Abstract

Background: Patients in the intensive care unit (ICU) who are on mechanical ventilation are at high risk of developing delirium. Virtual reality (VR) technology, as an emerging intervention method, shows promising application prospects in delirium prevention, but its specific experience in clinical practice still requires in-depth exploration.

Objective: This study aims to explore the real experiences of ICU nurses and mechanically ventilated patients in participating in VR delirium prevention, with the aim of providing practical evidence for the optimization and application of this technology in clinical practice.

Methods: A descriptive qualitative research design was adopted. From March to June 2025, using purposive sampling, participants were selected from the internal medicine, surgery, central, and respiratory ICU departments of a tertiary hospital in Zhengzhou. A total of 73 patients on mechanical ventilation were screened. Among them, 49 were excluded due to not meeting the Richmond Agitation-Sedation Scale (RASS) or Barthel Index (BI) score criteria, 5 had delirium at the time of enrollment, 1 was excluded due to visual impairment, and 2 voluntarily withdrew during the study. Finally, 16 patients on mechanical ventilation and 16 nurses were included for semistructured interviews. Data analysis was conducted using the inductive content analysis method.

Results: Through the analysis of the interview data, a total of 3 main themes and 14 subthemes were extracted. In terms of perceived benefits, patients experienced an immersive environment and a sense of empowerment driven by tasks, while nurses felt the convenience of resource integration, the intimacy of the nurse-patient relationship, and a sense of professional significance. In terms of perceived challenges, patients faced difficulties with the interaction interface and physical and mental obstacles, while nurses encountered difficulties in communication assessment and responsibility definition. In terms of perceived needs, patients expected personalized content design and continuity of nursing services, while nurses suggested differentiated content adjustment, comprehensive functional integration, and standardized safety management.

Conclusions: The participants expressed a positive attitude towards the prevention of delirium based on VR and reported various perceived benefits, challenges, and needs. Future research should prioritize content personalization, functional integration, and safety management. Meanwhile, it is necessary to recognize the limitations of this technology in specific target populations. For those who do not meet the inclusion criteria, adaptive alternative intervention measures should be developed to promote the precise and sustainable application of VR-based delirium prevention.

KEYWORDS

intensive care unit; mechanical ventilation; delirium; virtual reality; qualitative research

Introduction

Delirium is an acute brain syndrome characterized by impaired consciousness. It has an acute onset, a short course, and rapid symptom fluctuations [1]. In the intensive care unit (ICU), patients receiving mechanical ventilation are at a high risk of developing delirium, with an incidence rate of up to 50% - 80% [1,2]. It is also associated with prolonged mechanical ventilation, increased hospital stay, cognitive impairment, and an increased risk of adverse events (AEs) [3-5]. Prevention is of the utmost importance.

XSL•FO
RenderX

Its onset is related to various causes, such as neuroinflammation and an imbalance of neurotransmitters, as well as risk factors such as anxiety, pain, and sleep disorders [6]. The prevention strategies mainly include both pharmacological and nonpharmacological interventions. Common sedative and analgesic drugs have side effects and may even induce delirium [7-9], so nonpharmacological interventions are more favored. Measures such as sleep improvement [10], early activity [11], and music therapy [12] can intervene in the risk factors of delirium and improve the comfort and function of patients. However, traditional single measures have limited effects, and the implementation of bundled care faces the challenge of insufficient resources in the busy ICU environment [6,13]. Therefore, it is necessary to explore efficient and operational new prevention methods.

Virtual Reality (VR) technology integrates computer and sensing technologies, enabling the creation of immersive and interactive virtual environments, providing novel support and rehabilitation experiences for patients [14]. Studies have shown that VR shows potential in alleviating anxiety in conventional ICU patients [15], improving sleep [16], promoting activities [17], and enhancing cognitive training [18], and can reduce the incidence of ICU delirium and improve mechanical ventilation [19,20]. Moreover, evidence supports that VR can be safely used in patients with mechanical ventilation [21], and can effectively alleviate their anxiety [22] and improve cognitive function [23], and promote early activity [24].

At present, this field is still in the exploration stage, and there is a lack of in-depth understanding of the real experience of ICU nurses and mechanically ventilated patients using VR to prevent delirium. As implementers, the experiences of nurses affect the intervention effect; as users, the tolerance and acceptance of patients are the key to the application of the technology [25,26]. Qualitative research methods can deeply explore the feelings, needs and obstacles of participants, and providing rich details for understanding complex experiences [27].

Therefore, this study adopted a qualitative research design, using semistructured interviews to deeply explore the experiences and feelings of ICU nurses and mechanically ventilated patients regarding participation in the VR delirium prevention intervention. The aim was to provide practical evidence for optimizing the application of this technology in clinical settings.

Methods

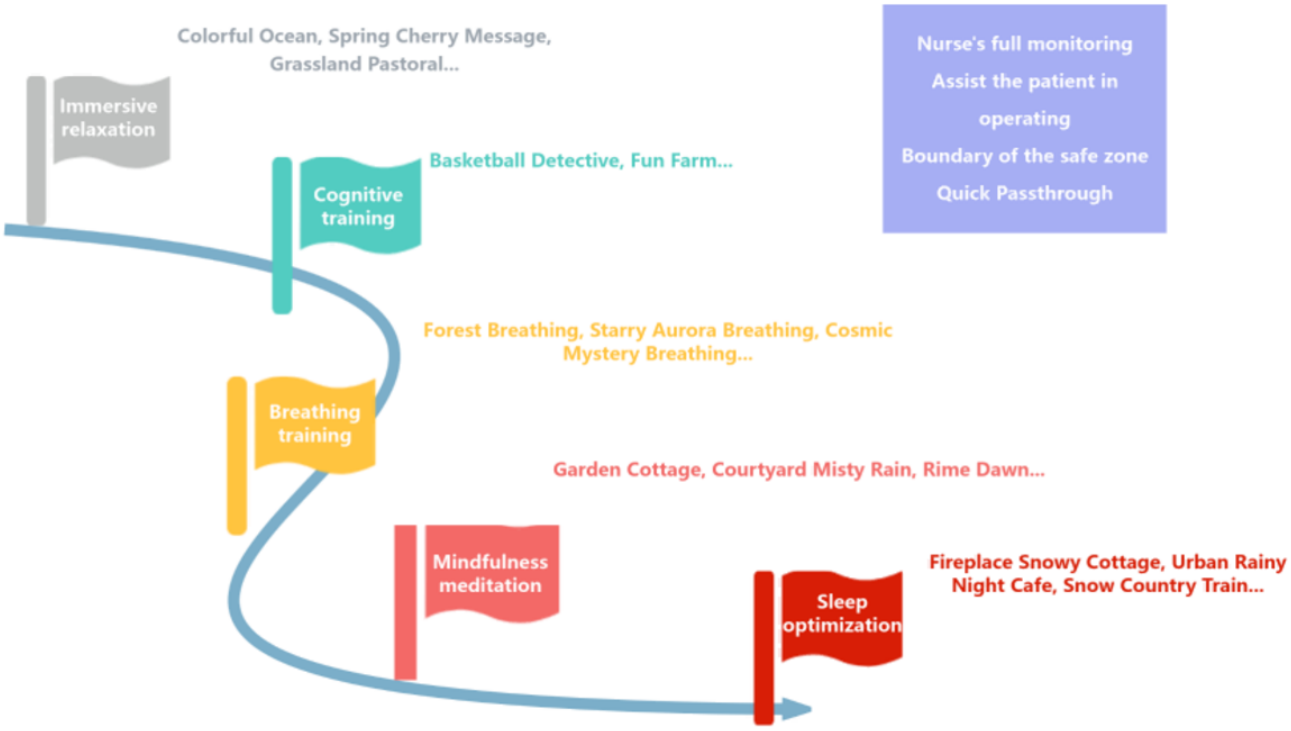
Overview

This study aims to explore the experiences and feelings of ICU nurses and mechanically ventilated patients regarding the use of VR technology for the prevention of delirium, and to provide practical evidence for the application of VR technology in the prevention of delirium in the ICU.

Design

This study used a descriptive qualitative research method, systematically collecting and analyzing textual data to deeply explore the characteristics of the phenomenon and its background. It is suitable for exploring emerging fields [28,29]. Data were collected through semistructured interviews, and their flexible nature helps to deeply uncover the true experiences of the respondents and obtain rich subjective experience data [30], thereby comprehensively presenting the cognition and practice of ICU nurses and patients regarding VR technology in preventing delirium. The research process followed the unified standard list for qualitative research reports, COREQ (Consolidated Criteria for Reporting Qualitative Research) [31], to ensure the quality and rigor of the study.

Setting



From March to June 2025, this study was conducted in the central ICU, internal medicine ICU, surgical ICU, and respiratory ICU of a tertiary hospital in Zhengzhou City. The participants were selected using purposive sampling. After the patients were enrolled, they received the VR technology-based delirium prevention program until they were transferred out of the ICU or had their tubes removed. Each patient was matched with 1 nurse, and all the participants or their families signed the informed consent form. To ensure the homogeneity and continuity of the intervention and to avoid fragmentation and contamination effects, the VR intervention was implemented by the same nurse for each patient from the time of enrollment. During this period, this nurse was solely responsible for the VR intervention and did not participate in other bedside care to ensure the integrity of the nurse's participation and the accuracy of the interviews. All nurses received unified VR technology and delirium management training. AE refers to any adverse medical events, unexpected injuries, or abnormal clinical signs experienced by the study participants. The determination of an AE does not depend on whether there is a causal relationship with the study device, whether it is foreseeable, whether medical intervention is required, or whether there are serious consequences [32]. For digital intervention schemes that combine software and hardware, the physical and mental adverse manifestations of the participants and the technical problems caused by the equipment and clinical operation procedures need to be distinguished; the former belongs to subjective physical and mental discomfort induced by digital intervention and falls within the category of AEs, while the latter are technical problems such as program freezing, network interruption, and abnormal hardware compatibility, which do not constitute AEs and are only recorded as information on the feasibility of the study. Only when equipment failure subsequently leads to physical and mental damage to the participants, can this secondary damage be determined as an AE [33].

The VR intervention uses the domestic PICO 4 device (PICO, ByteDance). It is divided into 4 modules each day at 9 AM: immersive relaxation (5 minutes), cognitive training (15 minutes), and breathing training (8 minutes); at 8:30 PM, there is mindfulness meditation (5 minutes) and sleep experience optimization (20 minutes). Immersive relaxation leads them to explore scenes such as colorful oceans, spring cherry blossoms, and grassland pastoral; interactive functional training trains patients' cognitive functions through fun mini-games such as the fun farm and the detective of basketball; forest breathing, starlight aurora breathing, and mystery of the universe breathing assist patients in conducting breathing training; mindfulness meditation allows patients to follow the guidance to meditate

XSL•FO
RenderX

in natural soundscapes such as the garden cabin, courtyard drizzle, and dawn of frosty mist; sleep optimization experience creates scenes such as a French fireplace snow cabin, urban rainy night café, and snow country train, combined with white noise, to help patients optimize the sleep experience (the specific process of the plan is shown in Figure 1).

Figure 1. Virtual reality delirium prevention plan diagram.

In terms of safety measures, nurses provide continuous supervision and assistance to patients during the operation; the Pico equipment is equipped with a safety zone boundary indication (a blue barrier will appear when the body or handle touches the safety boundary, and the view will switch to the real world if it exceeds the safety boundary) and a quick passthrough function (the nurse or patient can double-click on the side of the helmet to switch the helmet's view to the real world), to ensure patient safety.

Participant Recruitment

This study selected the participants using purposive sampling in the ICU of the aforementioned hospital from March to June 2025.

Inclusion criteria for ICU nurses were as follows: (1) having received training in delirium care before participating in this study and are capable of independently conducting delirium prevention or care for mechanically ventilated patients; (2) having received training related to VR technology and can proficiently use VR equipment; (3) having been included using the maximum difference sampling method from different years of work experience, but with ICU work experience of ≥3 years and different job titles, so that the nurses participating in the study have different levels of delirium management experience; and (4) having voluntarily participated and signed the informed consent form. Exclusion criteria were not having been on duty during the study period and not being current nurses of this hospital.

Inclusion criteria for patients undergoing mechanical ventilation were as follows: (1) ICU patients; (2) first-time patients who underwent invasive mechanical ventilation, and the expected duration of invasive mechanical ventilation was≥48 hours; (3) age of ≥18 years; (4) a Richmond Agitation-Sedation Scale (RASS) score of 0 to +1 (patients within this range are awake or in a mild state of restlessness and can understand and follow instructions) and Barthel Index (BI) of ≥40 points (this score range ensures that the patients have the physical strength and activity ability to complete VR interactive actions); (5) no delirium at the time of enrollment; and (6) voluntary participation and signing of informed consent. Exclusion criteria were as follows: (1) patients with cognitive impairment or mental disorders who cannot cooperate; (2) severe visual or hearing impairment; and (3) various activity contraindications, such as severe cardiac or pulmonary insufficiency, recent major surgery or trauma, intracranial lesion, uncontrolled endocrine or metabolic disorders, etc.

This study used the maximum difference sampling strategy within the framework of purposive sampling. It purposefully included nurses of various ages, years of experience, professional titles, and ICU types, as well as patients of different ages, educational backgrounds, ICU types, and diseases (Table 1). Considering that participants from different backgrounds have diverse experiences and perceptions regarding VR delirium prevention, their acceptance of VR technology, immersive experience, and intervention needs may also vary. Therefore, this sampling method aims to obtain diverse perspectives in order to enhance the transferability of the research results. The determination of the sample size is based on the criterion of data saturation. That is, when the same topic is repeatedly encountered in 3 consecutive interview materials, and the newly

XSL•FO
RenderX

collected data no longer provide additional information or details to enrich the existing topics, it is considered that the data have reached saturation.

Data Collection

This study established a 7-member research team consisting of 1 associate professor (HZ) from the nursing college, 2 ICU nurse managers (MJ and HX), 2 ICU nurses, and 2 nursing graduate students (JL and Yuhao Zhao). All of them possess knowledge of delirium management and have received training in qualitative research.

The interview outline was initially drafted by 2 ICU nurse managers (MJ and HX) through a literature review, group discussion, and expert guidance. It was then optimized and finalized after preliminary interviews with 2 nurses and 2 patients. The interviews were conducted by 2 nursing graduate students (JL and Yuhao Zhao) with experience in delirium-related research and familiarity with delirium management. The interview outline is shown in Table 2.

Table . Outline of interviews with mechanically ventilated patients in ICU[a] and nurses.

Interviewee	Specific issues
Patient	• What is your understanding of VR[b] technology? • How did you feel when experiencing the VR device? • What psychological and physiological changes did you experience before and after using the VR device, and what impacts did it have on you? • What problems or barriers did you encounter during the experience? • From a patient's perspective, what suggestions or improvement ideas do you have for the application of VR technology?
Nurse	• What is your understanding of VR technology? • How do you perceive the application of VR technology in preventing delirium among mechanically ventilated patients in ICU? • What are the main advantages of VR technology? • What problems or barriers do you think exist in the application of VR technology for delirium prevention in mechanically ventilated patients in ICU? • From a health care perspective, what suggestions or improvement ideas do you have for the application of VR technology in delirium prevention among mechanically ventilated patients in ICU?

[a]ICU: intensive care unit.

[b]VR: virtual reality.

After the patients complete the VR intervention (either extubation or transfer out of the ICU), a semistructured interview is conducted with the patients and the matching nurses within 30 to 60 minutes. To reduce memory bias, the interview arrangement is as follows: for patients who have been extubated in the ICU, it is conducted beside the curtain at the bedside (with a "Interview in progress, please do not disturb" sign hanging outside the curtain, strictly restricting the entry of irrelevant personnel to minimize the risk of external interference and information leakage); for those who have been transferred to the general ward and have been extubated, it is conducted in the meeting room of the ward; for patients who have been discharged from the ICU but have not been extubated, communication is carried out through writing or typing; the interviews with the nurses are all conducted in the department meeting room.

Two graduate students (JL and Yuhao Zhao) majoring in ICU nursing served as interviewers. Before the interview, they communicated with the participants, agreed on the interview time and location, and informed them of the interview process. During the interview, the researchers asked questions based on the outline and made flexible follow-up inquiries, recorded both

XSL•FO
RenderX

verbal and nonverbal information, and took notes and made audio recordings simultaneously. If the interviewee became emotionally agitated, they would pause and adjust. The audio data was encrypted and stored, accessible only to the research team. On the day of the interview, 2 ICU nurses (HX and Hao Li) transcribed the text, and after the participants confirmed it, they summarized and analyzed it. When there were no new themes in 3 consecutive sets of data, it was determined that data saturation had been reached. To reduce the potential bias that might arise from both the interviewer and the interviewee having the same background in ICU nursing, the following control measures were adopted in this study: (1) both of the 2 nursing graduate students (JL and Yuhao Zhao) who conducted the interviews received systematic training in qualitative research and conducted preinterview exercises before the formal interviews, which strengthened their neutral stance and reflective awareness and prevented them from bringing their own clinical experience or preconceived opinions into the interview process; (2) the interviews strictly followed a semistructured outline, and the interviewers were required to avoid leading or judgmental language and encourage the interviewees to freely and fully express their true feelings; and (3) after each interview, each interviewee would check the interview records to ensure that the collected information accurately reflected their true intentions rather than the subjective interpretation of the interviewers.

Data Analysis

This study used the inductive content analysis method. Two nurses independently (HX and Hao Li) coded the data, and a nonclinical background associate professor reviewed it to prevent the influence of the analysts' backgrounds on the interpretation of the results. The team conducted 3 rounds of discussions to resolve differences and reach consensus, ensuring the accuracy and consistency of the analysis results. This method does not require a predefined theoretical framework and can systematically summarize concepts and themes from the original data, which is suitable for exploring complex phenomena and helps to deeply understand the real experiences of the research object [28-30]. The specific analysis steps are as follows:

1. Data Preparation: Transcribe the interview recordings into text, perform deidentification to protect privacy, and read through the entire text to grasp the overall content.
2. Line-by-line Coding: Analyze the text line by line, identify and mark meaningful content units, and form initial codes. For example, the patient's description, "feeling as if I were on the beach, without the cold machines," is coded as "immersive relaxation."
3. Cluster Subthemes: Group and integrate similar initial codes to form more general sub-themes. For example, the codes "immersive relaxation" and "multisensory soothing" can be classified as "immersive VR situational experience."
4. Extract Core Themes: Further integrate the subthemes, abstract, and refine the core themes that can reflect the essence of the phenomenon. For instance, through the analysis of multiple subthemes, the core theme "benefits of perceived involvement in VR delirium prevention" can be ultimately extracted.
5. Verification and Improvement: Cross-verify the text content with nonverbal information recorded in the interviews (such as expressions and tone) to enhance the credibility of the results.

The research team handled coding disputes through a structured 3-round discussion: in the first round, each presented the basis for the coding; in the second round, they focused on the main points of disagreement and delved deeper into the original text for discussion; in the third round, they aimed to reach consensus, based on the majority opinion and the research purpose, to determine the final coding and themes.

After inductively extracting themes and subthemes from interview data, the research team used the Systems Engineering Initiative for Patient Safety (SEIPS) model as a theoretical framework to organize and interpret findings [34]. The SEIPS model describes a work system that consists of 6 interacting elements, named Persons, Tasks, Tools and Technology, Organization, Internal Environment, and External Environment, and holds that work process outcomes are shaped by interactions and adaptations among these elements. In this study, extracted themes and subthemes were mapped onto the 6 SEIPS elements to systematically identify facilitating factors and implementation obstacles for VR-based delirium prevention in the ICU.

Rigour

This study adheres to the rigorous framework for qualitative research proposed by Guba and Lincoln [35]. To ensure the quality of the research, the following aspects were implemented: reliability was ensured through independent transcription and coding by 2 individuals (HX, Hao Li and Huijie Zhao) and review by a third party; credibility was achieved by extending the interview duration, reaching consensus with the research team, and conducting triangulation of data with field notes; transferability was enhanced through maximum difference sampling; confirmability was ensured by fully preserving the data, using software for analysis, and following a strict bottom-up process to avoid interference of theoretical presuppositions in data analysis.

Ethical Considerations

This study was conducted in accordance with the Helsinki Declaration and was approved by the Bioethics Committee of Henan University on September 2, 2024 (approval number: HUSOM2024-434). All participants or their legal representatives were fully informed of the study purpose, process, potential risks and benefits, as well as the right to withdraw at any time without affecting their clinical treatment, and signed a written informed consent form before enrollment. All interview data were anonymized to protect the identities of the participants. Each participant was assigned a unique code (Patient P1-P16, Nurse N1-N16), and the transcripts and final reports do not contain any personal identification information. The audio files were stored on a device with password protection, accessible only to the research team. This study did not provide any economic or other forms of compensation to the participants.

XSL•FO
RenderX

Results

Overview

The study evaluated a total of 73 ICU patients aged 18 years or older who underwent invasive mechanical ventilation for the first time and whose expected duration of invasive mechanical ventilation was≥48 hours. Among them, 49 patients were excluded due to noncompliance with the RASS score and BI score criteria. 5 patients had delirium at the time of enrollment, 1 patient was excluded due to visual impairment, and 2 patients voluntarily withdrew during the study. In total, 32 participants were included in this study, including 16 ICU patients undergoing mechanical ventilation and 16 ICU nurses. During the VR intervention process, some patients experienced adverse physical and mental reactions, including dizziness, anxiety, and tension induced by the intervention, fatigue, and physical discomfort. These symptoms could be alleviated by suspending the VR intervention, and no additional clinical treatment was required. According to the definition [32,33], the above situations were classified as AEs. The study also recorded several process obstacles, mainly including clinical diagnosis conflicts and difficulties in equipment operation. These obstacles did not directly harm the patients, but led to the premature termination of the VR intervention. The combination of these 2 types of problems resulted in 23 VR interventions failing to be completed as planned. General information of the participants is shown in Table 1, and the records of VR intervention compliance and adverse experiences are shown in Tables 3 and 4. Based on the interview data, a total of 3 themes and 14 subthemes were extracted (Figure 2).

Table . VR[a] intervention compliance and experience records.

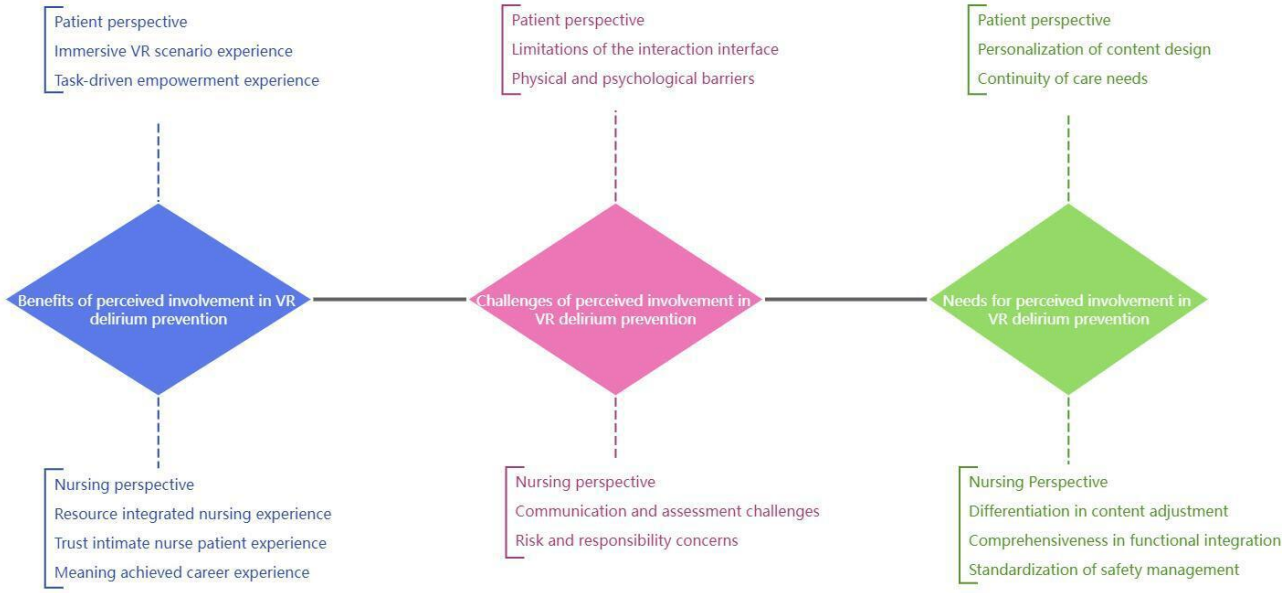
Indicator	Result	Notes
Total hospitalization days of the patients (days)	192	—[b]
Number of daily plans (times)	2	—
Total number of plans (times)	384	—
Actual completion times (times)	361	The overall compliance rate was 94.0%.
Average duration of each use (minutes)	24	—
Number of incomplete times (times)	23	It was not completed due to both AEs[c] and process obstacles.

[a]VR: virtual reality.

[b]Not applicable.

[c]AE: adverse event.

Table . VR[a] negative experience records.



Types of negative experience	Number of events	Number of affected patients	Notes
AEs[b]			
Vertigo	4 times	1 patient	The symptoms will subside on their own after stopping VR use, and no medical intervention is required.
Nervousness and anxiety	3 times	3 patients	The symptoms will subside on their own after stopping VR use, and no medical intervention is required.
Fatigue or physical discomfort	7 times	5 patients	The symptoms will subside on their own after stopping VR use, and no medical intervention is required.
Process obstacles			
Clinical diagnosis and treatment conflicts	6 times	5 patients	Conflicts in clinical work such as suctioning and blood gas sampling
Difficulty in operating the equipment	3 times	3 patients	Problems with executing operations

Figure 2. Themes and subthemes in the research. VR: virtual reality.

Benefits of Perceived Involvement in VR Delirium Prevention

Patient Perspective

Immersive VR Scenario Experience

Most patients undergoing mechanical ventilation reported that the VR delirium prevention intervention provided them with multisensory relaxation and immersive experiences, breaking the monotony of the hospital ward. Through the interactive functions of VR, patients could actively participate in simulation activities and feel that their physical functions had been exercised.

> *Wearing the VR device, I can go to a peaceful beach. In front of me is the illuminated sea surface, and in my ears are the sounds of the waves and the chirping of birds. This temporarily makes me forget my illness and my mood becomes much more relaxed. Especially when I have a tube inserted and am often thirsty, the mini-game in the VR where you open the refrigerator and see the cold air and beverage images makes me feel extremely refreshing and quenched.* [P8]

> *I listened to the sounds of the fireplace and the rain in the VR, and followed the voice to empty myself in the forest. The environment became quiet, and I could fall asleep unconsciously. I became less sensitive to the alarm sounds and conversations around me. The small games played through the controller allowed me to move even when the tubes were plugged in, and my arms felt less stiff; the fruit-picking game made my mind more agile, and I could concentrate without daydreaming.* [P9]

Task-Driven Empowerment Experience

Most patients believe that the game settings and real-time feedback in the VR environment enable them to immerse themselves more deeply in the experience, allowing them to gain a sense of freedom and control that is different from reality.

> *In VR, it made me feel that I could still do many things, unlike before when I could only lie down. Every time I completed a small task, there would be a reward prompt on the screen. That sense of achievement made me very happy. Although I knew it was a simulation, seeing the training data improve little by little, I felt that I was getting closer to a normal life, no longer a passive patient receiving treatment.* [P11]

Nursing Perspective

Resource-Integrated Nursing Experience

Most nurses believe that VR has overcome the limitations of time and space by integrating multiple measures for preventing delirium, and it is efficient and convenient to use. Compared with traditional bundled measures, nurses have felt that VR has alleviated their workload in delirium prevention.

