evidence on how these decisions specifically impact clinical outcomes is still emerging [13,14].

Although the interaction format is often discussed in terms of usability and user experience, its implications extend beyond engagement alone. The way tasks are designed and presented directly influences the cognitive demands placed on users, which, in turn, affects both measurement accuracy and clinical validity [13]. For instance, the visual appearance of an avatar in a therapeutic virtual environment can shape user trust and therapeutic alliance [15], while real-time biofeedback mechanisms can simultaneously enhance motivation through gamification principles and improve clinical performance by enabling timely intervention [16,17]. However, design decisions can also degrade performance when they fail to account for the cognitive demands placed on users [18]. This is particularly critical when the target population includes individuals with limited cognitive resources, such as children or older adults, who are more vulnerable to the effects of extraneous cognitive demands [19-21]. In such cases, poorly calibrated design choices can introduce systematic bias, degrade measurement fidelity, and compromise the validity of clinical assessments [22].

Cognitive load, the mental effort required to process information and execute tasks [23,24], is substantially influenced by design choices. This relationship has been extensively studied in educational and e-learning contexts, where optimizing information presentation is essential for learning outcomes [25]. Research in this domain consistently demonstrates that appropriate modality selection and content structure reduce cognitive load and improve performance. For example, visual presentations combined with narration outperform voice-only formats, and temporally organized content enhances effectiveness in mobile learning [26,27]. These findings underscore that cognitive load is not solely determined by task content but also substantially shaped by how information is presented and how users interact with it [28,29]. Consequently, failing to optimize interaction formats in digital assessments may lead to “noise” in the data, where performance reflects interface-induced load rather than the target clinical construct. However, despite the clear relevance of these principles to digital health, empirical studies examining cognitive load in this domain have focused primarily on clinical workflows and professional users [30,31], while patient-facing assessment and intervention tools have received comparatively less attention. This gap is consequential because elevated cognitive load in assessment contexts can inflate error rates, slow response times, and reduce completion rates, thereby introducing confounding variables that mask a child’s true cognitive ability. Addressing this issue is therefore essential for designing digital assessment tools that are not only developmentally appropriate but also clinically valid, particularly for pediatric populations.

Building on this background, this study investigated how variations in the interaction format affect cognitive load and performance validity in a tablet-based Stroop task for children. The Stroop task, one of the most widely used paradigms for assessing selective attention and inhibitory control [32], provides an ideal model for examining how the interaction format influences cognitive load. In its classic form, participants name the ink color of a color word while ignoring its meaning, with performance typically faster and more accurate when color and meaning match (congruent trials) and slower with more errors when they conflict (incongruent trials) [33]. This performance difference reflects the cognitive effort required to resolve interference, making the paradigm particularly sensitive to design-induced variations in mental demands [34].

To investigate how these design variations affect both cognitive demands and measurement validity, we compared two response formats in a tablet-based Stroop task for children: selecting written color-word labels (text condition), which preserves semantic conflict, versus selecting color patches (color condition), which eliminates semantic processing demands. This distinction is particularly relevant for pediatric populations, in whom reading is not yet fully automated and text-based response options may conflate reading fluency with inhibitory control [35]. Cognitive load was measured using prefrontal functional near-infrared spectroscopy (fNIRS), a noninvasive neuroimaging method well suited for monitoring attentional effort in interactive tasks with children, alongside behavioral measures of accuracy and reaction time [36].

Through this approach, the study addressed two primary research questions:

- Does the interaction format (text-based vs color-based response selection) affect cognitive load and behavioral performance?

XSL•FO
RenderX

- If so, do these performance differences translate into differential clinical validity, as measured by associations with standardized attention assessments?

By addressing these questions, the study aimed to underscore the importance of interaction format calibration in pediatric digital assessments. In addition, it aimed to provide empirical guidance for designing Stroop-based attention tools that are both developmentally appropriate and clinically valid for children.

Methods

Participants

Inclusion and Exclusion Criteria

The study recruited typically developing children aged 6-12 years, a developmental period during which attentional control is maturing and cognitive resources remain limited compared to adults [37]. Inclusion criteria included (1) no history of psychiatric, neurological, or developmental disorders; (2) no visual or color vision impairments; and (3) sufficient language and communication abilities to follow instructions and complete the task. Children who did not meet any of these criteria were excluded from participation.

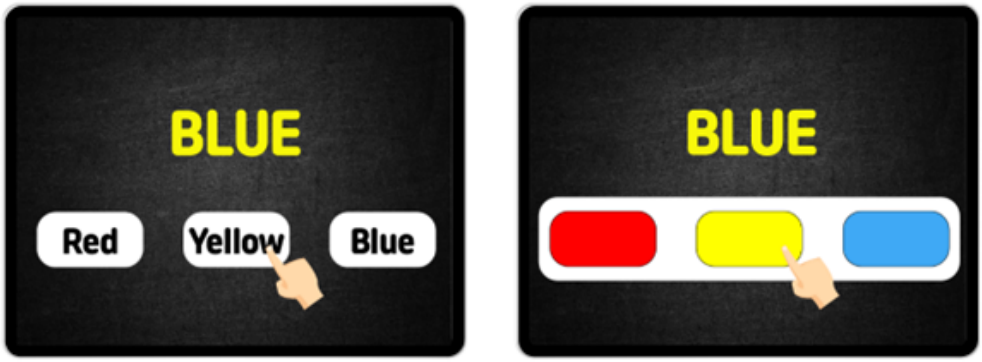
Sampling Procedures

Participants were recruited through convenience sampling via local community advertisements in the Republic of Korea between January and September 2023. A total of 137 children were initially enrolled. Of these, 7 (5.1%) were excluded due to technical issues during data acquisition (eg, cloud transfer failure, fNIRS calibration failure), and 3 (2.2%) withdrew during the session. The final analytic sample comprised 127 (92.7%) children who participated in this within-subjects comparison design.

Participant Characteristics

Typically developing children were selected to establish a baseline effect of the interaction format on cognitive load and task performance without the confounding influences of clinical symptoms [37]. This sample ensured sufficient developmental readiness to perform tablet-based tasks, while capturing meaningful individual variation in attentional functioning.

Sample Size, Power, and Precision



The sample size was determined by the available participant pool during the recruitment period. A sensitivity analysis (paired-sample t test, 2-tailed, α=.05, power=0.80, n=127) indicated that the study was powered to detect effects of Cohen $d \geq 0.25$, corresponding to small-to-medium effects. This threshold is below or comparable to effect sizes typically reported in pediatric Stroop studies [38], suggesting adequate statistical power for the primary within-subject comparisons.

Task and Procedure

Stroop Task Design

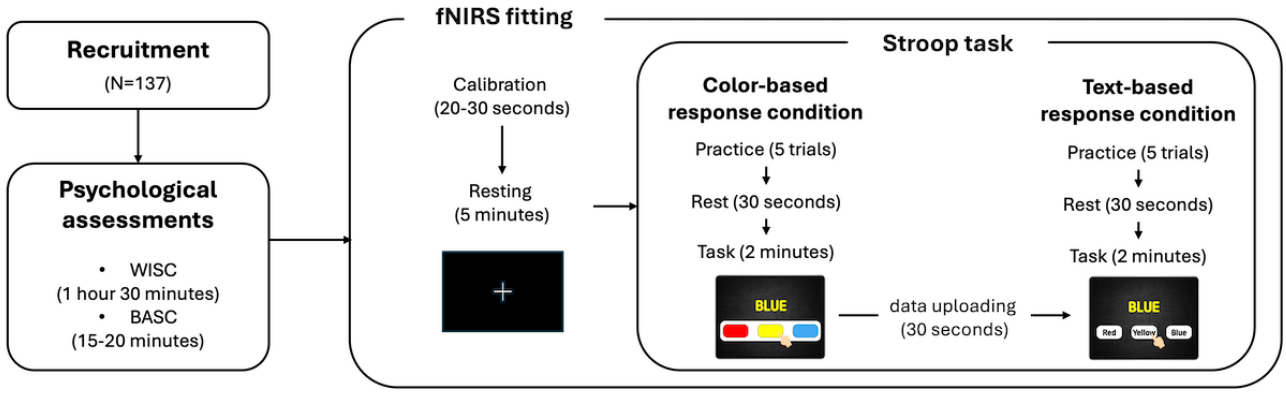
The experiment was conducted on a tablet (Samsung Galaxy Tab Advanced2) and implemented two Stroop-based tasks that systematically manipulated the interaction format (Figure 1). Both tasks presented participants with color words displayed in incongruent ink colors (eg, the word “blue” written in yellow ink), requiring participants to identify the ink color while ignoring the word meaning. This core Stroop conflict was preserved across both conditions to maintain sensitivity to attentional control and inhibitory processes.

Figure 1. Stroop task conditions used in a within-subject comparison of interaction formats among 127 typically developing children aged 6-12 years. (Left) Text-based response condition, where participants identified the ink color by selecting a written label. (Right) Color-based response condition, where participants identified the ink color by selecting the corresponding color patch.

In the *text condition*, participants identified the ink color by selecting from among written color-word labels (eg, “Yellow,” “Red,” “Blue”). This format preserved the traditional Stroop paradigm and maintained the semantic conflict central to clinical and attentional assessment contexts [39,40]. The automatic tendency to process word meaning directly competed with the controlled requirement to report the ink color, requiring active suppression of irrelevant semantic processing and elevating cognitive load through inhibitory control and conflict resolution [41-43].

In the *color condition*, participants identified the ink color by selecting a color patch instead of a written label. This format retained the core Stroop conflict, as the stimulus still presented a mismatch between word meaning and ink color. However, it eliminated the additional layer of interference arising from competing verbal response options [44]. By removing word-word competition at the response stage, this condition aimed to reduce unnecessary cognitive demands, while preserving the attentional control requirements central to the Stroop effect [45,46]. This manipulation reflects how interface elements, such as response modality, can be deliberately

XSL•FO
RenderX



adjusted to calibrate cognitive demands for specific populations in digital assessment contexts. Within the cognitive load theory framework [24], this design reflects the distinction between intrinsic and extraneous loads. The core Stroop conflict between word meaning and ink color constitutes the intrinsic load, which was held constant across both conditions. The response format manipulation targeted the extraneous load: the text condition introduced additional semantic processing at the response stage, whereas the color condition eliminated this secondary interference.

To minimize extraneous influences unrelated to interaction format manipulation, both conditions used identical visual presentation parameters (font size, button size, layout) and response mechanics (touch-based selection). The two conditions differed only in the format of response options provided to participants.

Experimental Protocol

All participants completed the study following a standardized protocol, as shown in Figure 2. Upon arrival, participants first completed standardized assessments of cognitive ability (intelligence quotient [IQ]) and behavioral attention. These assessments characterized individual differences in cognitive ability and attentional functioning, allowing control for these factors in subsequent analyses.

Figure 2. Overview of the experimental procedure for a within-subject comparison of two Stroop task response formats in 127 typically developing children aged 6-12 years. Participants completed standardized cognitive (K-WISC-V) and behavioral (BASC-2) assessments, followed by fNIRS device fitting, a 5-minute resting-state baseline, and two Stroop task conditions (color-based response and then text-based response, 45 trials each) separated by a 30-second rest interval. BASC-2: Behavior Assessment System for Children, Second Edition; fNIRS: functional near-infrared spectroscopy; K-WISC-V: Korean version of the Wechsler Intelligence Scale for Children, Fifth Edition.

Following the assessments, participants were fitted with the fNIRS device, and a brief calibration was performed to ensure signal quality. A 5-minute resting-state baseline was then recorded while participants fixated on a white cross presented on a black background under quiet, dimly lit conditions. This baseline served as a reference for subsequent task-related neural activity.

After the baseline recording, participants performed both Stroop tasks. The color condition was administered first, followed by the text condition. Although randomization is standard, this fixed order was intentionally chosen to provide a scaffolding effect for the pediatric participants [47], ensuring task comprehension with the more intuitive format before introducing the higher linguistic demand of the text condition. To account for potential order effects, we incorporated a rest period and treated performance as a within-subject comparison.

Each task began with five practice trials to ensure comprehension. Participants could repeat the practice block if they required additional familiarization. Following a 30-second rest period, the main task block was presented, consisting of 45 trials per condition. Accuracy (correct/incorrect) and reaction time (time from stimulus onset to response) were recorded for each trial. Trial presentation was self-paced, with the next trial appearing immediately after a response was registered. A 30-second interval separated the two task conditions to allow data uploading and provide a brief rest.

All procedures were conducted in a quiet, controlled laboratory environment to minimize distractions and ensure consistent conditions across participants. The entire session, including assessments, device setup, baseline recording, and task performance, lasted approximately 90 minutes.

Data Acquisition

Psychometric Assessments

To control for individual differences and ensure reliable interpretation of task performance, multiple standardized measures were used.

General cognitive ability was assessed using the Korean version of the Wechsler Intelligence Scale for Children, Fifth Edition (K-WISC-V) [48], a widely used and validated measure of intelligence in children [49]. Administration was carried out by a licensed clinical psychologist following standardized procedures. The assessment yielded five primary index scores: the Verbal Comprehension Index (VCI), Visual Spatial Index (VSI), Fluid Reasoning Index (FRI), Working Memory Index (WMI), and Processing Speed Index (PSI). From these indices, a full-scale intelligence quotient (FSIQ) score was derived, providing a comprehensive measure of general intellectual functioning. IQ assessment was included to characterize the cognitive profile of the sample and to control for potential variance in Stroop performance.

Attention-related functioning was evaluated using the Korean version of the Behavior Assessment System for Children,

XSL•FO
RenderX

Second Edition (BASC-2) [50], a comprehensive and validated measure of children's behavioral and emotional functioning [51]. The parent-report form was used to obtain ecologically valid observations of children's everyday attentional behaviors. The BASC-2 consists of 160 items rated on a 4-point Likert scale ("never" to "almost always"), yielding composite and subscale scores. For this analysis, we focused on the Attention Problems subscale, which captures tendencies such as distractibility and difficulty sustaining focus, providing a behavioral index of attentional control in real-world contexts [52]. In contrast to the Stroop task, which reflects laboratory performance, BASC-2 ratings capture everyday attentional functioning, providing a complementary perspective for evaluating the clinical relevance of different interaction formats. This dual perspective allowed examination of whether different interaction formats show differential associations with standardized measures of attention, serving as a criterion for evaluating clinical relevance. T scores from the Attention Problems subscale as the primary indicators of behavioral attentional functioning in all analyses.

Neuroimaging

Cortical activation during task performance was measured using fNIRS, a noninvasive neuroimaging method that detects changes in oxygenated and deoxygenated hemoglobin concentrations in the cortex. fNIRS was selected for its robustness against motion artifacts, ecological suitability for interactive tablet-based tasks, and safety for pediatric populations [53,54].

The NIRSIT Lite device (OBELAB) was used, providing 15 measurement channels covering the prefrontal cortex (PFC). The PFC is closely associated with attentional control, working memory, and inhibitory processes underlying cognitive load [55,56]. The device operates with near-infrared light at wavelengths of 780 and 850 nm, with intensities below 5 mW to ensure participant safety. The optode array was specifically designed to accommodate the smaller head sizes typical of children, with source-detector distances of ~3 cm to maximize cortical sensitivity, while maintaining signal quality.

The device was secured on participants' foreheads using an adjustable headband, positioned to cover bilateral prefrontal regions. Following placement, a brief calibration procedure was performed to verify signal quality across all channels. Signal quality was evaluated using a signal-to-noise (SNR) threshold of 30 dB; channels falling below this threshold were to be excluded from analysis. All channels met the quality threshold across all participants. At the time point level, data points with SNR *z* scores exceeding 2.58 were identified as outliers and removed prior to connectivity computation. Continuous recording of hemodynamic responses was maintained throughout the resting-state baseline and both Stroop task conditions, enabling quantification of task-related prefrontal activation as an objective index of cognitive effort. Data were sampled at 8.138 Hz and stored for offline preprocessing and analysis.

Analytic Strategy

Behavioral Data

Data from the paper-based assessments (K-WISC-V and BASC-2) were scored according to the standardized procedures provided in each manual. For BASC-2, T scores from the Attention Problems subscale were used as indicators of behavioral attentional functioning. Behavioral performance on the Stroop task was quantified using accuracy (proportion of correct responses) and reaction time (mean response latency in milliseconds) for each condition. To account for differences in trial completion and speed-accuracy trade-offs, a composite performance score was calculated as follows:

where ACC refers to accuracy and RT refers to reaction time.

This composite index is conceptually equivalent to the Rate Correct Score [57], providing an integrated measure of task efficiency that accounts for potential speed and accuracy trade-offs. Paired-sample *t* tests were conducted to compare accuracy, reaction time, and composite performance between the color and text conditions, as all participants completed both tasks. Effect sizes were calculated using Cohen d for paired samples.