> *In the past, when preventing delirium, we were under great mental stress. We had to prevent tube removal, chat with the patients, adjust the lighting, play music, and conduct cognitive training. When there were fewer staff, it was even more chaotic. Now with VR, patients can listen to the sound of waves and the virtual wind. Their vital signs are stable, and they cooperate with the treatment. One device replaces multiple operations, saving manpower and time. This enables us to focus more on observing the patient's condition and optimizing the care, which is beneficial for both the nurses and the patients.* [N6]

Trust Intimate Nurse-Patient Experience

VR technology provides a new platform for nurse-patient interaction. Nurses participate throughout the patient's experience, achieving close and continuous interaction, thus making the nurse-patient relationship feel more intimate.

> *Previously, nursing work was mostly routine operations, with limited communication with patients.*

XSL•FO
RenderX

> *Now, with the help of VR, we can assist patients in wearing the equipment, select appropriate scenarios based on their emotions and needs, and then provide companionship, guidance, and encouragement. This enables us to deeply understand their feelings, which has strengthened the trust between us and the patients and made our relationship more intimate.* [N1]

Meaning Achieved Career Experience

Most nurses stated that the application of VR technology has enabled them to transform from traditional disease caregivers to comprehensive protectors of patients' physical and mental health, allowing them to have a deeper understanding of the value and significance of their work.

> *Previously, tasks such as administering injections, changing dressings, and monitoring clinical progress were important, but they were more like following medical instructions, lacking warmth. Wearing VR devices for patients was not simply handing something over. Seeing them experience it and nodding or giving a thumbs-up, I felt a great sense of achievement. At the same time, VR also exposed me to cutting-edge nursing concepts, and from it, I gained new professional knowledge and skills, allowing me to truly understand that our work is not only about saving lives, but also about helping patients regain hope. This is the true meaning of nursing.* [N13]

Challenges of Perceived Involvement in VR Delirium Prevention

Patient Perspective

Limitations of the Interaction Interface

Some patients reported that the interactive interface of the VR system affected their overall experience of using it.

> *Looking at all the buttons and menus on this device, I'm totally lost. I don't know how to operate it. I memorize the steps, but the moment I turn around, I forget everything.* [P6]

> *When the scenes change too rapidly, one may feel dizzy. Some games are too realistic. For instance, in the basketball shooting game, I felt as if that basketball was really going to hit me, which was a bit scary. Some scenes are in the air, and I have a bit of acrophobia.* [P5]

Physical and Psychological Barriers

Patients undergoing mechanical ventilation are bedridden for a long time, resulting in physical weakness, reduced limb strength, and mobility. When using VR equipment, they are prone to fatigue and consume a lot of energy. Some patients are unfamiliar with VR technology and are worried that the equipment might cause harm to their bodies; thus they have reservations and are very nervous when using it.

> *I'm lying in a hospital bed and haven't exercised in a long time. I tried some scenes in the VR, but found that I had to constantly raise my hands and turn my head. However, my body was too weak and I couldn't manage to follow the movements.* [P4]

> *When performing the movements and adjusting the helmet, I was extremely cautious, fearing that I might pull the tubes. During my first attempt, all I could think about was 'Will the tubes in my nose be damaged, affecting the machine's air supply?' When using it, my body unconsciously tensed up.* [P13]

Nursing Perspective

Communication and Assessment Challenges

The nurses reported that patients with intubation had difficulty accurately conveying the complex emotions experienced in the VR environment, fearing that misunderstandings would affect the implementation of the intervention; moreover, most of the nurses stated that it was difficult to quantitatively assess the patient's experience and changes in the risk of delirium, which would hinder the precise application of VR in the prevention of delirium.

> *Every time I try to understand the patient's feelings, I can only rely on observing their expressions and subtle gestures. Sometimes the patient shakes their head, and it's hard to tell whether they are looking at different scenes or expressing dissatisfaction. I'm afraid of misunderstanding, and not only can't help them, but it even makes them feel worse.* [N7]

> *The problem is that currently there are no specific tools or guidelines available to assess the effectiveness of VR use in ICU patients. We have to rely on our own observations and guesswork to determine how patients are experiencing it and whether the risk of delirium caused by VR has decreased.* [N4]

Risk and Responsibility Concerns

Some nurses pointed out that although VR technology is already mature, when it is used as a medical device in the ICU, there are concerns about legal risks due to the lack of clinical guidelines and clear responsibility definitions.

> *We are quite optimistic about VR technology. However, when it is used in the ICU, the rules and responsibilities are not clear. We don't know who should be held responsible if something goes wrong. Both the nurses and the hospital could be involved. This uncertainty makes us feel very unsure.* [N13]

Needs for Perceived Involvement in VR Delirium Prevention

Patient Perspective

Personalization of Content Design

Most patients expect VR content to be more diverse and personalized, in order to alleviate the monotony of the hospital ward. They have a greater demand for emotional interaction with family members, and hope that VR can provide immersive family scenarios or recreate cherished memories, thereby alleviating the emotional void caused by isolation.

XSL•FO
RenderX

> *If there were furry cartoon animals or beautiful Chinese-style scenes in VR, just looking at them would make one's mood improve.* [P17]

> *I really want to see the familiar rural courtyard and the villagers working in the fields. I even more desire to return home and see the family members having meals and chatting together. Even just hearing their voices would be extremely comforting.* [P5]

Continuity of Care Needs

Most patients hope to extend VR technology into continuous care, in order to obtain a continuous relaxation experience and psychological support.

> *While I was in the ICU with the tubes, VR helped me divert my attention and do activity training. After being discharged from the ICU, the tubes were still there, and I was always worried. I hope the VR program in the ICU can be continued in the general ward, at least until the tubes are removed, which can alleviate anxiety and also contribute to recovery.* [P2]

Nursing Perspective

Differentiation in Content Adjustment

Most nurses suggest that VR content should be designed differently based on the age and cultural background of the patients, in order to better match their actual situations.

> *It is suggested that VR content should be categorized based on age groups and cultural backgrounds. Young men can have more elements of science fiction and espionage; female patients can focus on intangible cultural heritage and fashionable art. Elderly people can concentrate on opera, history, and tea drinking and playing chess in tea houses. The content should be developed in line with the regional cultural background of the patients, such as the scenery of the Jiangnan water towns or the folk customs of the northwest. At the same time, the duration of the content should be controlled to avoid patient fatigue.* [N13]

Comprehensiveness in Functional Integration

Some nurses stated that, based on the characteristics of patients with tracheal intubation, nonpharmacological preventive measures should be systematically integrated into VR. VR not only needs to provide a relaxing experience, but also should incorporate educational and motivational elements in order to better support the long-term prevention and rehabilitation of patients.

> *The application of VR in the ICU can be more comprehensive. In terms of training, more virtual scenarios can be designed so that patients can perform breathing exercises in different scenarios. This offers more options and is easier for them to stick to. Additionally, vivid and intuitive animations can be used to perform the principles of the disease and the treatment process for them, which will help them understand better. The effect will be better than watching ordinary videos.* [N8]

Standardization of Safety Management

The ICU environment has high requirements for equipment safety. Nurses believe that the introduction of VR technology poses risks related to equipment and fire safety; therefore, strict management measures should be implemented.

> *The ICU environment is quite special, with high oxygen concentration and a large number of multi-drug resistant patients. If VR equipment is introduced, strict control over disinfection procedures and consumable management is necessary; otherwise, cross-infection could easily occur. Fire safety also needs to be considered. If the equipment gets hot or is charging, and if a circuit short-circuit were to happen, it would be a big problem. These aspects of wearing, monitoring, and disinfection could all increase our workload.* [N14]

The correspondence between the extracted themes and the elements of the SEIPS model [34] is summarized in Table 5.

XSL•FO
RenderX

Table . Correspondence of elements in the SEIPS[a] model.

SEIPS model components	Promoting factors	Obstacle factors
Persons	• Patient: immersive situational experience brings emotional relaxation and psychological empowerment (3.1.1) • Nurse: resource integration sense, nurse-patient intimacy, and professional achievement sense (3.1.2)	• Patient: limited physical capacity, dizziness, anxiety, difficulty in operation, and concerns about the tubes (3.2.1) • Nurse: difficulties in communication, lack of dedicated assessment tools, and concerns about liability risks (3.2.2)
Tasks	• VR[b] integrates multiple nonpharmacological interventions such as relaxation, cognitive training, breathing exercises, meditation, and sleep optimization (2.2)	• Conflicts with clinical operations such as suctioning and blood gas sampling (Tables 3 and 4); wearing, monitoring, and disinfecting the equipment adds additional workload (3.3.2)
Tools and technology	• PICO 4 safety zone boundary indicators, quick perspective function, and multisensory virtual environment (2.2, 3.1.1)	• Interface is complex and some scenarios cause discomfort, content lacks personalization, and function integration is insufficient (3.2.1, 3.3)
Organization	• Unified specialized training and full-time nurses ensure the continuity of intervention throughout the process (2.2)	• Lack of standardized operation procedures, unclear definition of responsibilities, and absence of continuous care support systems (3.2.2, 3.3.1)
Internal environment	• The VR virtual environment can go beyond the physical space limitations of the ICU[c] ward and create an immersive relaxation environment (3.1.1).	• The high-oxygen environment in the ICU has strict requirements for the electrical safety of equipment; the presence of multidrug-resistant bacteria imposes strict demands on disinfection procedures; and tubing restricts physical movement (3.2.1, 3.3.2).
External environment	• The policy environment is relatively lenient, allowing for exploratory clinical applications.	• There is a lack of industry guidelines and regulatory norms for ICU VR applications in China; and the equipment access and charging procedures are unclear (3.2.2).

[a]SEIPS: Systems Engineering Initiative for Patient Safety.

[b]VR: virtual reality.

[c]ICU: intensive care unit.

Discussion

Principal Findings

Based on the SEIPS model framework [34] elaborated in the methodology section, this study analyzed the perceived promoting factors and obstructive factors for the promotion of VR delirium prevention intervention among ICU nurses and mechanically ventilated patients, focusing on 6 interacting elements: personnel, tasks, tools and technologies, organization, internal environment, and external environment. The model indicates that the effectiveness of the application of new technologies is not only determined by the technical attributes of the tools themselves, but also depends on whether the tools can effectively adapt to the operator's capabilities, task processes, the environment they are in, and the supportive organizational system. The higher the degree of adaptation, the better the final implementation effect.

Perceived Benefits and Limitations in Human-Technology Interaction

In the SEIPS model, human and technological tools are 2 closely integrated elements, and the quality of their interaction directly affects the technology application experience [34]. In this study, the positive interaction between humans and technology resulted in perceived benefits. VR, through multisensory virtual scenes, shifted patients' attention away from pain and monitoring noises, creating a perceptual space isolated from the physical environment of the ICU, making patients feel emotionally relieved and at ease. The immediate feedback from gamification interaction enabled patients to gain a sense of active control while lying passively, compensating for the loss of autonomy due to illness, which is consistent with previous findings that VR can alleviate anxiety in ICU patients [22]. What the nurses experienced was not the sequential execution of traditional bundled care, but a more continuous process; the full-time companionship also generated scarce interaction opportunities in routine care, allowing nurses to perceive an intimate nurse-patient relationship and a sense of achievement; this is

XSL•FO
RenderX

consistent with the conclusion proposed by Dailah et al [36] that digital tools can enhance the satisfaction of the nursing profession. These indicate that when the technical functions are well adapted to human needs, the interaction between human and technological elements can produce positive effects.

However, there are also limitations in the interaction between the two, and the obstacles stem from the mismatch between human physiological, psychological, and cognitive characteristics and technological design. Physically, patients' long-term bed rest leads to muscle strength decline and limited mobility, while VR interaction requires head rotation and upper limb movement, and the mismatch between ability and demand results in fatigue and limited participation; some patients' dizziness may be due to the physical settings of the device screen not matching the patient's line of sight focus, but this reaction is tolerable for most patients and does not cause safety issues [37]; psychologically, patients' concerns about pipeline safety, the way of wearing the equipment close to the tracheal tube, trigger physical and mental tension. Additionally, interaction interfaces exceeding their cognitive levels lead to operational difficulties, and the lack of personalization and insufficient function integration reflect the adaptability limitations of VR technology for patients from different cultural backgrounds. Among the 73 patients in this study, 49 (67.12%) cases were excluded due to not meeting the standards for consciousness or activity ability. This high exclusion rate clearly defines the applicable boundaries of VR intervention; that is, VR is more suitable for mechanically ventilated patients with clear consciousness and certain activity ability, and is more difficult to implement for patients with deep sedation or severely impaired functions, suggesting that the disease stage plays a regulatory role in the interaction between humans and technology.

Implementation Process Guarantees and Barriers in Task and Organization

In the SEIPS model, tasks and organizational elements are mutually dependent [34]. The sequence, complexity, and resource requirements of tasks are constrained by organizational scheduling, personnel allocation, and institutional regulations, while organizational support affects the quality of task completion. In this study, both provide implementation support. At the task level, VR integrates multiple nonpharmaceutical interventions into the same device, facilitating nurses' unified execution; at the organizational level, unified specialized training and full-time nurses' continuous responsibility ensured the continuity of task execution. Both are important conditions for achieving a 94.0% compliance rate in this study, demonstrating their role in the implementation effect.

However, in clinical application, there are also contradictions between task characteristics and organizational resources. The task time is fixed as either morning or afternoon, which conflicts with the unpredictable nature of the organizational environment. The fixed-time characteristics of VR tasks and clinical operations such as suctioning and blood gas collection compete with each other. Among the 23 times the intervention was not completed in this study, 6 times it was interrupted due to this reason. This is similar to the mechanism that makes bundle care difficult to implement in busy ICUs. However, VR intervention has advantages such as equipment integration and strong operability, making it more flexible in terms of time usage [6,13]. There is a contradiction between the additional workload of the task and the organization's human resource allocation. Equipment preparation, wearing monitoring devices, and disinfection after use increase the complexity of the task. When incorporated into the routine process, it will compete for limited human resources. The organizational support lags behind the task requirements. Specifically, there is a lack of effective communication tools for patients with mechanical ventilation, making it difficult for patients to obtain timely information; there is a lack of standardized operating procedures, resulting in no norms for task execution; the responsibility attribution is unclear, causing nurses to have legal-level risk concerns; and there is a lack of supporting continuity care systems. This is essentially an inability of organizational elements to make adaptive adjustments to new task types. Consistent with the qualitative research by Thissen et al [38] on the implementation obstacles of the ICU computerized intensive care information system, the mismatch between task processes and organizational systems is the main resistance to the implementation of new technologies. In the future, the operation process of VR intervention in ICUs can be adjusted, personnel arrangements can be optimized to make it more in line with clinical needs, and the existing mismatch problems in the implementation process of new technologies can be improved.

Physical Space and Policy Norms in Environmental Constraints

The internal environment in the SEIPS model, which refers to the physical characteristics of the workplace [34], has a facilitating effect on the implementation of VR, but there are also limitations that need to be considered. The facilitating effect is manifested in that the VR scene builds a virtual natural environment for patients through a combination of audio and visual means, compensating for patients' need for environmental diversity, which is consistent with the findings in previous studies that VR improves the environmental experience of ICU patients [39]. However, due to the influence of the special clinical environment of the ICU, the application of VR requires strict management. Analyzing the reasons, the high-oxygen environment in the ICU ward combined with the slight heat generation during the operation of the VR headset poses potential fire safety hazards, which is also a concern for nurses in practical applications. Secondly, the ICU ward has the characteristic of multiple colonization of drug-resistant bacteria, and the VR equipment has the application requirement of multiple people sharing. This makes surface disinfection of the equipment an important part of infection control, and currently, there is no standardized operating specification for VR equipment in clinical practice, which to some extent increases the difficulty of clinical infection control. The study points out that the head-mounted display may become a carrier of microbial transmission in the medical environment, and the current classification and management requirements are still insufficient, suggesting the need to establish cleaning, disinfection, and reuse norms for VR equipment [40]. In addition, various treatment tubes such as tracheal intubation and monitoring leads left by

XSL•FO
RenderX

ICU patients will limit the range of head and upper limb movements of patients. Therefore, VR scenes that require significant body coordination should consider the patient's physical condition.

The external environment refers to the macro policies and regulatory factors outside the organization [34]. From the perspective of the external environment, there are currently no professional guidelines or regulatory norms for the application of VR technology in ICU scenarios. Garrett et al [41] believe that the lack of complete policies will affect the configuration willingness of medical institutions and is not conducive to the regular and sustainable implementation of VR technology in the ICU. Therefore, in the future, lightweight, easy-to-disinfect, and compatible with medical tubes dedicated VR hardware can be developed, and equipment cleaning and disinfection norms can be established, and industry standards can be improved to ensure the feasibility and standardization of VR intervention in the complex physical environment of the ICU.

Limitations

This study is a single-center design, and there are certain limitations in the representativeness of the sample, which may affect the transferability of the results; future multicenter longitudinal studies can be conducted to more comprehensively evaluate the long-term effects of VR in different social and cultural contexts. At the same time, the inclusion criteria limit the participants to those who are conscious and have certain activity abilities among mechanical ventilation patients. Therefore, when extending the conclusion to patients with deeper sedation or poorer functional status, caution is needed; future simplified VR programs can be developed for the excluded subgroups. The adverse experiences reported in this study were all brief and mild subjective feelings, and no serious AEs occurred. However, relevant data still need to be collected in the future to establish a more complete safety assessment framework.

Conclusions

This study, based on the experiences of patients and nurses, identified the perceived benefits, challenges, and demands of both in the prevention of VR delirium. Patients gained immersive experiences and a sense of task-driven empowerment; nurses shared the convenience of integrating nursing resources, experiencing a closer nurse-patient relationship, and professional significance. Both parties pointed out challenges such as insufficient technical adaptation, difficulties in communication and assessment, and ambiguous responsibility definitions. They also expressed diverse demands for personalized content, functional integration, and safety management. The exclusion rate of up to 67.1% indicates that VR intervention is only applicable to specific groups of people, not all ICU mechanically ventilated patients. These findings enrich the understanding of the application of VR technology in ICU delirium prevention from a qualitative perspective, suggesting that when promoting this technology in the future, attention should be paid to clinical individual differences and organizational support, establishing a screening process for matching patients and interventions, and formulating alternative intervention plans for those who are not suitable.

Abstract

Background: The epidemiological situation of major emerging infectious diseases (MEIDs) continues to be severe. This requires each country and region to be vigilant, strengthen cooperation, and take effective prevention and response measures. This highlights the public's demand for education on health and safety measures. Virtual interactive systems have played a critical role in many fields. Consequently, we designed and developed a virtual interactive system (People's War Against Pandemic) aimed at training the public to respond to MEID outbreaks.

Objective: This study aimed to evaluate the efficacy of a novel storyline-driven virtual interactive system (People's War Against Pandemic) in enhancing emergency preparedness and infectious disease health literacy among adolescents.

Methods: A single-blind (outcome assessors blinded), 2-arm, parallel-group randomized controlled trial was conducted in a secondary vocational school from October 2023 to December 2023 in Luzhou, Sichuan. A total of 120 adolescents were recruited through on-site recruitment and were randomly assigned to the intervention group (n=60) and the control group (n=60). The intervention group was trained using a virtual interactive system and traditional lectures, whereas the control group received only traditional lectures. Self-reported questionnaires assessing emergency preparedness for MEIDs and infectious disease health literacy were used to evaluate the effect of the virtual interactive system before and after the intervention. Repeated-measures ANOVA was used to scrutinize variations in outcome indicators across time points within and between groups.

Results: The results showed that emergency preparedness and infectious disease health literacy scores improved in both the control and intervention groups. Additionally, emergency preparedness and infectious disease health literacy scores in the intervention group were higher than those in the control group (P<.001). A repeated-measures ANOVA revealed significant group, time, and group × time interaction effects in emergency preparedness and infectious disease health literacy scores.

Conclusions: The virtual interactive system was effective in improving adolescents' self-reported emergency preparedness and infectious disease health literacy in the face of MEIDs.

Introduction

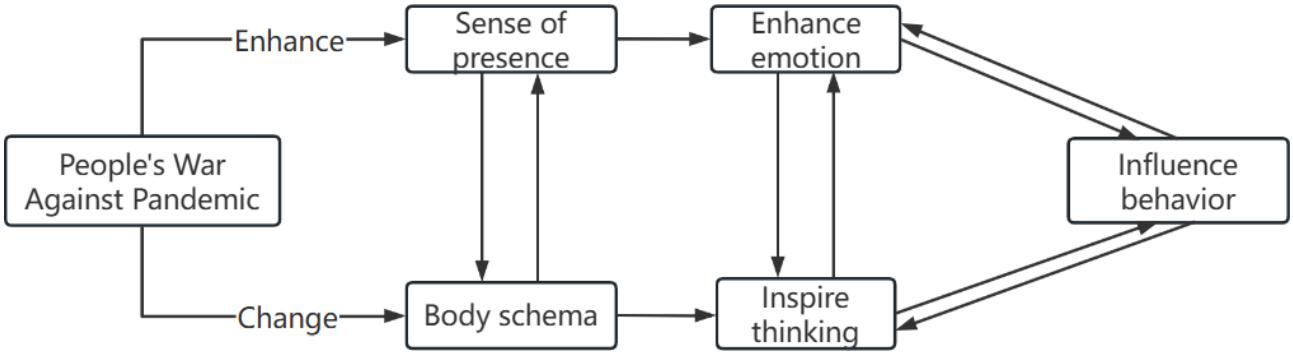
Background

With the deepening development of globalization, increased population mobility, accelerated urbanization, and changes in the ecological environment, the frequency, scope, and impact of major emerging infectious diseases (MEIDs) in the world have increased in recent years [1]. MEIDs such as SARS, H1N1 influenza, Middle East respiratory syndrome (MERS), Ebola virus disease (EVD), and COVID-19 have posed significant threats to human health and social stability [2]. Research has indicated that the world will continue to face the growing and increasingly severe challenges posed by MEIDs [3]. Therefore, global preparedness for MEIDs is urgently needed, requiring heightened vigilance, strengthened cooperation, and effective preventive and response measures from every country and region.

Due to their distinctive physiological and psychological characteristics, adolescents exhibit more complex susceptibility to and transmissibility of MEIDs compared with adults, highlighting their vulnerability in public health emergency preparedness [4]. Adolescents spend most of their time in schools characterized by large populations and complex hierarchical structures, alongside frequent collective activities and numerous public spaces on campus. If there is a sudden outbreak of MEIDs, the spread rate is often extremely rapid. It seriously affects the progress of teaching, disrupts the orderly daily management of the campus, and potentially poses serious threats to the lives and safety of individuals within the school [5]. Meanwhile, it may cause widespread psychological panic and social disorder. Currently, the emergency preparedness among adolescents in many countries and regions remains deficient, which is mainly manifested by the lack of disease prevention knowledge, weak response capabilities in emergency situations, and insufficient protective measures and coping resources, which aggravate the threat of MEIDs to adolescents [6]. Therefore, enhancing the emergency preparedness among adolescents for MEIDs is a crucial task in safeguarding the health and social stability of adolescents. It is also an essential condition for achieving the Sustainable Development Goals related to health and well-being [7].

At present, education on emergency preparedness for adolescents is mainly based on traditional classroom teaching, brochures, and lectures [8]. However, surveys indicate that these methods often lack interest, interaction, and practicality, and thus struggle to attract the interest of adolescents [9]. The effectiveness of this education is poor, and the ability of adolescents to respond to MEIDs could not be effectively improved [9,10]. Additionally, the uneven distribution of educational resources means that adolescents in remote and impoverished areas often cannot access high-quality educational services, resulting in problems of educational equity [11].

In recent years, the rapid development of the information technology industry has continuously highlighted the application advantages of the virtual interactive training model, opening new avenues for enhancing emergency preparedness. Virtual interactive technology has been used for mass casualty education and military emergency training as part of urban or national emergency preparedness protocols [12,13] and to promote physical activity to reduce stress [14-16]. Notably, the health care industry has actively carried out virtual interactive training in emergency preparedness for MEIDs [17-19], demonstrating its efficacy in improving the emergency response capabilities of nursing students, medical workers, and emergency management personnel. This is supported by a study within the National Health Service (NHS) in the United Kingdom, which found that virtual reality (VR) training significantly improved the performance of frontline health care workers in infection control measures and personal protective equipment usage during the COVID-19 pandemic compared to traditional training methods [20]. Similarly, a systematic review and meta-analysis confirmed the positive impact of virtual experiments on learning effectiveness across various educational contexts [21]. However, a significant research gap remains. Previous interventions have primarily targeted professional populations within the health care or military sectors. There is a paucity of studies focusing on adolescents in general educational settings. Moreover, existing programs for the public often lack a comprehensive and engaging design that integrates knowledge acquisition, decision-making training, and behavioral simulation into an immersive, storyline-driven experience [22]. This limits their potential to effectively captivate and educate the adolescent demographic.



To fill this gap and better equip adolescents to cope with outbreaks of MEIDs, we designed and developed a virtual interactive system, “People’s War Against Pandemic” [23]. This system allows adolescents to learn essential knowledge and response skills through simulated outbreak scenarios within a narrative framework. This study aimed to test the effectiveness of this virtual interactive system in improving emergency preparedness for MEIDs among adolescents in Luzhou City, Southwest China. Here, we report the results of this study.

Theoretical Framework: Embodied Cognition Theory

Embodied cognition theory posits that cognition arises from the dynamic interaction between the individual, the environment, and tools, and is grounded in sensory and bodily experiences, with perception serving as the basis for action [24]. In this study, the immersive, interactive, and imaginative features of the virtual system foster a deep sense of presence, enhancing emotional engagement. This affective response, mediated by presence, can restructure cognitive frameworks and ultimately promote behavioral change. Furthermore, the system supports the development of new body schemas [25], enabling the projection of real-world motor actions onto sensorimotor experiences within the virtual 3D environment [26]. Consequently, the activation of sensory and motor systems in this embodied context elicits bodily presence, linking physical actions to emotional and cognitive processing, which guides behavior and, in turn, enriches emotional experience, forming a cyclical feedback loop among emotion, cognition, and action (Figure 1).

Methods

Study Design

This study was a single-blind, 2-arm, parallel-group randomized controlled trial (RCT). The CONSORT (Consolidated Standards of Reporting Trials) checklist was used when writing this report (Checklist 1).

Sample Size Calculation

The sample size was calculated following a 2-mean test randomized controlled design: $n_1 = n_2 = 2[(t_{\alpha/2} + t_{\beta})S / \delta]^2$. The primary indicator (emergency preparedness for MEIDs) was used to calculate the sample size for this study. A 2-sided test was used to set the test level (α=0.05) and the test efficiency ($1 - \beta = 0.8$); then $t_{\alpha/2}$=1.96 and t_{β}=0.84. The SD (S=16.5) and the expected effect size (δ=9.5) were derived from an internal pilot study conducted by our research team prior to the main trial (n=12 adolescents recruited from the same target population). Based on these parameters, the required sample size was calculated as n_1=n_2=48. The total required sample size was 96 participants. Accounting for a 20% dropout rate, the sample size was calculated to be at least 60 participants in each group. It is important to note that this sample size is adequate for testing efficacy under controlled conditions but may not be representative of the entire adolescent population.

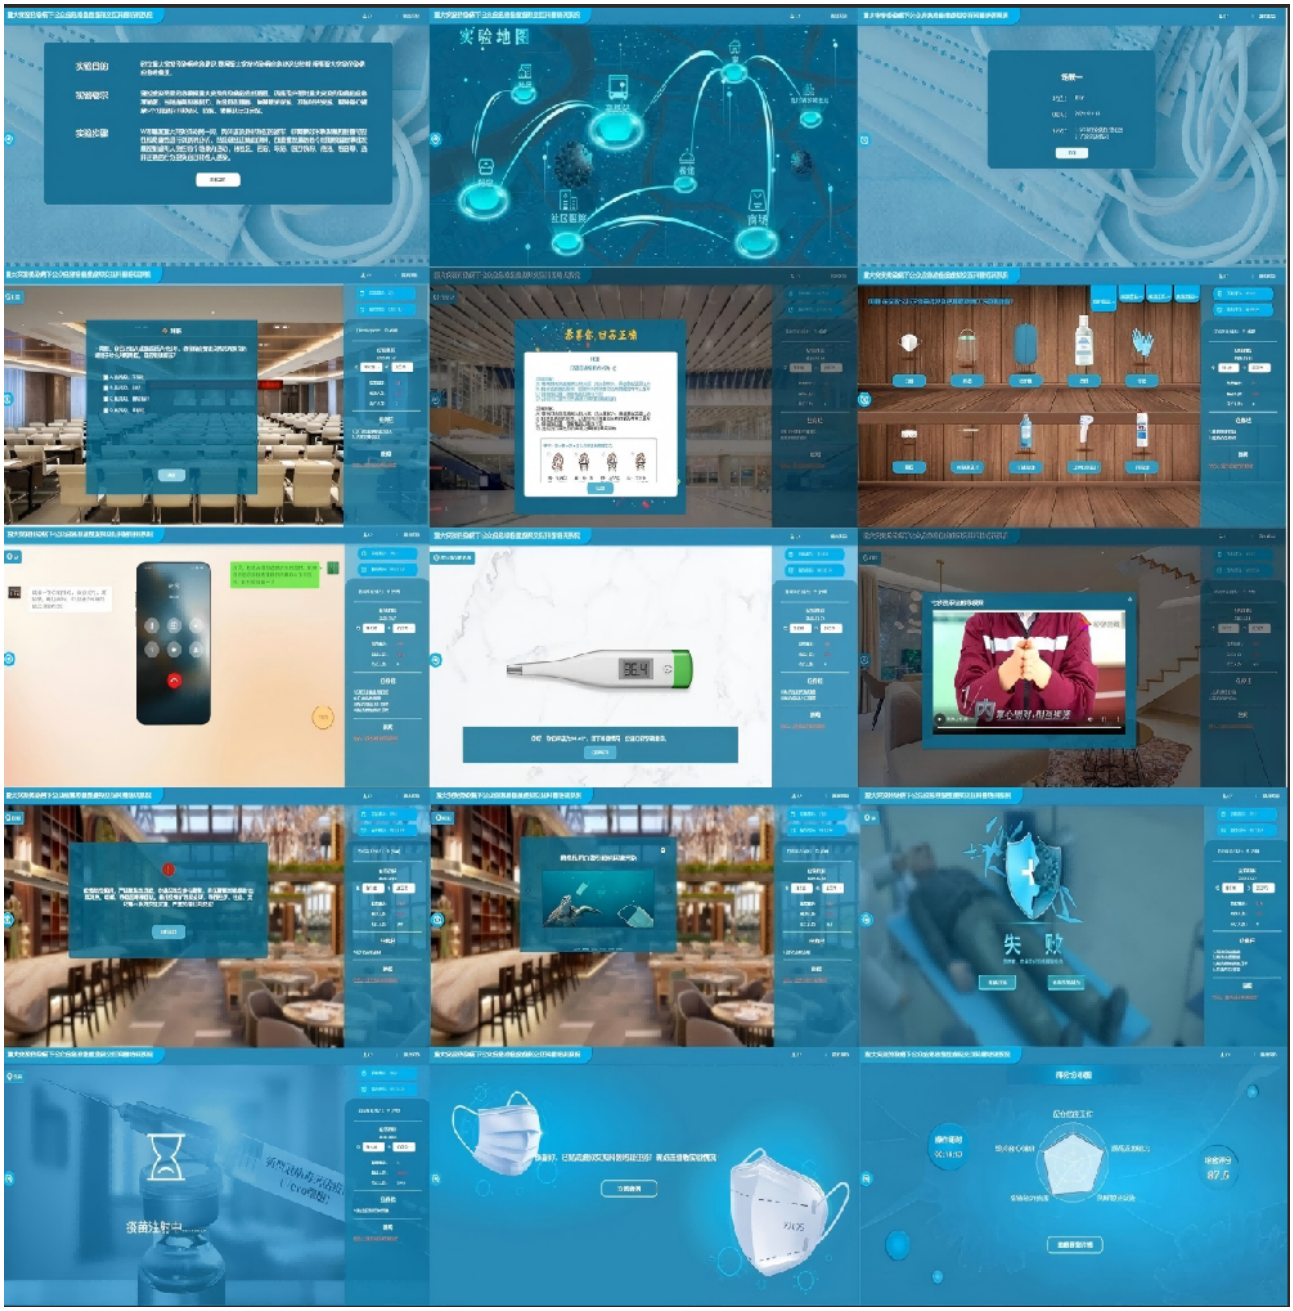
Participants and Study Settings

This study used a single-center design, with participants recruited from a secondary vocational school in Luzhou, Sichuan. Thereafter, they were randomized into either a control group or an intervention group. This site was selected due to its accessibility and established collaboration, which facilitated the implementation and monitoring of the RCT. Although this approach enhanced the internal validity of the study by controlling for institutional-level confounding factors, it limits the generalizability of our findings to adolescents in other geographic, cultural, or educational settings. Therefore, the results should be interpreted as preliminary evidence of the intervention's efficacy within this specific context.

The eligibility criteria for participation were as follows: (1) aged 10 to 19 years and (2) informed consent and voluntary participation in this study (participants below 18 y of age required the consent of the guardian). The exclusion criteria were as follows: (1) participants did not cooperate in completing the questionnaire and (2) participants were participating in or had participated in similar studies.

Intervention Methods

Design of a Virtual Interactive System



The virtual interactive system was called People's War Against Pandemic, and the interface diagram is shown in Figure 2. The background storyline is the outbreak of an MEID in a certain place, and participants need to identify and analyze the harmfulness and controllability of the pandemic's development. At each stage of the pandemic's spread, participants can act in each scene according to the development of the storyline and avoid infecting themselves and others through the correct selection of key interactive nodes. Participants can acquire knowledge and skills for the prevention and control of MEIDs, adjusting emergency-related emotions and changing behavioral tendencies. People's War Against Pandemic has the following functional modules:

- Virtual interactive training module: There are 9 scenes and multiple tasks involved in the daily lives of teenagers.
- Knowledge corner module: It contains educational articles and videos on MEIDs.
- Intelligent evaluation module: It can help participants consolidate their knowledge of MEIDs.
- Forum community module: It provides users with a platform for communication.
- User management module: The educational information in the knowledge corner module can be edited, and data collection, integration, classification, and application can also be implemented.

Both groups received conventional lectures on MEIDs education, and the intervention group additionally received a lecture on the virtual interactive system developed by our team, resulting in a total intervention period of 4 weeks followed by a 2-week follow-up evaluation. The duration of the intervention and follow-up was designed to evaluate the initial efficacy and usability of the system; however, it did not allow for assessment of long-term knowledge retention or sustained behavioral change. The trial was conducted from October 2023 to December 2023.

XSL•FO
RenderX

Figure 2. Scene interface of the virtual interactive system "People's War Against Pandemic."

Control Group

The traditional thematic lecture–based education method was used for a total of 4 weeks. Face-to-face lectures were organized by uniformly trained researchers once a week, with each session lasting for about 40 minutes. Participants were taught the same training knowledge as that provided in the emergency preparedness training content and the knowledge corner. The difference between the 2 groups was that there were no elements such as a storyline, virtual scenes, interaction, or scoring in the thematic lecture–based learning.

Intervention Group

Participants were taught the same lectures as the control group each week (conducted by researchers who taught the control group), and then they used the People's War Against Pandemic for about 40 minutes. Teenagers needed to use the system to complete a storyline task and watch no fewer than 4 articles or videos in the knowledge corner once a week. At least a retest of wrong choices was completed in the intelligent evaluation module. During the implementation of the trial, the researchers monitored participants' completion status through the user management module, and those who did not finish the task were reminded on the spot or by sending a text message or phone call. This trial was administered by 2 researchers who had systematically studied how to use the system.

Ensuring Intervention Fidelity

To ensure the consistency and quality of the lecture intervention across both groups, the following measures were implemented:

- Standardized training: All researchers responsible for delivering the lectures underwent a unified training session.

XSL•FO
RenderX

This training covered the exact script, key talking points, and duration of the lecture to minimize presenter variability.
- Use of a structured protocol: A detailed, slide-by-slide presentation protocol was developed and strictly adhered to by all lecturers. This protocol ensured that the core content, examples, and explanations were identical across both the control and intervention groups.
- Monitoring: The principal investigators periodically observed the lecture sessions to ensure compliance with the standardized protocol.

Adverse Event Records

During the trial, participants may experience a series of adverse events, such as dizziness, nausea, and eye fatigue [27]. In order to prevent and mitigate these adverse reactions, researchers always paid attention to the health status of the participants and ensured their safety. No adverse events were reported during this study.

Outcome Measurement

Sociodemographic Questionnaire

Sociodemographic data for all participants were gathered using a self-designed questionnaire, including sex, age, ethnicity, family economic income, registered domicile, and self-assessment of infectious diseases.

Emergency Preparedness for MEIDs

The emergency preparedness questionnaire for major emerging infectious diseases (EPQ-MEIDs; Multimedia Appendix 1) was developed by our team [1]. The questionnaire included 48 items across 5 dimensions: cooperation with prevention and control work (17 items), preparation of emergency knowledge and coping strategies (16 items), protection of materials and equipment (5 items), adjustment of economic resources (5 items), and maintenance of physical and mental health (5 items). A 5-point Likert scale was used for each item, ranging from 1 (“completely disagree”) to 5 (“completely agree”), with a total score ranging from 48 to 240. The higher the score, the better the emergency preparedness. The Cronbach α coefficient of the questionnaire was 0.953, and the test-retest reliability was 0.900.

Infectious Disease–Specific Health Literacy

Infectious Disease–Specific Health Literacy (IDSHL; Multimedia Appendix 2) Scale was developed by Jin et al [28] in 2016 to evaluate the ability of adolescents to acquire and understand the basic knowledge and information related to infectious disease prevention and control. This scale comprises 22 items across 4 dimensions: basic knowledge and concepts of infectious diseases, prevention of infectious diseases, management and treatment of infectious diseases, and identification of pathogens and sources of infection. It consists of 10 judgment questions and 12 single-choice questions. The difficulty coefficients of the 22 questions ranged from 1.19 to 4.08, and the difficulty coefficient for each question was used as the score for a correct answer. Incorrect answers received no score, whereas correct answers received the corresponding score. The full score was 38.62 points. Higher scores signify a stronger sense of infectious disease health literacy among adolescents. The Cronbach α coefficient of the scale was 0.832.

System Usability

The System Usability Scale (SUS; Multimedia Appendix 3) was compiled by John Brooke [29] in 1986 and translated into the Chinese version by Wang [30], which was used to assess the overall usability of the system [31]. A 5-point Likert scale was used to evaluate the 10 items. Among them, the odd-numbered items were positively scored, and the actual score was the “original score minus 1.” The even-numbered items were reverse-scored, and the actual score was “5 minus the original score.” If an item was not filled in, the original score was given by default as 3 points, and the actual score was 2 points. The final total score was the sum of all items multiplied by 2.5, with a total score of 100 points. Higher scores indicate better usability of the system. The Cronbach α coefficient of the scale was 0.900.

Data Collection

The sociodemographic questionnaire, the EPQ-MEIDs, and the IDSHL Scale were administered at baseline (T1), 2 weeks of intervention (T2), 4 weeks of intervention (T3), and 2 weeks after the intervention (T4). The SUS was administered at 2 weeks of intervention (T3). The baseline data of the participants were collected after the participants or their guardians signed the informed consent. The researchers who collected the data received standardized training.

Statistical Analysis

The data were analyzed using SPSS (version 26.0, IBM Corp). The Shapiro-Wilk test was used to assess the normality of the distribution and the homogeneity of variances. Frequencies, percentages, means, and SDs were used for statistical analysis. The 2-tailed *t* test, Mann-Whitney *U* test, or chi-square test, as applicable, was used to compare the demographic characteristics of the participants. The overall comparison of outcome indicators between the 2 groups across 4 time points was conducted using repeated-measures ANOVA, and an independent-samples *t* test was used to test baseline differences in each index. Significance was defined as $P<.05$.

Randomization

A random number table was generated using Excel 2016, and the numbers were divided into the intervention and control groups with an allocation ratio of 1:1. The random numbers were then placed in opaque, sealed envelopes and kept by people who did not participate in the study. Therefore, the allocation sequence was concealed from both participants and researchers at the time of enrollment. For each eligible adolescent, the researcher randomly selected one of the envelopes (for each envelope selected by the researcher, the total number of envelopes would be reduced by 1) and allocated them to the intervention or control group. Participants used a code instead of their real names to conceal allocation information, so that the researchers could not know the grouping of the participants. However, due to the nature of the interventions (virtual interactive system vs traditional lecture), participants became aware of their group assignments upon commencement of the intervention.

XSL•FO
RenderX

Blinding

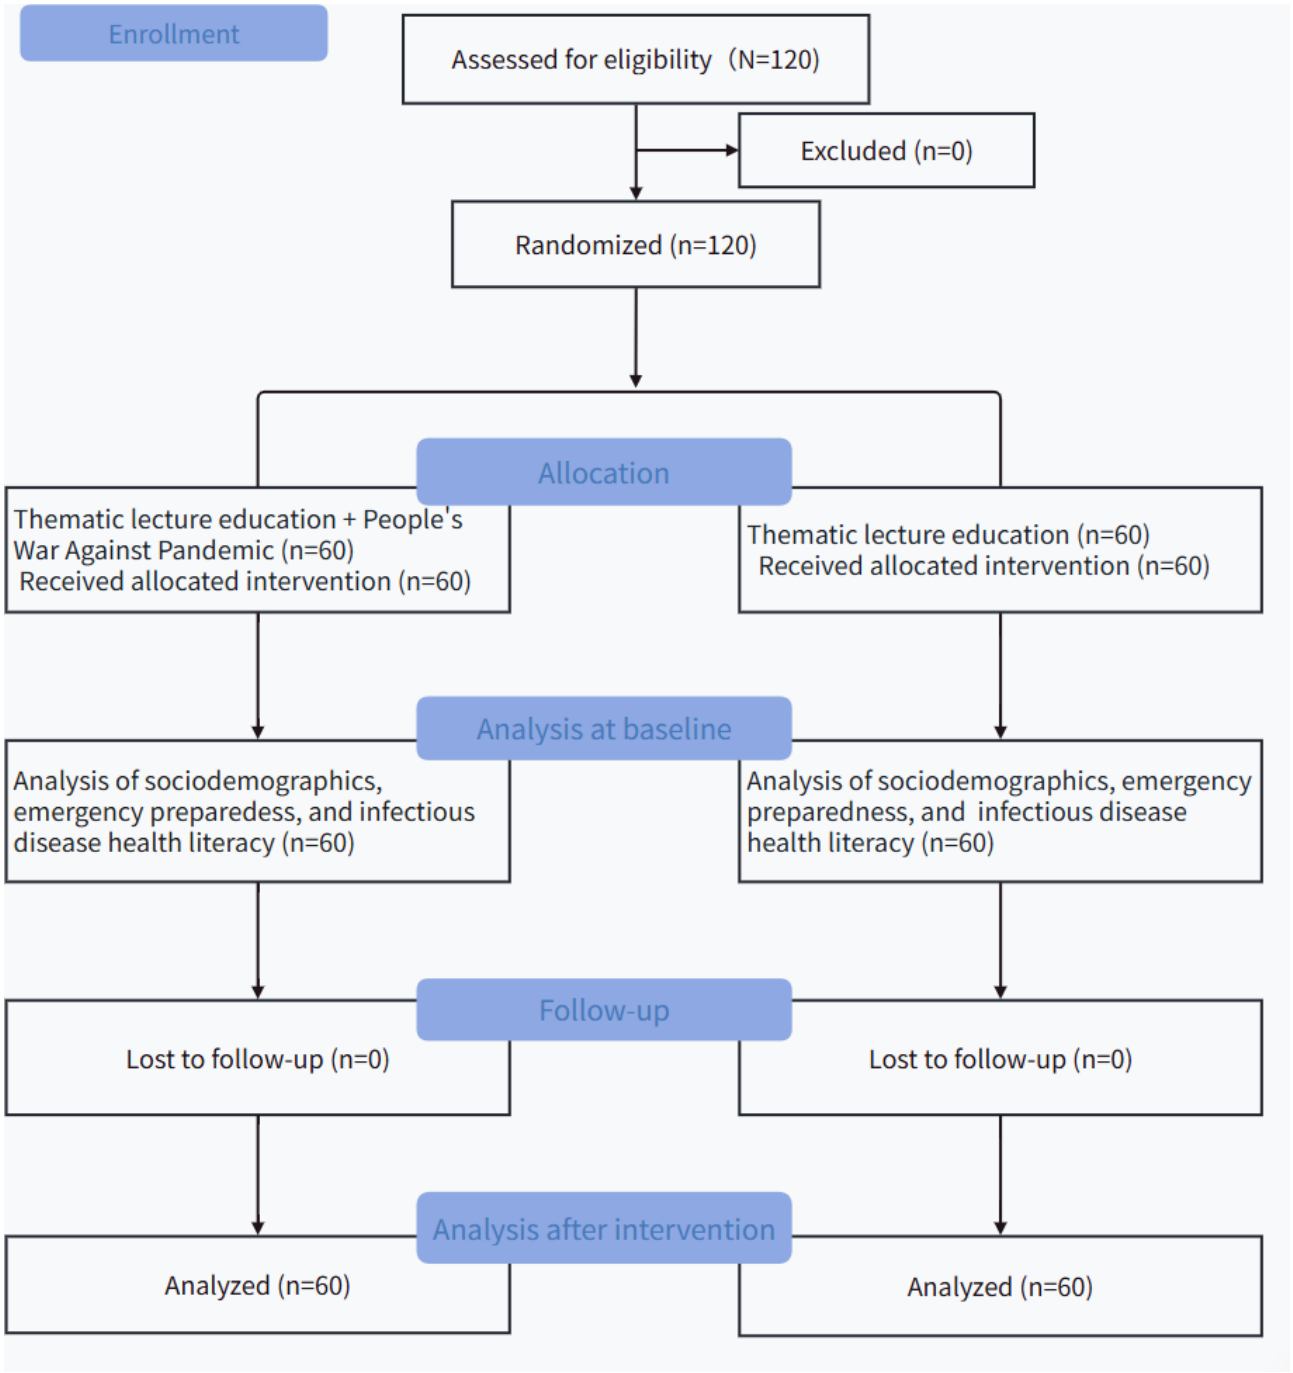
Given the overtly different nature of the 2 interventions, blinding of the participants and the trial implementers was not feasible. Therefore, only the data collectors and analysts were blinded; that is, the data collectors were not clear about the grouping, and the data analysts obtained only data marked as A and B groups.

Preventing Contamination

The intervention sessions for the control and intervention groups were scheduled at different times (eg, on different days or in different time slots on the same day) to minimize opportunities for immediate interaction and discussion about the group-specific activities. All participants were explicitly instructed at the beginning of the study not to discuss the specific content of their training sessions (especially the virtual interactive system) with students from other groups until the entire study was completed. The importance of this for the validity of the research was emphasized. The researchers managing the virtual interactive system for the intervention group were different from those primarily involved in data collection, further reducing the risk of inadvertently mentioning the system to control group participants.

Ethical Considerations

The trial was conducted in accordance with the Declaration of Helsinki, approved by the Human Research Ethics Committee of the Affiliated Hospital of Southwest Medical University (KY2022001), and registered with the Chinese Clinical Trials Registry (ChiCTR2200060919). Once selected, the participants signed an informed written consent form, including explanations about the study's purpose and research participation conditions. All information shared by the participants was kept confidential. A gift was given to participants after completing daily tasks and questionnaires every week, and participants who participated in the whole study were rewarded with 50 RMB (US $7.5).



Results

Participant Flow

A total of 120 participants were recruited and randomly allocated to the intervention group (n=60) and the control group (n=60). All 120 participants completed the 6-week assessments. Ultimately, the analysis comprised 120 participants. Figure 3 shows the CONSORT flowchart of the recruitment process.

XSL•FO
RenderX

Figure 3. CONSORT flow diagram of participant recruitment, allocation, and follow-up in a randomized controlled trial evaluating a virtual interactive system for emergency preparedness among adolescents in Luzhou, China (2023).

Demographic Characteristics

The demographic information of the participants is presented in Table 1. The mean age was 17.60 (SD 0.56) years for the intervention group and 17.65 (SD 0.52) years for the control group. The following variables did not demonstrate significant differences between the 2 groups: sex, age, ethnicity, family economic income, or place of residence, indicating that the groups were homogeneous.

Changes in Emergency Preparedness Scores Over Time

As shown in Table 2, at baseline, there was no significant difference in the average score of emergency preparedness for MEIDs between the 2 groups (*P*=.55). However, the average emergency preparedness score for the intervention group at T2, T3, and T4 was higher than that of the control group. The difference was statistically significant (*P*<.001).

XSL•FO
RenderX

Table . Comparison of emergency preparedness questionnaire for major emerging infectious diseases (EPQ-MEIDs) scores between the intervention and control groups across the 4 assessment time points (baseline, 2 wk, 4 wk, and 2-wk follow-up)[a].

Groups	T1	T2	T3	T4
Control, mean (SD)	182.55 (12.69)	184.13 (11.29)	194.52 (10.65)	198.87 (16.75)
Intervention, mean (SD)	184.13 (16.25)	194.28 (11.98)	221.00 (15.25)	220.32 (11.41)
t test (*df*)	0.595 (118)	4.777 (118)	11.029 (118)	8.198 (118)
P value	.55	<.001	<.001	<.001
Cohen *d*	0.109	0.872	2.014	1.497

[a]Repeated-measures ANOVA results for EPQ-MEIDs scores: *F* statistic estimate, *P* value, and ηp^2 for group are 109.186 (1, 118), <.001, and 0.481; for time (overall) are 129.692 (2.786, 328.790), <.001, and 0.524; and for time × group interaction are 23.476 (2.786, 328.790), <.001, and 0.166, respectively.

The data were tested for normality and met this assumption. However, Mauchly test of sphericity indicated a violation of the sphericity assumption (W=0.887; P<.05). Therefore, we applied the Greenhouse-Geisser correction to adjust the degrees of freedom and reported the corrected values. The results were as follows—group: $F_{1,118}$=109.186 (P<.001; ηp^2=0.481), time: $F_{2.786,328.790}$=129.692 (P<.001; ηp^2=0.524), and time × group interaction: $F_{2.786,328.790}$=23.476 (P<.001; ηp^2=0.166), indicating that the interaction effect between time and group on emergency preparedness scores was significant.

The results of the simple effects analysis (Table 3) showed that the emergency preparedness scores of the intervention group differed significantly over time ($F_{3,177}$=117.890; P<.001; ηp^2=0.666). This demonstrated that the virtual interactive system training had a substantial effect, which improved markedly from baseline to week 4 and was maintained at the 2-week follow-up. Although the emergency preparedness scores of the control group also differed significantly across time ($F_{2.508,147.974}$=26.136; P<.001; ηp^2=0.307), there was no significant difference between T2 and T1 (P=.97, which is >.05), indicating that the emergency preparedness scores increased slowly in the control group, and that the effect was weaker than that in the intervention group.

XSL•FO
RenderX

Table . Simple effects analysis of emergency preparedness questionnaire for major emerging infectious diseases (EPQ-MEIDs) scores in the intervention and control groups over time.

Groups across time	Mean difference (i − j)	*F* test (*df*)	*P* value	ηp^2
Between-group comparisons				
Intervention vs control (T1[a])	1.583	0.354 (1, 118)	.55	0.003

Cohen *d*	−0.155	0.472	0.714	0.737

[a]The independent-samples 2-tailed *t* test was used for between-group comparisons at each time point. The repeated-measures ANOVA assessed the overall effects across time and between groups. Repeated-measures ANOVA results for emergency preparedness questionnaire for major emerging infectious diseases (EPQ-MEIDs) scores: *F* statistic estimate, *P* value, and ηp^2 for group are 18.480 (1, 118), <.001, and 0.135; for time (overall) are 35.047 (3, 354), <.001, and 0.229; and for time × group interaction are 5.652 (3, 354), <.05, and 0.046, respectively.

[b]T1: baseline.

[c]T2: 2 weeks of intervention.

[d]T3: 4 weeks of intervention.

[e]T4: 2 weeks after intervention.

The 2 sets of data were tested for normality, and the data satisfied Mauchly sphericity test (W=0.943; P>.05). The results were as follows—group: $F_{1,118}$=18.480 (P<.001; ηp^2=0.135), time: $F_{3,354}$=35.047 (P<.001; ηp^2=0.229), time × group interaction: $F_{3,354}$=5.652 (P<.05; ηp^2=0.046), indicating that the interaction effect between time and group on health literacy scores was significant.

The results of the simple effects analysis (Table 5) showed that the health literacy scores of the intervention group differed significantly across time ($F_{2.587,152.620}$=34.896; P<.001; ηp^2=0.372), indicating that the virtual interactive system training had a substantial effect on improving infectious disease-related health literacy. The scores increased markedly from baseline to week 4 and were maintained at the 2-week follow-up. For the control group, health literacy scores also differed significantly across time ($F_{3,177}$=6.235; P<.001; ηp^2=0.096). Although there was a significant increase from T1 to T2 (P=.04), no significant difference was found between T3 and T2 (P=.16), indicating that the effect of traditional lectures on improving adolescent health literacy was relatively slow and weaker than that of the virtual interactive system.

Availability of the Virtual Interactive System

The total average usability evaluation score of the virtual interaction system by adolescents was 85.75, as shown in Table 6. The item with the highest score on the scale was item 1, “I will be willing to use (login/access) this system frequently,” and the item with the lowest score was item 6, “I thought there was too much inconsistency in this system.”

XSL•FO
RenderX

Table . Availability score of the virtual interactive system (n=60)[a].

Items	Mean (SD)
1. I will be willing to use (login/access) this system frequently.	3.833 (0.376)
2. I think this system is too complex.	3.500 (0.624)
3. I think this system is easy to use.	3.700 (0.530)
4. I think I need the help of technical staff to use this system.	3.550 (0.62)
5. I think the various modules of this system are integrated very well.	3.017 (0.596)
6. I thought there was too much inconsistency in this system.	2.650 (0.606)
7. I think most people can learn to use this system quickly.	3.733 (0.446)
8. I think this system is troublesome to use.	2.917 (0.530)
9. I am confident to use this system skillfully.	3.733 (0.634)
10. In order to operate the system, I need to learn a lot of new knowledge.	3.667 (0.475)
Total score	85.750 (5.152)

[a]Values were transformed contribution scores per standard System Usability Scale (SUS) scoring. Odd items (positive): contribution = (raw score – 1); even items (negative): contribution = (5 – raw score). Sum of contributions × 2.5 = total SUS score.

Discussion

Virtual Interaction Systems Could Enhance the Emergency Preparedness of Adolescents for MEID Outbreaks

Historical pandemics have demonstrated that adolescents are not only potential vectors for pathogen transmission but also a critical force in epidemic prevention and control [32]. The participation and cooperation of adolescents in epidemic prevention and control are key factors in curbing the spread of the epidemic [33]. Although health departments and government agencies play a central role in formulating response strategies and providing medical services, these efforts are likely to be in vain without the active response of adolescents. Therefore, effective emergency preparedness for adolescents can significantly reduce the risk of transmission during MEID outbreaks [34].