Neuroimaging Data

Functional connectivity (FC) and global efficiency were selected as neural indices because the study aimed to assess PFC network–level organization during sustained task performance rather than localized hemodynamic responses. Global efficiency provides an index of how efficiently information is integrated across the PFC network and has been shown to relate to the cognitive load burden in fNIRS studies [58]. Prefrontal fNIRS data were preprocessed to obtain estimates of the FC. Resting-state connectivity was computed as Pearson correlation coefficients between all pairs of fNIRS channels and then transformed using Fisher *Z* transformation to stabilize variance and approximate normality [59]. Prior to connectivity analysis, raw optical density data were motion-corrected using a moving SD approach and band-pass-filtered (0.005-0.1 Hz) to remove physiological noise, following standard fNIRS preprocessing procedures [60]. Task-related connectivity during each Stroop task was calculated using the same procedure. Cognitive activation was operationalized as the difference between task-related and resting-state connectivity as follows:

This subtraction isolates connectivity changes specifically attributable to task engagement, controlling for baseline individual differences in PFC network strength. In addition to connectivity strength, global efficiency was computed from task-related connectivity matrices using graph-theoretical analysis. Global efficiency is defined as the average inverse shortest path length across nodes in a network and provides an index of how efficiently information can be exchanged across the PFC network [61]. Higher global efficiency indicates more economical neural organization, whereas lower efficiency suggests greater cognitive demands and less efficient processing [58]. Together, ΔFC and global efficiency provided complementary measures of PFC network dynamics during task performance. To examine condition differences in these neural

XSL•FO
RenderX

indices, paired-sample *t* tests were conducted comparing ΔFC and global efficiency between the color and text conditions.

Clinical Correlation Analysis

To evaluate the clinical relevance of each interaction format, Pearson correlations were computed between BASC-2 Attention Problems T scores and task performance indices (accuracy, reaction time, composite performance) in each condition. Fisher *r*-to-*z* transformation was applied to test whether correlation coefficients differed significantly between the two conditions. Stronger correlations with standardized behavioral measures indicated greater clinical validity for a given interaction format.

Predictive Modeling

Random forest regression models were used to examine the relative contribution of behavioral, neural, and psychometric measures in predicting Stroop task performance. A random forest was selected for several reasons. First, the dataset included heterogeneous predictors spanning behavioral, neural, and psychometric domains, which are unlikely to conform to linear assumptions [62]. Second, a random forest offers stability with a modest sample size by aggregating predictions across multiple decision trees through bootstrap resampling, reducing overfitting risk [63]. Third, a random forest provides variable importance estimates, enabling assessment of the relative influence of different predictor types [64].

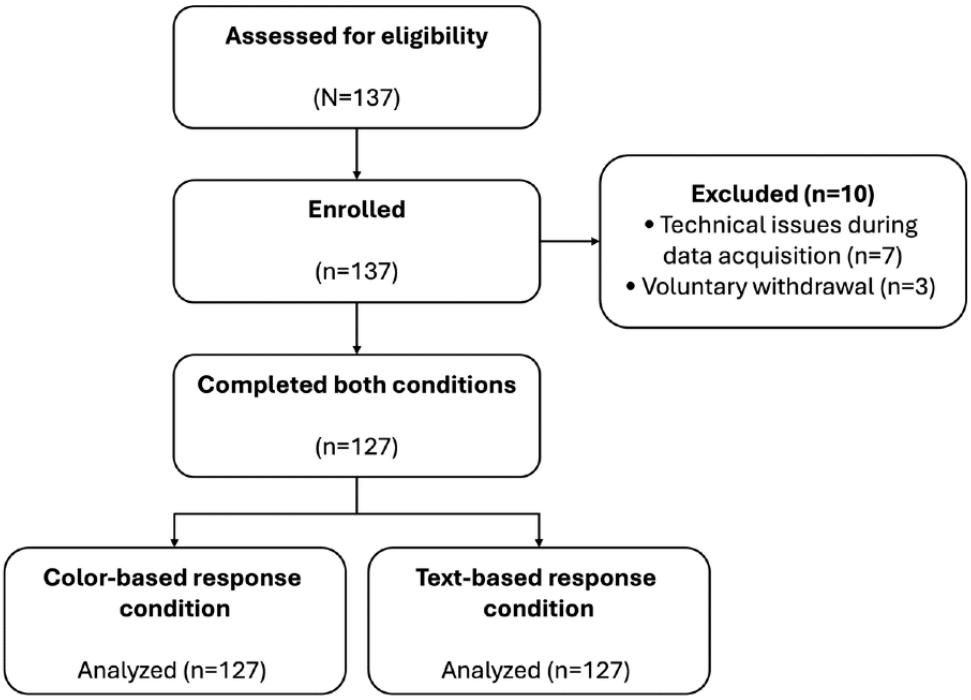
All predictor variables, including task performance measures (accuracy, reaction time, composite performance), neural indices (ΔFC, global efficiency), and psychometric scores (FSIQ, BASC-2 Attention Problems T scores), were entered into the models. The models were fitted separately for each condition (color and text) to examine whether the importance of neural versus behavioral predictors varies across interaction formats.

To control for potential confounding by age and general cognitive ability, additional models were fitted using residualized outcome measures. Specifically, age and the FSIQ were regressed out of the composite performance measure using linear regression, and the resulting residuals were used as dependent variables in supplementary random forest models. This approach ensured that observed predictor effects were not attributable to basic demographic or intellectual factors.

Model performance was evaluated using the out-of-bag (OOB) prediction error, which provides an unbiased estimate of generalization performance without requiring a separate validation set. Variable importance was assessed using the mean decrease in accuracy, which quantifies the reduction in model accuracy when a given predictor is randomly permuted. All random forest models were implemented using *scikit-learn* in Python with 500 trees with default hyperparameters (mtry=p/3 for regression, where p is the number of predictors).

Ethical Considerations

All procedures involving human participants were conducted in accordance with the ethical standards of the Institutional Research Committee and with the Declaration of Helsinki. The study protocol was reviewed and approved by the Institutional Review Board (IRB) of the Korea Brain Research Institute (approval number: KBRI-202103-HR-02). Written informed consent was obtained from the legal guardians of all child participants prior to enrollment, and verbal assent was obtained from the children using developmentally appropriate language. Participants and their families were informed of their right to withdraw from the study at any time without penalty. Guardians received KRW 30,000 (~US $22) as compensation for participation and transportation expenses, and child participants received a small gift valued at ~KRW 20,000 (~US $15). All collected data were deidentified and stored securely to ensure confidentiality and privacy, and no identifiable images of participants were collected.



Results

Sample Characteristics and Descriptive Statistics

The flow of participants through each stage of the study is depicted in Figure 3. The final sample comprised 127 children (n=55, 43.3%, girls; n=72, 56.7%, boys; mean age 9.15, SD 1.56 years, range 6-12 years).

XSL•FO
RenderX

Figure 3. Participant flowchart depicting enrollment, exclusions, and final analytic sample in a within-subject comparison of two Stroop task response formats (color-based vs text-based response) among typically developing children aged 6-12 years. Of 137 children assessed for eligibility, 127 (92.7%) completed both tasks and were included in the final analyses.

Detailed descriptive results are provided in Table 1. All primary analysis variables had complete data for all participants; no missing data imputation was required. On the K-WISC-V, the mean FSIQ was 105.71 (SD 12.08), with subscale scores within the normative range. The Attention Problems subscale of the BASC-2 yielded a mean T score of 46.76 (SD 9.15), also within the normative range.

[a]BASC-2: Behavior Assessment System for Children, Second Edition.

[b]Not applicable.

[c]FSIQ: full-scale intelligence quotient.

[d]K-WISC-V: Korean version of the Wechsler Intelligence Scale for Children, Fifth Edition.

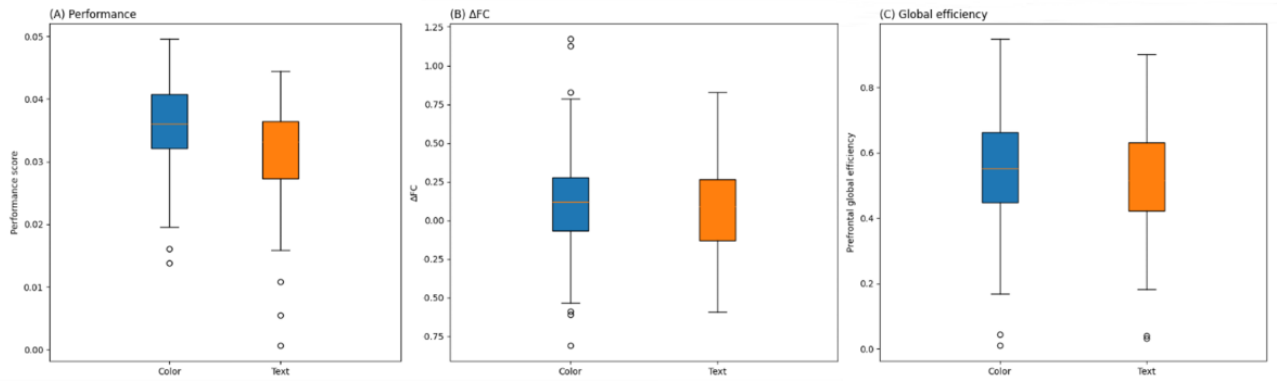
[e]VCI: Verbal Comprehension Index.

[f]VSI: Visual Spatial Index.

[g]FRI: Fluid Reasoning Index.

[h]WMI: Working Memory Index.

[i]PSI: Processing Speed Index.



[j]FC: functional connectivity.

In the Stroop task, accuracy was higher in the color condition (mean 0.91, SD 0.09) than in the text condition (mean 0.86, SD 0.16). Reaction times were also shorter in the color condition (mean 1183.21, SD 146.78 ms) compared to the text condition (mean 1268.56, SD 145.18 ms). Composite performance was correspondingly greater in the color condition (mean 0.036, SD 0.007) than in the text condition (mean 0.031, SD 0.008), reflecting more efficient task execution overall.

XSL•FO
RenderX

Neuroimaging measures derived from prefrontal fNIRS data showed parallel patterns. Task-related FC (Fisher *Z* transformed) was numerically higher in the color condition (mean 0.81, SD 0.28) than in the text condition (mean 0.76, SD 0.24). When resting-state connectivity was subtracted to isolate task-specific change ΔFC, values were again greater in the color condition (mean 0.12, SD 0.33) than in the text condition (mean 0.07, SD 0.29). Prefrontal global efficiency was modestly higher in the color condition (mean 0.55, SD 0.17) than in the text condition (mean 0.53, SD 0.17). All three neural indices consistently showed numerically higher values in the color condition. For visualization of distributional patterns across conditions, boxplots of performance, ΔFC, and prefrontal global efficiency are shown in Figure 4.

Figure 4. Boxplots comparing Stroop task indices between color-based and text-based response formats in 127 typically developing children aged 6-12 years (within-subject design). (A) Performance score, (B) task-evoked connectivity change (ΔFC), and (C) prefrontal global efficiency. FC: functional connectivity.

Condition Comparisons and Correlations

Paired-sample *t* tests indicated significant condition differences for all three behavioral measures. Accuracy was significantly higher in the color condition (t_{126}=3.81, *d*=0.34, 95% CI 0.03-0.08; *P*<.001). Reaction time was significantly shorter in the color condition (t_{126}=–7.72, *d*=–0.69, 95% CI −107.2 to −63.5; *P*<.001). Composite performance was significantly better in the color condition (t_{126}=6.81, *d*=0.62, 95% CI 0.003-0.006; *P*<.001). Effect sizes ranged from medium to large, suggesting that the interaction format had a more pronounced impact on manifest behavior than on observable neural network changes within this sample size. In contrast, neural indices showed no reliable differences between conditions. The task-related FC did not differ significantly (t_{126}=1.65, *d*=0.15, 95% CI −0.01 to 0.10; *P*=.10). Similarly, ΔFC (t_{126}=1.65, *d*=0.15, 95% CI −0.01 to 0.10; *P*=.10) and prefrontal global efficiency (t_{126}=1.52, *d*=0.14, 95% CI −0.01 to 0.05; *P*=.13) showed no significant differences, although all trended in the direction of higher values in the color condition.

Correlational analyses with BASC-2 Attention Problems T scores, a validated behavioral measure of attentional difficulties, showed that higher scores (indicating more attention problems) were associated with lower composite performance in the color condition (*r*=−0.20, 95% CI −0.37 to −0.03; *P*=.03), whereas the corresponding performance in the text condition was not significantly related (*r*=−0.05, 95% CI −0.23 to 0.12; *P*=.56). Fisher *r*-to-*z* transformation indicated that this difference approached but did not reach conventional significance (*z*=1.54, *P*=.12). Neural indices showed weak and nonsignificant correlations with attention problems in both conditions: color ΔFC (*r*=−0.07, 95% CI −0.24 to 0.10; *P*=.42), color global efficiency (*r*=−0.05, 95% CI −0.23 to 0.12; *P*=.55), text ΔFC (*r*=–0.14, 95% CI −0.31 to 0.03; *P*=.10), and text global efficiency (*r*=0.03, 95% CI −0.14 to 0.20; *P*=.73). Complete correlation coefficients are provided in Table 1.

Random Forest Feature Importance

To examine which features contributed to individual differences in performance within each interaction format, we estimated contributions using condition-specific random forest models with permutation-based variable importance (reported as normalized percentages; see the *Methods* section for details). Variables with higher importance scores contributed more to reducing the prediction error across decision trees.

In the color condition, age showed the largest contribution (58.86%), followed by cognitive measures including the PSI (17.06%) and the FSIQ (10.25%). Smaller contributions came from BASC-2 Attention Problems (4.79%), gender (4.75%), and neural indices (ΔFC: 2.82%; global efficiency: 1.47%). The model achieved a cross-validated R^2 of 0.091, corresponding to ΔR^2=0.100 relative to a mean-only baseline. Full importance values are provided in Table 2.

Age (years)	0.375 (0.184)	73.21
PSI (K-WISC-V)	0.044 (0.065)	8.53
ΔFC	0.033 (0.024)	6.34
Global efficiency (prefrontal)	0.023 (0.008)	4.40
Gender	0.018 (0.015)	3.51
FSIQ (K-WISC-V)	0.014 (0.044)	2.78
Attention problems (BASC-2)	0.004 (0.018)	0.77
WMI[j] (K-WISC-V)	0.002 (0.039)	0.47

[a]Strict models include all demographic, psychometric, and neural predictors.

[b]Features are ranked by normalized importance.

[c]$Mean_{perm}$: mean permutation importance across bootstrap samples. Higher values indicate greater contribution to model prediction.

[d]Normalized percentages add up to 100% within each condition.

[e]PSI: Processing Speed Index.

[f]K-WISC-V: Korean version of the Wechsler Intelligence Scale for Children, Fifth Edition.

[g]FSIQ: full-scale intelligence quotient.

[h]BASC-2: Behavior Assessment System for Children, Second Edition.

[i]FC: functional connectivity.

[j]WMI: Working Memory Index.

In the text condition, age again dominated (73.21%), with contributions from the PSI (8.53%), neural indices (ΔFC: 6.34%; global efficiency: 4.40%), gender (3.51%), and the FSIQ (2.78%). BASC-2 Attention Problems (0.77%), and the WMI (0.47%) contributed minimally. The model achieved a cross-validated R^2 of 0.233, corresponding to ΔR^2=0.274 relative to baseline.

Because age and the FSIQ contributed strongly in the original models, we conducted supplementary analyses using residualized outcome measures. Age and the FSIQ were first regressed out of composite performance (color: R^2=0.271; text: R^2=0.413), and the resulting residuals were used as dependent variables in new random forest models with neural indices and BASC-2 Attention Problems as predictors.

In the residualized color condition model, neural indices emerged as the largest contributors: global efficiency (39.79%) and ΔFC (35.75%), followed by BASC-2 Attention Problems (24.46%). In the residualized text condition model, a similar pattern emerged: global efficiency (43.60%), ΔFC (33.02%), and BASC-2 Attention Problems (23.37%). Residualized models achieved cross-validated R^2 values of 0.113 (color) and 0.202 (text), indicating that after controlling for age and general cognitive ability, neural and behavioral attention measures accounted for 11% to 20% of the remaining variance in performance. Complete residualized importance values are provided in Table 3.

Table 3. Random forest permutation importance by condition for typically developing children (n=127) aged 6-12 years completing two Stroop tasks (within-subject design; residualized models[a], with age and FSIQ[b] regressed out).[c]

Condition and features	$Mean_{perm}$[d] (SD) across validation folds	Normalized importance score (%)[e]
Color-based response		
Global efficiency (prefrontal)	0.605 (0.044)	39.79
ΔFC[f]	0.543 (0.050)	35.75
Attention problems (BASC-2[g])	0.372 (0.038)	24.46
Text-based response		
Global efficiency (prefrontal)	0.640 (0.067)	43.60
ΔFC	0.484 (0.048)	33.02
Attention problems (BASC-2)	0.343 (0.037)	23.37

[a]Residualized models control for age and the full-scale intelligence quotient.

[b]FSIQ: full-scale intelligence quotient.

[c]Features are ranked by normalized importance.

[d]$Mean_{perm}$: mean permutation importance across bootstrap samples. Higher values indicate greater contribution to model prediction.

[e]Normalized percentages add up to 100% within each condition.

[f]FC: functional connectivity.

[g]BASC-2: Behavior Assessment System for Children, Second Edition.

Discussion

Principal Findings

This study examined how the interaction format influences cognitive load and measurement validity in a tablet-based Stroop task for children. Using within-subject comparisons between color-based and text-based response formats, combined with prefrontal fNIRS and clinical behavioral measures, we addressed two primary questions: whether the interaction format affects cognitive load and performance and whether performance differences translate into differential clinical validity.

Behavioral results clearly demonstrated the effects of interaction formats. The color-based response condition yielded significantly faster responses, higher accuracy, and better composite performance compared to the text-based response condition (all $P<.001$, with medium-to-large effect sizes). Critically, color-based performance showed a significant correlation with parent-reported attention problems (BASC-2; $r=-0.20$, $P=.03$), whereas text-based performance did not ($r=-0.05$, $P=.56$). Although the relatively wide CIs suggest that the precise magnitude of these associations warrants replication, this differential pattern indicates that the color format showed a pattern more consistent with clinical validity by better isolating attentional control from other cognitive demands. Random forest analyses further revealed that after controlling for age and general cognitive ability, neural indices of prefrontal efficiency (global efficiency, ΔFC) emerged as the dominant predictors of individual performance differences in both formats, accounting for ~35% to 44% of residual variance.