The results of this study suggest that virtual interactive system training can enhance adolescents' emergency preparedness more effectively than traditional lectures alone. This finding aligns with previous research conducted among nursing students and health care workers, which also found that virtual simulation training significantly improved emergency response skills and knowledge retention [19,35,36]. While a direct statistical comparison is not feasible due to differing outcome measures, the magnitude of improvement observed in our adolescent population appears substantial. For instance, the intervention group's emergency preparedness score increased by approximately 20% from baseline to the end of the intervention, a rate of improvement that is comparable to, and in some cases exceeds, the effects reported in studies with professional groups using similar simulation-based training [37]. This suggests that narrative-driven virtual interactive systems could achieve meaningful learning outcomes in a general adolescent population, not just among motivated health care trainees.

Our study extends this evidence by demonstrating that similar benefits can be achieved in a nonprofessional, adolescent population using a narrative-based, publicly-focused platform, a finding corroborated by other research highlighting the efficacy of VR in creating engaging learning environments without physical space restrictions [38]. This can be attributed to the interaction of various factors. On the one hand, "People's War Against Pandemic" provided rich environmental stimulation through virtual pandemic life scenarios. Moreover, its multidomain task modes offer more targeted stimulation to participants, granting them comprehensive sensory experiences. This helps them familiarize themselves with and master quarantine norms as well as basic self-help and mutual rescue skills. On the other hand, the effectiveness of the system can be explained by the theory of embodied cognition. Unlike passive learning in lectures, our virtual system provides a highly immersive environment that promotes embodied learning. Users learn by doing and making decisions within a simulated context. This approach has been shown to enhance situational awareness, deepen cognitive understanding, and facilitate the transfer of knowledge into behavioral intention and change [39]. Furthermore, the immersive nature of VR and augmented reality systems has been specifically linked to increased user engagement and improved comprehension levels in educational interventions [38], while also being effective in developing empathy through perspective-taking, which could be crucial in fostering compliance with public health measures that protect others.

In this study, after just 2 weeks of training in the intervention group, the emergency preparedness score was close to that of the control group after 4 weeks of education. This may be because the comprehension of scientific knowledge about infectious diseases in lectures was difficult to understand, requiring sustained stimulation over a longer period before effects began to appear [40]. It is evident from this that "People's War Against Pandemic" could enhance adolescents' emergency preparedness more rapidly compared to lectures, highlighting its application advantages.

However, it is important to interpret these findings with caution. In this study design, the intervention group received

XSL•FO
RenderX

approximately 80 minutes of total educational exposure (a 40-min lecture + 40-min virtual system use), while the control group received only 40 minutes of lecture-based education. Therefore, the observed superior outcomes in the intervention group may be partially or wholly attributable to the increased time-on-task rather than any inherent superiority of the virtual interactive system as a pedagogical modality. This confounding variable precludes a direct comparison of the relative efficacy of the 2 instructional methods under time-equivalent conditions.

Virtual Interaction Systems Could Enhance IDSHL Among Adolescents

Studies have indicated that enhancing IDSHL among adolescents can help alleviate their panic and maintain social stability [41]. Therefore, IDSHL is regarded as one of the critical indicators for evaluating the effectiveness of health education on infectious diseases [42].

The results of this study found that traditional lecture education had a slower effect, while "People's War Against Pandemic" boasts a more significant advantage in enhancing adolescents' IDSHL. Jacque et al [43] integrated infectious disease knowledge into a school curriculum and found improvements in health literacy, albeit to a lesser extent than observed in our study. This difference in efficacy may be attributed to the pedagogical approach. While their study used a traditional classroom-based curriculum, our interactive system provided experiential learning through simulation, which is posited to lead to deeper cognitive processing and engagement [21]. The meta-analysis further supports that the impact of virtual experiments on learning effectiveness is significant and can be influenced by factors such as the design and implementation of the virtual experience [21], which aligns with our system's thoughtful integration of multiple interactive modules. First, most traditional lectures are static, graphic-and-text-based education, lacking interaction [44]. However, "People's War Against Pandemic" provides opportunities for real-time feedback and dynamic participation, enhancing the learning interest and enthusiasm of adolescents and promoting their active involvement in the practice of infectious disease prevention and control. Second, the storyline and task design of "People's War Against Pandemic" are continuous and logical, which can progressively enhance adolescents' health literacy regarding infectious diseases, from basic theoretical knowledge to specific operational practice. Finally, neuroscientists believe that virtual systems involving task failures will lead to emotional arousal, promoting an increase in noradrenaline levels in the amygdala, which helps reinforce the process of memory formation and stabilization. This is beneficial for the retention of knowledge [45].

Furthermore, the observed plateauing of scores at follow-up warrants careful consideration. While common in educational and behavioral interventions, as the initial intensity of the training fades, it highlights the potential need for "booster" sessions or the integration of such virtual training into regular school health curricula to sustain its effects. This pattern underscores that emergency preparedness is not a one-time educational event but a skill that may require periodic reinforcement. Future studies should prioritize long-term follow-up assessments (eg, 6 mo, 1 y) and, where ethically and logistically feasible, use behavioral measures or simulations closer to real-world scenarios to evaluate the true translational impact of the virtual interactive system on actual emergency response behaviors.

The Usability of Virtual Interaction Systems Was Relatively High, Capable of Meeting the Core Needs of Adolescents

The average SUS score in this study was 85.75, indicating that this system had excellent usability [46]. The results showed that item 1 scored the highest, followed by items 7 and 9, suggesting that the system's design was intuitive, the user interface was friendly, and the operation process was straightforward, fulfilling users' needs and expectations. Salamah et al [47] pointed out that user satisfaction with a system is a key factor driving their intention to revisit. The innovation of the system, the practicality of the content, and the ease of use are the 3 direct factors affecting user satisfaction. Item 6 ("I thought there was too much inconsistency in this system") received the lowest transformed contribution score, identifying perceived internal consistency as the relatively weakest aspect of the system and the most useful target for future refinement. Nonetheless, the overall SUS score of 85.75 indicates excellent usability.

Limitations

First, this study was conducted at a single vocational school in Luzhou, Sichuan, which may limit the generalizability of the findings to adolescents in other regions or educational contexts. However, following the Spatial Statistic Trinity (SST) framework, we have provided comprehensive details to enhance transferability.

Regarding population characteristics, our participants were adolescents aged 16 to 19 years (mean 17.60, SD 0.56) from a lower-middle-income region of China, with demographic profiles typical of vocational school populations in Southwest China (eg, 107/120, 89% female participants; 96/120, 80% rural areas). These characteristics are relevant to similar socioeconomic and educational settings.

The study used a randomized controlled design with concealed allocation, standardized intervention protocols, and complete follow-up (0% attrition), which strengthens internal validity and supports replication in analogous study contexts.

For estimation methods, the study used repeated-measures ANOVA with Greenhouse-Geisser correction where appropriate, reported effect sizes (partial η^2), and provided raw data for key outcomes. Transparent reporting of these methods allows researchers to compare our estimates with those from their own settings.

The interaction of these 3 elements suggests that our findings are likely transferable to similar adolescent populations in comparable educational settings (eg, vocational schools in other Chinese cities with similar sociodemographic profiles). However, transferability to dissimilar populations (eg, younger adolescents, different cultural contexts, or nonvocational school settings) requires further empirical testing.

XSL•FO
RenderX

Although the sample size was statistically adequate for this RCT, a larger and more diverse sample would further improve the representativeness of the results. Second, the intervention and follow-up periods were relatively short, which precludes conclusions regarding the long-term efficacy of the virtual interactive system. Future multicenter studies with extended follow-up durations are recommended to validate these preliminary findings and further explore the transferability of the intervention across diverse populations and settings.

Conclusions

The findings of this study demonstrate that, compared with traditional lectures alone, the addition of the "People's War Against Pandemic" virtual interactive system to lecture-based education led to significantly greater improvements in self-reported emergency preparedness and infectious disease health literacy among adolescents. These results suggest that the system effectively enhanced participants' perceived readiness and knowledge regarding MEIDs. However, as the outcomes were measured using self-report questionnaires, conclusions regarding actual behavioral changes or objective decision-making skills cannot be drawn from this study. Future research should incorporate objective behavioral assessments or simulated emergency scenarios to evaluate the translation of these self-reported improvements into real-world response capabilities. Due to the unequal total educational time between groups, the observed effects may reflect increased learning time rather than the inherent superiority of the virtual modality. Future research using time-controlled designs is needed to isolate the specific contribution of virtual interactive training. The system has a good user experience and a certain usability, which was worthy of promotion and use.

Acknowledgments

We express our sincere thanks to all participants involved in this study and to Roger Watson of the University of Hull for his assistance with language. Generative AI tools were not used at any stage in the preparation of this manuscript.

Funding

This research was supported by the Sichuan Science and Technology Program (grant 2021JDKP0102) and the Project of Southwest Medical University (grant 2021SKTD02).

Abstract

Background: Gamification, the integration of game elements into education and game-based learning, is increasingly applied to laparoscopic skills training. However, systematic evidence on its effectiveness and practical feasibility remains limited and fragmented.

Objective: This study aimed to evaluate the effectiveness and feasibility of gamified interventions and game-based learning in improving laparoscopic skills education.

Methods: We searched PubMed, Embase, Cochrane Library, Web of Science, Scopus, and ClinicalTrials from January 1, 2000, to July 1, 2026, for studies evaluating gamification and game-based learning in laparoscopic skills education. Eligible studies included interventional and observational studies involving medical students, residents, or surgeons, with measurable performance outcomes. Study quality was assessed using ROBINS-I (Risk of Bias In Non-randomized Studies-of Interventions), RoB 2 (Cochrane Risk of Bias Tool 2), and NIH quality assessment tools. Standardized mean differences (SMDs) were pooled using random-effects models; between-study heterogeneity was quantified by τ^2 and described by the I^2 statistic (inconsistency), while the Cochran Q test tested homogeneity. Certainty of evidence was assessed by the Grading of Recommendations Assessment, Development and Evaluation (GRADE).

Results: A total of 39 studies involving 2102 participants were included. Video game–based interventions served mainly as training tools or assessments, whereas gamified contexts incorporated competitive or collaborative motivational elements. Three subgroup meta-analyses were performed. Game-based learning vs no training yielded a pooled Hedges g of −0.04 (95% CI −7.14 to 7.06; I^2=96.7%; 95% prediction interval −13.95 to 13.61), game-based learning vs conventional laparoscopic training yielded 0.49 (95% CI −1.39 to 2.36; I^2=79.4%; prediction interval −3.60 to 4.51), and gamified vs nongamified training yielded 0.87 (95% CI −5.08 to 6.81; I^2=61.6%). None of the 3 comparisons reached statistical significance, and all prediction intervals crossed the null, indicating that true effects may range from beneficial to harmful across settings. Risk of bias was mostly moderate, and certainty of evidence ranged from very low to moderate. Leave-one-out analysis showed that pooled estimates in the first 2 subgroups were driven largely by individual studies and were not robust.

Conclusions: Both game-based learning and gamified contexts are feasible adjuncts for basic laparoscopic skills training and may enhance motivation and deliberate practice; however, meta-analytic evidence did not demonstrate a statistically significant advantage over no training or conventional laparoscopic training, and the results were not robust to leave-one-out analysis. Generic video games showed limited efficacy for advanced, procedure-specific skills, and the evidence is constrained by heterogeneous outcome measures, small numbers of studies, moderate risk of bias, and a lack of long-term follow-up. As the first synthesis to compare video game-based and gamified context-based approaches within a unified framework, this review provides educators

XSL•FO
RenderX

with guidance for integrating task-aligned gamified modules into existing curricula, while highlighting that robust efficacy and sustained operative transfer remain to be demonstrated by larger, standardized studies.

KEYWORDS

systematic review; gamification; laparoscopy; medical education; video games

Introduction

Laparoscopic surgery has become widely adopted across various medical specialties, including general surgery, obstetrics, and urology [1]. Developing effective educational programs to facilitate skill acquisition outside of the clinical setting is crucial for preparing surgeons for proficient surgical performance in the operating room. To date, structured basic skills training programs, such as the Fundamentals of Laparoscopic Surgery (FLS) [2] and Fundamentals of Endoscopic Surgery [3], are widely used. Moreover, cadavers and high-fidelity virtual reality simulators are used for complex laparoscopic skills training, enabling trainees to gain a comprehensive understanding of disease processes, anatomical structures, and procedural steps. 3D reconstruction, 3D printing, and immersive virtual reality technologies, which have been proven effective in surgical planning and skill training, can further strengthen the core visuospatial competencies required for laparoscopic surgery [4-6]. The complexity inherent in laparoscopic skill acquisition involves critical capabilities, including depth perception [7], haptic feedback [8], conversion between 2D and 3D visualization [9], and precise hand-eye coordination [10]. Conventional training methods typically prioritize teaching surgical techniques and promoting trainees' technical proficiency, but often neglect factors such as fatigue and burnout, which negatively impact learning efficiency and outcomes.

Gamification refers to the implementation of game-design elements within educational contexts to create engaging and self-reinforcing learning experiences and has been widely adopted in fields such as military and aviation training. In medical education, apart from gamified that creates a game-like environment, learning directly developed based on video games is also quite common. The former involves integrating game mechanics to construct a game-like educational context [11], which fosters competition through leaderboards, points, and rewards, or cooperation via friendly interactions and mutual support among trainees. The latter involves the direct application of video games for educational purposes, including entertainment-oriented games and serious games specifically designed for medical skill training, exemplified by Underground (developed by Cutting Edge) [12]. Gamification addresses learners' needs for context, enhances interpersonal interactions, and stimulates intrinsic motivation [13]. In addition, it can also improve knowledge learning efficiency [14,15] and enhance skills performance across multiple metrics, including task completion time, error rate, and movement economy [16].

Compared with other medical or nonmedical educational contexts, the integration of gamification into laparoscopic training presents unique advantages. Many video game mechanics closely align with key laparoscopic skills [17], suggesting that both fundamental and procedural laparoscopic skills can be effectively enhanced through gamified training approaches. Additionally, performance scores or rankings obtained from video games may serve as supplementary metrics for evaluating laparoscopic competencies, providing educators with novel insights into trainees' skill acquisition and performance assessment. Previous studies have demonstrated that integrating video games into laparoscopic training significantly improves basic laparoscopic skills [18] and enhances learning efficiency [18]. Gamified contexts have also been shown to enhance laparoscopic skill performance [19] and increase trainees' motivation for ongoing and subsequent autonomous practice [20,21]. However, a few studies found no significant differences in skill outcomes between video game groups and control groups [22]. The considerable heterogeneity observed in gamification approaches and intervention strategies across existing research indicates ongoing challenges in standardizing the implementation of gamification within laparoscopic training programs.

Several systematic reviews have previously explored gamification in medical education, but their guidance for applying gamified strategies specifically within laparoscopic training remains notably limited. For instance, Xu et al [11] recently reviewed gamified learning in medical education, highlighting its potential to enhance engagement and immersive learning experiences. However, their review primarily addressed nontechnical skills such as clinical reasoning and decision-making. Similarly, earlier reviews by Gupta et al [23] and Jalink et al [24] mainly focused on video game interventions and did not thoroughly address gamified contexts. Gupta et al [23] included only a limited number of laparoscopic-related studies and did not explicitly consider basic laparoscopic skill training, while the review by Jalink et al [24] lacks significant advancements over the past decade. Given the potential value of gamification for laparoscopic skills training and game-based learning and the absence of detailed guidance from existing reviews, a comprehensive systematic evaluation is necessary. This review differs from previously published reviews. It comprehensively and systematically investigated the application of game-related elements in laparoscopic teaching innovatively, identified the current application status of this teaching tool, and provided guidance and references for its future development direction.

This systematic review aims to evaluate the feasibility and effectiveness of gamification and game-based learning in training both basic and advanced skills within laparoscopic education.

Methods

Eligibility Criteria

This systematic review was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [25]. A protocol was prospectively registered with the PROSPERO database (CRD42024539802) prior to study initiation.

Eligible studies were original research articles investigating gamified interventions for laparoscopic skills training in simulation-based or clinical settings. Gamified interventions were defined as the use of game-like elements to motivate and engage learners in laparoscopic education. Included studies addressed either basic laparoscopic tasks or procedural skills related to laparoscopic surgery, particularly within gastrointestinal, hepatobiliary, or general surgical contexts. Participants were required to have a medical background, including medical students, residents, or practicing physicians. Outcomes were required to have indicators evaluating the laparoscopic skills, including objective metrics like completion time and subjective assessments like Global Operative Assessment of Laparoscopic Skills and FLS.

The exclusion criteria were as follows: (1) non-English publications; (2) full text not available; (3) studies involving veterinary or nonhuman participants; and (4) review articles, conference abstracts, posters, technical notes, and basic science research.

Search Strategy

We searched 6 databases (PubMed, Embase, Cochrane Library, Scopus, Web of Science, and ClinicalTrials.gov), using the free text words and subject headings to conduct the search strategy. The search time limit was January 1, 2000, to July 1,2026. The full reporting of all literature search components, including database platforms, search syntax, citation tracking, deduplication, and search date, was conducted in accordance with the 16-item PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search extension) checklist [26]. All databases were searched individually rather than via a unified integrated retrieval platform, and all relevant literature was exclusively retrieved from electronic bibliographic databases. Hand searching of reference lists of all included studies was performed to identify additional cited and citing relevant articles for potential inclusion. No attempts were made to contact study authors, clinical experts, device manufacturers, or other personnel to request supplementary unpublished studies, raw data, or additional unpublished results. No published validated search filters (either original or modified versions) were adopted in this review. Besides, no complete or partial search strategies from previously published systematic reviews were adapted or reused for database retrieval. The detailed search strategy and PRISMA-S checklist are presented in Multimedia Appendix 1. Articles included after full-text screening require further reference retrieval. Zotero 6.0.36 (Corporation for Digital Scholarship, Roy Rosenzweig Center for History and New Media at George Mason University) is used to manage all included studies.

Study Selection

Three authors (XM, ZW, and MS) initially screened all records, excluded clearly irrelevant titles and abstracts, and retrieved the full texts of potentially eligible articles. Two authors (XM and WL) independently reviewed the remaining articles, assessed reference lists, and performed final screening of titles, abstracts, and full texts. Disagreements were resolved through discussion, with a third author (YL) arbitrating when consensus could not be reached.

Data Collection, Extraction, and Analysis

Data extraction was performed independently by 1 reviewer (XM) using Microsoft Excel. Extracted information included study characteristics (author, year, and design), participant demographics, intervention details, types of gamification approaches, laparoscopic skills, and outcomes. Measurement outcomes included video game rankings and laparoscopic skill performance. For the qualitative synthesis, studies were grouped according to the following four prespecified dimensions: (1) participant population (medical students, surgical residents, or practicing surgeons), (2) intervention type (video game–based training vs gamified instructional contexts), (3) targeted laparoscopic skills (basic tasks such as peg transfer vs advanced procedural skills such as suturing or cholecystectomy), and (4) study design (randomized controlled trials [RCTs], nonrandomized interventional studies, and observational studies). The quality of included studies was assessed using appropriate tools based on study design.

Pooled Effect

All meta-analyses were performed using R software (version 4.6.1; R Core Team). For all continuous outcomes, the standardized mean difference (SMD) was calculated as the summary effect measure, with Hedges g correction applied to account for small-sample bias. A random-effects model with Hartung-Knapp-Sidik-Jonkman [27] adjustment was applied. Because the included studies assessed laparoscopic performance using different instruments and scales (eg, task completion time in seconds and peg transfer scores), all outcome measures were assumed to assess a common underlying construct of basic or advanced laparoscopic proficiency, thereby justifying the use of SMD to standardize results across heterogeneous metrics. The Nagashima correction [28] was used when calculating prediction intervals

Heterogeneity

Heterogeneity among studies was quantified using the between-study variance (τ^2) and described by the I^2 statistic, which expresses the inconsistency of results—the proportion of total variability due to true between-study differences rather than sampling error—as a relative measure, not an absolute measure of the magnitude of heterogeneity. Cochran Q test was used to test the null hypothesis of homogeneity [29].

Sensitive Analysis

Sensitivity analyses were performed to assess the robustness of the pooled estimates. Given the small number of studies within each subgroup (k=2 - 4), formal sensitivity analyses were limited. Where feasible (subgroups with k≥3), a leave-one-out

XSL•FO
RenderX

analysis was conducted to examine the influence of individual studies on the pooled effect. For the subgroup comprising only 2 studies (k=2), sensitivity analysis could not be meaningfully performed and results are interpreted with caution.

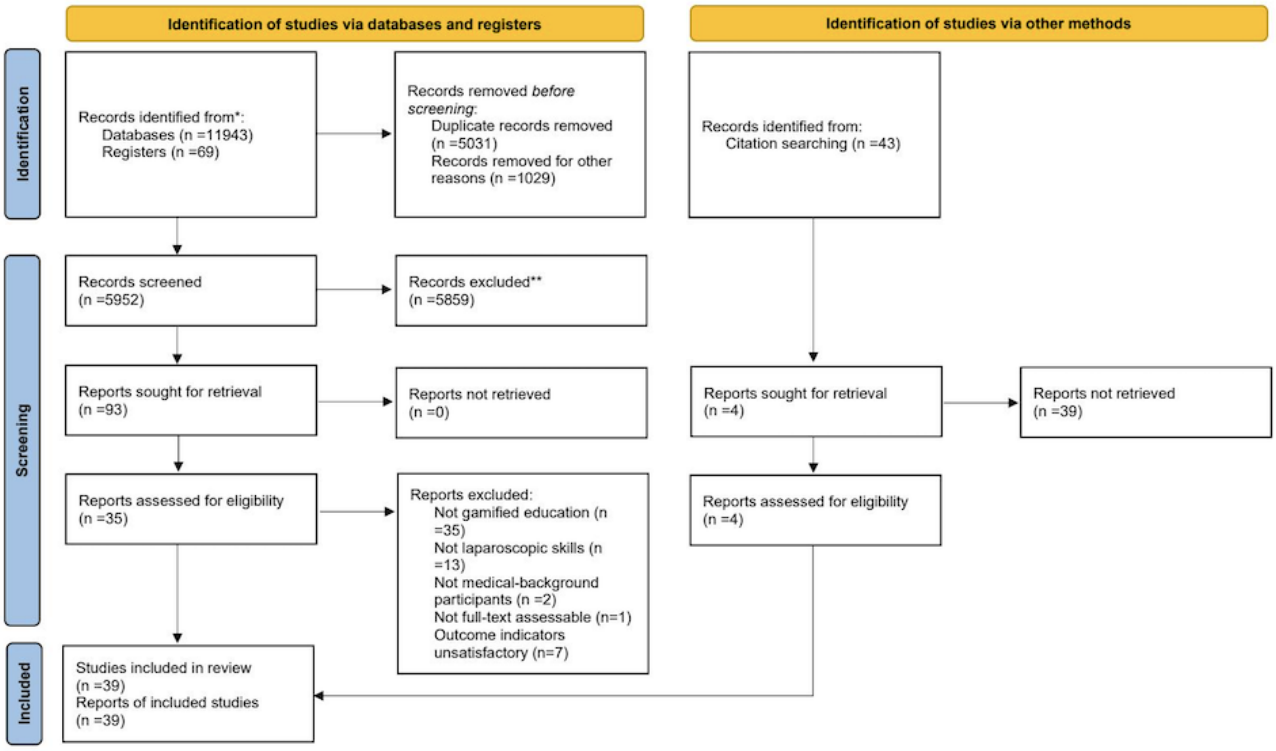
Meta-Analysis

In this review, to reduce publication bias, only RCTs with SD and q value were included in meta-analysis, and other studies only adopted qualitative research methods. For studies that only reported median and IQR without SD, we estimated SD using the formula previously described by Wan et al [30]. Studies with severely skewed data and limited sample size were excluded from quantitative synthesis and only narratively summarized.

Quality Assessment

Included studies were categorized into interventional studies and observational studies. The ROBINS-I (Risk of Bias In Non-randomized Studies-of Interventions) quality assessment tool [31] was used to evaluate the quality of nonrandomized studies and pre-post studies, with ratings classified as low, moderate, high, and no information. RCTs were evaluated using the RoB 2 (Cochrane Risk of Bias Tool 2) quality assessment scale [32], with assessment categorized as low, some concerns, and high. For observational cohort and cross-sectional studies, methodological quality was assessed using the National Institutes of Health (NIH) Quality Assessment Tool for Observational Cohort and Cross-Sectional Studies [33]. The overall quality of each study was graded as good (low risk of bias), fair (moderate risk), or poor (high risk) according to the NIH official criteria. Given the qualitative nature of the synthesis, all studies meeting the eligibility criteria were included in the narrative summary. For the main conclusions, greater interpretive weight was placed on studies with stronger methodological quality (rated as “Good” on NIH tools or “Low risk of bias” on RoB 2 and ROBINS-I), larger sample sizes, and direct relevance to the review question as defined by the inclusion criteria. Studies rated as “Poor” or “High risk of bias” were not excluded but were interpreted with caution, and their influence on the overall conclusions was explicitly noted in the Discussion section.

Certainty of Evidence



The certainty of evidence for each critical and important outcome was assessed using the GRADE (Grading of Recommendations Assessment, Development and Evaluation) framework [34].

Results

Study Characteristics

The initial database search yielded 12,012 records. After title and abstract screening, 93 articles were selected for full-text review. Moreover, 43 records were identified from citation searching, and after removing duplicates, 4 records were selected for full-text review. Following full-text assessment, 39 articles [16,18,20-22,24,35-67] met the inclusion criteria and were included in the final analysis (Figure 1). The included studies consisted of 29 interventional [16,18,20,22,35-37,39,47-67] and 10 observational [21,38-46] studies. The publication years ranged from 2005 to 2026, with the highest number published in 2017 (n=5, 12.82%). Detailed study type of each study is presented in Table 1.

[b]RCT: randomized controlled trial.

Participant Characteristics

A total of 2102 participants were included across all studies. All participants had a medical background, including 814 medical students and 905 physicians (eg, surgeons, residents, and interns; Table 1). Handedness was reported in 723 participants—628 were right-handed, 93 left-handed, and 2 ambidextrous [35]. Participants represented various specialties, including general surgery (n=179), obstetrics and gynecology (n=90), urology (n=33), and vascular surgery (n=10). Moreover, 89 participants reported experience playing musical instruments [16,18,36,37].

Quality Assessment of the Included Studies

Of the 10 observational studies, 7 were rated fair quality of risk, and 3 good quality. Detailed assessment results are presented in Table 2. Among the 29 interventional studies, 21 were rated as some concerns or moderate risk of bias, 3 were rated as high risk of bias, and 5 were rated as low risk of bias. Detailed assessment results are presented in Figure 2.

Figure 2. Summary of risk of bias of interventional studies assessed by RoB 2.0 (left) [18,20,22,35-37,47-49,51,53,55,56,58-66] and ROBINS-I (Risk of Bias In Non-randomized Studies-of Interventions; right) [39,50,52,54,57].

Gamification Approaches of the Included Studies

Gamified strategies in laparoscopic education were categorized into game-based learning and gamified context-based approaches, with 34 articles [18,22,35-45,47-65] and 5 articles [20,21,46,65,66] included, respectively.