The observed performance differences are consistent with the intended manipulation of cognitive load. The text-based response format required dual semantic processing: participants had to ignore the word meaning while simultaneously mapping the ink color to a written label [33]. In contrast, the color-based response format preserved the core Stroop conflict while eliminating competing verbal response options, thereby reducing extraneous cognitive load [45]. Consistent with this interpretation, the color condition showed not only superior behavioral performance but also descriptively higher prefrontal efficiency (ΔFC, global efficiency). Although these neural differences did not reach statistical significance, such small-to-moderate effects are consistent with the typical magnitude observed in fNIRS research with developmental populations [65]. In addition, PFC maturation continues throughout childhood, and the developing PFC networks in our sample may not yet exhibit sufficiently stable connectivity patterns to produce detectable condition-level differences [66]. Furthermore, because both conditions shared the core Stroop conflict and differed only in the response format, the neural workload differences may have been too subtle to detect at the group level.

It is worth noting that modifying the response format may have also altered the relative contribution of different cognitive processes at the response selection stage. However, the preservation of the core Stroop conflict at the stimulus level and the significant association between color-based performance and clinical attention measures suggest that the fundamental inhibitory control construct was maintained across both formats. Moreover, color-based formats may be especially appropriate for children in early literacy stages, for whom text-based responses could introduce construct-irrelevant variance related to reading ability rather than attentional control [35].

As an exploratory analysis, random forest analyses provided a complementary view of how individual differences relate to task performance in each format. In the strict models, age had the largest contribution in both formats, and cognitive measures, such as the PSI and FSIQ, accounted for much of the remaining

XSL•FO
RenderX

signal, with neural features (prefrontal global efficiency, ΔFC) contributing smaller percentages (Table 2). Because age and IQ dominated these models, we conducted residualized analyses that removed their variance from the outcome prior to modeling. In these residualized models, neural indices carried most of the remaining predictive signal in both formats, with BASC-2 Attention Problems accounting for the remainder (Table 3).

These findings highlight two key points. First, the higher contribution of BASC-2 Attention Problems in the color condition is consistent with the stronger correlation observed between color-based performance and the clinical attention benchmark, suggesting that the lower-load interface better isolates attentional control from other developmental influences. Second, the dominant role of age and IQ in the strict models underscores the need to treat these variables as covariates in attentional research, echoing prior findings that developmental and general cognitive factors exert a substantial influence on performance [35,67]. Notably, however, the relative contribution of age was smaller in the color format (58.86%) than in the text format (73.21%). This pattern suggests that reducing semantic interference was associated with lower cognitive load indicators and a smaller relative contribution of developmental differences dominating performance, thereby providing a clearer assessment of attentional control.

At the same time, format-specific nuances emerged that distinguished average performance from individual variability. In terms of mean values, both ΔFC and global efficiency were descriptively higher in the color condition, which is consistent with more efficient prefrontal organization when cognitive demands are lower [61]. However, random forest analyses revealed a complementary pattern: in the text condition, individual differences in these same neural indices showed higher predictive importance, indicating that variability in neural efficiency became a stronger determinant of performance under elevated cognitive load.

This pattern reflects two distinct aspects of neural function. First, the color format was associated with descriptively higher average neural efficiency across all children, consistent with reduced cognitive demands. Second, the text format was associated with a greater role of individual neural capacity. When semantic interference increased, the children's ability to maintain efficient prefrontal processing became more critical for successful performance. This aligns with cognitive load theory, specifically the reduction in extraneous load, while preserving intrinsic task demands, which posits that when extraneous demands are high, individual capacity for managing cognitive resources becomes a limiting factor [24]. Prior evidence supports this interpretation, showing that elevated cognitive load disrupts inhibitory processing and exacerbates individual differences in performance [68].

The relatively modest cross-validated R^2 values (modest cross-validated performance in residualized models) reflect the inherent complexity of predicting individual performance from neural and psychometric measures alone. These models were designed to estimate the relative contribution of heterogeneous features rather than to achieve precise behavioral forecasting [69]. From this perspective, the key insight is not the absolute predictive accuracy but rather the shift in variable importance: neural indices became dominant predictors once age and general cognitive ability were controlled, accounting for 35% to 44% of residual variance. This underscores that PFC network efficiency captures performance variance distinct from broader developmental and intellectual factors.

Taken together, these findings have direct implications for the design of digital assessment tools for children. For clinical diagnostic guidelines, age-based normative standards should serve as a primary framework, given the dominant role of age in predicting performance. However, age-based norms and interface optimization are complementary: although norms ensure appropriate score interpretation across developmental stages, optimized response formats can reduce construct-irrelevant variance and improve measurement precision at every age level. The observation that the interaction format influences behavioral performance and clinical validity, with suggestive trends in neural efficiency, underscores the need to explicitly consider cognitive load when designing Stroop-based assessments. Specifically, reducing extraneous semantic demands through color-based response formats may enhance both measurement accuracy and ecological validity in pediatric populations.

Limitations

This study has several limitations. First, although the within-subject design controlled for stable individual differences, the fixed task order (color followed by text) introduces the possibility of practice or fatigue effects. However, practice effects would be expected to benefit the second condition, potentially reducing rather than inflating the observed differences. The fact that the color condition showed superior performance despite being administered first suggests that the format effects were robust to any potential order confounds. Second, the sample comprised typically developing children aged 6-12 years, limiting the generalizability to broader developmental stages and clinical populations. Third, the neural feature set was necessarily coarse, relying on global efficiency and condition-level ΔFC; finer-grained metrics, such as event-locked or channel-specific analyses, may offer greater sensitivity. Finally, inferences about feature contributions relied on random forest models with modest predictive performance (R^2=9%-23%). These results should be regarded as exploratory estimates of relative importance rather than robust predictive models. Nonetheless, they provide a valuable starting point for understanding the complex interplay between interface design and neurocognitive function in children.

Future Directions

Future work should (1) counterbalance the task order and include repeated sessions to assess reliability; (2) extend the age range and incorporate clinical subgroups to evaluate external validity; (3) use more sensitive neural measures, including time-resolved connectivity and channel-specific analyses; and (4) apply mediation or structural equation models in preregistered analyses to formally test whether neural indices statistically account for format-related performance differences.

XSL•FO
RenderX

Conclusion

The findings of this study demonstrate that the interaction format influences both cognitive load and measurement validity in tablet-based Stroop assessments for children. Color-based response options, which reduce extraneous semantic processing demands, yield better behavioral performance and stronger correlations with clinical attention measures compared to text-based options. Random forest analyses further revealed that neural indices of prefrontal efficiency become the dominant predictors of individual differences once age and general cognitive ability are controlled.

These results underscore the importance of interaction format calibration in pediatric digital assessments. To the best of our knowledge, this study provides some of the first empirical evidence directly comparing how the response format affects both neural indices of cognitive load and clinical validity in a pediatric sample, extending cognitive load theory from educational settings into digital health assessment design. As digital cognitive assessments become more prevalent in research and clinical settings, careful attention should be paid to how interface design shapes cognitive load for ensuring that these tools are both developmentally appropriate and clinically valid. For Stroop-based attention assessments in children, this work offers initial guidance: prioritizing response formats that minimize extraneous cognitive demands may enhance both measurement fidelity and clinical utility.

Abstract

Background: Attention-deficit/hyperactivity disorder (ADHD) is a common neurodevelopmental disorder in children, characterized by inattention, hyperactivity, and impulsivity that significantly disrupt daily functioning. Comprehensive ADHD assessment requires multimethod and multi-informant evaluation, and objective attention measures can complement this process. Serious game–based assessments may further support this process by combining structured task mechanics and dynamic audiovisual guidance in a child-oriented digital environment.

Objective: This study aimed to develop and validate Attention Robots, a serious game designed for assessing behavioral attention indicators in children and adolescents. The goal was to examine whether its outputs corresponded with indicators from the widely used D2-R Test of Attention as preliminary evidence of convergent validity.

Methods: In this preliminary cross-sectional convergent validation study, 58 participants (34 male and 24 female individuals) aged 6-18 years, recruited through clinical referral and community sources, completed Attention Robots followed by the D2-R test. The original group variable, assigned by the project psychologists, identified 19 participants in the experimental group and 39 participants in the control group. Attention Robots presents timed rows of robot stimuli and asks participants to identify and select predefined target robots. Spearman and Pearson correlations compared working speed, omissions, commissions, concentration, and precision across both instruments.

Results: Primary cross-test correlations were positive. Spearman correlations were observed for working speed (ρ=0.905, 95% CI 0.84-0.94; *P*<.001), omissions (ρ=0.333, 95% CI 0.08-0.54; *P*=.01), commissions (ρ=0.496, 95% CI 0.27-0.67; *P*<.001), concentration (ρ=0.926, 95% CI 0.88-0.96; *P*<.001), and precision (ρ=0.607, 95% CI 0.41-0.75; *P*<.001). Pearson correlations showed a similar pattern for working speed (r=0.911, 95% CI 0.85-0.95; *P*<.001), omissions (r=0.278, 95% CI 0.02-0.50; *P*=.04), commissions (r=0.396, 95% CI 0.15-0.59; *P*=.002), concentration (r=0.922, 95% CI 0.87-0.95; *P*<.001), and precision (r=0.574, 95% CI 0.37-0.72; *P*<.001). These findings support preliminary convergent correspondence between corresponding behavioral indicators, but they do not establish interchangeability, discriminative validity, diagnostic use, or superior engagement or acceptability.

Conclusions: Attention Robots provides preliminary evidence of convergent validity with the D2-R for behavioral attention indicators in children and adolescents. The innovative aspect of this study is the translation of D2-R–based attentional demands into a child-oriented serious game environment with robot-based stimuli, dynamic audiovisual guidance, and structured behavioral

XSL•FO
RenderX

data capture. Unlike previous digital or serious game approaches, this study empirically compares game-derived indicators with corresponding indicators from an established attention test rather than evaluating only task feasibility, engagement, or intervention effects. This work contributes to the field by providing a preliminary validation of a serious game format that may support the collection of objective attention-related data in children and adolescents. In applied contexts, Attention Robots could be further developed as a complementary tool within multimethod ADHD assessment, although larger studies are required to evaluate subgroup performance, agreement, diagnostic use, and user experience before clinical adoption.

Introduction

Background

Attention-deficit/hyperactivity disorder (ADHD) is characterized by an enduring pattern of inattention, hyperactivity, and impulsivity that significantly disrupts functioning or development [1]. ADHD is estimated to affect approximately 5%-8% of children worldwide [2]. ADHD is also associated with measurable difficulties in sustained attention, inhibitory control, working memory, processing speed, and executive functioning [3,4]. Based on individual symptoms, three diagnostic categories delineate the types of ADHD: (1) predominantly inattentive ADHD, (2) predominantly hyperactive-impulsive ADHD, and (3) combined type ADHD [5].

According to the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*) [6], an ADHD diagnosis should be informed by the presence of symptoms that are frequent and persist for at least 6 months, typically manifesting between the ages of 3 and 6 years. Additionally, these symptoms should be observable across multiple settings, such as at home and at school. Consequently, it is essential to identify a significant functional impact across academic, social, and everyday life domains, and it requires a thorough evaluation of symptoms and impairments across these domains [7]. In this context, neuropsychological assessments offer objective measures that complement clinical observations and self-report measures [8], helping to confirm and specify the nature of cognitive deficits. For example, studies using tasks like the Go/No-Go or Stop-Signal Task have revealed impairments in inhibitory control among individuals with ADHD [9].

Building on the strengths of these objective methods, recent advances have introduced serious games as promising tools for both the assessment and treatment of ADHD [10,11]. Prior literature suggests that such systems may leverage interactivity and immersion to help maintain attention during evaluation [12], and can objectively capture real-time behavioral data. They have also been reported as potentially more enjoyable and less intimidating for some children than traditional formats [13].

In parallel with the development of serious games, there is a growing trend toward the use of AI-driven tools that leverage biometric data, such as electroencephalography, electrodermal activity (EDA), and eye-tracking, to support ADHD assessment and diagnosis [14]. These signals provide objective insight into attentional and cognitive states, and their integration is increasingly considered essential in modern digital interventions [15]. As a result, the incorporation of biometric data gathering into serious games has been proposed as a critical step toward enabling future AI-based applications in personalized ADHD detection and treatment [14].

Related Work

In the realm of neuropsychological evaluation, ecological validity refers to how well an assessment reflects real-life situations [16]. Studies evaluating the ecological validity of traditional paper-and-pencil neuropsychological tests in both clinical and nonclinical populations have raised concerns about their limited ability to predict real-world functioning [17,18]. To address this, novel assessments have been developed to improve ecological validity. Some of these replicate traditional cognitive tasks [19], while others use technological systems to assess cognitive functioning [20].

Traditional neuropsychological tools remain central to the diagnosis of cognitive impairments associated with ADHD. However, technological advancements have enabled computer-based cognitive assessments that offer a precise and dynamic assessment of ADHD-related deficits [21,22]. For instance, in the study performed in [23], the authors introduced a game in which participants control a raccoon avatar that jumps over gaps, recording jump distances as a measure of attention. Another widely used digital assessment is the Conners' Continuous Performance Test [18,24], which presents stimuli requiring quick responses, except when a specific "X-stimulus" appears, demanding inhibition. This test is based on the Go/No-Go paradigm [18,25], and multiple studies confirm its effectiveness in distinguishing individuals with ADHD from neurotypical controls [8]. These computerized tests facilitate precise measurement of sustained attention, working memory, and response inhibition [26], and are praised for their accuracy, adaptability, and standardized protocols [27,28].

Building upon these advances in adaptive cognitive assessments, recent systematic reviews have highlighted the growing role of AI-driven tools in improving ADHD diagnosis. In [29], the authors reviewed 98 studies from 2021 to 2024 and analyzed the application of AI models to biometric and behavioral data, such as electroencephalography, electrocardiogram, and magnetic resonance imaging data, as well as task performance data. Their findings emphasize the promise of physiological signals for objective diagnosis, while noting critical challenges,

XSL•FO
RenderX

including the lack of standardized datasets, limited clinical adoption, and interpretability issues in deep learning models. Similarly, in [14], the authors conducted a scoping review focusing on unorthodox diagnostic approaches, including AI-enhanced gamification and real-time cognitive data collection. In parallel, the EPIDIA4Kids study [15] presents preliminary findings on the feasibility of using multimodal biometric data, including electroencephalography, eye tracking, and pupillometry, for noninvasive ADHD symptom screening in children.

Although recent studies have begun to demonstrate the potential of gamification for ADHD rehabilitation, there remains a gap in the development of serious games explicitly designed for ADHD detection and treatment [30]. Furthermore, most existing solutions lack validation against well-established standardized attention tests.

In this study, and consistent with the usage adopted in recent reviews of technology-driven interventions for ADHD [10], the term serious game refers to an interactive digital system designed for a purpose beyond entertainment, in this case the assessment of attentional performance. Within this broader framing, gamification refers more specifically to the incorporation of selected game-like elements into the assessment process. Attention Robots is therefore presented as a serious game for assessment, while incorporating a limited set of gamified interaction elements rather than reward-driven entertainment mechanics.

Objective

In light of these considerations, this study presents Attention Robots, a serious game designed to quantitatively assess user attention. Although grounded in the principles of the D2-R Test of Attention [31], Attention Robots is not a direct digital transcription of the paper format. Instead, it introduces a computer-based interactive environment with robot-based stimuli, dynamic audiovisual instructions, row highlighting, auditory row-transition cues, and multimodal data acquisition. The robot theme was chosen by the psychology and design team as a developmentally appropriate visual format for children and adolescents: it was intended to be nonthreatening for younger participants while also avoiding an overly childish appearance for older ones. This design also provided a flexible visual framework for implementing rule-based task mechanics while preserving core attentional demands. More specifically, the current version of Attention Robots combines a serious game framework with selected gamified interaction elements, as noted earlier, but it was designed as a structured assessment environment rather than as a reward-based or progression-based entertainment game.

To examine preliminary convergent validity, we conducted a controlled study with 58 participants and compared the behavioral indicators obtained from Attention Robots with those obtained from the D2-R test. The analyses focused on cross-instrument correspondence rather than diagnostic classification, agreement, or user-experience superiority.

Methods

Research Design Overview

This study was designed as a preliminary cross-sectional convergent validation study. The aim was to examine the association between behavioral indicators obtained from Attention Robots and the same indicators obtained from the D2-R Test of Attention. The study did not include experimental manipulation, random assignment, diagnostic classification analysis, or longitudinal follow-up. The authorized ethical protocol dictated the specific order in which both instruments were administered: Attention Robots was administered first, and the D2-R test was administered in a second session. Therefore, rather than being a randomized experiment, crossover research, or diagnostic accuracy study, the study should be interpreted as a behavioral cross-instrument validation study.

Participant Characteristics

The dataset comprises a total of 58 participants, with 34 (59%) male and 24 (41%) female individuals. Participants' ages range from 6 to 18 years, covering a wide developmental span from early childhood to late adolescence. The average age of the participants is approximately 13.4 (SD 3.90) years. Based on the original demographic group variable assigned by the project psychologists, 19 (33%) participants were classified in the experimental group and 39 (67%) participants in the control group. In this variable, experimental participants were coded as 1 and control participants as 2. Within the experimental group, 17 (89%) participants were male and 2 (11%) were female, whereas the control group comprised 17 (44%) male and 22 (56%) female participants. Sex and group were taken from the original demographic source, and the group variable was used for descriptive reporting only, as all validation analyses were conducted in the pooled sample. This broad age range was retained to examine whether the behavioral indicators obtained from Attention Robots showed correspondence with those of the reference attention assessment across the intended population, rather than to establish age-specific normative performance.

Sampling Procedures

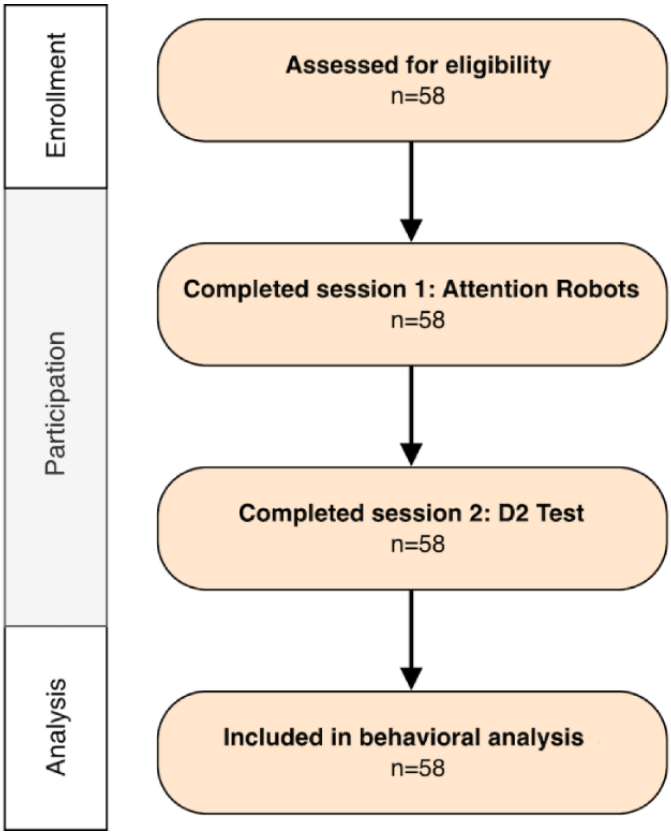
Participants diagnosed with ADHD were referred by a specialized neurodevelopmental disorders unit within the Child and Adolescent Mental Health Service at General University Hospital Dr Balmis in Alicante, Spain. Diagnoses were established by licensed clinical psychologists from this specialized neurodevelopmental disorders unit based on clinical interviews with the patients, their families, and teachers, as well as structured assessments, following *DSM-5* criteria. Healthy control participants were recruited through personal contacts and recommendations from study participants and staff. Therefore, the study used a convenience-based recruitment approach, with ADHD participants recruited from a clinical referral setting and control participants recruited from the local community.

Inclusion and Exclusion Criteria

Participants were included in the analysis if they were aged 6-18 years, had documented parental permission before participation,

XSL•FO
RenderX

and completed both assessment sessions. Exclusion criteria included cooccurring mental conditions that could affect cognitive performance, such as intellectual disabilities or autism spectrum disorders, as well as the use of medication that could affect attention during the assessment.



Sample Size, Power, and Precision

This was a feasibility/convenience sample for an initial validation study. No a priori power analysis was performed; therefore, effect estimates are interpreted with 95% CIs to indicate statistical precision. The sample size should be understood as supporting preliminary cross-instrument validation, rather than as a basis for drawing specific normative conclusions based on age, sex, or group.

Ethical Considerations

Prior to initiating data collection, ethical approval was obtained from the Hospital Ethics Committee of the Alicante Institute for Health and Biomedical Research (ISABIAL; PI2022-139) and the Ethics Committee of the University of Alicante (UA-2023-05-17_1). This procedure was required because the data were collected from participants between the ages of 6 and 18 years. Before the assessment sessions, the psychologist responsible for the study met with the parents or legal guardians and the child to explain the study procedures, including the purpose of the study, the 2 assessment sessions, the tasks to be completed, the approximate duration of the sessions, the voluntary nature of participation, and the handling of participant data. Parents or legal guardians were given the written informed consent document to read and sign before the child participated in the study. Children also received an age-appropriate verbal explanation of the sessions, and the psychologist confirmed that they understood what they would be asked to do before starting the assessments. Each participant was assigned a unique study code at enrollment. The research dataset used for analysis did not contain directly identifiable information, and access to study data was restricted to the clinical psychology team responsible for participant recruitment and follow-up. The flow of participants included in the study is summarized in Figure 1. No financial compensation was provided to participants. All figures and supplementary materials do not contain identifiable images of individual participants.

Figure 1. Participant flow for the analysis study sample.

Instruments and Measures

Attention Robots

Attention Robots was developed as part of the Attention Game Series [32] to provide a structured digital task for capturing behavioral indicators of attentional performance in children and adolescents. In this study, it was evaluated as a complementary assessment format and not as a stand-alone diagnostic instrument or longitudinal monitoring tool. Although the game format was designed to be child-oriented, user-experience outcomes such as enjoyment, immersion, acceptability, and preference were not measured in this study.

Furthermore, the aforementioned game series will incorporate an array of devices designed to collect biometric data from players, encompassing a diverse range of physiological markers such as cerebral activity, electrodermal responses, cardiac rhythm, ocular tracking, among others.

XSL•FO
RenderX

The integration of biometric data with performance metrics is intended to support future research on multimodal ADHD-related screening and monitoring. However, these uses require further validation and are not evaluated in this paper. In this context, Attention Robots represents the second serious game of the Attention series. Figure 2 shows the game's start screen, and the game binaries are available in [32]. The game was developed under the guidance and expertise of a cadre of academic professionals specialized in psychology.

In this scenario, the player is presented with an array of diverse robots, each distinguished by unique attributes. The player's objective is to identify and mark the robots that meet certain criteria, such as having precisely 2 arms, whether they are both on one side or one on each side, and remaining upright. This task assesses the player's ability to pay attention to specific robot features according to the given rules.

The robot theme was selected because it provided an age-flexible and nonthreatening visual context; it was intended to be accessible for younger participants without appearing overly childish to older adolescents. Methodologically, this choice also created a broader design space for implementing task mechanics and visual rules while maintaining the core demands of selective attention, sustained scanning, inhibitory control, and speed-accuracy balance.

As shown in Figure 3, the game is situated on a grid consisting of 14 rows, each of which contains 47 columns featuring different robot variations. This number of elements per row was selected to fit the computer display while preserving left-to-right visual scanning and the timed row-by-row structure, in consultation with the psychology team, and differs from the 57 elements per row of the D2-R. This extensive grid offers ample opportunities for players to assess their attention and decision-making abilities.

The game begins with a structured process designed to facilitate player understanding and engagement. As shown in Figure 4, users first encounter the main menu, where they can start the game.

Upon selecting the "start" option, a comprehensive video tutorial commences, providing both voice and written explanations of the game mechanics. This tutorial lasts approximately 2 minutes, ensuring that players are well-informed. In Figure 5, a screenshot of the beginning of the tutorial is shown.

Figure 2. Cover screen of Attention Robots.

XSL•FO
RenderX

Figure 3. Attention Robots game grid.

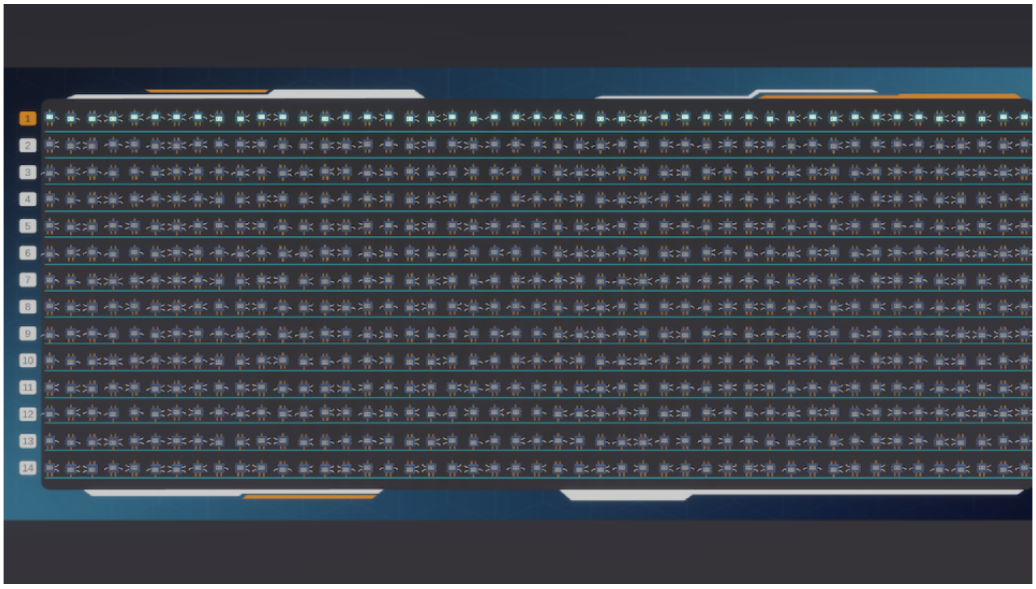


Figure 4. Main menu of Attention Robots.

XSL•FO
RenderX

Figure 5. Attention Robots beginning of the tutorial.

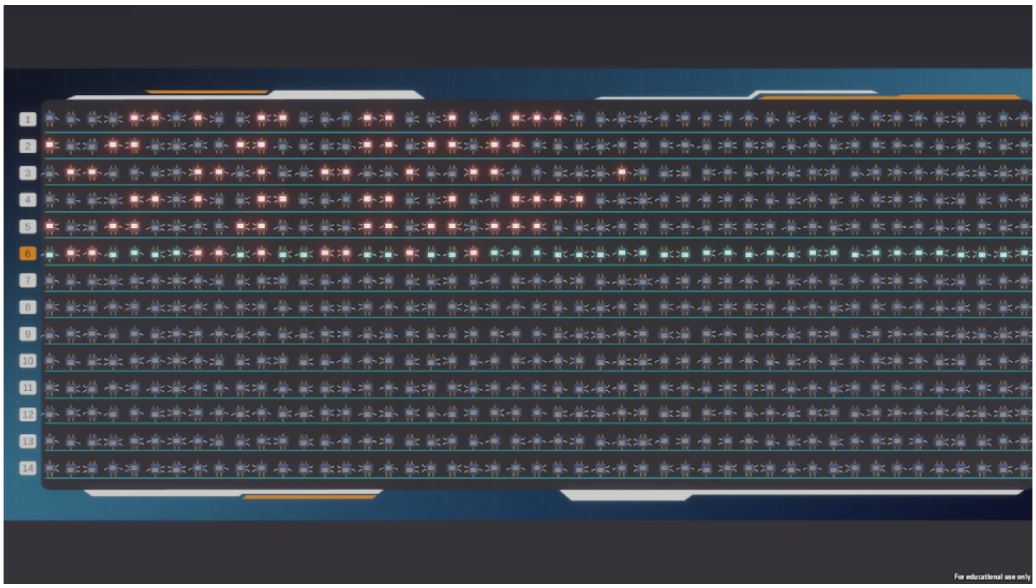
Following the tutorial, a concise and informative example is presented to illustrate the game's mechanics in a practical context, as shown in both Figure 6 and Figure 7. This example serves as a final preparatory step before the game officially begins. Progression to the actual game is subject to the psychologist's assurance that the player comprehends the rules.

During the game, players are asked to identify robots that adhere to the criteria outlined in the tutorial within a specific time frame of 20 seconds per line. The transition between lines is denoted by a distinct audio cue and the highlighting of the next line. The effect of this guidance on engagement or performance was not evaluated separately in this study. Correctly identified robots are marked in red for reference, and players can rectify mistakes by clicking on the robots again. The game concludes by presenting a clear differentiation between correctly and incorrectly marked robots. Figure 8 shows a screenshot of the game in progress.

The game recorded the following events and outputs: (1) hits, defined as correctly selected target robots; (2) omissions, defined as target robots that should have been selected but were not; (3) commissions, defined as nontarget robots selected incorrectly by the participant; (4) the last robot marked in each row, use to compute working speed (WS) and (5) where the gaze of the player was focused during the game.

From these recorded game events, additional metrics can be derived, including total commissions and total omissions.

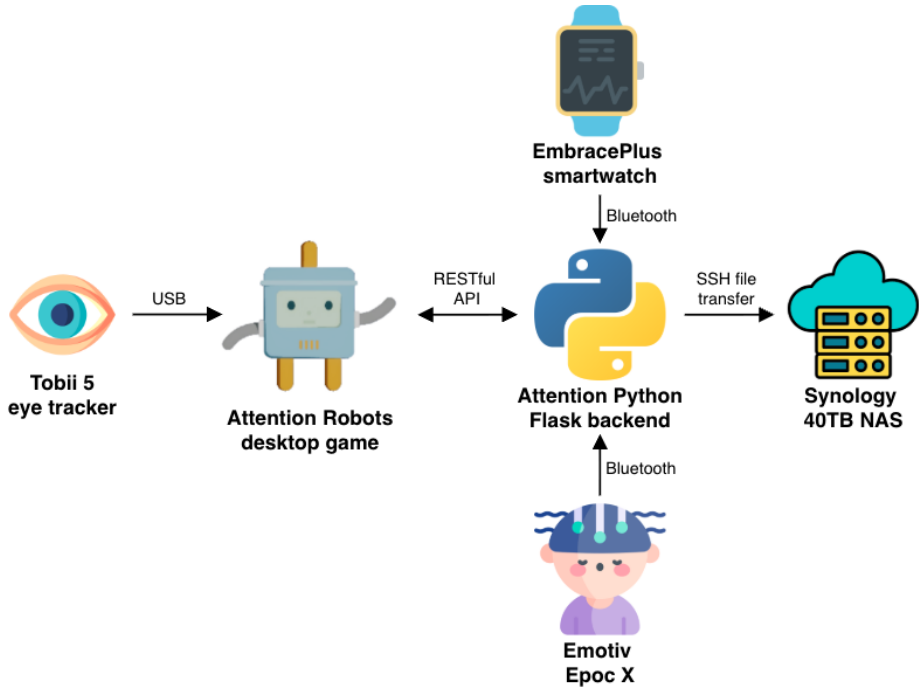
Figure 6. Attention Robots example: correct robot marked.



XSL•FO
RenderX

Figure 7. Attention Robots example: wrong robot marked.

Figure 8. Attention Robots game screenshot.



Attention Robots Software and Hardware Architecture

To facilitate data acquisition from multiple devices, a comprehensive software and hardware architecture, as depicted in Figure 9, has been implemented for Attention Robots within the broader Attention Game Series. The architecture separates the Unity game [33] from the data-management layer through a backend application program interface, allowing game events and behavioral outputs to be stored in a structured way independently of the game interface. In this study, this architecture is included only to document the technical context of Attention Robots; the validation analyses used the behavioral indicators reported above.

Although the platform was designed to be extensible to additional devices and future multimodal studies, those components were not analyzed in this manuscript and are not part of the evidence reported here. Therefore, the results should be interpreted as a behavioral cross-instrument validation of Attention Robots against the D2-R test. The broader multimodal data analysis will be conducted in an independent study using the dataset described in the *Scientific Data* data descriptor [34] and the data-capture system presented in this work, applying AI models to support ADHD screening research. Accordingly, this paper focuses on Attention Robots as a structured data-capture and behavioral assessment tool and on its preliminary correspondence with the D2-R test, rather than on analysis of the broader multimodal dataset.

The D2-R Test of Attention

The D2-R Test of Attention [31] is a paper-and-pencil test that involves various characters and symbols, in which the individual who takes part in the test is required to scan through a set of characters and mark specific ones that meet certain criteria. The test takes approximately 8 minutes to complete, and it has demonstrated its successful application in individuals aged 6 to 80 years [31].

The test consists of 14 lines with 57 items each. These lines contained the letters “d” and “p,” which could appear with 1 or 2 small dashes above or below. Participants have 20 seconds per line to carefully mark, from left to right, every letter “d” showing 2 dashes (both above, below, or one above and one below).

As described in [31], the following information is collected from the D2-R test: (1) WS, the sum of the last well-marked element in each row; (2) omissions, the sum of the omitted elements, when the participant skipped a target element (which should be marked); and (3) commissions, the sum of incorrectly marked elements, when the participant marked an element that should not be marked.

Two derived metrics were then calculated: concentration, computed as CN = WS – (O + C), and precision, computed as P = ([WS – CN]/WS)×100, where O denotes omissions and C denotes commissions.

Because concentration and precision are derived from WS, omissions, and commissions, they were interpreted as secondary composite indicators rather than independent primary outcomes.

This test showed good psychometric properties for its application through internal consistency Cronbach α values of 0.94 for general answer (the number of elements processed), 0.95 for correct guesses (the number of correctly marked target elements), 0.94 for omissions, and 0.93 for commissions [31].

Measures and Covariates

The primary behavioral indicators were WS, omissions, and commissions, obtained from both Attention Robots and the D2-R test. Due to their derivation from WS, omissions, and commissions, concentration and precision were regarded as secondary composite indicators. Demographic variables included age, sex, and the original group variable assigned by the project psychologists. The group variable was used for descriptive reporting only, and the main validation analyses were conducted in the pooled sample. The current behavioral validation analyses did not incorporate the biometric and eye-tracking data that were gathered during the Attention Robots session for future multimodal study.