Among game-based learning approaches, “Underground” was the most frequently selected game, featured in 9 out of 34 (26.47%) studies [16,39,41,43,44,47-50], necessitating specific Nintendo equipment. The next most popular was “Super Monkey Ball 2,”(developed by SEGA) selected in 6 [44,45,53,55-57] of 34 (17.65%) studies, compatible with Nintendo [44,45,51,52] or intelligent devices [53]. Specific game titles and platforms are listed in Tables 3 and 4 and Textbox 1. The 4 gaming platforms provided are Nintendo, intelligent device, PlayStation, and Xbox.

In the gamified contexts, 4 studies [20,21,46,65] implemented competitive elements (80%), and one study [66] implemented collaborative elements (20%).

Textbox 1. Overview of theoretical grounding in included studies.

Theoretical grounding

- Skill Transfer Theory [15,22,35,37,45,51,57-60,63]
- Perceptual Learning and Attentional Weighting Theory [38,55,58]
- Deliberate Practice Theory [20,21,46,59]
- Self-Determination Theory [23,46,49,65,66]
- Neuroplasticity Theory [15,38,51]
- Moderating Effect of Cognitive Styles [64]
- Warm-Up Effect Theory [24,52,53,61,62]
- Multimodal Training Theory [18,36,51,64]
- Cognitive Task Analysis Theory [18,36,48]
- Functional Task Alignment Theory [47,50]
- 3D>2D Visual Training Advantage Theory [37,40,42,56,58]
- Adult Learning and Distributed Practice Theory [50,58]
- Feedback Valence Theory [67]

Feasibility of Gamified Interventions of the Included Studies

Among the included studies, 34 articles applied video games as either training tools or assessment tools for laparoscopic skill development. Out of 34 studies, 26 [16,18,23,35-37,47-64,67] (76.47%) used video games as substitutes for traditional training, with interventions categorized into the following 3 modes: during training, pretraining, and warm-up. The most commonly used mode was during-training (17/26 [16,23,35,37,48,49,51,54-60,64,67], 65.38%). Details are summarized in Table 5. During training refers to the use of self-directed or structured gameplay between 2 tests, pretraining [18,36,50,62] involves completing designated game tasks prior to performance testing, without time constraints, and warm-up [47,52,53,67] refers to short gaming sessions (typically 10 - 18 minutes) immediately before testing, without specific game-task requirements.

XSL•FO
RenderX

Table . Summary of studies using video games as alternative training tools (n=26).

Training phase and author	Year	Training tools	Results
During training			
Harrington et al [16]	2018	Average 5 hours/week voluntarily for 4 consecutive weeks, and completed final video gaming session 24 hours prior to testing.	The intervention group demonstrated significant improvements in dominant ($P \leq .004$) and nondominant ($P < .05$) instrument movements, path lengths ($P \leq .04$), time taken ($P \leq .02$), and end score [$P \leq .046$; task-dependent].
Ju et al [35]	2012	Nintendo or PlayStation for 30 minutes between 2 tests.	Participants assigned to Nintendo or PlayStation 2 groups both demonstrated significant improvement in bead transfer and suturing scores. The Nintendo group improved more in bead transfer scores when compared to the PlayStation 2 group ($P < .05$).
Giannotti et al [58]	2013	Nintendo training for 60 minutes a day, 5 days a week, for 4 weeks.	The intervention group showed a significant improvement in performance ($P < .05$) for 13 of the 16 considered performance metrics.
Graafland et al [48]	2017	Regular BLTC[a], enhanced by 2 separate 30-minute sessions of serious gaming, containing 10 play sessions.	The intervention group solved more problems than the control group ($P = .03$), and recognized a larger proportion of problems, although this parameter was nonsignificant ($P = .14$).
Boyle et al [60]	2011	3 hours on Nintendo.	The intervention group showed a significant performance improvement for one metric in the bead transfer task compared with controls.
Chalhoub et al [54]	2018	Any kind of game.	No significant difference existed in evolution between control and gamers ($P = .12$), nor between intervention and gamers ($P = .19$). Significant advantage was found in evolution of the intervention group over the control group ($P = .04$).
Adams et al [59]	2012	XBOX 360 or Nintendo during 6 weeks.	Residents who played more than 10 hours of video games weekly had the fastest times on the simulator both before and after testing ($P = .05$).
Rosenberg et al [23]	2005	Play any type of game on XBOX over a 2-week period and then play the same game for 2 hours before the second test.	The Top Spin group completed significantly faster in Object Transfer and Tracing ($P < .05$). The Amped 2 group completed faster in Object Transfer, Tracing, and Knot-tying and had better EHC[b] (in Tracing and Suture Placement). The third Project Gotham Racing 2 group completed faster in Object Transfer and had better EHC in Tracing ($P < .05$).

XSL•FO
RenderX

Training phase and author	Year	Training tools	Results
Middleton et al [37]	2013	Nintendo 1 hour/day for 2 (Group A) or 4 (Group B) consecutive days.	Both groups demonstrated greater improvement, including accuracy in EHC (*P*=.04), faster completion time (*P*=.04), decreased number of left-handed movements (*P*=.03), decreased left-handed total path length (*P*=.03), decreased total number of grasping attempts (*P*=.04), and improved left-handed economy of movement (*P*=.05) for the BCG[c] task.
Vradelis et al [64]	2026	Complete four 1-hour distributed training sessions (2 sessions before midterm test, 2 after) over 2 weeks.	Serious games are only effective for basic skills and do not significantly improve the overall performance of advanced clamping tasks (*P*=.08); the core advantage of the box trainer is to significantly reduce the error rate of basic operations (*P*<.001).
Byrns et al [51]	2025	After familiarization, each participant performed 6 consecutive, timed attempts of a standardized arthroscopic triangulation task using a suture manipulator, hooks, and rubber bands inside the box trainer.	All groups improved significantly from first to last attempt (*P*<.001): Consultants: time reduced by 44% (103 seconds → 58 seconds), All trainees: time reduced by 39% (161 seconds → 99 seconds); junior trainees: time reduced by 57% (187 seconds → 80 seconds); and medical students: time reduced by 45% (234 seconds → 129 seconds)
de Araunjo et al [55]	2016	All VG groups completed 3 weeks of supervised training on the Nintendo Wii console, with a required minimum of 3 hours of gameplay per week (capped at 7 hours/week to avoid overtraining).	Combined video game groups significantly outperformed the nongaming control (*P*=.003). First-person shooter (ShotG, *P*=.002) and surgery-themed (SurgG, *P*=.02) groups had significantly higher surgical scores versus control; the racing game group showed no significant benefit versus control (*P*=.28), despite the longest training duration
Lin et al [56]	2018	First completed 3 sequential skill-based training games in the video-based box trainer, then finished the subsequent laparoscopic suturing training in the conventional video-based box trainer, with a total training time of 60 minutes	There were no significant differences in baseline characteristics between the 3 groups except for gender distribution, and all 3 training models were well-accepted by participants, with no significant between-group difference in satisfaction and acceptability ratings (all *P*>.05). All participants reported significant improvement in all 5 core domains of laparoscopic suturing skills after training (*P*=.001), with no significant difference in the degree of improvement across the 3 groups.

XSL•FO
RenderX

Training phase and author	Year	Training tools	Results
Mirmoghtadaie et al [49]	2022	The intervention group completed preoperative LC[d] training via a validated serious game on dedicated tablets, with a mean total game training time of 62.3 (SD 41.1) minutes completed the day before surgery.	The serious game training group significantly outperformed the traditional training group across all measured outcomes: they had a higher preoperative theoretical LC skill score (*P*=.02), required significantly fewer attempts to reach the 80% proficiency threshold (*P*=.001), had a shorter mean operation time (*P*=.03), fewer attempts to complete the operation without complications (*P*=.04), and a higher final surgical skill score (*P*=.01).
Karim et al [67]	2025	Group A received automatic audiovisual negative feedback (buzzer + LED alert for errors); Group B had all feedback disabled. All participants practiced voluntarily for 2 weeks on FLS[e] peg-transfer tasks.	The negative-feedback group practiced significantly shorter per session (*P*=.03). No significant differences in skill improvement or repeat practice willingness existed between groups. Single negative gamified feedback discouraged sustained practice without boosting laparoscopic performance.
Schlickum et al [61]	2009	40 medical novices were split into 3 arms for 5-week daily systematic game training: Half-Life (3D spatial FPS game), Chessmaster (pure cognitive chess game), and a no-game control group. All took pre- and posttests on MIST-VR and GI Mentor II endoscopic simulators.	Both game groups improved on basic MIST-VR tasks. Only the Half-Life group gained significant progress in GI Mentor navigation tasks. Training with spatially similar video games generated positive skill transfer to endoscopic operation.
Sadandanan et al [57]	2008	30 participants completed baseline laparoscopic tasks (peg transfer, condom cutting, rubber band stretching), then received a 10-minute Super Monkey Ball video game warm-up before repeating the same simulator tests. Paired *t* tests compared pre-post performance.	Posttest scores showed significantly more pegs transferred, fewer drops, faster cutting, and more stretched rubber bands (all *P*<.05). A brief single video game warm-up instantly enhanced basic laparoscopic psychomotor skills, especially for medical students.
Pretraining			
Bokhari et al [62]	2010	Complete 50 levels (randomly repeated 4 times) of the game with the dominant and the nondominant hands (twice each), and then completed the task	The intervention group outperformed the task with fewer errors and superior movement proficiency (*P*<.05), as well as increased ambidexterity with improvement in proficiency of the nondominant hand over time.
IJgosse et al [50]	2018	Train on Underground for 3 sessions and on the FLS video trainer and the LapSim for the fourth session	The Underground group outperformed the control group on Camera Navigation (*P*<.01), Instrument Navigation (*P*<.01), and Coordination (*P*=.01), but no significant effect on Peg Transfer (*P*=.60).
Lang et al [18]	2023	Laparoscopic inguinal hernia modules first on TS[f] instead of VR[g]	TS group needed significantly fewer attempts to reach proficiency (*P*=.028).
Kowalewski et al [36]	2017	Medical students and surgeons completed LC modules on TS. Medical students of TS group first started LC on TS instead of VR	Surgeons outperformed students in patient preparation (*P*<.001), access and laparoscopy (*P*=.008), LC (*P*<.001), and overall score (*P*=.02).
Warm-up			

XSL•FO
RenderX

Training phase and author	Year	Training tools	Results
Plerhoples et al [53]	2011	10 minutes to warm-up	The intervention group made fewer errors in object positioning (*P*=.01), tissue manipulation task (*P*=.05), and total errors (*P*=.002), but similarly on other metrics.
Jalink et al [47]	2015	15 minutes to warm-up	The intervention group showed a 19.61% improvement in Cobra Rope score, compared to a 0.77% score decrease in group 2 (*P*=.002).
Gentile et al [52]	2012	3 games (6 minutes each) to warm-up	The intervention group showed significantly faster on their first attempt of Cobra Rope drill task. The intervention group had better total suturing scores (*P*<.05).
Andrews et al [63]	2019	28 trainees were randomized: control group directly finished 3 graded LapSim laparoscopic tasks; intervention group warmed up for 10 minutes with PS3 Move motion game Flight Control HD prior to simulation testing.	No performance gaps in easy early tasks. The warm-up group made far more clip errors and simulated blood loss in the hardest vessel-clipping task (*P*<.05). This motion-sensing video game warm-up failed to benefit and even impaired complex laparoscopic performance.

Among the 34 studies, 9 [22,36-40,42,44,45] (30%) used video game performance or ranking scores as surrogate assessment tools, exploring correlations with laparoscopic skill levels. Detailed outcomes are summarized in Table 6. Kulkarni et al [42] reported strong correlations between scores on XBOX or Nintendo games and performance in laparoscopic tasks, such as Sugar Cube Stacking, Cutting, and total composite scores. IJgosse et al [68] found that participants with greater laparoscopic experience achieved higher scores in the Underground game, although no statistically significant difference was observed between expert and intermediate groups.

XSL•FO
RenderX

Table . Summary of studies using video game scores as assessment tools for laparoscopic skills (n=9).

Study	Year	Assessment tools	Results
Rosser Jr et al [44]	2017	Game scores from SMB[a] or Underground	The SMB score had a moderate correlation with intracorporeal suturing (ρ=0.39), and the final score involving all three tasks (ρ=0.39), but low correlations with Pea Drop Drill (ρ=0.11) and FLS Peg Transfer (ρ=0.18). The Underground score had a small correlation with intracorporeal suturing (ρ=0.09) and final score (ρ=0.13).
Datta et al [38]	2020	Game scores from 2D game (customized) and 3D game (customized)	Small significant correlation between performance on the Rope Pass task and the 3D game (Kendall τ=-0.151). Small significant correlation between the Paper Cut task and the 2D game (Kendall τ=-0.180). Overall laparoscopic performance was also significantly correlated with both the 3D and 2D games (Kendall τ=-0.134, Kendall τ=−0.163). No significant correlation between the peg transfer task and both games.
Kulkarni et al [42]	2020	Game scores from Call of Duty Operation Black Ops Zombies (XBOX) and Monkey Ball Banana Blitz (Nintendo)	The laparoscopy skills scores correlated significantly with both XBOX and Nintendo scores. There was a stronger correlation between the Nintendo highest score and the total of the laparoscopic skills score (ρ=0.734) compared with the correlation between the XBOX and the total laparoscopic skills score (ρ=.412).
Goris et al [40]	2014	Complete laparoscopy tasks on Nintendo	Game score showed a significant, high correlation with FLS[b] Peg Transfer (*r*=0.812).
Rosser Jr et al [45]	2007	Game score of Super Monkey Ball 2 (Nintendo), Star Wars Racer Revenge (PlayStation 2), and Silent Scope (XBOX)	All video games used to quantify the subjects' demonstrated video game skill were highly correlated with laparoscopic skill and suturing ability. Super Monkey Ball 2 showed the highest correlation (*r*=0.63), followed by Silent Scope (*r*=0.50).
IJgosse et al [39]	2020	Game scores from Underground (Nintendo)	Both experts (*P*=.02) and intermediates (*P*=.04) outperformed novices in terms of task completion speed, but experts did not outperform intermediates. No correlations were calculated.
Rosenberg et al [22]	2005	Scores of Top Spin, Street Race, Cone Challenge, and Amped 2.	The laparoscopic task measurement that best correlated with video game performance was time to complete the objective. This difference was more pronounced in the simpler tasks (object transfer and figure-of-eight). The more-complex tasks (suturing and knot-tying) showed little difference.
Kowalewski et al [36]	2017	Scores of patient preparation, access and laparoscopy, and LC from Touch Surgery	Surgeons outperformed students in all 3 tasks. No correlations were calculated.

XSL•FO
RenderX

Study	Year	Assessment tools	Results
Middleton et al [37]	2013	Nintendo Wii Scores	Better game score rankings demonstrated a moderate correlation with decreased time to completion (ρ=0.5), faster right-handed speed (ρ=0.694), and decreased right-handed total path length (ρ=0.521) for the EHC[c] task. No significant correlations were found for the BCG[d] and the THM[e] tasks.

[a]SMB: Super Monkey Ball.

[d]BCG: bimanual clipping and grasping.

[e]THM: two-handed manipulation.

Creating a competitive context mainly involves rewarding top-ranked participants and regularly updating the leaderboard. Websky et al [20] developed a peer-group benchmarks group to enhance collaborative settings, which resulted in better performance in efficiency and training motivation relative to the control group. Specific interventions and results are listed in Tables 7 and 8.

XSL•FO
RenderX

Table . Summary of included studies on gamified contexts implementation.

Author	Year	Gamified contexts	Results
Verdaasdonk et al [46]	2009	An online competition	More attempts (>30, *P*=.008) correlated with higher scores. The motivation score did nonsignificantly correlate with the final score on the simulator.
El-Beheiry et al [21]	2017	Leaderboards are advertised both in class and via email on a biweekly (top 3) and monthly basis (top 10)	The mean simulator usage time was significantly higher in CC[a] in the fourth month of observation (*P*=.011), and the opposite was found in the fifth month (*P*=.007). CC finished the course earlier (*P*=.01), and were significantly faster (*P*=.03) in Peg Transfer than the control group. More residents in CC continued to use the simulator voluntarily after the course (*P*=.002).
Hashimoto et al [65]	2015	The top performer after 10 sessions would be awarded a gift card for a flight simulator experience (valued at approximately $150)	During the first LC[b], CC performed better in completion time (*P*=.01), movements (*P*=.04), and path length (*P*=.04). During the final LC, CC performed better in movements (*P*=.02) and path length (*P*=.02). CC reported higher mean state anxiety before (*P*<.001) and after (*P*<.001) the study than the control group.
Websky et al [20]	2013	Peer-group benchmarks group (PGDG)	PGDG performed significantly better in completion time and right-hand instruments path length (both *P*<.001) than the control group. PGDG had more visits (*P*<.001).
Satchwell et al [66]	2019	A colon-themed progressive game narrative, real-time performance leaderboard, achievement badges, and hourly top-performer rewards, and a final grand prize for overall top rank	The gamified curriculum group showed significantly superior clinical performance in live patient colonoscopies, the study's primary endpoint. Blinded expert assessment using the validated JAG DOPS[c] scale found a highly significant between-group difference in overall technical skill (*P*=.001), with the gamified group also achieving a significantly higher cecal intubation rate (88.9% vs 61.1%, *P*=.047) and shorter procedure time for successful intubations (*P*=.002).

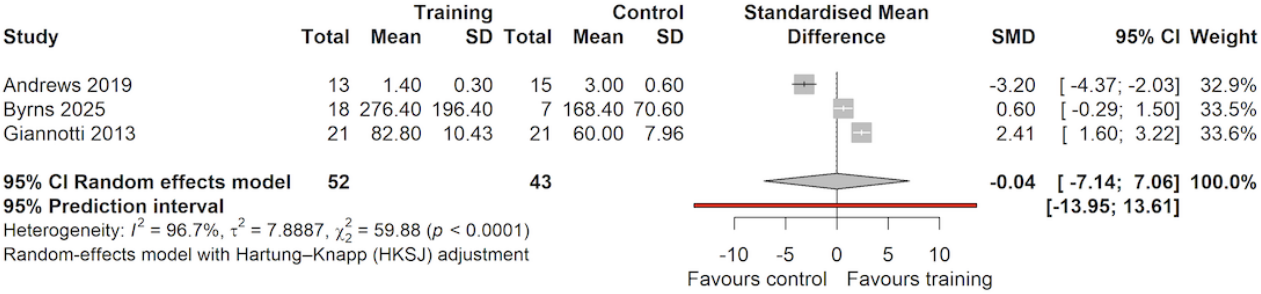
Table . Summary of included studies on training tools and gamification elements.

Author	Type	Training tool	Gamification elements
Verdaasdonk et al [46]	Competitive	Laparoscopic VR[a] simulator	Multicenter online skills competition, real-time online leaderboard and public score display, quantitative scoring system, material reward, and unlimited practice attempts
El-Beheiry et al [21]	Competitive	VR or simulation-based laparoscopic modules (unspecified platform)	Skills competition, leaderboard, prizes, and bragging rights
Hashimoto et al [66]	Competitive	Laparoscopic simulator (possibly VR-based)	Real-time feedback, task scoring, and staged challenges
von Websky et al [20]	Mixed	VR Endoscopy simulator	Leaderboard, badges, progress bars, and staged challenges
Satchwell et al [66]	Collaborative	Simulation-based modules	Learners earn points, unlock badges, and advance storylines; tasks completed in teams to get group rewards

[a]VR: virtual reality.



Meta-Analysis

Of all 39 studies included in this review, 9 studies [20,35,48,49,51,56,58,63,65] matched the criteria for inclusion in the meta-analysis. Of the total, 3 [51,58,63] studies compared game-based learning with a no-intervention (blank) control group, 3 [48,49,56] compared it with conventional laparoscopic training, and 2 [20,65] examined gamified vs nongamified learning. Only 1 study [35] compared different video game platforms.

Subgroup meta-analyses were conducted to compare the effectiveness of game-based learning against different control conditions on laparoscopic skill performance. The SMD was used as the effect measure, and data were pooled with a random-effects model. Furthermore, 4 studies [20,48,58,65] required the use of the formula by Wan et al [30] to estimate the SD from IQR. The detailed data were shown in Multimedia Appendix 2.

As illustrated in Figure 3, 3 studies [51,58,63] (95 participants) evaluated game-based learning vs no training. The pooled Hedges *g* was –0.04 (95% CI –7.14 to 7.06), with a 95% prediction interval ranging from −13.95 to 13.61. The I^2 statistic indicated noteworthy inconsistency (I^2=96.7%), with a between-study variance of τ^2=7.89 (Q=59.88; *P*<.001).

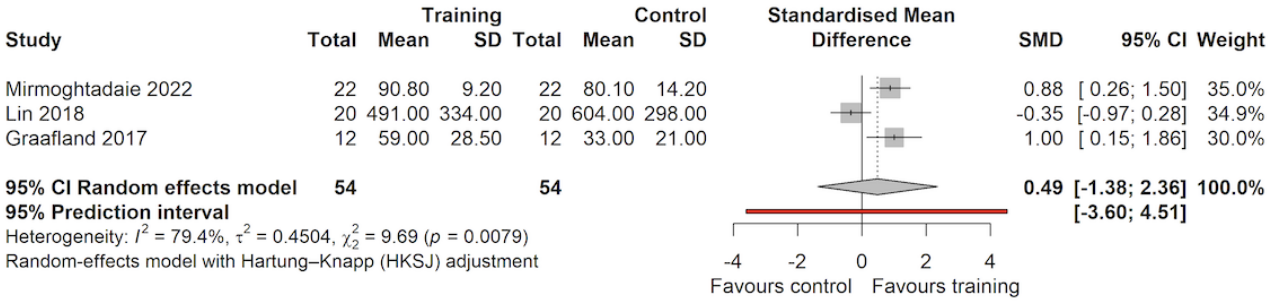


Figure 3. The effect of game-based learning compared with no training showed a better outcome than the no-training group [51,58,63]. SMD: standardized mean difference.

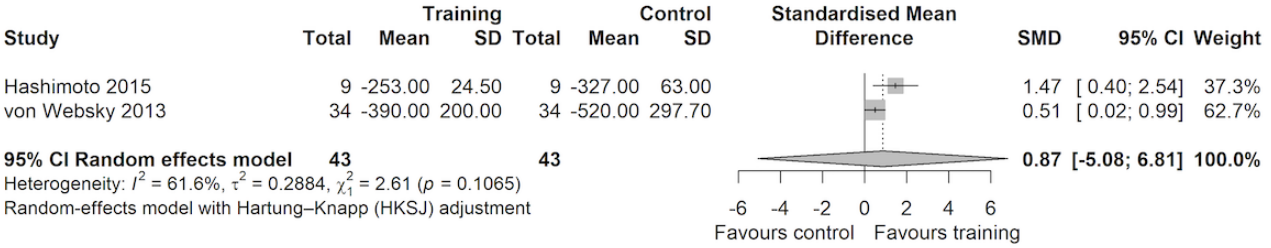
As illustrated in Figure 4, 3 studies [48,49,56] (108 participants) compared game-based learning with conventional laparoscopic training. The pooled Hedges *g* was 0.49 (95% CI –1.39 to 2.36), with a 95% prediction interval ranging from –3.60 to 4.51. The I^2 statistic indicated noteworthy inconsistency (I^2=79.4%), with a between-study variance of τ^2=0.45 (Q=9.69; *P*=.008).

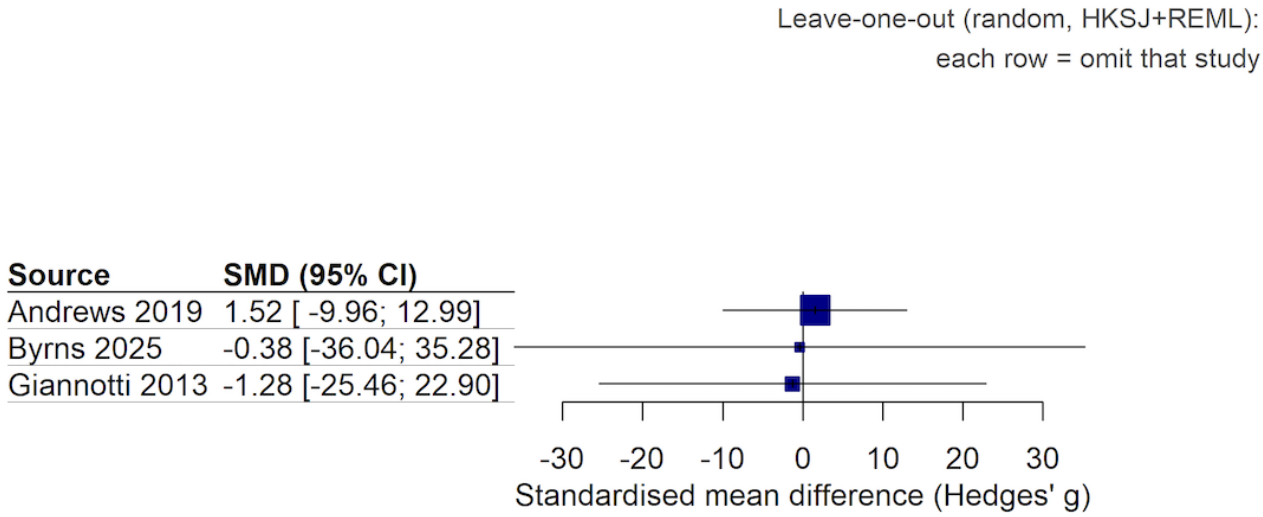


XSL•FO
RenderX

Figure 4. Game-based learning tended to be more effective than conventional laparoscopic training, with the exception of the study by Lin et al [48,49,56]. SMD: standardized mean difference.

As illustrated in Figure 5, 2 studies [20,65] (86 participants) compared gamification training with nongamification training. The current outcome was task completion time, where smaller values correspond to better performance. Raw time data were negated before calculating Hedges *g* to align effect directions with other end points. A positive effect size thus indicates better performance among participants receiving training. Under the random-effects model, the pooled Hedges *g* was 0.87 (95% CI –5.08 to 6.81). The I^2 statistic indicated inconsistency (I^2=61.6%), with a between-study variance of τ^2=0.29 (Q=2.61; *P*=.11).

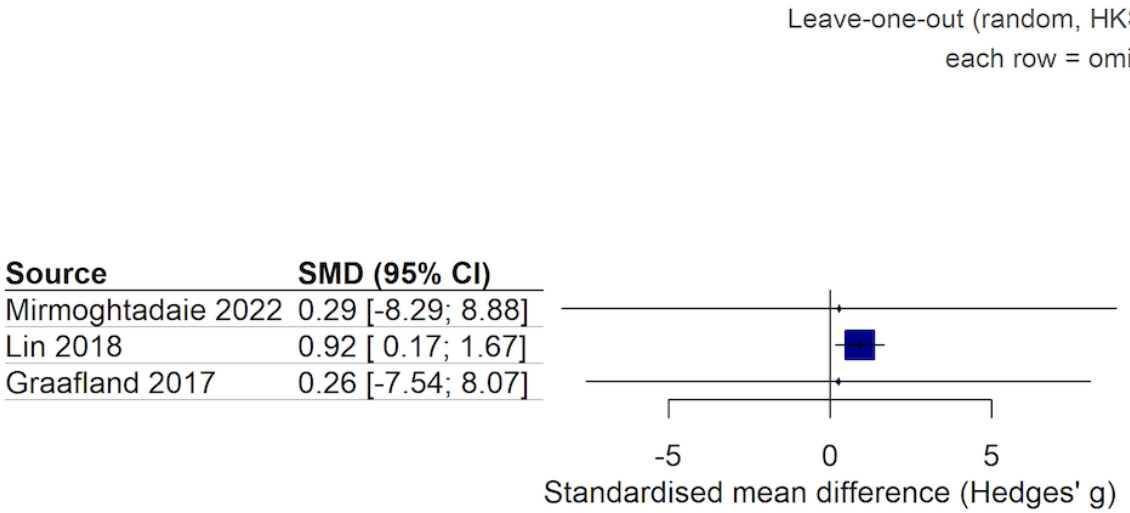
Figure 5. Gamification showed a significant improvement over nongamified learning [20,65]. SMD: standardized mean difference.