Quality of Measurements and Instrumentation

The quality of the behavioral measurements was supported by a number of methods. Every participant was subject to the same task guidelines and timetable. In the Attention Robots session, participants completed a video tutorial and a practical example before starting the task, and the psychologist confirmed that the participant understood the rules. Before the assignment started, a computer technician was in charge of setting up and calibrating the recording devices and confirming that the system was operating correctly. The D2-R test was administered following its standardized instructions. The behavioral dataset used in these analyses contained complete values for all participants across the five indicators analyzed. Since the primary variables were derived from structured task outputs and D2-R scoring, no formal interrater reliability analysis was carried out.

Regarding instrumentation, Attention Robots was an ad hoc serious game–based assessment tool developed for this study within the Attention Game Series. It recorded hits, omissions,

XSL•FO
RenderX

commissions, the last marked robot in each row, and gaze-related information. Only behavioral markers comparable to those of the D2-R test were examined in this paper. The D2-R Test of Attention, which has been shown to have psychometric qualities for assessing attention [31], served as the standard reference measure. As part of the larger data-capture platform, biometric devices were used during the Attention Robots session, but these recordings were not analyzed in this study.

Masking was not applied because participants and staff were aware of the assessment procedures, and the 2 instruments were clearly different in format.

Evaluation Procedure and Data Collection

This section describes the comparative analysis between Attention Robots and the D2-R test [31], a standardized paper-and-pencil measure of attention.

Our goal was to examine potential correlations between the scores obtained from the Attention Robots test and those from the D2-R test. These analyses were intended to assess convergent validity and cross-instrument correspondence, not interchangeability, discriminative validity between ADHD and neurotypical participants, or stand-alone diagnostic use.

As noted earlier, the central objective of this section is to conduct an empirical evaluation and comparison of the Attention Robots test and the D2-R test. This evaluation was conducted through a controlled experiment, with its key features outlined in Textbox 1.

The experiments took place in 2 sessions of approximately 20 minutes, most of them carried out in the afternoons. The ISABIAL ethical committee confirmed that the Attention Robots test should always be performed in the first session and the D2-R test in the second session. Therefore, a crossover 2×2 experiment cannot be considered here since the approved experimental protocol must be followed in the specified sequence. The 2 sessions were not conducted on the same day. The second session took place at least on the following day and, depending on participant availability, could be scheduled later. Although scheduling was flexible, the protocol followed in each session was the same for all participants.

First, a comfortable environment was created, and demographic data were collected. Each participant was always accompanied by at least one psychologist and a computer technician. The computer technician was responsible for placing and calibrating the recording devices at the beginning of the session. The psychologist remained during the instruction phase to ensure that the participant understood the task rules. Once setup and instruction were completed, the task proceeded, while the staff remained available nearby only in case of technical issues, participant doubts, or difficulties in cooperation.

Afterward, the content and activities of the upcoming session were explained. Each session proceeded as follows:

- Session 1: Attention Robots test:
  - The measuring elements (electroencephalography headset, EDA/heart rate wristband, and Tobii eye tracking) were placed and calibrated, and their proper operation was verified.
  - Participants played the Attention Robots test on a high-end gaming computer.
  - The following data were gathered: (1) the test indicators (WS, omissions, and commissions); (2) biometric data (EDA/heart rate); and (3) Tobii eye tracking data.
  - The total duration was approximately 10 to 15 minutes.
- Session 2: D2-R test:
  - The participants performed the standard D2-R test on a table using pencil and paper.
  - The following information was gathered: the test indicators (WS, omissions, and commissions).
  - The total duration was approximately 8 minutes.

After each session, participant data and outputs from both tests were stored in anonymized form. The stored records were identified only by study code, and the dataset used in these analyses was anonymized. Data were retained in the secure institutional storage infrastructure in accordance with the approved ethical and data-protection procedures.

The experimental sessions proceeded without any significant incidents affecting the behavioral assessment. A few younger participants expressed discomfort with wearing the electroencephalography headset. In these cases, electroencephalography acquisition was omitted, and the session continued without affecting the behavioral assessment.

Textbox 1. Main features of the experiment.

Null hypotheses

- H_{0A}: No correlation is found in the total number of the last well-marked elements (working speed) between the D2-R test and the Attention Robots test.
- H_{0B}: No correlation is found in the omitted elements between the D2-R test and the Attention Robots test.
- H_{0C}: No correlation is found in the incorrectly marked elements (commissions) between the D2-R test and the Attention Robots test.
- H_{0D}: No correlation is found in the concentration between the D2-R test and the Attention Robots test.
- H_{0E}: No correlation is found in the precision between the D2-R test and the Attention Robots test.

Dependent variable

- Correlation between attention test

Independent variable

- Use the D2-R Test of Attention.
- Use the Attention Robots test.

Location

- University Institute for Computing Research (Alicante, Spain)

Date

- From June 2022 to July 2023

Participants

- 58 participants aged 6 to 18 years

Missing Data

The dataset contained complete Attention Robots and D2-R values for all 58 participants across WS, omissions, commissions, concentration, and precision. Thus, the proportion of missing data for the primary behavioral analyses was 0%, and missing completely at random testing and multiple imputation were not applicable. Biometric recordings were collected for future work and were not included in the current analyses; incomplete electroencephalography acquisition caused by headset discomfort did not affect inclusion in the behavioral dataset.

Results

Overview

In this section, the experiment results are presented. A total of 58 participants took part in the experiment. The mean age of the study participants was 13.4 (SD 3.90) years, comprising 24 female and 34 male individuals. The statistical significance was determined from the reported tests and corresponding *P* values.

Experiment Results

Multimedia Appendix 1 contains the demographic variables and behavioral indicators obtained from the D2-R test and Attention Robots for each participant. Table 1 presents the descriptive statistics for both instruments, including maximum, minimum, mean, median, mode, and SD for the WS, omissions, commissions, concentration, and precision.

Correlation Analysis

The main analytic goal was to determine whether behavioral indicators from Attention Robots were correlated with corresponding indicators from the D2-R test.

First, we calculated the Spearman correlation coefficient (SCC) [35], which evaluates the monotonic relationship between 2 variables. In a monotonic relationship, the variables tend to change at the same time, but not necessarily at a constant rate [36], and are less sensitive to outliers. These calculations can be seen in Tables 2 and 3. Table 2 presents the SCC values, while Table 3 presents the *P* value matrix.

The SCC values represented in Table 2 can be interpreted as follows: values close to 1 indicate a strong positive monotonic relationship, meaning that as one variable increases, the other tends to increase; values close to –1 indicate a strong negative monotonic relationship, meaning that as one variable increases, the other tends to decrease; and values close to 0 suggest a lack of a monotonic relationship, meaning there is little or no association between the variables.

Table 4 summarizes the 5 prespecified cross-test SCC results with approximate 95% CIs.

Table 4. Spearman correlation results.

D2-R vs Attention Robots	Spearman coefficient (95% CI)[a]	*P* value
Working speed	0.905 (0.84-0.94)	<.001
Omissions	0.333 (0.08-0.54)	.01
Commissions	0.496 (0.27-0.67)	<.001
Concentration	0.926 (0.88-0.96)	<.001
Precision	0.607 (0.41-0.75)	<.001

[a]CIs were calculated using Fisher *z* transformation and are interpreted as precision estimates for the Spearman correlations.

Then, the Pearson correlation coefficient (PCC) was calculated [35]. This statistical metric measures the strength and direction of a linear relationship between 2 variables [37]. It quantifies the degree to which variations in one variable correspond with variations in another variable. It is sensitive to outliers. Table 5 presents the PCC values, and Table 6 presents the *P* value matrix.

The PCC values represented in Table 5 have the following interpretation: values close to 1 indicate a linear relationship, values close to –1 indicate a negative linear relationship, and values close to 0 indicate no linear relationship.

Table 7 summarizes the 5 prespecified cross-test PCC results with 95% CIs.

Therefore, based on the results obtained through the SCC and PCC, we can reject the null hypotheses H_{0A}, H_{0B}, H_{0C}, H_{0D}, and H_{0E}. Accordingly, the analyses support statistically significant associations between the corresponding indicators obtained from the D2-R test and the Attention Robots test. Specifically, correlation is found between the D2-R test and the Attention Robots test in the total number of the last well-marked elements (WS), in the omitted elements, in the wrongly marked elements (commissions), and in concentration and precision.

These findings should not be interpreted as evidence that Attention Robots and the D2-R test are interchangeable or that Attention Robots can discriminate ADHD from neurotypical participants. They support preliminary convergent validity for corresponding behavioral indicators only.

Threats to the Experimental Validity

Validity threats were analyzed using the four categories described by [38]: conclusion, internal, external, and construct validity.

Conclusion validity pertains to factors that may lead to erroneous inferences about the observations [38]. In this study, 5 null hypotheses were tested using the PCC and SCC [36,37], yielding statistically significant *P* values at .05, thereby affirming our initial hypotheses with a considerable degree of certainty.

Internal validity concerns the design of the study, particularly whether the results are genuinely reflective of the data [38]. An important internal validity issue in this study was the fixed administration order, because Attention Robots was always administered before the D2-R according to the approved ethics protocol. This order could not be counterbalanced and may have introduced practice or fatigue effects [39]. In addition, although the procedure was standardized across participants, the interval between sessions depended on participant availability, which may have introduced additional variability. Additional internal validity considerations include the need for psychologist and technician support during device setup and instructional comprehension before the task began, as well as minor discomfort with the electroencephalography headset in some younger participants. The primary internal validity threat examined was instrumentation, as flawed tools could skew experimental outcomes.

To mitigate this, game development and experimental design were closely monitored by a team of neuropsychology experts. Additionally, the ethical committee of the ISABIAL approved the experiment. Participant attrition, or mortality, was addressed by scheduling sessions around participant availability, ensuring no dropouts. The sample should be interpreted as a feasibility/convenience sample for preliminary validation, and inference should be based on the reported correlation estimates, *P* values, and CIs [40].

Construct validity examines the degree to which the experimental setup and selected measures accurately represent the concept under investigation [38]. The D2-R variables, a well-established test for measuring attention [31], were used to avert validity issues. Additionally, Attention Robots underwent thorough testing by game developers and a pilot test prior to the experiment.

External validity relates to the generalizability of the results [38]. The participant age range was 6 to 18 years, which allowed the initial validation to cover the intended target population. However, developmental differences across this span may influence absolute performance levels, so these findings should be interpreted as evidence of overall cross-instrument association across a heterogeneous age range rather than age-specific performance equivalence. In addition, recruitment differed between groups: participants with ADHD were referred from a specialized clinical unit, whereas healthy control participants were recruited through personal contacts and recommendations. This difference may introduce selection bias and limit generalizability. Although both neurotypical individuals and people with ADHD participated, no differentiation was made in the analysis. Future studies should include age-stratified results, age-adjusted models, and analyses by group and clinical representation.

Discussion

Principal Findings

The primary objective of this study was to examine whether the behavioral indicators obtained from the Attention Robots test corresponded with the same indicators obtained from the D2-R test [31]. The results supported the 5 prespecified correlation hypotheses and provided preliminary evidence of convergent validity [41] for Attention Robots as a complementary behavioral attention-assessment format. These findings should be interpreted as evidence of correspondence between both tests, not as evidence that Attention Robots can replace the D2-R test or be used as a stand-alone diagnostic instrument.

Interpretation

The results are consistent with the design of Attention Robots. The game is based on a timed visual-search task in which participants must identify target robots according to specific rules. This structure preserves several demands of the D2-R test, including sustained scanning, selective attention, inhibitory control, and a speed-accuracy balance [31]. The strongest correspondence was observed for WS, while the derived concentration measure showed similarly high associations. Because concentration is calculated from WS, omissions, and commissions, it should be interpreted as a composite indicator rather than as an independent source of evidence. One possible explanation is that error-related indicators may be more sensitive to differences between both formats, such as stimulus design, screen layout, audiovisual guidance, and response modality [42].

XSL•FO
RenderX

A complementary explanation lies in each indicator. WS summarizes the amount of material processed within the time limit, a production measure that is largely preserved when the task moves from paper to screen. In contrast, omissions and commissions are low-frequency events that capture lapses of sustained attention and failures of inhibitory control [24,25], so a small number of discrepant responses can shift their totals considerably, and their skewed, nonnormal distributions can affect the size of correlation estimates [37]. This pattern is also consistent with the heterogeneity of executive functioning described in ADHD populations, where speed-related and inhibition-related performance do not necessarily covary within the same individual [3,9].

The convergence between the 2 correlation methods strengthens this interpretation. SCC and PCC yielded the same qualitative pattern, with the strongest associations for WS and concentration, and an intermediate association for precision. The weakest associations were observed for commissions and omissions. These results suggest that the observed relationships are monotonic and approximately linear. They are also not driven by a small number of extreme scores [36,37]. This correspondence is also coherent with the broader finding that computerized adaptations of attention tasks tend to preserve the constructs measured by their traditional counterparts while introducing format-specific variance [8,16]. Within this framework, the strong association for WS indicates that the game preserves the temporal and perceptual demands of the D2-R. The weaker associations for omissions and commissions most likely reflect the surface differences between formats, as described above. However, the present design cannot fully separate construct differences from format effects.

There are a number of limitations to this study. First, the sample was based on convenience recruitment, and no a priori power analysis was performed. Therefore, the results should be considered preliminary [40]. Second, the analyses were carried out in the pooled sample, and the age range was wide. This limits conclusions about age-specific performance. Third, ADHD and neurotypical participants were not analyzed separately, so the study does not evaluate discriminative validity or diagnostic classification. Fourth, Attention Robots was always administered before the D2-R test, following the approved ethical protocol, so order effects cannot be ruled out. Fifth, no agreement analysis was performed, so the results do not show whether scores from both tests can be used interchangeably [41]. Lastly, although biometric information was gathered during the Attention Robots session, it was not examined in this paper.

Similarity of Results

These findings are also aligned with previous studies showing that computerized tasks, virtual environments, and serious games can be used to collect behavioral indicators related to attention and executive functioning [8,30]. However, many serious game studies focus primarily on feasibility, engagement, training effects, or diagnostic classification, rather than on direct comparison with standardized tests. This study contributes to this literature by directly comparing game-derived behavioral indicators with corresponding indicators from an established attention test. This comparison helps clarify which aspects of game performance closely align with paper-and-pencil measures and which may instead reflect task-specific features of the digital environment. However, this study only analyzed behavioral data. Although Attention Robots was designed as a child-oriented serious game, user-experience outcomes such as enjoyment, immersion, acceptability, and preference were not measured. Therefore, this study cannot conclude that Attention Robots is more engaging or more acceptable than traditional paper-and-pencil assessments.

Placing these results next to specific prior efforts clarifies this contribution. Virtual reality continuous performance tests have been compared with their traditional counterparts at the level of overall task performance [8,20], and driving or runner video games have been related to symptom measures and diagnostic status in ADHD [18,23]. Serious games have also been studied mainly as training or rehabilitation tools, with systematic reviews focusing on symptom improvement and cognitive outcomes rather than on measurement validity [11,30]. In contrast, this study compared each behavioral indicator of the game directly with the corresponding indicator of a normed attention test [31], which allows the correspondence to be examined separately for speed, error, and composite measures.

The observed pattern of correspondence is also consistent with this previous work. Validation studies of computerized and virtual reality attention tasks typically find that the strength of association with traditional instruments varies across indicators and that part of the variance is attributable to format-specific factors rather than to the measured construct [8,16]. Within the continuous performance test tradition, omissions and commissions are likewise treated as related but separable indicators of inattention and impulsivity [24,25], so their weaker cross-format correspondence in this study is not unexpected. These results extend this literature to a robot-themed cancellation game for children and adolescents, showing that the strongest correspondence occurs for speed-based and composite indicators and the weakest for infrequent error events.

Generalizability

Our findings may be cautiously generalized to the population and conditions that the study was designed to represent. The sample covered the intended age range of 6 to 18 years, and the anchor instrument, the D2-R, is validated for individuals from 6 to 80 years of age [31]. Sessions were short, structured, and supervised, and took place in a comfortable environment. A psychologist verified that each participant understood the task, in line with how standardized attention tests are administered in practice [31]. Since the behavioral indicators are automatically recorded by the game itself, this component of the platform could in principle be used in clinical or research settings with similar technical resources.

At the same time, several characteristics of the sample constrain generalizability. Recruitment was based on convenience sampling [38]. Participants with ADHD were referred from a specialized clinical unit, and control participants were recruited through personal contacts and recommendations, which may introduce selection bias and limit the representativeness of both groups. Moreover, the analyses were conducted on the pooled sample across a wide age range, so the results describe the

XSL•FO
RenderX

overall association between instruments rather than age-specific or group-specific performance. In addition, the 2 groups differed in sex composition, so group and sex are confounded in this sample, and neither can be interpreted independently of the other. Finally, data were collected in a single geographic and institutional context and under a fixed administration order, so site-related effects and order-related effects, such as practice or fatigue, cannot be excluded [38].

Within these constraints, what generalizes most defensibly is the association between corresponding indicators, not the interchangeability of individual scores. The game preserves the core attentional demands of a validated cancellation test [31], and research on computerized and virtual reality assessment indicates that well-designed digital formats can retain the constructs of the instruments they adapt [8,16]. Extending these findings to individual clinical interpretation in real-world practice would additionally require age- and group-stratified norms, agreement analyses between formats, and replication in larger multisite samples with balanced recruitment.

Implications

The results should also be interpreted in the broader context of ADHD assessment. ADHD diagnosis requires information from different sources and settings, including clinical interviews, family and teacher reports, and structured assessments [7]. For this reason, Attention Robots should be considered a complementary tool for collecting objective behavioral data, not a diagnostic tool by itself. Clinical guidelines state that ADHD cannot be established from a single observation: the symptoms must be shown to occur in more than one setting, such as home and school, and the information must come from several people who know the child, typically parents and teachers [6,22]. This information is usually gathered with rating scales, but their quality depends on which of these adults are available and on how each of them perceives the child's behavior, which is inevitably subjective. A task such as Attention Robots complements these scales because it records the child's actual performance automatically, adding objective attention-related data. This need for objective measures that do not depend on an external observer is one of the main reasons behind the growing interest in computerized approaches to ADHD assessment [5,14].

The practical relevance of this approach lies in its ability to automatically and consistently record performance through an interface that may be more accessible to children and adolescents than traditional formats. Since hits, omissions, commissions, and the last marked element are stored as discrete events, scoring requires no manual correction of a paper sheet, and the full response record remains available for later inspection. Realizing this benefit in individual clinical work would nevertheless require age- and group-stratified norms and cutoffs, which the present pooled design was not intended to produce. A realistic development path is illustrated by computerized continuous performance tests, which became clinically usable once normative data and standardized scoring were established [24]. Because Attention Robots stores every response as a discrete event, the same records that supported this validation could also support longitudinal monitoring, in which repeated sessions of the same child are compared over time, although such use would first require evidence of test-retest reliability [24], which this study does not provide.

The findings also matter for the multimodal research that the platform was built to support. Attention Robots is the data-acquisition layer of a system that records data from various devices during the same session. By establishing that 5 of its behavioral indicators align with those of a standardized instrument, this study provides a reference for the multimodal dataset released separately [34]. This interpretation is also consistent with recent research on AI-based and multimodal approaches for ADHD assessment, where behavioral and biometric data are considered promising but still require further validation before clinical use [14,29].

Finally, the results have implications for the design of digital assessment instruments. Rather than creating a new task and studying it in isolation, this work adapted the structure of an existing validated test into a game format and then measured how much of the original measurement behavior was preserved. Previous game-based approaches to ADHD assessment have generally been developed as novel tasks that are subsequently related to symptom measures or diagnostic status [18,23], and serious games more broadly have been evaluated mainly as interventions [11,30]. The present approach, in which each game indicator has a direct counterpart in a normed test [31], follows the same logic as adaptations of established instruments to virtual environments [20] and offers a replicable strategy for building child-oriented digital assessments whose outputs remain psychometrically interpretable.

Conclusions

Attention assessment in ADHD still relies largely on clinical interviews and rating scales based on subjective observation. Although standardized tests such as the D2-R provide objective measurements, their paper-and-pencil format may be less appealing to children and does not use interactive digital environments. Serious games have been proposed as a more engaging means of capturing attention-related behavior, but most have been validated against symptom scales or diagnostic status rather than an established, normed attention test. This study addressed this gap by developing Attention Robots, a serious game that reproduces the attentional demands of the D2-R, and examining the convergence between the behavioral indicators obtained with both instruments in children and adolescents. The findings provide preliminary evidence of convergent validity for selected attention-related behavioral indicators, with stronger convergence for WS and concentration than for error-related indicators. The game combines robot-based stimuli, dynamic audiovisual guidance, and structured behavioral data collection in a child-oriented environment and, unlike previous digital and serious game approaches, it was directly compared with an established standardized attention test [30,31]. Nevertheless, the current evidence is preliminary, is limited to behavioral indicators, and should not be interpreted as demonstrating diagnostic validity.

In real-world settings, Attention Robots could be developed further as a complementary component of multimethod ADHD assessment. Realizing this potential will require a staged

XSL•FO
RenderX

validation process in which the indicator-level correspondence demonstrated in this study is followed by additional evaluation before the tool can be considered for applied use. Accordingly, these findings position Attention Robots as a structured source of objective attention-related behavioral data and as a foundation for the multimodal research supported by the platform. Future studies should use larger and more appropriately stratified samples, report demographic characteristics separately for each group, examine age-adjusted and group-specific models, evaluate agreement between scores [41] and diagnostic performance, and directly assess user experience. They should also investigate the broader multimodal data collected through the platform to determine whether combining behavioral, eye-tracking, electroencephalography, and physiological measures provides useful information for ADHD-related screening and assessment research [34].

Acknowledgments

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing. The GenAI tool used was ChatGPT-5.5. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. The authors take collective responsibility for this declaration.

Funding

This work was supported by the following funding sources: the AgroVAL project (TSI-100122-2024-10), funded by the Recovery, Transformation, and Resilience Plan of the European Union Next Generation through the Ministry for Digital Transformation and the Civil Service; the KOSMOS-UA project (PID2024-155363OB-C43), funded by the Spanish Ministry of Science and Innovation; the BALIDA-AA project (CIPROM/2024/13), funded by Conselleria de Educación, Cultura, Universidades y Empleo (Generalitat Valenciana); the IAEAV project (INREIA/2024/176), funded by the Conselleria de Innovación, Industria, Comercio y Turismo (Generalitat Valenciana); the ENIA Chair of Artificial Intelligence from the University of Alicante (TSI-100927-2023-6), funded by the Recovery, Transformation, and Resilience Plan of the European Union Next Generation through the Ministry for Digital Transformation and the Civil Service; and the grant RED2022-134656-T, funded by MCIN/AEI/10.13039/501100011033.

Data Availability

Multimedia Appendix 1 contains the behavioral metrics and demographic variables used in these validation analyses. Raw biometric recordings (electroencephalography, electrodermal activity/heart rate, and eye-tracking) were collected for future multimodal research and are not publicly released as part of this paper.

Conflicts of Interest

None declared.

Abstract

Background: Recent advances in digital therapeutics (DTx) have led to the development of game-based, home-delivered interventions for children with attention-deficit/hyperactivity disorder (ADHD). Prior studies have demonstrated the feasibility and clinical potential of DTx for reducing ADHD symptoms but have primarily evaluated usage metrics, including training frequency and duration, which do not capture in-game performance or learning processes during training. In addition, the association between task difficulty regulation during DTx training and ADHD symptom improvement in children has not been well studied.

Objective: This study aimed to examine whether task difficulty regulation during DTx training is associated with ADHD symptom improvement in children and to evaluate the clinical relevance of difficulty-related behavioral measures as indicators of treatment response.

Methods: In this study, a secondary post hoc analysis of data from 35 children aged 6 to 13 years with ADHD who participated in a randomized controlled trial was performed. The participants had completed a 4-week training program comprising 5 digital cognitive tasks from the DTx Neuro-World. During training, task difficulty was automatically adjusted in real time according to participants' response accuracy to maintain an appropriate challenge level. Training difficulty was quantified by 3 indices: average task difficulty, task difficulty variability, and task difficulty slope. Associations between difficulty indicators and ADHD symptom changes were examined using regression analyses and group comparisons.

Results: We found that lower average task difficulty during tasks 1, 2, and 4 of Neuro-World was associated with improvements in ADHD symptoms, as assessed by the total Korean-ADHD Rating Scale (K-ARS) score. In addition, the average task difficulty of tasks 1 to 4 was related to improvements in hyperactivity/impulsivity symptoms of ADHD, as assessed by the K-ARS hyperactivity or impulsivity subscore, but not to improvements in inattention symptoms. Moreover, lower variability of task difficulty in task 5 improved ADHD hyperactivity/impulsivity symptoms, as assessed by K-ARS, but did not affect Korean-Child Behavior Checklist scores. Finally, we found that a negative task difficulty slope was associated with the alleviation of ADHD hyperactivity or impulsivity. These findings should be interpreted with caution, given the exploratory nature of the study and the absence of formal correction for multiple comparisons.

Conclusions: As an exploratory investigation, our study provides a novel perspective by demonstrating that individualized and stable regulation of task difficulty, rather than the mere attainment of higher difficulty levels, is associated with ADHD symptom improvement. These findings indicate that dynamic difficulty trajectories derived from in-game behavioral data are clinically relevant, going beyond the conventional focus in the literature on usage metrics or overall training intensity. Our results support the role of individualized difficulty trajectories as potential digital biomarkers of clinical response. This approach has important implications for the design of DTx that incorporate personalized and adaptive difficulty regulation to enhance clinical effectiveness and scalability.

attention-deficit/hyperactivity disorder; cognitive training; digital therapeutics; game-based digital content; task performance; task difficulty levels

Introduction

Attention-deficit/hyperactivity disorder (ADHD) is a common neurodevelopmental disorder that affects approximately 5% of children and adolescents worldwide [1]. Children with ADHD often experience persistent difficulties with attention, impulse control, and activity level, which can interfere with academic performance, classroom behavior, and peer relationships [2]. These difficulties frequently persist into adolescence and adulthood, affecting daily functioning, emotional development, and long-term quality of life [3,4]. Although stimulant medication and behavioral therapy are well-established first-line treatments for ADHD, their effectiveness varies across individuals [5]. Many children discontinue medication because of adverse effects, such as appetite suppression or sleep disturbances [6,7], and access to behavioral therapy is often limited by financial, geographic, or scheduling constraints [8]. Real-world effectiveness may also be influenced by family involvement and environmental support [9,10]. These limitations emphasize the importance of developing treatment approaches that are accessible, sustainable, and feasible in real-world settings. Interventions that actively engage children, reduce treatment burden, and can be integrated into daily routines offer a practical approach to this challenge.

Digital therapeutics (DTx) have emerged as an innovative approach to supplement or extend traditional ADHD treatments through software-based therapeutic programs [11,12]. These interventions use structured, evidence-informed tasks to target cognitive processes such as attention, response control, and working memory [13,14]. A key strength of DTx is their ability to deliver therapeutic content in everyday environments, which allows children to engage in treatment at home, within their daily routines [15-17]. Game-based formats support motivation and sustained engagement in repeated practice without the fatigue or disengagement often associated with traditional cognitive exercises, making them particularly suitable for pediatric populations [18,19]. For example, EndeavorRx, the first Food and Drug Administration–authorized prescription DTx for pediatric ADHD, has been shown to improve attention performance among children aged 8 to 12 years, including those who discontinued medication [11]. Virtual reality–based digital programs have similarly been shown to reduce impulsive or aggressive behavior and improve social responsiveness [20]. Collectively, these findings suggest that DTx can produce clinically meaningful benefits by combining therapeutic mechanisms with engaging and adaptive delivery formats [21]. Continued advances in DTx increasingly emphasize the development of personalized and adaptive DTx to address symptom heterogeneity in children with ADHD.

Cognitive training using DTx also generates performance-level behavioral data, which have been underutilized in DTx research. Most previous studies have relied on usage-based indicators such as total training time, number of sessions completed, or session duration [22-24]. These values reflect engagement frequency but provide limited insight into cognitive performance quality or learning processes during training. Game-based DTx platforms commonly use adaptive algorithms that adjust task difficulty in real time based on an individual's performance [25,26]. Although task difficulty adaptation is a central feature of many DTx systems, its clinical relevance has rarely been examined directly. Studies of task-difficulty dynamics within web-based cognitive training programs for stroke rehabilitation have suggested that difficulty regulation patterns convey clinically meaningful information, but comparable research in ADHD populations remains scarce [27]. Specifically, it remains unclear how training under task difficulty levels matched to a child's capacity and ability to maintain or regulate those levels across repeated sessions of DTx is related to ADHD symptom improvement. Clarifying this relationship between performance and ADHD symptom improvement or impairment is essential for advancing both the understanding and development of DTx.

Based on the literature and our recent findings in children with ADHD who used the DTx Neuro-World [28-31], we hypothesized that stable and individualized regulation of task difficulty improves ADHD symptoms. Our hypothesis departs from previous approaches focused on increasing absolute difficulty levels. To test this hypothesis, this study examined associations between quantified difficulty patterns and changes in attention, hyperactivity/impulsivity, and overall behavioral functioning in children with ADHD.

Methods

Recruitment

This study enrolled pediatric patients aged 6 to 13 years who had been clinically diagnosed with ADHD at the outpatient pediatric psychiatry clinic of Keimyung University Dongsan Hospital in the Republic of Korea. Participants were selected using clinic-based convenience sampling during routine outpatient visits. In the first phase, 34 children were recruited from December 2021 to December 2022; in the next phase, an additional 34 children were enrolled from December 2022 to March 2023. Data collection occurred concurrently with each recruitment phase.

Recruitment Sampling Procedures

Recruitment was conducted using a convenience sampling strategy. Eligible children and their legal guardians were informed about the study by clinicians or trained research staff during routine clinic visits, and participants who met the

XSL•FO
RenderX

inclusion criteria were consecutively enrolled. As part of the original trial design, all enrolled participants were randomly assigned to either the intervention group (DTx) or the control group (non-DTx).

Inclusion and Exclusion

Children with comorbid neurological or psychiatric conditions other than ADHD, including posttraumatic stress disorder, psychosis, severe obsessive-compulsive disorder, or severe depression, were excluded. Participants with physical limitations that could interfere with the use of the DTx program (eg, deformities of the hands or arms or the use of prosthetic limbs) were also excluded. In addition, 4 children declined participation.

Participant Characteristics

The original randomized controlled trial enrolled a total of 64 children, who were randomly assigned to either the control group (n=29) or the DTx intervention group (n=35). Building on the primary study [28-30], this study represents a secondary post hoc analysis focused exclusively on the participants who completed the DTx intervention. Accordingly, only the data from the 35 children assigned to the intervention group were analyzed in this study because the primary objective was to examine associations between in-game behavioral metrics and ADHD symptom changes derived from DTx training-session data, rather than to compare intervention efficacy between the control and DTx intervention groups. All participants were Korean and were recruited from a single clinical institution. Socioeconomic status and the education level of the legal guardian were not collected.

Sample Size, Power, and Precision

The target sample size was determined based on feasibility and previous literature, with an anticipated attrition rate of approximately 10%, and a total of 64 participants were enrolled (control group: 29; intervention group: 35). An a priori power analysis conducted using G*Power (version 3.1.9.7) indicated that a minimum of 24 participants was required to detect a medium-to-large effect size (d_z=0.6; α=.05; power=0.80) in paired comparisons, confirming that the target sample size was achieved. For this secondary analysis, 35 participants in the intervention group who completed the training were included. Given the negligible attrition, the final sample size remained consistent with the original assumptions. A post hoc power analysis for the regression models, assuming a medium-to-large effect size (f^2=0.35; α=.05; number of predictors=2), indicated that a minimum of 31 participants was required. The achieved sample size of 35 yielded an observed power of 0.80, confirming that the analysis was sufficiently powered. No interim analyses or formal stopping rules were applied. As this is an exploratory secondary analysis, the findings should be interpreted with caution, particularly regarding the precision of parameter estimates.

Ethical Considerations

Phase 1 of the study was approved and registered by the institutional review board of Keimyung University Dongsan Hospital (number 2021-10-080), and phase 2 was approved and registered with the Korea Clinical Research Information Service (number KCT0009326). Prior to enrollment, written informed consent was obtained from the legal guardians of all participants, and the experimental procedures were explained to the participants to obtain their assent. The consent form explicitly indicated that anonymized data could be used for clinical outcome reporting as well as for secondary analyses and future research without requiring additional consent. Participants received modest compensation of approximately US $200, equivalent to approximately 270,000 Korean won, upon the completion of the study.

All study data were deidentified prior to analysis, and each participant was assigned a unique study identification code; no direct personal identifiers were retained in the analytical dataset. Data handling procedures complied with applicable institutional and regulatory guidelines to ensure the privacy and confidentiality of all participants. No personally identifiable information is included in this study or its supplementary materials, and access to the deidentified data was restricted to authorized research personnel.

Data Collection

To minimize potential confounding effects on treatment response, participants were instructed to maintain their usual daily routines and to continue prescribed medications without adjustment. After informed consent was obtained, all participants completed baseline assessments using the Korean-ADHD Rating Scale (K-ARS) and the Korean-Child Behavior Checklist (K-CBCL) to assess ADHD symptoms and emotional and behavioral functioning. Following the baseline assessment, participants in the intervention group completed a home-based digital cognitive training program. The DTx intervention consisted of 20 training sessions delivered over 4 weeks, with 5 sessions per week (Figure 1).

Home-based training allowed participants to complete sessions in a familiar environment while maintaining flexibility in scheduling. To ensure that task performance reflected genuine cognitive engagement, caregivers were instructed to provide a quiet and independent setting during each session, thereby minimizing environmental distractions. Within 1 week after the completion of all training sessions, participants returned to the clinic for postintervention assessment, during which the standardized measures administered at baseline were repeated.

Figure 1. Overview of the experimental procedure for participants in the digital therapeutics (DTx) intervention group. This figure illustrates the overall study flow, including participant enrollment, baseline assessment, the 4-week home-based Neuro-World digital cognitive training intervention, and the postintervention assessment conducted within 1 week after the completion of all DTx training sessions. The original randomized controlled trial enrolled 64 children with attention-deficit/hyperactivity disorder (ADHD); however, only the 35 participants assigned to the DTx intervention group were included in the post hoc analysis for this study.