A study by Ju et al [35] showed a further comparison between different video games. Both groups achieved statistically significant improvements in the bead transfer task (Wii: mean score improvement 62, SD 14; *P*<.001; PS2: mean score improvement 40, SD 14; *P*=.01), yet the between-group difference in improvement magnitude did not reach statistical significance. For the intracorporeal suturing task, neither group showed a statistically significant change in performance after the intervention. Double counting in the meta-analyses did not occur.

Sensitivity Analysis

To determine whether the pooled estimate was driven by a single study, we performed leave-one-out sensitivity analyses (Figure 6). The SMD reversed direction after omitting one of the following studies: (1) study by Andrews et al [63]: 1.52 (95% CI –9.96 to 13.00), (2) study by Byrns et al [51]: –0.38 (95% CI –36.04 to 35.28), (3) study by Giannotti et al [58]: –1.28 (95% CI –25.46 to 22.90), and every 95% CI still spanned the null, indicating a nonrobust pooled estimate.



XSL•FO
RenderX

Figure 6. Leave-one-out sensitivity analysis for subgroup 1 [51,58,63]. HKSJ: Hartung-Knapp-Sidik-Jonkman; SMD: standardized mean difference.

The pooled estimate for subgroup 2 was highly sensitive to the included studies (Figure 7). The overall nonsignificant result for group 1 was attributable mainly to the study by Lin et al [56]: after its exclusion, the pooled SMD shifted to 0.92 (95% CI 0.17 to 1.67; P=.04) with I^2=0%, whereas excluding the study by Mirmoghtadaie et al [49] or Graafland et al [48] did not change the nonsignificant conclusion (SMD 0.29, 95% CI –8.29 to 8.88; and SMD 0.27, 95% CI –7.54 to 8.07, respectively).

Figure 7. Leave-one-out sensitivity analysis for subgroup 2 (Mirmoghtadaie et al [49], 2022; Lin et al [56], 2018; and Graafland et al [48], 2017). HKSJ: Hartung-Knapp-Sidik-Jonkman; SMD: standardized mean difference.

Certainty of Evidence

GRADE certainty assessment was performed for three comparisons of laparoscopic training interventions. Evidence for gamification versus nongamification was moderate certainty. Evidence for game-based learning vs no training was low certainty. Evidence for game-based learning versus conventional laparoscopic training was very low certainty. Detailed GRADE assessments are provided in Multimedia Appendix 3.

Discussion

Principal Findings

This systematic review evaluated the feasibility and effectiveness of gamified interventions, including game-based learning and gamified context-based approaches, in laparoscopic skills training. Video games were primarily used as supplementary training tools or assessment platforms, whereas gamified contexts incorporated motivational elements, such as competition and collaboration, to enhance learner engagement and participation [16,39,45,49,69,70]. Overall, qualitative evidence suggested that gamified interventions may provide educational benefits in laparoscopic training, particularly in improving psychomotor performance, cognitive outcomes, and learner motivation [16,20,21,49,58,65]. However, the magnitude of these effects appeared to vary depending on the training objectives, intervention characteristics, and assessment domains.

Previous studies have reported that video game-based training may improve basic psychomotor abilities, including task completion time, movement efficiency, and error reduction among surgical trainees [35,37,59,62]. Serious games, such as Touch Surgery (developed by Kinosis Ltd) and Dr. Game,

XSL•FO
RenderX

Surgeon Trouble (developed by Amsterdam UMC), have also shown potential value in supporting theoretical knowledge acquisition, procedural understanding, and intraoperative decision-making [18,36,48]. Nevertheless, the transferability of these benefits to advanced laparoscopic performance remains uncertain. Current evidence suggests that video games may facilitate basic visuospatial and psychomotor skill development but have limited ability to reproduce the procedural complexity, instrument manipulation, and cognitive demands required for advanced operative tasks [22,50,64].

Compared with conventional laparoscopic training, game-based learning demonstrated comparable performance outcomes in selected basic skill tasks but has not consistently demonstrated superiority for procedure-specific training [56]. This may be related to differences in intervention design, insufficient surgical specificity, variable training exposure, and heterogeneous outcome assessment methods across studies [16,42]. Therefore, video games are more appropriately considered complementary training resources rather than replacements for established simulation-based curricula.

Gamification strategies may provide additional educational value by modifying learner motivation and engagement through structured feedback, competition, or collaboration [23,46,65,66]. Competitive gamification has been associated with improvements in dexterity, performance efficiency, and practice motivation. For example, Hashimoto et al [65] reported reduced movement variability and shorter instrument paths following competitive training, while El-Beheiry et al [21] observed improved task completion and increased voluntary practice in competitive environments. In contrast, collaborative gamification may facilitate teamwork, communication, and sustained learner participation, suggesting that different gamification elements may influence distinct aspects of surgical education [20,54].

Despite these encouraging findings, the current evidence remains limited by considerable variation in intervention protocols, target skills, participant characteristics, and outcome measurements [16,45]. Although gamified approaches are accessible and potentially cost-effective compared with traditional simulation platforms, many commercial video games lack sufficient surgical specificity and may not adequately reproduce the technical and cognitive demands of laparoscopic procedures [16,45]. Further well-designed studies with standardized training protocols, validated assessment tools, and clinically relevant outcomes are required to determine the optimal role of gamification in surgical education.

Pooled effects were small to moderate and none reached statistical significance. Inconsistency among studies was substantial (I^2=61.6% - 96.7%); because I^2 measures inconsistency rather than the magnitude of heterogeneity, between-study dispersion is better reflected by the between-study variance (τ^2) and, above all, by the prediction intervals, which were far wider than the CIs and crossed the null in every comparison. The true effect may therefore range from harmful to beneficial across settings, and a uniform benefit of gamification cannot be assumed. It is important to distinguish the average effect from the distribution of true effects. Although the three pooled estimates were small (near-zero for game-based learning versus no training, or moderate, none was statistically significant, and the 95% prediction intervals were far wider than the CIs and crossed the null in every comparison. This indicates that, beyond the average effect, the true effect in a given setting is likely to vary widely—from negligible or harmful to substantial benefit, so the benefit of gamification cannot be assumed to be uniform across populations, training protocols, or outcome domains. Notably, the very wide prediction intervals may reflect not only genuine between-study dispersion but also the small number of studies in each subgroup, since with so few studies the between-study variance (τ^2) is estimated imprecisely and the intervals become correspondingly uncertain. Reporting only I^2 would have obscured this, because a high I^2 is a proportion and indicates neither the magnitude nor the clinical relevance of the dispersion.

Heterogeneity

The I^2 statistic indicated substantial inconsistency across all 3 subgroups. Differences in outcome types may represent the most important potential contributor. Such heterogeneity was expected given the diversity of training interventions, assessment methods, and participant characteristics included in this review. The outcomes included distinct dimensions of laparoscopic performance, including time efficiency, accuracy, error rates, and technical skills. Laparoscopic performance is a multidimensional construct encompassing psychomotor coordination, efficiency, accuracy, and cognitive decision-making. Therefore, combining these outcomes into a single estimate may obscure domain-specific effects and contribute to substantial heterogeneity.

The pooled studies also differed in what was measured. This included outcomes from different performance domains (time-based efficiency, error counts, kinematic measures such as path length and movements, technical scores, problem-solving and situational awareness, and nontechnical measures such as state anxiety [16,20,37,48,59,65]), tasks at different levels (basic transfer and suturing [22,56,58] vs cholecystectomy and other procedural tasks [20,49,65]), and inconsistent outcome direction, since “lower is better” measures (time, errors, and path length) required reversal before pooling. Pooling such heterogeneous outcome constructs into a single standardized mean difference therefore limits the interpretability of the pooled estimate and likely contributes to the high between-study dispersion observed. In addition, training duration and training modalities were also important potential sources of variability. Longer training durations tended to be associated with greater performance improvements, suggesting a possible dose-response relationship between training exposure and skill acquisition. In contrast, video games used solely as warm-up activities were unlikely to produce significant improvements and might even have limited benefits for physical skill development.

Certainty of Evidence and Robustness of Findings

The robustness of the pooled estimates was examined using leave-one-out sensitivity analysis. This revealed that the pooled estimate for the game-based learning vs no-training subgroup was not robust; the SMD reversed direction and every 95% CI still spanned the null after omitting any single study (Andrews

XSL•FO
RenderX

and Hewett [63], Byrns et al [51], or Giannotti et al [58]). In the game-based learning vs conventional training subgroup, the overall nonsignificant result was driven largely by a single study; its exclusion shifted the pooled estimate to a statistically significant positive value and eliminated inconsistency, whereas excluding the other 2 studies did not change the nonsignificant conclusion. Given the small number of studies in each subgroup (k=2‐4) and the substantial between-study heterogeneity observed, these results should be interpreted with caution and are not sufficient to establish robust effectiveness.

According to the GRADE framework, the certainty of evidence was rated as moderate to very low across the evaluated outcomes. The main reasons for downgrading were substantial inconsistency among studies, methodological limitations, limited sample sizes, and imprecision of effect estimates. Although gamified interventions demonstrated potential benefits in laparoscopic training, the current evidence remains insufficient to support definitive conclusions regarding their superiority over conventional training approaches.

To translate gamification and game-based learning into meaningful educational practice, careful instructional design is essential. Instead of using commercial video games in isolation, future efforts should prioritize the development or customization of task-aligned, evidence-informed gamified modules that complement existing laparoscopic curricula [44,59]. Embedding competitive or collaborative game elements within simulation-based training can promote learner autonomy, increase deliberate practice, and enhance motivation [21,65]. However, the design must avoid overemphasizing entertainment at the expense of clinical relevance or technical fidelity [50]. Alignment with validated assessment tools, such as OSATS (Objective Structured Assessment of Technical Skills) [71] or FLS metrics, can enhance educational value while ensuring objective evaluation [35,48,55,65]. Instructors should also consider learner variability when integrating gamified approaches—tailoring difficulty levels, feedback frequency, and reward mechanisms to the learner's stage of training may optimize both engagement and skill acquisition. As interest grows in intelligent surgical training ecosystems, gamification could play a complementary role when combined with adaptive learning algorithms and real-time performance analytics [38,55,58].

Limitations

Despite the promising findings, this review has several limitations. First, substantial heterogeneity existed in gamification formats, training duration, participant characteristics, assessment tools, and outcome measures, which limited the comparability among studies and complicated quantitative synthesis. Second, several potentially eligible studies could not be included in the meta-analysis because they reported medians and IQRs rather than means and SDs. Although statistical conversion methods are available, such transformations may introduce estimation uncertainty and potential bias. Consequently, subgroup analyses were restricted by the limited number of available studies. Third, the small number of studies in each subgroup (k=2‐4) was below the minimum threshold (typically ≥10) recommended for testing funnel plot asymmetry, so small-study effects could not be reliably assessed. Notably, such tests detect small-study effects—a pattern in which smaller studies report systematically larger effects—which may arise from publication bias but also from other causes such as poorer methodological quality in smaller studies, true heterogeneity, or chance. Because publication bias and other contributors to asymmetry cannot be excluded, pooled estimates should be interpreted cautiously. Fourth, although both interventional and observational studies were included, several studies had methodological limitations, particularly regarding randomization procedures, allocation concealment, and blinding, which may have affected the certainty of evidence. Fifth, most studies evaluated short-term skill acquisition rather than long-term retention or clinical transfer. Although gamification may enhance motivation and engagement during initial training, whether these benefits can be sustained over prolonged training periods remains unclear.

Future studies should adopt standardized outcome measures, clearly define training protocols, and incorporate longitudinal follow-up to evaluate long-term educational effects. Researchers should also report complete statistical parameters, including means and SDs, to facilitate future evidence synthesis. Furthermore, future investigations should explore whether adaptive gamification strategies, such as dynamic difficulty adjustment, personalized feedback, and progressive challenges, can maintain learner engagement and support sustained skill development throughout extended training programs.

Conclusion

In summary, this review confirms that gamified interventions and game-based learning are feasible adjuncts for laparoscopic skills education and may support basic psychomotor skill acquisition and learner motivation; however, the pooled meta-analytic estimates did not reach statistical significance and were not robust to leave-one-out analysis, so a definitive advantage over conventional training cannot be established. Game-based learning and gamified contexts each have distinct strengths; the former serves well as supplementary training or warm-up tools, while the latter offers a framework for curriculum-wide engagement design. A key finding is that generic video games do not reliably improve advanced procedural competence, underscoring the need for task-aligned, curriculum-integrated gamified modules rather than isolated commercial games. This review differs from prior work by comparing both major gamification approaches within a single analytical framework and by mapping their underlying theoretical foundations to the evidence base. Its contribution lies in providing educators with an evidence-informed rationale for selecting specific gamified strategies based on training objectives—competitive elements for technical proficiency, collaborative elements for team-based skills—and in highlighting implementation realities, including the motivation paradox whereby positive attitudes do not guarantee sustained voluntary practice. Looking ahead, the integration of gamified instructional design with adaptive learning algorithms and standardized assessment tools may represent the next step toward personalized, proficiency-based laparoscopic training. Until then, gamification should be viewed as a valuable

Abstract

Background: Serious games are increasingly explored as scalable, engaging interventions for major depressive disorder (MDD). However, most trials evaluating game-based interventions rely on weak comparators or inactive controls, making it difficult to disentangle intervention-specific effects from nonspecific benefits.

Objective: This study aimed to evaluate the effectiveness and feasibility of a home-based serious game targeting cognitive control (CC) training in adults with MDD, compared against a closely matched active control game.

Methods: This was a home-based, minimal-contact, parallel-group randomized controlled trial. Adults aged 18 to 65 years with a current *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]) diagnosis of MDD were recruited via clinical referrals from a mental health center in Israel between November 2021 and April 2023. Participants completed 30 sessions of 30 minutes each over 6 weeks. The experimental arm received Legends of Hoa'manu (LoH), an adaptive action-based serious game integrating CC training with emotional stimuli, whereas the control arm received a closely matched game (LoH_control) with comparable aesthetics and structure but without adaptive CC training or emotional content. The preregistered primary outcome was change on the Montgomery-Åsberg Depression Rating Scale (MADRS), and the secondary outcome was feasibility. Tertiary outcomes included depression severity, illness severity, global improvement, well-being, functioning, participation, rumination, and response and remission; CC and durability were exploratory. Participants were randomized 1:1 (computer-generated pseudorandom sequence, permuted blocks of 4), with allocation concealed until after baseline. Participants and outcome assessors were blinded to allocation.

Results: Of 57 randomized participants (LoH: n=28, 49%; LoH_control: n=29, 51%), 48 (84%) completed postintervention, and 44 (77%) completed 1-month follow-up; all 57 were analyzed by intention-to-treat using linear mixed models. The mean adherence was 20.7 (SD 9.48) of 30 (69%) sessions, early abandonment was uncommon (<10% of sessions), and all 3 post hoc feasibility benchmarks were met. Both arms showed significant reductions in depressive symptoms over time (P<.001; η^2_p=0.49); MADRS reductions were 6.8 (95% CI 3.4-10.3) points in LoH and 9.8 (95% CI 6.4-13.3) in LoH_control, with no significant group×time interaction ($F_{1,49.4}$=1.57; P=.22; η^2_p=0.03). CC composite scores improved modestly over time (P=.045; η^2_p=0.09). No intervention-related adverse events were reported.

Conclusions: This is among the first randomized trials of a home-based serious game combining action-based gameplay with CC training against a closely matched active control in MDD. Both arms improved comparably, with no added benefit from the targeted training, implicating nonspecific, engagement-related processes. The findings indicate that comparator design matters in digital mental health. Home-based serious games are feasible and could widen access to care, but no-contact and dismantling trials must identify the active components.

Introduction

Major depressive disorder (MDD) is a recurring and seriously impairing condition and a leading contributor to global disability [1,2]. Despite available pharmacological and psychotherapeutic treatments, more than two-thirds of patients fail to achieve remission after first-line pharmacotherapy, and 15% to 30% remain treatment resistant [3]. Even responders frequently experience residual symptoms and treatment-related side effects [3,4]. There is therefore a pressing need for scalable, accessible add-on or alternative treatment strategies.

One candidate target is cognitive control (CC), that is, the goal-directed mental operations encompassing inhibition, working memory (WM), shifting, and attentional control [5,6]. Cognitive models of depression posit that deficits in CC, particularly impaired inhibition and WM updating, sustain depressive symptoms by allowing mood-congruent negative information to persist in WM and by impairing disengagement from negative thoughts [7-10]. Difficulty disengaging from negative content fosters rumination, a less adaptive form of emotion regulation, which in turn maintains negative affect and increases vulnerability to recurrent depressive episodes [9,11,12]. Consistent with this account, CC deficits have been reported in adults with current or remitted MDD [13-17], although findings are not uniform [18,19]. Neuroimaging studies link these deficits to dysfunction in prefrontal regions, including the anterior cingulate and dorsolateral prefrontal cortices [20]. Functional imaging in depressed adults further shows reduced recruitment of these regions during cognitively demanding tasks, suggesting that CC-related networks may be a tractable target for intervention. Together, these findings provide a plausible mechanistic rationale for interventions that train CC as an indirect means of reducing depressive symptoms.

Computerized CC training paradigms, typically involving repeated practice with adaptive difficulty, may serve as such a therapeutic approach [21]. Importantly, in this framework, CC training is not conceived as a direct treatment for depression analogous to psychotherapy or pharmacotherapy; rather, any reduction in depressive symptoms is expected to arise indirectly, as a downstream consequence of improved inhibition, WM updating, and attentional disengagement from negative material, and, in turn, reduced rumination [22,23].

However, computerized CC training studies in both clinically depressed individuals and preclinical depression have shown mixed effects on depressive symptoms. Specifically, several trials have reported reductions in rumination or depressive symptoms following CC training [24-26], whereas others found no benefit beyond placebo training [11]; recent meta-analyses and reviews likewise indicate that effects tend to be small and inconsistent [22,23,27-29]. Augmenting CC training with emotionally salient stimuli has been proposed to better target affective regulation deficits [30-32], and some studies using emotional CC training have reported improvements in depressive symptoms. Among these, there is a small subset of interventions specifically designed for remote digital delivery [30,33]. Even so, findings remain inconsistent: recent meta-analyses conclude that benefits of CC training on mood tend to be small and not always condition specific [22,23,34].

Adherence is a critical determinant of training success but is often poor in conventional CC interventions, which rely on repetitive exercises with minimal interactivity [22,35,36]. Higher adherence is generally associated with larger training effects [37], yet many participants do not reach effective dosing thresholds [36]. This challenge is amplified in MDD, where reduced motivation and anhedonia are core features that further depress engagement with repetitive, low-reward tasks [37,38]. Serious games, digital games designed for purposes beyond entertainment, offer a way to integrate adaptive challenge, immersive context, and reward-based motivation into cognitive training [39-44]. Action video games in particular have been associated with improvements in attentional control and CC [45,46], and their combination of time pressure, multisensory coordination, and continuous prediction provides mechanics theoretically aligned with CC training [40,47].

Few studies, however, have combined home-based delivery with action game mechanics in clinically depressed adults. Remote tablet-based interventions have shown good adherence and sustained engagement [42], and action games have demonstrated promising cognitive benefits in depressed samples [48,49]; yet, these elements have rarely been integrated in a single trial. Keefe et al [41] delivered a remote, action game–inspired intervention for 6 weeks and observed improvements in sustained attention but no advantage over an active control on depressive symptoms. Earlier work by Anguera et al [39,40,50] in older adults reported gains in CC and modest mood benefits, although these did not consistently extend across mood measures. A home-based, action game–based intervention for adults with current MDD, evaluated against a closely matched active control game, has therefore not yet been reported.

This trial addressed this gap by evaluating Legends of Hoa'manu (LoH), a home-based, tablet-delivered serious game that integrates action mechanics, adaptive CC training, and emotional stimulus identification, against a closely matched active control game. The active control (LoH_control) was designed to match LoH on patient involvement and time on task, while omitting the action mechanics that are hypothesized to drive cognitive improvements [51] so that any superiority of LoH over LoH_control on clinical outcomes or CC could be attributed to those specific mechanics.

We tested the following hypotheses derived from our study aims:

- (H1) Effectiveness (preregistered primary end point): Experimental group participants would show larger reductions in depressive symptoms on the

XSL•FO
RenderX

Montgomery-Åsberg Depression Rating Scale (MADRS) from baseline to postintervention than those randomized to the matched control game; this benefit would persist at 1-month follow-up.
- (H2) Feasibility (preregistered secondary end point): The video game intervention would be feasible, defined per the trial registration as ≥50% of randomized participants completing ≥20 of the 30 prescribed sessions. Additional feasibility metrics (retention, adherence, and intrinsic motivation [Intrinsic Motivation Inventory] interest/enjoyment) and 3 post hoc benchmarks drawn from comparable digital mental health trials are reported as complementary reference points.
- (H3) Tertiary outcome superiority (preregistered tertiary end point): Participants randomized to LoH would show larger improvements on the preregistered tertiary outcomes than those randomized to the matched control game.
- (H4) We tested an exploratory mechanistic hypothesis (not formally preregistered): gains in CC would be associated with reductions in depressive symptoms, consistent with cognitive models implicating CC deficits in MDD.

Both H1 and H3 were preregistered as directional, confirmatory superiority hypotheses and are reported here as such. However, we note that prior evidence for CC training in depression is mixed, with effects that are often small or not condition specific [22,23,34]; superiority over a closely matched, engaging active control was therefore uncertain a priori and is best understood as a hypothesis the present trial was designed to test rather than a strongly expected outcome.

Methods

Open Science Practice

This trial was prospectively registered with the Israeli Ministry of Health Clinical Trials Registry (registration number MOH_2021-07-20_005979) on July 12, 2021, before enrollment of the first participant. The first participant was enrolled on November 21, 2021. The registration record is directly accessible at [52]. As the registry record is maintained in Hebrew, an English translation is provided in Multimedia Appendix 1. We note that the registry's brief public summary lists some early administrative details (delivery on a "mobile phone," a "2- to 4-week" training period, and reassessment "after 3 months") that are inconsistent with the registry's own detailed requirements and with the full preregistered protocol; the trial was conducted as specified in the protocol—a tablet-delivered, 6-week intervention with a 1-month follow-up—as reported here.

The study protocol and deidentified data are available on the Open Science Framework (OSF) repository [53]. No amendments were made to the registered protocol after trial initiation. Three deviations from the registered design are noted: (1) the realized sample size was 57 rather than the preregistered 60 (a 5% shortfall), which occurred because enrollment closed at the end of the funded recruitment window and was further constrained by COVID-19–related delays to clinical referrals and onsite assessments during 2021 - 2022; (2) 1 participant assigned to LoH_control inadvertently received the LoH intervention owing to an intervention distribution error (1/57, 1.8% protocol-execution deviation); and (3) the Global Assessment of Functioning, which was listed in the trial registration, was not administered.

The trial is reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2025 statement [54] and its CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) extension for web- and mobile-delivered interventions [55]; completed checklists are provided in Checklist 1.

Participants

Trial Setting

Data collection for the trial took place between November 21, 2021, and April 2023. Participants with a current depressive episode were recruited from "Merhavim" Medical Center. Eligible participants from all racial, ethnic, and gender categories were aged between 18 and 65 years. A minimum score of 13 on the 17-item Hamilton Rating Scale for Depression (HDRS-17) [56] was required. Additional inclusion criteria were a primary *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]), diagnosis of MDD, with a single or recurrent episode, with the additional requirement of a current episode with a duration of ≥4 weeks. Participants needed to be without antidepressant medication or on an adequate (ie, at least the lowest effective) and stable (ie, for ≥6 weeks) dosage. Concomitant psychotherapy was allowed if ongoing for at least 3 months prior to baseline. Participants were excluded from the study if they met any of the following criteria: problematic gaming, as assessed by the Gaming Disorder Test [57]; a diagnosis of a significant neurological disorder or comorbid psychiatric disorder; any relevant unstable medical condition (eg, acute or unstable cardiac disease); use of an investigational drug within 6 weeks prior to baseline; or suicidal risk, indicated by a score of 4 to 6 on item 10 of the MADRS or a suicide attempt during the current depressive episode.

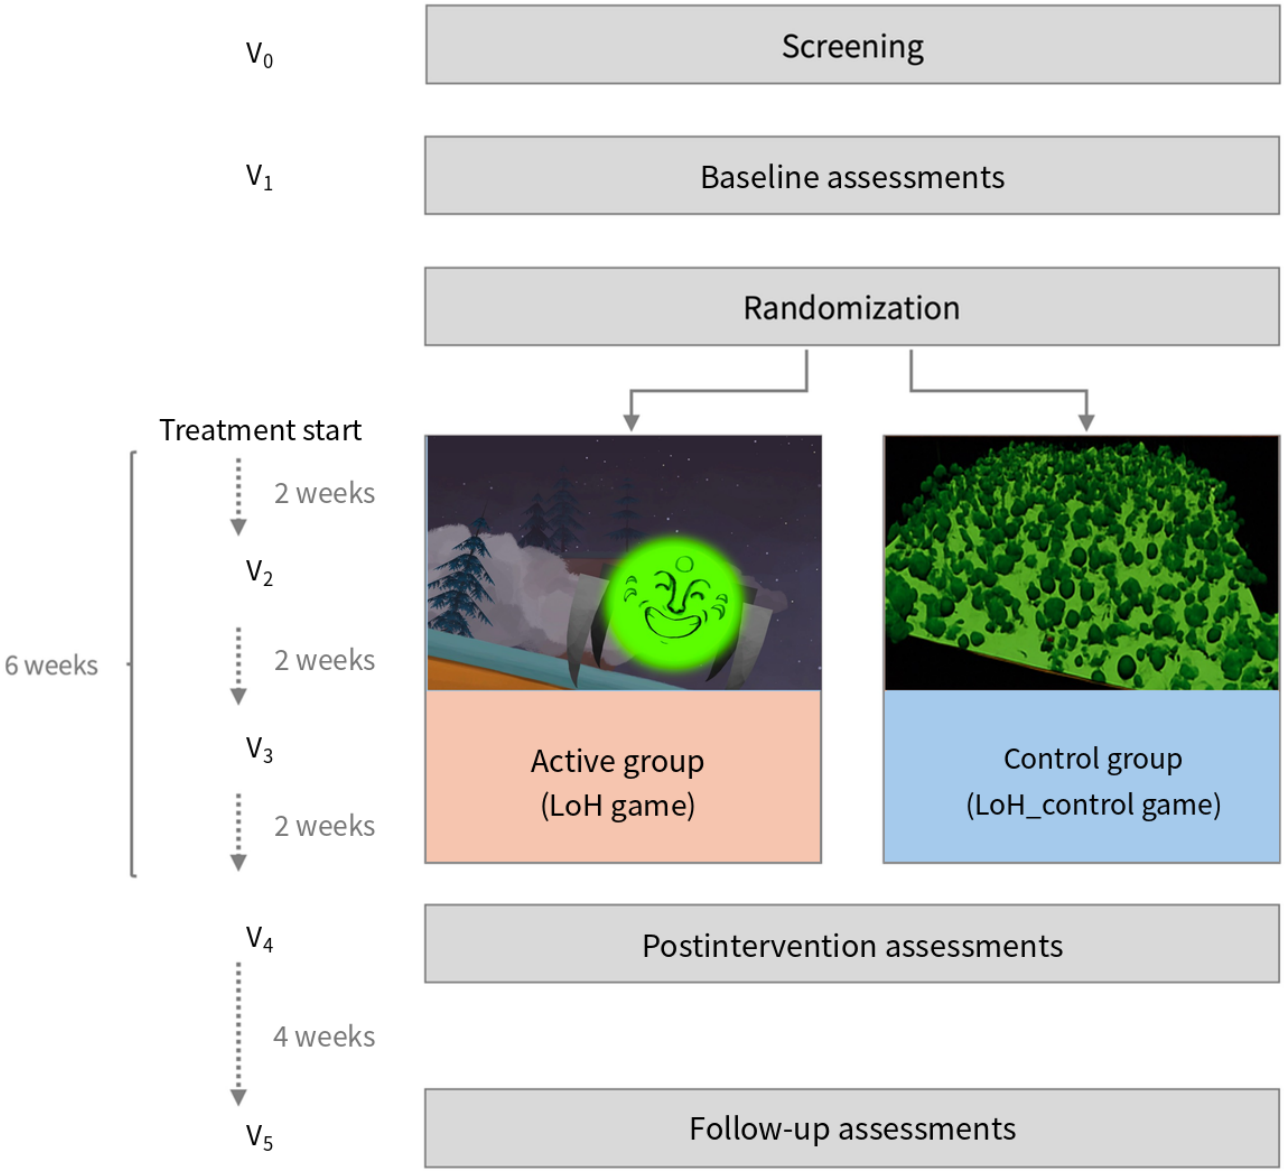
Recruitment and Screening

Participants were recruited through clinical referrals from psychiatrists, psychologists, and social workers at Merhavim Medical Center. Interested individuals were contacted via phone by a member of the study team and invited to an in-person screening visit (V_0) at Merhavim, where eligibility was assessed. No flyers, social media, or website-based recruitment were used.