Instrumentation: K-ARS and K-CBCL

The K-ARS is a widely used standardized instrument for assessing ADHD-related symptoms in children and adolescents. It was adapted for Korean populations from the ADHD Rating Scale-IV, the reliability and validity of which had previously been established [32]. The K-ARS is a reliable and clinically useful tool for evaluating, screening, and monitoring ADHD symptomatology in Korean children. It consists of 18 behavior-rating items reflecting the *DSM* (*Diagnostic and Statistical Manual of Mental Disorders*)-based ADHD symptom domains, including 9 items assessing inattention and 9 items assessing hyperactivity-impulsivity [33,34]. Each item is rated on a 4-point scale, with higher scores indicating greater symptom severity [34]. The instrument is typically completed by caregivers or teachers, and both forms are recognized for their high validity and reliability in assessing ADHD-related behaviors [19,33].

The K-CBCL is a culturally validated adaptation of the widely used Child Behavior Checklist, which was originally developed by Achenbach and Rescorla and translated and standardized in Korea by Oh and Kim [35,36]. The Child Behavior Checklist was subsequently adapted for Korean populations to create the K-CBCL, which consists of 121 parent-reported items that assess children's behavioral and emotional problems [37]. As a standardized instrument for caregivers of children aged 6 to 18 years, the K-CBCL evaluates adaptive functioning and problematic behaviors observed during the previous 6 months [35]. The K-CBCL includes several empirically derived syndrome subscales, such as anxious/depressed, withdrawn/depressed, somatic complaints, social problems, thought problems, attention problems, rule-breaking behavior, and aggressive behavior [38]. These subscales are further organized into internalizing problems, which comprise anxious/depressed, withdrawn/depressed, and somatic complaints, and externalizing problems, which include rule-breaking behavior and aggressive behavior as the primary domains [39]. Collectively, the subscales of the K-CBCL provide a comprehensive assessment of emotional, behavioral, and social functioning, and the K-CBCL serves as a reliable and widely used measure for screening and monitoring psychological symptoms in Korean children.

The K-ARS provides a focused evaluation of inattention and hyperactivity or impulsivity in children with ADHD, whereas the K-CBCL captures a wide spectrum of internalizing and externalizing problems as well as social and behavioral adjustment. Together, the K-ARS and K-CBCL give complementary perspectives on ADHD-specific symptoms and broader behavioral functioning, enabling a multidimensional assessment of ADHD symptom change over time.

Instrumentation: Cognitive Training Program

Neuro-World is a game-based DTx software developed by Woorisoft Co, Ltd, to enhance cognitive function in children with ADHD (Figure 2). The DTx contents include five cognitive tasks, each lasting approximately 5 minutes: (1) identifying shared features among animal figures under continuously changing visual conditions, (2) rearranging sequences of animals to match target patterns, (3) memorizing and recalling animal positions to find matching pairs, (4) independently controlling left and right spaceships to collect target items while avoiding obstacles, and (5) coordinating dual spaceship control to collect targets and avoid obstacles simultaneously. A CONSORT-eHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist describing the Neuro-World intervention and study procedures was completed and submitted separately for editorial review [40] (Checklist 1). We previously demonstrated the effectiveness of Neuro-World in improving cognitive processing speed, working memory, decision-making, and core symptoms of ADHD, and ongoing research is examining its scalability and long-term effects [28-30]. In this study, we further investigated the effects of task difficulty regulation in Neuro-World on ADHD symptom improvement or impairment in the 35 children with ADHD in the intervention group.

XSL•FO
RenderX

Figure 2. The cognitive digital tasks of the game-based digital therapeutics (DTx) software Neuro-World: (1) identifying shared features of animal figures under dynamically changing visual conditions, (2) rearranging sequences of animals to match target patterns, (3) remembering and recalling animal locations to form matching pairs, (4) independently controlling 2 spaceships to collect targets while avoiding obstacles, and (5) coordinating dual spaceship control to perform both actions simultaneously.

Data Sources

Task difficulty in Neuro-World was continuously modified in real time according to the participants' digital task performance to maintain an optimal level of task engagement. Difficulty levels were set to range from 1 (lowest) to 20 (highest). Task difficulty was increased after reaching task-specific predefined thresholds of consecutive correct responses and decreased following consecutive incorrect responses. Depending on the DTx task, greater difficulty was achieved by increasing either the task speed or its cognitive load, such as processing or retaining information. To determine whether task difficulty dynamics differentially affected ADHD symptom improvement, we used 3 indicators derived from the task difficulty-adjustment system: the average task difficulty, task difficulty variability, and task difficulty slope (Table 1). These 3 indicators represent distinct aspects of how the DTx task difficulty regulates the DTx training process and served as the main behavioral variables in the analysis.

Table . Operational definitions and detailed descriptions of task difficulty indicators derived from the Neuro-World digital therapeutics (DTx).

Indicator	Definition	Interpretation
Average task difficulty	The mean task difficulty level across 20 training sessions for each of the 5 tasks.	• The overall individual difficulty level during DTx training for each task. • Higher values indicate that more difficult levels were performed.
Task difficulty variability	The SD of task difficulty across 20 training sessions for each of the 5 tasks.	• Individual variability in task difficulty during DTx training for each task. • Higher values indicate greater variability, whereas lower values indicate more consistent performance.
Task difficulty slope	The linear trend of task difficulty across 20 training sessions for each of the 5 tasks, estimated using a regression model.	• The rate of difficulty changes over time (β_1). • Positive values indicate increasing task difficulty during training, whereas negative values indicate decreasing task difficulty.

Data Analysis

Data analyses were conducted using regression models and independent-samples 2-tailed *t* tests with data from the 35 participants who received the DTx intervention. Separate regression models were constructed for average task difficulty and task difficulty variability, with postintervention psychological outcomes entered as dependent variables and baseline scores included as covariates to control for initial symptom severity. Because the game-based indicators were derived from multiple tasks with similar data structures, strong intercorrelations were observed. Including highly correlated indicators within a single model could introduce multicollinearity and compromise interpretability [41]. Accordingly, each indicator for the 35 participants who received the DTx intervention was analyzed using a separate regression

XSL•FO
RenderX

model. Task difficulty slope represents a regression-derived parameter (β) based on task difficulty over time and was therefore not included as a continuous predictor in an additional regression model. Instead, task difficulty slope values were categorized into positive and negative groups, and independent-samples 2-tailed *t* tests were conducted to compare psychological outcomes between the groups. This approach allowed an examination of whether the direction of task difficulty change was associated with differences in clinical measures. No missing data were identified for psychological or task-derived variables in the DTx intervention group (n=35); therefore, all participants were included in the analyses.

Results

Only the data from the 35 children assigned to the intervention group were analyzed in this study because the primary objective was to examine associations between in-game behavioral metrics and ADHD symptom changes (Table 2). Among these 35 children, 29 (82.9%) were male and 6 (17.1%) were female, with a mean age of 10.17 (SD 2.43) years. The baseline and postintervention score distributions of K-ARS and K-CBCL scores for 35 subjects are shown in Table 3.

Table . Demographic characteristics of the digital therapeutics (DTx) intervention group.

Demographic characteristics	Values
Gender, n (%)	
Male	29 (82.9)
Female	6 (17.1)
Total	35 (100)
Age (y), mean (SD; range)	10.17 (2.43; 6 - 13)

Table . Korean-Child Behavior Checklist (K-CBCL) and Korean-ADHD Rating Scale (K-ARS) scores from baseline to postintervention in the digital therapeutics (DTx) intervention group.

Scales	Baseline, mean (SD)	Postintervention, mean (SD)
K-CBCL (N=35)		
Total score	67.37 (10.46)	57.29 (9.53)
Internalizing problems	63.51 (10.29)	54.60 (9.92)
Externalizing problems	64.51 (11.44)	56.17 (8.74)
K-ARS (N=35)		
Total score	19.57 (9.34)	12.03 (7.59)
Inattention	10.09 (5.16)	6.97 (3.99)
Hyperactivity/impulsivity	9.49 (5.71)	5.06 (4.28)

Associations Between Average Task Difficulty and ADHD Symptoms

Neuro-World was previously shown to attenuate ADHD symptoms in the DTx intervention-treated participants [28-30] (Table 3). Here, we further examined the effects of digital task difficulty on ADHD symptom improvement in the DTx intervention group. Task difficulty was quantified using 3 indicators: average task difficulty, task difficulty variability, and task difficulty slope.

We first evaluated whether the average task difficulties of tasks 1 to 5 modulated ADHD inattention and hyperactivity/impulsivity as assessed by the K-ARS (to assess inattention and hyperactivity/impulsivity in ADHD) and the K-CBCL (to measure internalizing and externalizing symptoms).

The results of multiple regression analyses showed that the average task difficulties of tasks 1, 2, and 4 were significantly associated with ADHD symptoms as measured by the total K-ARS score, whereas none of the tasks were significantly associated with K-CBCL scores (Table 4, Multimedia Appendix 1). Among K-ARS domains, the average task difficulties of tasks 1 to 4 were associated with K-ARS hyperactivity/impulsivity scores with regression coefficients of 0.353, 0.337, 1.927, and 0.382, respectively, whereas effects on K-ARS inattention scores were not observed (Table 4). Positive regression coefficients indicate that higher average task difficulty was associated with higher postintervention symptom scores, reflecting a smaller degree of symptom improvement. Taken together, these findings indicate that training at lower average task difficulty was associated with improvements in specific ADHD symptoms, namely hyperactivity/impulsivity.

Associations Between Task Difficulty Variability and Changes in ADHD Symptoms

Given that we observed a positive correlation between average task difficulty and ADHD hyperactivity/impulsivity, we next performed multiple regression analyses to examine the associations between task difficulty variability and K-ARS and K-CBCL scores.

We found that the task difficulty variability of task 5 was positively associated with postintervention ADHD hyperactivity/impulsivity, as measured by the K-ARS hyperactivity/impulsivity subscore (β=0.721), but not with the K-ARS total score or the K-ARS inattention subscore (Table 5). However, the task difficulty variability of tasks 1 to 4 did not affect the total K-ARS score or the K-ARS inattention and hyperactivity/impulsivity subscores (Table 5). Moreover, the task difficulty variability of tasks 1 to 5 was not associated with the K-CBCL subscale scores (Multimedia Appendix 1). The positive regression coefficients indicate that higher variability in task 5 difficulty was associated with higher postintervention hyperactivity/impulsivity scores, reflecting a smaller degree of symptom improvement. These data suggest that children who trained with more consistent task difficulty levels tended to experience greater alleviation of ADHD hyperactivity/impulsivity symptoms. However, this finding should be interpreted with caution, as the *P* value (.05) was close to the significance threshold.

Comparison of ADHD Symptom Changes as a Function of Negative or Positive Task Difficulty Slope

To determine the effects of task difficulty slope on ADHD symptoms, the participants who received the DTx intervention were classified into positive and negative task difficulty slope groups, and independent-samples 2-tailed *t* tests were conducted. Baseline K-ARS hyperactivity/impulsivity scores did not differ between the negative slope group (mean 8.21, SD 5.89) and the positive slope group for any task (mean 11.00, SD 5.27; *P*>.05). Only the postintervention task difficulty slope of task 1 was associated with a between-group difference in ADHD hyperactivity/impulsivity, whereas the negative and positive task difficulty slope groups did not differ for tasks 2 to 5 (Table 6). Specifically, for task 1, the postintervention K-ARS hyperactivity/impulsivity scores differed significantly between the negative task difficulty slope group (mean 3.68, SD 3.06) and the positive task difficulty slope group (mean 6.69, SD 5.02; *P*=.04; Figure 3). However, significant differences in postintervention K-CBCL scores compared with baseline were not observed in the negative or positive task difficulty slope groups for any of the tasks (Multimedia Appendix 1).

Figure 3. Associations between digital therapeutics (DTx) task difficulty slopes and Korean-ADHD Rating Scale (K-ARS) hyperactivity/impulsivity scores. (Left) Results of paired-sample 2-tailed *t* tests comparing symptom changes between participants with negative (n=19) versus positive (n=16) task difficulty slopes. (Right) Corresponding baseline and posttraining psychological assessment scores for each task difficulty slope group (*P<.05, **P<.01, ***P<.001).

Discussion

Principal Findings

This study aimed to investigate whether task difficulty regulation during adaptive DTx training is associated with ADHD symptom improvement and to evaluate whether difficulty-related behavioral measures can serve as clinically meaningful indicators of treatment response. Consistent with our hypothesis, compared with the attainment of higher absolute difficulty levels, stable and individualized regulation of task difficulty was more strongly associated with improvements in ADHD symptoms, particularly hyperactivity and impulsivity. These results suggest that how task demands are dynamically adjusted during training may be a more clinically relevant factor than the overall level of difficulty achieved.

These findings extend prior research on digital interventions for ADHD by shifting the focus from training intensity and duration toward the structure of difficulty adaptation itself. Previous DTx studies have primarily emphasized treatment efficacy, engagement, and repeated exposure, such as in the AKL-T01 randomized trial [11], while adaptive cognitive training frameworks have generally assumed that progressively increasing task difficulty enhances cognitive outcomes [42,43]. These findings challenge this assumption by demonstrating that dynamic regulation of task difficulty may be more critical than the absolute level attained. Excessive or unstable increases in task demands may undermine behavioral stabilization processes, particularly in domains related to hyperactivity and impulsivity. This pattern is consistent with theoretical models of ADHD that emphasize regulatory control deficits and increased intraindividual variability, suggesting that interventions prioritizing stability over escalation may be better aligned with the neurocognitive profile of this population [44].

Task difficulty in DTx is known to modulate cognitive performance in children with ADHD, with excessively high task demands potentially limiting improvements in attention and cognitive control [45,46]. Children with ADHD also exhibit impaired inhibitory control and increased reaction time variability, reflecting instability in regulatory processes during task performance [47,48]. These observations are consistent with our results, which suggest that frequent changes or excessive increases in task demands may impose additional regulatory burdens, require ongoing adjustment of behavioral strategies, and interfere with stable behavioral control. This may be particularly relevant for hyperactivity-related behaviors. Moreover, given that children with ADHD exhibit deficits in self-regulation, including impulse control and behavioral stabilization [49], symptom improvement may be reduced when task demands exceed an individual's regulatory capacity.

One potential explanation for these findings is that task difficulty functions as a regulatory mechanism that modulates cognitive and behavioral load. High task difficulty or high variance may impose additional demands on inhibitory control and response adaptations, requiring users to continuously recalibrate their behavioral strategies. This process may be particularly challenging for children with ADHD, who typically show deficits in behavioral stability and increased variability in cognitive performance [50]. In addition, fluctuating or overly demanding tasks may increase perceived mental effort and regulatory burden, further interfering with sustained engagement [46]. In this context, stable and appropriately calibrated task difficulty may reduce regulatory burden, thereby facilitating more consistent engagement and behavioral control.

From a clinical and design perspective, these findings have important implications for the development of adaptive DTx systems. First, they suggest that adaptive algorithms should prioritize the stabilization and personalization of task difficulty rather than implementing uniform or progressively increasing difficulty schedules. Second, task difficulty trajectories may serve as potential digital biomarkers that reflect individual differences in regulatory capacity and treatment responsiveness, providing a clinically meaningful metric beyond traditional performance-based measures. This perspective is consistent with emerging approaches in digital phenotyping, which aim to capture dynamic behavioral patterns as indicators of underlying mental health states [51,52]. Finally, by emphasizing the importance of aligning task demands with individual functional capacity, these results support a conceptual shift in

XSL•FO
RenderX

the design of digital cognitive interventions from performance maximization to regulation optimization.

In summary, these findings suggest that the clinical effectiveness of adaptive DTx for ADHD depends not on achieving higher levels of task difficulty but on maintaining stable, individualized regulation of task demands over time. Conceptualizing task difficulty as a dynamic regulatory mechanism rather than a performance target provides a novel framework for understanding and optimizing digital interventions for ADHD. This perspective may contribute to the development of more effective, interpretable, and clinically meaningful game-based therapeutic systems.

Limitations

Two potential limitations must be considered when interpreting the findings. First, the sample size (n=35) was modest, and further validation in larger and more diverse clinical cohorts would strengthen generalizability. Nonetheless, our sample is comparable to or larger than those of other exploratory DTx studies, and the consistent patterns observed across multiple indicators provide preliminary confidence in the reliability of our findings. Second, multiple statistical comparisons were conducted across several task indices and outcome measures. While the results showed meaningful convergence across related analyses, this study was exploratory in nature, and formal correction for multiple comparisons was not applied. Several findings had *P* values close to the conventional significance threshold (approximately 0.04 - 0.05), potentially raising the risk of type 1 error, and should be interpreted with caution. Group distributions were limited, which may constrain the precision of performance-symptom correlations, as well as overall statistical power and generalizability. Studies with larger samples would enable more restrictive statistical correction strategies and validation using confirmatory designs. In addition, individual differences in baseline symptom severity and regulatory capacity may moderate responses to adaptive difficulty, which warrants further investigation.

Future Work

Future research should extend these findings by examining adaptive digital training frameworks that prioritize individualized and stable difficulty regulation across larger and more diverse clinical samples. Such studies should also examine whether adaptive algorithms specifically designed to maintain stable task difficulty lead to greater clinical improvement compared to conventional difficulty escalation approaches. In addition, future studies should systematically investigate how task structure and adaptive control strategies interact to influence symptom-specific outcomes, including hyperactivity and broader behavioral regulation. Such efforts will help refine adaptive algorithms and further enhance the clinical applicability and interpretability of game-based DTx for ADHD.