Sample Size

A power analysis was conducted using G*Power (version 3.1.9.7; Heinrich Heine University Düsseldorf) [58]. Sample size estimation was based on the CC outcome. Prior randomized trials of computerized cognitive training in individuals with elevated depressive symptoms have reported medium-to-large effects on clinical outcomes (d≈0.73 on depressive symptoms [24]). This effect size assumption was further supported by meta-analytic estimates of computerized cognitive training effects on depressive symptoms [30] and by earlier cognitive-emotional training trials in MDD and in older adults [32,33,39,40]. To allow for a more conservative estimate, we

XSL•FO
RenderX



planned for a medium effect size (Cohen *d*=0.65). Under this assumption, a total sample size of 60 participants (30 per group) provides 80% power to detect a between-group difference at an α of .05. These effect size estimates were derived largely from trials using inactive or minimal-treatment comparators. A comparison against a closely matched active control likely corresponds to a smaller true between-arm difference; the assumed effect size of 0.65 should therefore be regarded as optimistic, and the trial was likely underpowered for the effect sizes expected between 2 engaging digital interventions (see "Limitations" section).

Study Design and Procedures

Trial Design

The study was a double-blind randomized controlled trial. Figure 1 depicts the study design. Interested participants were screened for eligibility (V_0). Eligible participants were assessed at baseline (V_1) and were then randomized in a 1:1 ratio to receive either the active LoH game intervention or the matched active control arm (LoH_control).

Figure 1. Study design of the home-based, parallel-group randomized controlled trial of LoH (active) versus a closely matched active control game (LoH_control) in adults with MDD (n=57 randomized). Study visits are denoted V_0 (screening) through V_5 (1-month follow-up). The full assessment battery was administered at 3 visits (V_1: baseline, V_4: postintervention, and V_5: follow-up). During mid-intervention assessments (V_2 and V_3), only the following assessments were administered: MADRS, PHQ-9, CGI-S, CGI-I, and RRS-22. CGI-I: Clinical Global Impressions-Improvement; CGI-S: Clinical Global Impressions-Severity; LoH: Legends of Hoa'manu; MADRS: Montgomery-Åsberg Depression Rating Scale; MDD: major depressive disorder; PHQ-9: Patient Health Questionnaire-9; RRS-22: Ruminative Responses Scale (22-item).

Randomization

Randomization used a validated computer-generated pseudorandom sequence with permuted blocks of 4 (1:1 allocation ratio), prepared by the co-principal investigator (PI), who had no contact with participants. Participants were assigned sequentially in order of enrollment. The allocation list was held by the PI; after completion of baseline assessment, the PI released the participant's assignment to the unblinded staff member responsible for intervention distribution. Outcome

XSL•FO
RenderX

assessors remained blinded to allocation. No additional allocation concealment procedures (eg, centralized automated assignment) were used. Both the active and the control games were self-administered, and study staff were available to assist remotely whenever needed.

Blinding

Overview

Participants were blinded to their group assignment and did not know whether the game they played was considered active or control; assessors were fully blinded to both group assignment and the game administered. Blinding was assessed by asking participants to guess their group allocation at weeks 1 and 6.

Participants were asked to train for up to 5 days per week for a period of 6 weeks, which equaled a total of 30 treatment sessions. Each session consisted of 30 minutes of training for an expected total of 15 hours of gameplay. As per protocol, in case of missing or canceled treatment sessions, participants were allowed to complete training over the weekends and during week 7 directly after the treatment period but before the postintervention assessment. Participants were asked to maintain a consistent training environment, including minimizing potential distractions, and were encouraged to adhere to a regular training schedule. By promoting these consistent conditions, we sought to ensure the training could be delivered in an optimal and focused setting. A subset of the assessments was repeated 2 and 4 weeks from the beginning of training (V_2 and V_3, respectively). The full assessment battery was repeated within a week of the end of the treatment period (V_4; postintervention; always at least 24 hours after training was completed), and approximately a month later (V_5; follow-up assessment).

Session Orientation and Supported Start

During the V_1 baseline visit, after randomization and tablet handover, an unblinded staff member gave a brief in-person walkthrough of how to operate the tablet and the assigned game and then sat alongside the participant while they completed their first 30-minute training session. This ensured the participant could navigate the interface, troubleshoot technical issues, and be at ease with the setup before continuing the remaining intervention independently at home. Subsequent sessions were entirely self-administered. Unblinded study staff remained reachable by phone for technical or logistical questions throughout the 6-week training period. On a per-need basis, unblinded study staff would provide reminders or encouragement to participants who appeared to have difficulty adhering to training procedures.

Outcomes

Overview

The trial was prospectively registered with depressive symptom change on the MADRS as the primary end point, feasibility as the secondary end point, and tertiary end points spanning symptoms, well-being, rumination, function, and participation. Exploratory end points included CC change, durability across the 1-month follow-up, as well as treatment expectancy and intrinsic motivation. This analysis follows this structure; intrinsic motivation is reported within the secondary feasibility framework—consistent with standard practice in feasibility studies of digital mental health interventions (deviation is disclosed here per CONSORT recommendations). A within-arm exploratory analysis testing whether CC gains are associated with depressive symptom reductions is reported as an additional mechanistic analysis (not formally preregistered as a hypothesis).

The trial was designed as a feasibility and effectiveness study, and its outcome hierarchy follows the preregistration and was not altered post hoc. The MADRS was chosen as the primary (effectiveness) end point following clinical standards for depression trials. Feasibility was the secondary end point because, given the novelty of this home-based, minimal-contact serious game intervention, establishing that the protocol could be delivered and completed per protocol was a central goal of this first trial. CC was exploratory, assessed to probe the proposed training mechanism rather than as a confirmatory clinical outcome, and, because the assessment battery shares task demands with the LoH training mini-games, change on it cannot be cleanly interpreted as generalizable transfer (see “Discussion” section).

Primary Outcome (MADRS)

The preregistered primary outcome was change in depressive symptoms on the MADRS [59], from baseline (V_1) to postintervention (V_4), reflecting the hypothesis that the LoH intervention would reduce depressive symptoms more than the active control game. Statistical inferences for the primary outcome were performed at an α of .05. The MADRS is a clinician-administered scale with 10 items scored on a 7-point scale (0 - 6). The total score ranges between 0 and 60, with higher scores indicating greater depression severity.

Secondary Outcome (Feasibility)

Feasibility outcomes comprised (1) adherence (completed training sessions and total minutes played); (2) retention at postintervention (V_4) and follow-up (V_5); and (3) intrinsic motivation, assessed at the end of week 1 and at V4 with the Intrinsic Motivation Inventory (IMI [60]). All 5 IMI subscales (interest/enjoyment, effort/importance, perceived competence, perceived choice, and pressure/tension) are reported separately; pressure/tension serves as a proxy for subjective tolerability (lower scores indicate greater tolerability).

The preregistered feasibility threshold was completion of ≥20 of the 30 prescribed sessions by ≥50% of randomized participants. We additionally applied 3 post hoc benchmarks drawn from comparable digital mental health trials [40,61,62]: retention at V_4 ≥70%, mean adherence ≥60%, and mean IMI interest/enjoyment in the active arm above the scale point (4/7)—framed as reference points rather than prespecified criteria. Expanded session-level in-game involvement metrics from server-side gameplay logs are reported in Multimedia Appendix 2; these correspond to the “training progress” pillar of the 4-pillar cognitive training evaluation framework of Harvey et al [63] (relabeled from “training engagement” in the framework of Harvey et al to avoid confusion with the engagement framework of Plass et al [64]).

XSL•FO
RenderX

Tertiary Outcomes

Tertiary outcomes were chosen because CC deficits in MDD are theorized to operate through perseverative negative thinking that, in turn, impairs everyday functioning and reduces well-being. The preregistered selection also follows current state-of-the-art recommendations for computerized cognitive training trials [63]. It included MADRS-based response (≥50% reduction from baseline) and remission (MADRS ≤10) rates. The other tertiary outcomes capture (1) near-transfer—depressive symptoms; (2) far transfer—severity of illness, global improvement, and rumination; and (3) ecological transfer—well-being, functional capacity, plus participation in daily activities. Depression severity, a near-transfer measure, was assessed using the Patient Health Questionnaire-9 (PHQ-9 [65]), a self-reported measure with scores ranging from 0 to 27. Severity of illness, a more distant transfer measure, was assessed using the Clinical Global Impressions-Severity (CGI-S) scale [66]. The CGI-S is a clinician-rated measure used to evaluate the overall severity of a patient's illness at a given time based on the rater's clinical experience, ranging from 1 (normal, not at all ill) to 7 (among the most extremely ill patients). Global improvement was assessed using the companion Clinical Global Impressions-Improvement (CGI-I) scale [66], a clinician-rated measure of change relative to the patient's condition at admission, ranging from 1 (very much improved) through 4 (no change) to 7 (very much worse). Rumination was assessed using the full Ruminative Responses Scale (RRS-22 [67]), a 22-item self-reported scale measuring participants' tendency toward repetitive negative thinking. Items are rated on a 4-point Likert scale, ranging from 1 (almost never) to 4 (almost always), and a total score is derived, with higher scores indicating greater levels of rumination.

Concerning ecological transfer, well-being was measured using the World Health Organization (WHO)-5 Well-Being Index [68], a 5-item self-reported scale with positively worded statements scored on a 6-point Likert scale, ranging from 0 (none of the time) to 5 (all of the time), assessing subjective well-being over the past 2 weeks. Higher scores reflect better well-being. Functional capacity was assessed using the University of California, San Diego, Performance-based Skills Assessment (UPSA [69]), which evaluates functional capacity in 5 domains: medication management, financial management, using the telephone and communication, using public transportation, and planning leisure activities, using a simulation of 11 daily life tasks. Final scores range from 0 to 100. The Adult Subjective Assessment of Participation (ASAP [70]), a self-reported questionnaire, documents subjective and objective participation dimensions in daily life occupations of adults. Indices of objective participation include diversity (the percentage of activities in which the person participates) and intensity or frequency (ie, the prevalence of participation in activities). This measure also tracks activities that were stopped. Subjective dimensions include enjoyment (perceived pleasure in activities) and satisfaction (perceived fulfillment from participation), both rated on 7-point scales.

Exploratory Outcomes

Change in CC was preregistered as an exploratory outcome, motivated by the mechanistic hypothesis that the LoH intervention trains CC. It is reported alongside the primary and tertiary end points in the "Results" section. CC was assessed using a computerized cognitive assessment battery, the Adaptive Cognitive Evaluation (ACE; Neuroscape, University of California, San Francisco [71]). We administered 6 ACE tasks, collectively measuring inhibitory control, cognitive flexibility, WM updating, sustained attention, and visuospatial WM. One of the tasks (Fileter, measuring visual WM) was excluded from analyses because many participants did not understand the task demands. On the basis of factor analyses of the remaining 5 tasks, a CC composite score was created from normed scores. ACE task outcomes and factor analysis are given in Multimedia Appendix 3.

Additional exploratory analyses included treatment credibility and outcome expectancy, assessed at the end of week 1 and at V_4 with the Credibility/Expectancy Questionnaire (CEQ [72]; credibility 3 - 27, expectancy 3 - 27, higher scores indicate greater credibility/expected benefit). In addition, durability of treatment effects was defined as change in all outcomes between baseline (V_1) and 1-month follow-up (V_5) and is reported for each end point alongside the V1 to V4 analysis.

Interventions and Comparators

Design Rationale and Shared Features

The intervention is described using the TIDieR (Template for Intervention Description and Replication) checklist categories; a TIDieR summary table covering both arms is provided in Multimedia Appendix 4. The interventions were developed using Unity (version 2019.4.28f1; Unity Technologies). LoH and LoH_control versions 1.1.10 to 1.1.13 were used, corresponding to early bug corrections in the overall running performance, save system, and data collection, none of which affected the game content per se.

The distinction between the experimental (LoH) and active control (LoH_control) arms is not between a cognitively demanding and a cognitively inert condition, but between involvement matched and mechanism specific. Both arms load on cognitive engagement in the sense of Plass et al [64], offering structured goals, unambiguous feedback, and clear challenges. Critically, LoH_control was designed to match LoH on the patient's ability to become involved with the game and thus spend time on task (involvement matched) while omitting the action mechanics hypothesized to challenge and train attention and CC (mechanism specific). In addition, LoH leverages both cognitive and affective engagement [64]—the latter via emotionally valenced facial expressions in the N-back and Go/No-Go modules, which target the mood-congruent attentional bias implicated in MDD [30-33]—whereas LoH_control relies exclusively on cognitive engagement. Importantly, LoH_control was designed to have a similar look and feel as the active LoH game and to also induce robust in-game involvement.

XSL•FO
RenderX

Interventions were developed in Unity and distributed directly to participants through tablets with the assigned game installed on them. Gameplay metrics (session duration and in-game involvement metrics) were automatically logged and transmitted to the study server. Each game was played during 30-minute sessions, within which several tasks were iterated. Both game versions place the player in an adventure world with tasks and subtasks while they discover the Village, a hub designed to maintain the players' engagement by allowing them to exchange the points earned during play to personalize their game world via various aesthetic upgrades. Participants in both arms received identical instructions regarding gameplay and schedule.

Experimental Game

The game LoH is designed as a cognitive training platform that integrates emotional and cognitive elements through various interactive challenges. The game architecture combines fast-paced action video game mechanics—centered around a core action game hub where players control a friendly creature navigating flying sequences that demand both divided and focused attention [73]—with targeted cognitive training mini-games. LoH is specifically designed to provide structured variability and adapt to individual player abilities through a multidimensional, probabilistic dynamic difficulty adjustment [74]. By continuously adapting task demands across multiple parameters, this system maintains each player within their zone of proximal development throughout training [74], sustaining the level of controlled processing required for cognitive skill acquisition—beyond merely reducing boredom or frustration [51].

LoH includes 7 such dynamically adjusted mini-games, each targeting a specific CC ability such as WM, inhibitory control, cognitive flexibility, sustained attention, divided attention, and multitasking, as detailed in Multimedia Appendix 4. Additionally, a deductive reasoning task is included as a supplementary, nonadaptive mini-game. LoH incorporates emotional stimuli (eg, emotionally valenced facial expressions in the N-back and Go/No-Go tasks) to specifically target the mood-congruent attentional bias implicated in MDD—that is, the tendency to direct attention toward negatively valenced stimuli [7]. Positive reinforcement elements (collecting coins, personalized rewards) provide additional motivational scaffolding [75]. An earlier version has been shown to successfully enhance attentional control in children [76].

Active Control Game

The active control game (LoH_control) was designed to match the aesthetic and structural elements of the experimental game, an important feature to maintain experimental blinding. Critically, its mini-games lack the adaptive cognitive training components of LoH and its action-based high attentional demands. It consists of a central hub game and 4 distinct mini-games (a modified, no-action version of the flight hub, visual search, peripheral vision task, and decoration). These activities emphasize the slow and deliberate movement of focused attention through tasks such as guiding a bird character to collect resources, focusing on auditory cues in a peripheral vision task, or spotting concealed targets in a cluttered map. These activities were selected based on prior research that used similar tasks as control conditions for depressed or dysphoric participants [26]. As such, the control game does not challenge attentional control as much as LoH. Moreover, unlike LoH, which incorporates positive emotional reinforcement through collecting happy coins and working with happy facial expressions, the control game lacks emotionally salient features. Players were presented with a fixed sequence of these 4 mini-games, each played twice within the same training session. A description of the control mini-games is given in Multimedia Appendix 4.

Patient and Public Involvement

Adults with lived experience of depression contributed to the design of the LoH intervention prior to trial launch through structured user-feedback sessions. Feedback informed the gameplay tempo, the visual aesthetic of the Village hub, the wording and pacing of in-game instructions, and the difficulty calibration of the adaptive mini-games. Patients and members of the public were not involved in setting the research question, designing the trial protocol, interpreting study results, or preparing this manuscript. Findings will be disseminated to participants on request via the corresponding author and through lay summaries posted to the OSF repository.

Harms

Adverse events (CONSORT 2025 harms item) were assessed via open-ended questioning at each scheduled visit (V_2-V_5); spontaneous reports during between-visit phone contacts with study staff were also recorded. No adverse events related to the intervention were reported during the trial in either arm. Beyond adverse event surveillance, depressive symptom severity, including suicidality (MADRS item 10), was rated by a clinician at every study visit, providing continuous monitoring of clinical status throughout the trial. Per the protocol's prespecified stopping rules, any participant showing documented suicidal ideation (MADRS item 10 above the protocol-defined threshold) or a suicide attempt after commencing active or control training, emergent hypomanic or manic symptoms, or clinically significant deterioration in the investigator's judgment, would be withdrawn from study treatment and referred to their treating clinician for appropriate care; investigators reviewed clinical status at each visit and could withdraw a participant at any time on clinical grounds. The absence of a validated safety questionnaire is acknowledged in the "Limitations" section.

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and was approved by the Helsinki Committee of Merhavim Medical Center (approval 670 - 21) and the Ethics Committee of the Faculty of Medicine at the Hebrew University of Jerusalem (approval 0388 - 20-HMO). All participants provided written informed consent at V_0 prior to any study procedure. Participants received NIS 250 (approximately US $82); compensation was not contingent on adherence or completion, so that it could not pressure continued participation. All data were deidentified using study IDs; a single linking file was stored separately on a password-protected drive accessible only to the PI and unblinded staff. No figures or multimedia appendices contain images of identifiable participants.

Statistical Methods

Analytic Approach

All statistical analyses were conducted using R (R Foundation for Statistical Computing) [77,78]. Analysis was conducted by a person blinded to the group assignment (Mattan S Ben Shachar). Baseline measures were compared between groups, and the association between attrition and baseline measures was assessed, using *t* tests and chi-square tests. The primary analysis followed the intention-to-treat principle, retaining all randomized participants in their originally assigned groups. All outcomes with a baseline assessment were analyzed using linear mixed models (LMMs). LMMs with maximum likelihood estimation provide unbiased estimates under the missing-at-random assumption and were used as the primary handling strategy. We report here ANOVA-like omnibus *F* tests with Satterthwaite degrees of freedom. These models include fixed effects for time (baseline, postintervention, and follow-up), group (active vs control), and the time×group interaction. Random intercepts were specified for participants to account for individual variability at baseline.

As loss to follow-up at postintervention was strongly associated with the number of completed training sessions rather than with baseline symptom severity, the number of completed sessions (mean centered) was included as an additional covariate in all outcome models to reduce potential attrition-related bias and to make the missing-at-random assumption more plausible. This covariate was not part of the preregistered analysis plan and is itself a postrandomization variable; we therefore also report unadjusted models (omitting this covariate) as a sensitivity analysis in Multimedia Appendix 5, which yielded materially identical conclusions.

For significant time×group interactions, post hoc comparisons with Bonferroni correction were conducted. Effect sizes are reported using partial η^2_p with 2-tailed 90% CIs, and estimated mean differences are reported with 95% CIs. Statistical inference for the primary outcome (H1: MADRS group×time) was performed at an α of .05. Tertiary outcome (H3) and exploratory analyses (CC, durability, mechanism, and predictors) are reported with unadjusted *P* values.

The secondary feasibility outcomes include the preregistered feasibility threshold (H2: ≥50% of randomized participants completing ≥20 of the 30 prescribed sessions) assessed as a descriptive proportion against the registered threshold. Feasibility, in-game involvement, and intrinsic motivation metrics were evaluated using descriptive statistics, independent-sample *t* tests for continuous measures, and chi-square tests (with Yates continuity correction) for categorical comparisons. Session-level gameplay-log comparisons (early abandonment and per-session active gameplay duration) were analyzed with mixed effects models, including a random intercept for participant to account for the nesting of sessions within participants (Multimedia Appendix 2). As an exploratory analysis, we examined the association between within-participant changes in CC and change in depressive symptoms. We first computed residual scores by regressing baseline scores out of postintervention and follow-up measurements separately. This approach allowed for the examination of change independent of initial differences, controlling for baseline variability and regression to the mean.

Missing Data

Participant-level missing data (loss to follow-up) were 16% (9/57) at postintervention (V_4) and 23% (13/57) at 1-month follow-up (V_5). Item-level missing data within completed assessments were minimal. The primary analytic strategy of linear mixed models with maximum likelihood estimation under the missing-at-random assumption (described earlier) accommodates this level of missingness. We assessed the missing data mechanism using Little test of missing completely at random; the test was nonsignificant for the primary outcome and for the other clinical measures, with a single borderline exception. As a sensitivity analysis, we repeated the primary group×time analyses under multiple imputation by chained equations (m=20). Both analyses are reported in Multimedia Appendix 6 and yielded conclusions consistent with the primary models.

Results

Participants and Baseline Characteristics

Demographic and baseline characteristics of the study sample are summarized in Table 1. The participant flow is given in Figure 2. Following eligibility assessment (n=60), 57 of 60 (95%) participants were randomized to either the active (28/57, 49%) or control (29/57, 51%) intervention. The sample was predominantly women (21/28, 75% and 18/28, 64.3% in the control and active arms, respectively) with an average age of 38 (SD 12) years. The groups were well matched on demographic characteristics (all *P*≥.10) and on depression severity at baseline (HDRS-17: mean 24.52, SD 4.98 vs mean 22.50, SD 6.02, in the control and active arms, respectively). On the basis of the HDRS-17 scores, participants presented with moderate to severe depression at baseline, with mean scores in the severe range for the control arm and upper moderate range for the active arm.

Figure 2. CONSORT 2025 flow diagram for the trial of Legends of Hoa'manu (LoH; active) versus a matched active control game (LoH_control) in adults with major depressive disorder. The primary outcome (change in MADRS total score from baseline to postintervention, assessed at visit V_4) was analyzed for all randomized participants under the intention-to-treat principle using linear mixed models on all available data; consequently, the analyzed n equals the allocated n in each arm. One participant randomized to LoH_control received LoH in error (RBSC15) and was analyzed as allocated. Four participants (2 per arm) discontinued training but completed the V_4 primary outcome assessment and were subsequently lost before the 1-month follow-up (V_5), a secondary time point reported in the Results and in Multimedia Appendix 7. "Other reasons" denotes discontinuations for which a specific reason was not recorded (n=1 in LoH; n=2 in LoH_control). LoH: Legends of Hoa'manu; MADRS: Montgomery-Åsberg Depression Rating Scale.

Primary Outcome: Baseline to Postintervention Change in Depression (MADRS)

We report here analyses of changes from baseline (V_1) to postintervention (V_4) for all outcome measures. Analyses of the full dataset, including all midtraining time points (whenever available) and follow-up data, are provided in Multimedia Appendix 7. Note that because the number of sessions completed was found to be a strong predictor of missing patterns postintervention (at V_4), it was controlled for in the analyses. Unadjusted sensitivity analyses omitting this covariate are reported in Multimedia Appendix 5 and yielded the same conclusions. Table 2 includes the data for all outcome measures.

Analysis of the primary outcome (depressive symptoms) revealed a significant reduction in MADRS scores from baseline (V_1) to postintervention (V4; $F_{1,48.6}$=47.52; P<.001; η^2_p=0.49, 90% CI 0.32-0.61) across both arms. However, the effect of group was not significant ($F_{1,52.6}$=0.02; P=.90; η^2_p=0.00), nor was the group×time interaction ($F_{1,49.4}$=1.57; P=.22; η^2_p=0.03). Post hoc analyses showed a significant reduction in MADRS scores in both arms (active: −6.83 points, 95% CI −10.26 to −3.41; $t_{48.4}$=−4.01; P<.001; and control: −9.84 points, 95% CI −13.28 to −6.41; $t_{48.0}$=−5.76; P<.001).

Secondary Outcome (Feasibility)

Feasibility Threshold and Benchmarks

Full feasibility metrics are provided in Multimedia Appendix 2. The preregistered feasibility threshold for gameplay completion was met: 30 of 57 (52.6%; 95% CI 39.9% - 65%) randomized participants completed ≥20 of the 30 prescribed sessions, exceeding the preregistered ≥50% threshold; among the 53 participants with recoverable gameplay data, 30 of 53 (56.6%; 95% CI 43.3% - 69%) met this threshold.