Conclusion

This exploratory study presents an innovative perspective by demonstrating that stable and individualized regulation of task difficulty, rather than increases in absolute difficulty levels, is a key determinant of clinical response to adaptive digital cognitive training in children with ADHD. Analysis of detailed in-game behavioral data revealed that improvements in hyperactivity and behavioral regulation were more closely associated with stable, personalized difficulty regulation than with absolute difficulty levels or progressive increases in challenge. These results emphasize the role of task difficulty as a mechanism for modulating cognitive and behavioral load, differentiating this study from previous approaches that assumed a linear relationship between difficulty and symptom improvement. Accordingly, the findings highlight the importance of developing DTx that incorporate personalized difficulty trajectories based on real-time user performance. By advancing both conceptual and methodological frameworks for personalized adaptive DTx, this study contributes to the development of patient-centered interventions with enhanced clinical effectiveness and interpretability in real-world settings.

Abstract

Background: Educational escape rooms are increasingly used in medical education to promote engagement, collaboration, and active problem-solving. However, existing literature varies considerably in theoretical grounding and evaluation methodology, and limited evidence exists regarding how specific dimensions of gameful experience may relate to learners' perceived educational value.

Objective: This study aimed to evaluate preclinical medical students' perceptions of a student-designed medical escape room and to examine associations between dimensions of gameful experience and perceived educational value.

Methods: A cross-sectional study was conducted during the 2023-2024 and 2024-2025 academic years among 144 preclinical medical students participating in a student-designed educational escape room. The intervention integrated foundational medical sciences, collaborative problem-solving, and simulation-based procedural tasks. Participants completed anonymous questionnaires after the activity. Perceived educational value was assessed using the Diabetes Escape Room Perception Scale (DERPS), while gameful experience was measured using the Gameful Experience Scale (GAMEX). Descriptive statistics, reliability analyses, principal component analysis with Varimax rotation, Spearman correlation analyses, one-sample Wilcoxon signed-rank tests, and multiple linear regression models were performed using IBM SPSS Statistics version 29. Statistical significance was set at an α level of .05.

Results: Of the 144 participants, 140 (97.2%) completed all questionnaires. The sample was 52.1% (73/140) female, with a mean age of 20.8 (SD 1.5) years. Participants reported favorable perceptions of the escape room, with DERPS scores exceeding the neutral midpoint (mean 4.00, SD 0.50; t_{139}=35.50; P<.001). The GAMEX showed high internal consistency (Cronbach α=0.89), and factor analysis supported the original 6-factor structure. Enjoyment (mean 4.75, SD 0.41), Creative Thinking (mean 4.33, SD 0.56), Activation (mean 3.99, SD 0.63), Absorption (mean 3.70, SD 0.76), and Dominance (mean 3.48, SD 0.81) were above the scale midpoint (all P<.001). Scores on the Absence of Negative Affect dimension (mean 2.11, SD 1.12; P<.001) were below the midpoint, indicating that participants reported some degree of challenge-related negative emotions during the activity. Spearman correlation analyses demonstrated positive associations between DERPS scores and Enjoyment (ρ=0.534; P<.001), Creative Thinking (ρ=0.467; P<.001), and Absorption (ρ=0.319; P<.001). In multivariable regression analyses, Enjoyment was associated with both overall perception scores (β=0.385; P<.001; R^2=.442) and educational efficacy scores (β=0.279; P=.004; R^2=.350). Dominance was related to educational efficacy scores (β=0.194; P=.04).

Conclusions: This study extends existing research on educational escape rooms by combining a relatively large preclinical medical student sample with validated measures of learner perception and gameful experience. Unlike previous studies that primarily assessed satisfaction, the present study identified specific experiential dimensions—enjoyment and dominance—associated with perceived educational value. These findings contribute to a theory-informed understanding of game-based learning in medical education and provide practical guidance for designing immersive, learner-centered activities. These findings support the use of student-designed, digitally enriched escape rooms as engaging educational activities in preclinical medical education.

Introduction

Game-based learning has increasingly gained traction in higher education, particularly within the health professions, as an innovative approach to support student engagement, knowledge retention, and collaborative learning [1-3]. Rooted in experiential and constructivist learning theories, game-based learning leverages immersive environments and problem-solving mechanics to promote active participation and contextualized understanding [4-6]. By simulating real-world challenges and requiring students to apply prior knowledge in a time-pressured and collaborative format, games facilitate the development of critical thinking, decision-making, and teamwork skills, competencies essential for clinical practice [7].

One of the most prominent formats within this pedagogical movement is the educational escape room. In recent years, escape rooms have emerged as engaging and innovative educational tools within health care professions, offering experiential, game-based learning environments that promote teamwork, critical thinking, and active participation. Originally designed as recreational team-based puzzle games, escape rooms have been adapted into instructional tools that merge entertainment with curriculum-based content delivery [8,9]. Educational escape rooms offer immersive, story-driven experiences in which learners work collaboratively to solve domain-specific challenges under time constraints [10]. The format has been applied to various health disciplines, including nursing, pharmacy, public health, and increasingly, medical education [11-13].

Recent evidence suggests that educational escape rooms are increasingly being adopted not only as engagement tools but also as structured pedagogical interventions designed to support clinical reasoning, teamwork, communication, and experiential learning in health care education [9,14]. Emerging studies have also highlighted the growing integration of digital technologies, simulation-based elements, and immersive storytelling within escape room designs, particularly in response to the learning preferences of contemporary medical students [15]. In parallel, recent reviews have emphasized the need for more theoretically grounded and methodologically rigorous evaluations of educational escape rooms, particularly studies employing validated psychometric instruments and larger participant samples [14].

In medical education, escape rooms are particularly promising due to their capacity to integrate cognitive and psychomotor skills. Prior studies have shown their utility in reinforcing clinical reasoning, procedural competency, and communication within both undergraduate and postgraduate contexts [16-18], but also systematically explored the adoption of validated evaluation instruments [19]. Furthermore, escape rooms promote intrinsic motivation, emotional engagement, and interprofessional collaboration, factors that may support educational outcomes and learner satisfaction [20,21]. Despite the growing interest in educational escape rooms, several important gaps remain in the literature, particularly regarding their theoretical grounding and methodological consistency. In this context, recently funded initiatives, such as the Escape4Health project [22], have contributed to the development of structured design recommendations for educational escape rooms, aiming to support more standardized and theory-informed implementations [23]. However, these recommendations also highlight the ongoing need for empirically evaluated, systematically designed interventions that extend beyond isolated or ad hoc implementations in medical education.

However, studies on educational escape rooms have generally focused on narrow disciplinary contexts, such as nursing education, or on specific topics, such as basic life support [24-26]. In addition, many interventions are limited to small-scale implementations within single academic settings. As a result, escape room designs often target specific educational levels or isolated curricular components rather than broader, integrated applications across disciplines.

Moreover, a lack of theoretical grounding and inconsistent evaluation methodologies limit the generalizability and educational rigor of existing evidence [27]. Although learner perceptions are commonly assessed in educational escape room studies, evaluation approaches remain methodologically heterogeneous, and validated multidimensional instruments are inconsistently applied. In addition, studies vary considerably in their theoretical grounding, drawing on diverse frameworks and constructs that can make findings difficult to compare. Consequently, there remains a need for more theoretically integrated investigations examining how specific dimensions of gameful experience relate to perceived educational value within medical escape room activities [28,29]. Existing escape room studies in health care education also vary considerably in their design characteristics, target populations, and educational objectives, making comparisons across studies challenging. Together with differences in evaluation approaches and theoretical framing, this heterogeneity limits the synthesis and generalizability of findings.

Thus, despite the growing interest in educational escape rooms, several gaps remain in the literature. First, many studies rely primarily on satisfaction-based or nonvalidated evaluation approaches, limiting the comparability and robustness of findings across contexts. Second, relatively few studies have systematically examined how specific dimensions of gameful experience relate to perceived educational value in medical education settings. Finally, there is limited use of multidimensional, validated instruments that allow for a more structured analysis of learner perceptions [16,21,25].

To address these gaps, the present study evaluates a student–supervisor co-designed medical escape room using validated instruments, the Diabetes Escape Room Perception Scale (DERPS) [11] and the Gameful Experience Scale (GAMEX) [27], to examine students' perceived educational value and to explore how distinct dimensions of gameful experience contribute to these perceptions in a preclinical medical education context.

Methods

Study Design

This study employed a cross-sectional design to evaluate preclinical medical students' perceptions of a student-designed educational escape room and to examine associations between gameful experience and perceived educational value. Data were collected immediately after participation in the intervention.

Study Setting

The study was conducted in a simulation laboratory at the School of Medicine, Aristotle University of Thessaloniki, Greece. Data collection took place during the academic years 2023‐2024 and 2024‐2025, immediately following the completion of the escape room activity.

Participants

Inclusion and Exclusion Criteria

Inclusion criteria consisted of enrollment in the preclinical years of the undergraduate medical curriculum and participation in the educational escape room activity. Students who did not complete the postactivity questionnaires were excluded from analyses due to incomplete data.

Participant Characteristics

A total of 144 preclinical medical students participated in the study, of whom 140 (97%) provided complete questionnaire data. Participants had a mean age of 20.8 (SD 1.5) years. The sample was 52% female. All participants were enrolled in the same preclinical medical curriculum and had no prior experience with medical escape room activities.

Sampling Procedures

Participants were recruited using convenience sampling from the eligible population of preclinical medical students. Recruitment was conducted via course-related announcements delivered by faculty members. Participation was voluntary, and no incentives were provided.

No a priori power analysis was conducted. However, the achieved sample size (N=144; complete cases n=140) was considered adequate for correlational and multiple regression analyses and exceeded sample sizes commonly reported in similar educational escape room studies.

Educational Escape Room Intervention

Educational Escape Room Design

The escape room was designed through a student–supervisor co-design process involving iterative cycles of development, feedback, and refinement. Medical students contributed to the design of clinical scenarios and puzzles, while faculty ensured clinical accuracy, educational alignment, and appropriate difficulty. The final intervention was implemented in a simulation laboratory setting.

The escape room followed a structured, linear narrative consisting of eight sequential educational challenges, each aligned with core preclinical medical disciplines. The scenario was based on a fictional infectious disease ("Takamuri disease") and was designed to simulate disease progression through increasingly complex clinical and biomedical problems.

The sequence of activities was as follows: (1) measurement and interpretation of arterial blood pressure (physiology), (2) hematological interpretation of leukocyte distributions (hematology), (3) sequencing of glycolysis enzymes to unlock biochemical clues (biochemistry), (4) identification of affected organs based on clinical progression (anatomy and pathology), (5) classification and ordering of vertebrae (osteology), (6) interpretation of cellular structure disruption based on narrative clues (cell biology), (7) pH-based identification of pharmacological compounds and calculation of a treatment formula (pharmacology), and (8) a final integrated emergency scenario requiring cardiopulmonary resuscitation (CPR) on a simulation manikin combined with simultaneous team-based problem solving.

The CPR scenario represented the concluding stage of the escape room and served as a synthesis of prior tasks, integrating theoretical knowledge with basic clinical skills under time pressure. The progression between stages was strictly linear, with successful completion of each task unlocking access to the next.

Supervisors reviewed the content for clinical accuracy, educational alignment, and appropriate difficulty level, while students contributed to the design and usability aspects. The cycle was repeated until a final version of the escape room was achieved. The elective undergraduate course of "Medical Education" has acted as the ground for cultivating such pedagogical approaches and familiarizing students with the theoretical concepts. Then, short demonstrations (by video as well as actual hands-on sessions) played the role of icebreaking while a call for engagement and participation was also released to students by the academic staff. A small group of students volunteered to participate and formed the creators group. The whole design process was informed by the students-creators' firsthand experience with the preclinical curriculum, allowing the learning objectives, level of difficulty, and game mechanics to be closely aligned with medical students' educational needs. By adopting a peer-designed approach, the escape room promoted relevance, engagement, and authenticity, while ensuring that the content remained appropriate for the target student population.

Thus, the escape room designed and used in this study targeted medical students in their preclinical years. The primary objective was to assist medical students in acquiring basic medical knowledge and practicing basic clinical skills through an interactive, game-based learning experience. The educational content of the escape room was structured around fundamental preclinical subjects, including histology, biochemistry, hematology, anatomy, neurophysiology, and pharmacology, while each phase of the game was designed to test essential theoretical concepts relevant to these fields. Participants progressed through multiple riddles, each containing colored locked boxes that the players were required to successfully solve in order to advance. In the final room, participants were additionally asked to perform CPR on a simulation manikin as part of a game scenario in which the game master experienced

XSL•FO
RenderX

a simulated cardiac arrest. This final task aimed to connect the practical clinical skills of the players with their theoretical knowledge, resulting in a meaningful and comprehensive simulated experience.

Learning Objectives

The educational escape room aimed to achieve the following learning objectives:

1. Knowledge acquisition: enable preclinical medical students to reinforce and apply foundational medical knowledge from key subjects, including histology, biochemistry, hematology, anatomy, neurophysiology, and pharmacology.
2. Clinical skills development: provide students with the opportunity to practice essential basic clinical skills within a realistic simulated scenario.
3. Integration of theory and practice: promote the integration of theoretical knowledge with practical clinical decision-making through problem-solving tasks and simulation-based challenges.
4. Teamwork and collaboration: foster effective teamwork by assigning interdependent roles and requiring cooperation among participants to successfully solve puzzles and complete the final challenge.
5. Communication skills: enhance verbal communication and coordination under time pressure.
6. Critical thinking and problem-solving: develop students' analytical thinking by engaging them in sequential riddles that require logical reasoning and medical knowledge to progress.

The stated learning objectives reflect the intended pedagogical design of the escape room intervention and are included to describe its educational structure; they were not operationalized or directly assessed as study outcomes.

Game Mechanics and Narrative

The escape room employed a cooperative, time-limited game structure in which teams of five medical students solved a sequence of interconnected puzzles to progress through the scenario. Each puzzle required application of preclinical medical knowledge and clinical reasoning, with successful completion unlocking subsequent tasks. Progression was linear, ensuring that teams engaged with all educational components before advancing.

To promote collaboration and role interdependence, each participant was assigned a distinct role corresponding to a medical specialty, with access to uniquely colored keys or clues required to solve specific challenges. The final task integrated procedural and cognitive skills, requiring two participants to perform cardiopulmonary resuscitation on a simulation manikin while the remaining team members solved a concurrent puzzle. This design intentionally mirrored real-world clinical teamwork, emphasizing communication, coordination, and shared responsibility under time pressure.

A narrative framing involving a public health emergency was used to provide contextual coherence and enhance immersion; however, the narrative primarily functioned as a supportive engagement mechanism rather than as a learning objective in itself.

A standardized set of digital components was used consistently across all sessions, including QR codes, screen-based prompts, and audiovisual materials. Digital components were integrated alongside the physical environment to enhance interactivity and immersion, including the use of monitors and screens to deliver video briefings, audio files for scenario progression, and QR codes that provided access to clues and additional information. Interactive digital challenges and screen-based challenges were incorporated to support problem-solving and reinforce key concepts. Immediate feedback was provided through both physical cues (eg, unlocking mechanisms) and digital responses (eg, audiovisual prompts following correct or incorrect inputs), and teams were allowed limited guidance from a facilitator if progress stalled. These elements were implemented in a uniform manner across groups. No major technical issues or disruptions were observed during the delivery of the intervention.

Procedure

The escape room was conducted in a simulation laboratory over 60 minutes, with teams of 5 preclinical medical students each. Prior to starting, participants received standardized instructions on game rules, safety, and the learning objectives of the activity. The session was facilitated by 1 faculty member and 1 student facilitator, who provided guidance only when teams were stalled.

Teams progressed through a series of puzzles and clinical tasks using preprepared materials including locked boxes, simulation manikins, and task-specific props. Each session concluded with a debriefing to reinforce learning outcomes and discuss teamwork strategies. Immediately after completion, participants completed the 2 validated self-report questionnaires (DERPS and GAMEX) to evaluate perceptions and gameful experience. All procedures adhered to institutional ethical guidelines, and participants provided informed consent prior to participation.

Measures and Covariates: DERPS

DERPS is a 14-item validated instrument originally developed by Eukel et al [11] in the context of a diabetes-themed educational escape room. It assesses learner perceptions of engagement, teamwork, and perceived educational value using a 5-point Likert scale. In the present study, the DERPS was applied in a medical education escape room context with minor contextual adaptation in wording to align with the broader clinical content and scenario, without modification of the original scale structure or items. The instrument was used to capture generalizable dimensions of learner perception rather than diabetes-specific knowledge outcomes. Thus, although originally developed in a diabetes-specific context, DERPS was used in this study as a generic validated instrument for evaluating experiential and educational perception dimensions in escape room-based learning. No structural modifications were made, and the instrument was used strictly at the level of construct domains rather than content-specific knowledge.

GAMEX

The GAMEX is a 27-item validated instrument measuring 6 dimensions of gameful experience: Enjoyment, Absorption,

XSL•FO
RenderX

Creative Thinking, Activation, Absence of Negative Affect, and Dominance.

The dimension termed Absence of Negative Affect reflects the extent to which participants experience low levels of frustration, anxiety, or other negative emotions during the activity. Higher scores indicate fewer negative emotional experiences.

Composite Evaluation Form

An additional 5-item evaluation form assessed overall satisfaction with the session, including perceived experience, duration, effort, location, and materials. A composite score was calculated as the mean of these items to provide an overall global indicator of participants' appraisal of the educational session, reflecting a broad evaluative judgment across complementary aspects of the experience rather than a distinct latent psychological construct.

Covariates

No additional covariates were included in the analyses.

Statistical Analysis

Software and Preliminary Analyses

Data were analyzed using IBM SPSS Statistics version 29. Descriptive statistics (means, SDs, frequencies, and percentages) were computed. Normality and outliers were assessed using skewness and kurtosis.

Missing Data and Effect Sizes