The 3 additional post hoc benchmarks were also met. First, retention was high at both postintervention (48/57, 84%; ≥70% benchmark) and follow-up (V_5: 44/57, 77%). Attrition was comparable across arms (active: 6/28, 21%; and control: 7/29, 24%; Figure 2). Specifically, 5 participants in the control arm discontinued participation during the first 2 weeks of the intervention, and 2 discontinued training later but completed

XSL•FO
RenderX

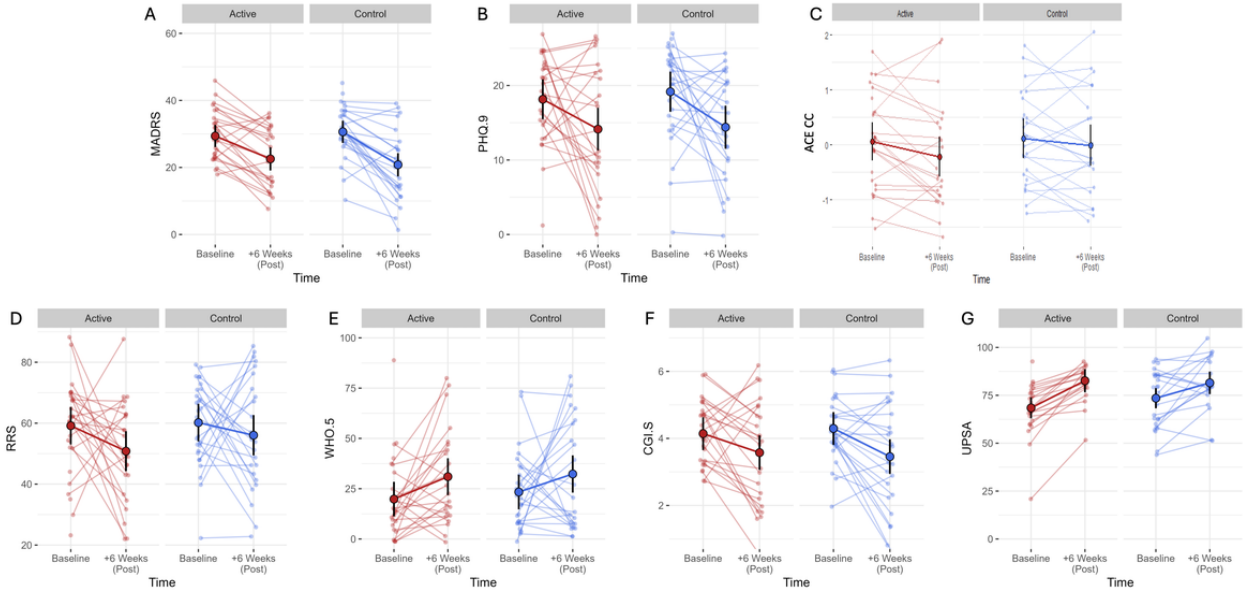
the postintervention (V_4) assessment before being lost to follow-up. In the active arm, 2 participants discontinued their participation during the first 2 weeks of the intervention and 2 after week 2 (V_2); 2 further participants discontinued training later but completed the V4 assessment before being lost to follow-up. The reasons for discontinuation are reported by arm in Figure 2; the most common were difficulty meeting the protocol's time requirements and finding the intervention unsuitable or not beneficial. Second, the mean adherence exceeded the 60% benchmark—participants completed, on average, 20.7 (SD 9.48) sessions of the 30 allotted sessions (mean 69%, SD 31.6%), with no significant between-group difference (t_{50}=1.25; P>.05). Third, the intrinsic motivation benchmark was met, with mean IMI interest/enjoyment in the active arm of 4.56 (SD 1.49) exceeding the scale midpoint (4/7).

In-Game Involvement

Server-side gameplay logs were recovered for 53 of 57 randomized participants (LoH: 27/28, 96%; and LoH_control: 26/29, 90%) due to hardware failure. The mean active gameplay duration per session was 26.2 (SD 8.7) minutes for LoH and 28.7 (SD 8.3) minutes for LoH_control, closely matching the prescribed 30-minute dose. Early abandonment (active gameplay <15 minutes) was uncommon and did not differ between arms (LoH: 41/503, 8.2% vs LoH_control: 30/564, 5.3%; mixed-effects logistic regression with a random intercept for participant, z=1.76; P=.08). Sessions were distributed across all day parts, and 25% occurred on weekends (LoH: 126/503, 25%; LoH_control: 137/564, 24.3%), with similar patterns in both arms, indicating integration into varied daily schedules. Weekly mean session duration was stable across weeks 1 to 6 in both arms, with no evidence of gameplay fatigue. The catch-up provision at weekends and/or in week 7 was used by 27 of 27 LoH and 25 of 26 LoH_control participants and accounted for approximately 28% of all sessions in both arms (LoH: 143/503, 28.4%; LoH_control: 157/564, 27.8%). Per-participant adherence was heterogeneous: 33% (9/27) of LoH and 58% (15/26) of LoH_control participants completed ≥80% of prescribed sessions, while 30% (8/27) of LoH and 23% (6/26) of LoH_control completed fewer than half. This range is typical of remote digital mental health interventions and represents a target for personalization in future trials. Among discontinuers, all completed at least two sessions before quitting. Full distributions, statistical tests, and figures are reported in Multimedia Appendix 2.

Intrinsic Motivation

Full results are given in Multimedia Appendix 8. At the end of week 1, IMI ratings were broadly comparable between arms for all subscales, except for perceived competence, which was higher in the control arm ($t_{39.98}$=−2.74; adjusted P=.03; mean difference −0.90, 95% CI −1.56 to −0.24).



At postintervention (V_4), the active arm reported higher interest/enjoyment ($t_{47.79}$=2.71; adjusted P=.02; mean difference 1.15, 95% CI 0.30-2.00) and higher effort/importance ratings (t_{48}=2.84; adjusted P=.02; mean difference 0.93, 95% CI 0.27-1.59) than the control arm, indicating that the active intervention was perceived as more enjoyable and more effortful. Pressure/tension scores were in the low-to-moderate range in both arms at both time points (LoH: mean 3.62, SD 1.58 at week 1; mean 3.90, SD 1.37 at V_4; LoH_control: mean 3.08, SD 1.21 at week 1; mean 3.13, SD 1.56 at V_4). Between-group comparisons were nonsignificant at week 1 ($t_{45.0}$=1.38; P=.17, mean difference 0.54, 95% CI −0.25 to 1.33) and at V4 ($t_{47.9}$=1.85; P=.07; d=0.52, mean difference 0.77, 95% CI −0.06 to 1.60). Although the V4 difference was not statistically significant, the effect size estimate (d=0.52) was in the direction of higher pressure/tension in LoH, consistent with the more attentionally demanding action game format.

Changes Between Baseline and Postintervention on Tertiary Outcome Measures

The results for the preregistered tertiary outcomes are summarized next and are depicted in Figure 3D-G.

XSL•FO
RenderX

Figure 3. Change in outcome measures from baseline (V_1) to postintervention (V4) by arm (LoH in red; LoH_control in blue). Scores are shown for (A) MADRS (clinician-rated depressive symptoms); (B) PHQ-9 (self-rated depression severity); (C) ACE CC composite score; (D) RRS-22 (rumination); (E) WHO-5 (well-being); (F) CGI-S (clinician-rated illness severity); and (G) UPSA (functional capacity). Thin lines: individual participants; thick lines: group means with error bars. ACE: Adaptive Cognitive Evaluation; CGI-S: Clinical Global Impressions–Severity; MADRS: Montgomery-Åsberg Depression Rating Scale; PHQ-9: Patient Health Questionnaire-9; RRS-22: Ruminative Responses Scale-22; UPSA: University of California, San Diego Performance-Based Skills Assessment; WHO-5: World Health Organization-5 Well-Being Index.

MADRS-Based Response and Remission

MADRS response (≥50% reduction from baseline) and remission (MADRS ≤10) rates at postintervention and 1-month follow-up were computed, comparing groups using 2-sided Fisher exact tests with nonresponder imputation for missing MADRS scores. The results, indicating no between-group differences, are summarized in Multimedia Appendix 9.

Depressive Symptoms (PHQ-9)

Changes from V_1 to V_4 showed a significant effect of time ($F_{1,49.16}$=10.72; P=.002; η^2_p=0.18, 90% CI 0.04-0.33). However, there were no significant effects of group ($F_{1,49.8}$=0.18; P=.67; η^2_p=0.004) nor a significant group×time interaction ($F_{1,49.8}$=0.08; P=.78; η^2_p=0.002; Figure 3A,B).

Rumination (RRS-22)

The effect of time was not statistically significant ($F_{1,98}$=3.75; P=.06; η^2_p=0.04, 90% CI 0.00-0.11). However, there was no significant effect of group ($F_{1,98}$=0.97; P=.33; η^2_p=0.01), nor a group×time interaction ($F_{1,98}$=0.43; P=.51; η^2_p=0.004).

Well-Being (WHO-5)

World Health Organization-Five Well-Being Index (WHO-5) demonstrated a significant improvement over time ($F_{1,46.5}$=5.17; P=.03; η^2_p=0.10, 90% CI 0.01-0.24). However, there were no significant effects for group ($F_{1,46.6}$=0.27; P=.60; η^2_p=0.006) nor a group×time interaction ($F_{1,47.03}$=0.06; P=.80; η^2_p=0.001).

Severity of Illness

Severity of illness, measured using the CGI-S scale, demonstrated a significant improvement over time ($F_{1,49.2}$=13.55; P<.001; η^2_p=0.22, 90% CI 0.07-0.36). However, there were no significant effects for group ($F_{1,52.8}$=0.003; P=.96; η^2_p=0.00) nor a group×time interaction ($F_{1,50.1}$=0.52; P=.47; η^2_p=0.01). Post hoc within-group comparisons showed a nonsignificant reduction from baseline to postintervention in the active arm (−0.57 points; 95% CI −1.11 to −0.03; $t_{48.8}$=−2.10; Bonferroni-adjusted P=.08) and a significant reduction in the control arm (−0.84 points; 95% CI −1.38 to −0.30; $t_{48.3}$=−3.11; Bonferroni-adjusted P=.006). As these P values are Bonferroni-adjusted for multiple comparisons and the CIs are unadjusted, the active-arm interval can exclude zero while its adjusted P value exceeds .05.

Global improvement was assessed with the clinician-rated CGI-I scale, which rates change relative to admission (1=very much improved to 7=very much worse; 4=no change). As CGI-I is defined relative to admission and therefore has no baseline value, it was not entered into the baseline-to-follow-up mixed models used for the other measures; instead, improvement was summarized descriptively and between-arm differences were tested at each postbaseline assessment. Participants were rated as improved: pooled CGI-I scores were significantly below the "no change" anchor at both postintervention (mean 2.96, SD 1.40; t_{47}=−5.16; P<.001; d=−0.74) and follow-up (mean 2.50, SD 1.32; t_{43}=−7.53; P<.001; d=−1.14), with 65% (31/48) of participants rated as at least minimally improved at postintervention and 75% (33/44) at follow-up (20/48, 42% and 25/44, 57%, respectively, rated much or very much improved). There was no significant difference between arms at postintervention ($F_{1,46}$=0.17; P=.68; η^2_p=0.004) or follow-up ($F_{1,42}$=0.46; P=.50; η^2_p=0.01).

RenderX

Functional Capacity

Functional capacity, measured using the UPSA scale, showed a significant improvement over time ($F_{1,38.9}$=33.16; P<.001; η^2_p=0.46, 90% CI 0.26-0.59). However, there were no significant effects for group ($F_{1,49.2}$=0.34; P=.56; η^2_p=0.007), nor a group×time interaction ($F_{1,39.6}$=2.56; P=.12; η^2_p=0.06). Post hoc analyses revealed significant improvement from baseline to postintervention in UPSA for both the active (14.19 points; 95% CI 8.60-19.79; $t_{38.8}$=5.13; P<.001) and the control (8.04 points; 95% CI 2.58-13.51; $t_{38.5}$=2.98; P=.01) groups.

Participation (ASAP Scale)

Objective (diversity and frequency) and subjective (enjoyment and satisfaction) aspects of participation did not differ by time, group, nor group×time interaction. The full analyses of the ASAP can be found in Multimedia Appendix 7.

Exploratory Analyses

Cognitive Control

Composite scores (normed to the V1 data), comprising the individual scores of the 5 tasks (TNT, Stroop, Flanker, TaskSwitch, and SAAT), were computed for the ACE battery assessments, which were administered at V_1 and V_4. Composite scores significantly improved from baseline to postintervention ($F_{1,44.6}$=4.36; P=.04; η^2_p=0.09). However, there were no significant effects of group ($F_{1,51.7}$=0.79; P=.38; η^2_p=0.015), nor a significant group×time interaction ($F_{1,45.5}$=0.49; P=.49; η^2_p=0.01). Post hoc analyses revealed that the changes between V1 and V4 were not significant for the active (−0.28 points; 95% CI −0.56 to 0.003; $t_{44.5}$=−1.99; P=.11) nor for the control arm (−0.14 points; 95% CI −0.42 to 0.15; $t_{44.5}$=−0.97; P=.67; Figure 3C).

Treatment Credibility and Expectancy (CEQ)

Credibility did not differ between arms at either time point (week 1: LoH: mean 12.96, SD 7.22; LoH_control: mean 15.00, SD 6.38; $t_{47.7}$=−1.07; P=.29, 95% CI for the between-arm difference −5.88 to 1.80; V_4: LoH: mean 13.29, SD 7.47; LoH_control: mean 13.46, SD 5.95; $t_{44.0}$=−0.09; P=.93; 95% CI for the between-arm difference −4.04 to 3.70) and was stable within each arm over time, indicating that the matched control design sustained equivalent perceived credibility across arms. Credibility and outcome expectancy are distinct constructs, however, and comparable credibility did not entail comparable expectancy: outcome expectancy was higher in LoH_control than in LoH at week 1 (mean 12.87, SD 6.14 vs mean 9.29, SD 5.63; $t_{48.9}$=−2.17; P=.04; d=−0.61, 95% CI for the between-arm difference −6.89 to −0.27), indicating that control participants began the trial expecting more benefit; however, it did not differ between arms at V_4 (mean 10.75, SD 6.18 vs mean 9.35, SD 6.66; $t_{46.9}$=−0.77; P=.45; 95% CI for the between-arm difference −5.06 to 2.27). Both arms showed small numerical reductions in expectancy from week 1 to V_4, more pronounced in LoH_control (Δ=−1.99, paired t_{23}=−1.82; P=.08).

Predictors of Change

We exploratorily examined several factors as predictors of change in MADRS symptoms. First, the relations between changes in CC (using standardized composite scores) and clinical measures were assessed using residualized change scores, calculated by regressing postintervention scores on baseline scores for all measures. Changes in CC were *not* significantly associated with changes in depressive symptoms (MADRS: r=0.05, 95% CI −0.25 to 0.34; t_{43}=0.33; P=.74; PHQ-9: r=0.04, 95% CI −0.25 to 0.33; t_{43}=0.28; P=.78), quality of life (WHO-5: r=−0.12, 95% CI −0.40 to 0.18; t_{43}=−0.79; P=.44), or rumination (RRS-22: r=0.15, 95% CI −0.15 to 0.43; t_{43}=1.02; P=.31).

Next, we examined whether perceived choice (subscale of IMI) was associated with change in MADRS scores following treatment (see full results in Multimedia Appendix 10). In short, higher perceived choice significantly predicted greater MADRS improvement in the active arm only (B=1.41; adjusted P=.006), with this relationship reversed for the control arm.

Next, we examined whether blinding guesses were related to improvement in MADRS scores across the study population. The results showed that there was no significant difference in MADRS change between the active and control arms, regardless of participant guesses in the blinding check (see full analysis in Multimedia Appendix 10). Finally, the association between game progression metrics and change in MADRS and CC scores are summarized in Multimedia Appendix 11.

Blinding Checks

Blinding was assessed at the end of week 1 and at the end of the 6-week intervention. There was no significant difference in participant guesses between the active and control treatment groups. At the end of week 1, 12/26 (46%) participants in the active arm and 20/28 (71%) participants in the control arm correctly guessed their group assignment (group comparison: χ^2_1=2.60; P=.11). At week 6, 17/25 (68%) participants in the active arm and 12/23 (52%) participants in the control arm correctly guessed their group assignment (group comparison: χ^2_1=0.68; P=.41). Full results are given in Multimedia Appendix 12.

Discussion

Interpretation

This randomized controlled trial examined the feasibility and effectiveness of a home-based, action-based serious game (Legends of Hoa'manu; LoH) for individuals with MDD, compared against a closely matched active control game. Four findings can be mapped directly to our hypotheses. First, the superiority hypothesis on the primary end point (MADRS) was not supported. Depressive symptoms improved over time across both arms, with no significant group×time interaction. Second, the feasibility hypothesis (secondary end point) was supported. A majority of randomized participants met the preregistered session completion threshold, retention was high at both postintervention and follow-up, and the additional post hoc

XSL•FO
RenderX

reference benchmarks for adherence and intrinsic motivation were met. In particular, participants rated the active intervention as more enjoyable and more effortful than the control. Third, the tertiary outcome superiority hypotheses were not supported. Several tertiary outcomes improved over time across both arms, although not all showed clear improvement, with no significant group×time interactions. Improvements in depression scores were maintained at a 4-week follow-up, with no significant deterioration in any outcome measure. Finally, exploratory analyses examined the proposed CC mechanism and a hypothesis-generating predictor of clinical response. The mechanism analysis was not supported as individual changes in CC scores were not associated with changes in depressive symptoms or rumination. Interestingly, within the active arm only, postintervention perceived choice (subscale from IMI) predicted greater reductions in depression symptoms—a hypothesis-generating finding that warrants replication. This set of results offers insights into the potential benefits and limitations of gamified cognitive interventions for depression while raising questions about mechanisms of therapeutic change.

Participants in both arms showed reductions in depressive symptoms in the range generally considered clinically meaningful for MADRS [79]. In several additional measures—including CGI-S, RRS-22, and MADRS—descriptive improvements were numerically larger in the control arm, although the absence of significant group×time interactions cautions against direct between-arm contrasts. This pattern is consistent with growing evidence that closely matched active digital controls can produce substantial symptom change [11,41,48,49,80,81]. Several nonspecific processes plausibly contribute to this convergence, such as structured daily activity analogous to behavioral activation [80,82], intermittent on-demand contact with study staff and ad hoc adherence reminders, as well as possible expectancy effects, and natural fluctuation including regression to the mean, which cannot be ruled out in the absence of a no-contact or waitlist arm [83]. This is reinforced by our CEQ data showing higher initial outcome expectancy in the control arm, which itself contributes to nonspecific symptom change in psychotherapy trials [84].

These mechanisms are common to many psychological and digital interventions and are difficult to disentangle without additional control conditions [83]. Beyond nonspecific factors, it is worth noting that LoH_control was not designed to be cognitively inert. The same logic applies broadly in the action video game literature, where games such as Tetris—which engage visuospatial attention, WM, and rapid decision-making—are routinely used as active controls precisely because they match the experimental condition on general cognitive engagement while omitting the specific action mechanics hypothesized to drive transfer effects in healthy individuals [46,73]. LoH_control was designed following this same principle. Its tasks involve attention, structured goals, and reward but lack the adaptive difficulty, action video game mechanics, and emotionally valenced stimuli that constitute the theoretically active ingredients of LoH [30-33,45,46,73]. The absence of superiority therefore raises the question of which specific components carry therapeutic weight, a question that future dismantling designs would be better positioned to address. Furthermore, the attentional demands embedded in LoH_control (visual search, peripheral vision, and deliberate target spotting) may have provided meaningful attentional stretch for adults with current MDD—a population whose baseline attentional capacity is typically lower [13,14,19] than that of young healthy adults in whom action game effects are most established [46]. Together, these features argue for future trials to include a no-contact or business-as-usual comparator alongside an active control, to better separate intervention-specific effects from the broader benefits of structured digital engagement.

The observed improvement in functional capacity (UPSA) in both arms is consistent with growing recognition that quality of life and functional capacity are key treatment outcomes in mental health beyond symptom reduction [85].

The relatively high retention and adherence observed here are noteworthy given both the intensity of the protocol (a 6-week, 30-session course) and its home-based, minimal-contact delivery. These rates are comparable to earlier digital interventions for MDD that were delivered in clinic or used fewer, less intensive sessions [32,33,40,44], and the present trial extends that work by showing that comparable feasibility can be achieved with a home-based protocol. The additional feasibility dimensions assessed beyond retention and adherence, including intrinsic motivation, daily life integration, subjective tolerability, and the gameplay-log analyses, provide further preliminary evidence of real-world fit.

The intervention used a minimal-contact, home-based design: after an in-person onboarding visit (V_1), the 6-week training phase was entirely self-administered with no scheduled remote clinician sessions, and most mid-study assessments (V_2 and V_3) were conducted by video—in contrast to many interventions labeled “remote” or “at-home” that incorporate substantial scheduled clinician contact. This feasibility may be attributable in part to the carefully designed game environment shared by both arms (structured schedules, aesthetic coherence, and motivating in-game goals [86]). Adherence was nevertheless heterogeneous across participants, suggesting that personalization may be needed to address adherence challenges in future home-based interventions for MDD. More broadly, home-based delivery of this kind may help overcome the stigma- and access-related barriers that often prevent individuals from seeking traditional mental health services [87].

While the preregistered secondary feasibility outcome was supported, the trial’s exploratory mechanistic question—whether LoH would specifically train CC—received a less affirmative answer. Specifically, although CC composite scores improved modestly over time across the full sample, the absence of a group×time effect and the lack of association between CC change and MADRS change do not support the targeted cognitive control account that motivated this trial. Several alternative explanations merit consideration. First, the ACE battery, which was used to assess CC, was administered at baseline and postintervention, allowing for test-retest effects. Indeed, practice and familiarity effects on computerized cognitive tasks are well documented [88] and may have contributed to the small improvement observed in both arms.

XSL•FO
RenderX

Moreover, the ACE tasks share substantial cognitive overlap with the LoH training mini-games (ie, both target response inhibition, task-switching, and sustained attention), which complicates interpreting any observed change as either generalizable transfer or task-specific learning [89]. Second, even the control game involved attention-demanding visuospatial tasks, structured goals, and reward elements, which could plausibly engage attentional networks despite not being designed as cognitive training. Third, the effect size for CC change was small, and the trial may have been underpowered to detect smaller, mechanistically meaningful contrasts in CC. The observed change on the ACE composite is best interpreted as a modest, time-related shift on a standardized composite score rather than a clinically interpretable index of cognitive recovery, consistent with the recognition that transfer from CC training is typically narrow and stimulus bound [89,90].

Within the active arm, higher postintervention perceived choice (IMI subscale) was associated with greater reduction in depressive symptoms. This finding should be interpreted with caution: it is post hoc, based on a single subscale among several tested, derived from a modest sample, and not corrected for multiple comparisons. It nevertheless converges with self-determination theory and prior work, suggesting that autonomy-supportive experience contributes to engagement and therapeutic response in digital and game-based interventions [51,86]. We therefore frame it as hypothesis generating: future adequately powered trials should test perceived choice as a candidate predictor of clinical response and as a potential target for autonomy-supportive design features (eg, schedule flexibility, optional content paths, and self-paced progression). We do not interpret this association as evidence for a specific cognitive training mechanism, nor for personalization frameworks more broadly.

Limitations

Several limitations should be considered. First, and most importantly, the trial used a closely matched active control without a no-contact or business-as-usual comparator. Although this matched design is a methodological strength, both arms improved comparably on the primary and tertiary outcomes, so we cannot rule out regression to the mean, time-related natural recovery, or contact-related expectancy effects [83], nor can we isolate the specific contribution of the targeted CC and action game components from the broader effects of structured digital activity. This concern is compounded by the unsupported exploratory CC mechanism analysis; yet whether this reflects insensitivity of the ACE composite, practice effects, the multicomponent nature of LoH, or the absence of a true mechanistic effect cannot be determined here. Second, the sample (n=57) was powered for a medium-to-large between-group effect (d=0.65), and was likely underpowered for the smaller differences expected when 2 engaging digital interventions are compared. Third, the exploratory analyses—including the perceived-choice finding—were post hoc and uncorrected for multiple comparisons and require replication. Fourth, our feasibility assessment was narrow as it did not include validated usability or acceptability scales (eg, the System Usability Scale [91]) or systematic capture of technical barrier metrics or support contacts, and the 3 additional benchmarks were post hoc rather than preregistered. Fifth, the battery included no neural measures, limiting tests of mechanistic predictions about prefrontal engagement [20]. Finally, follow-up was limited to 1 month, so longer-term durability is unknown.

Conclusions

This trial demonstrates that a 6-week, home-based, 30-session serious game intervention for MDD is feasible to deliver and acceptable to participants. To our knowledge, it is among the first trials to combine home-based, minimal-contact delivery with action game mechanics and a closely matched active digital control in adults with current MDD, differentiating it from prior studies that relied on weak or inactive comparators. Adults with MDD engaged with both an action-based, adaptive CC game and a closely matched active control game, and both arms showed clinically meaningful reductions in depressive symptoms and improvements in well-being and functional capacity. The trial did not demonstrate superiority of the active intervention, nor did it support the hypothesized CC mechanism, suggesting that, when compared against an engaging active control, nonspecific, engagement-related processes rather than CC training per se may drive symptom change. For the broader digital mental health field, our findings make 2 contributions: comparator design matters, as closely matched active digital controls can produce substantial symptom change; and the state-of-the-art evaluation framework for computerized cognitive training (training progress, near transfer, far transfer, and ecological transfer) [63] can be applied to a home-based, action-based intervention in adults with current MDD.

Practically, these results indicate that scalable, minimal-contact home-based serious games are deliverable outside the clinic and could help widen access to depression care and reduce stigma- and access-related barriers [87], provided future dismantling trials identify which gameplay components carry therapeutic weight. Future work should incorporate no-contact comparators to estimate nonspecific effects, augment behavioral measures with neural ones sensitive to the proposed mechanism, define richer feasibility criteria a priori, and test whether motivational signals such as perceived choice can guide personalization within stepped-care models.

Acknowledgments

We thank Izhak Shultz for his help with clinical assessments. We thank Mattan S. Ben-Shachar for his help with statistical analyses. We thank Michal Broday for her help with data collection.

Generative AI Use

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), the following tasks were delegated to GenAI tools under full human supervision: code generation, data analysis, visualization, reproducibility testing, proofreading and editing, reformatting, and quality assessment. The GenAI tool used was Claude Opus 4.8 (Anthropic). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. AI (Claude Opus 4.8) assistance in data analysis was limited to specific supplementary analyses (missing data/missing completely at random, and multiple-imputation sensitivity analyses) and to computing derived descriptive statistics. The primary outcome analyses were conducted by the study statisticians. All AI-assisted code and analyses were verified by the study statistician; no data were collected or generated by AI, and the authors take full responsibility for all results, content, and interpretations.

Funding

This study was supported by an Israeli Science Foundation grant awarded to MN (1700/18) and by a grant support from ERA NET NEURON to authors MN and DB. The NEURON "Network of European Funding for Neuroscience Research" is established under the organization of the ERA-NET "European Research Area Networks" of the European Commission. National funding agencies are the Ministry of Health for the Hebrew University of Jerusalem and Hadassah and the Swiss National Science Foundation for the University of Geneva. Game development was also funded in part by the Klaus J. Jacobs Foundation to DB. The study was sponsored in part by aMoon Fund.

Funding

The funders had no role in the design of the study; the collection, analysis, or interpretation of data; the writing of the manuscript; or the decision to submit for publication.

Data Availability

Deidentified participant-level data and the study protocol are available in the Open Science Framework repository [53].

Authors' Contributions

MN, DB, and LL conceptualized the study. MN, DB, and LL designed the trial and developed the study methodology. AP, ZM, DB, and MN led the development of the intervention and game software. EB, TS, NL, and LL oversaw clinical implementation of the trial. NO, NL, NA, EB, TS, and LL conducted participant recruitment and data collection. NO, NA, MF, AP, and DB performed the formal analyses and curated the data. NO and MN wrote the initial draft of the manuscript. All authors contributed to reviewing and editing the manuscript. MN and LL supervised the project. MN and DB acquired funding. All authors approved the final manuscript.

Conflicts of Interest

AP, ZM, MN, and DB are inventors on a patent concerning dynamic difficulty adjustment mechanics in gamified cognitive training interventions. International Publication Number: WO 2023/006189A1. Priority date: July 27, 2021. The patent is co-owned by the University of Geneva and Hebrew University of Jerusalem, which are committed to open access. The game (ie, Legends of Hoa'manu) intervention used in this study is available for noncommercial academic research use upon request through licensing or collaboration agreements. The remaining authors declare no conflicts of interest.

Abstract

Background: Cardiometabolic risk factors emerging during childhood and adolescence may persist into adulthood and increase the risk of cardiovascular disease. Although physical activity improves cardiometabolic health, maintaining regular participation remains challenging. Active video games (AVG), which combine physical activity with video game enjoyment, may provide an engaging approach to promote physical activity participation.

Objective: This study aims to evaluate the effects of AVG on cardiometabolic health in children and adolescents and to explore potential moderators of these effects.

Methods: PubMed, Web of Science, the Cochrane Library, and Embase were searched from database inception to July 2026. Eligible randomized controlled trials (RCTs) evaluating AVG in children and adolescents aged 4 - 18 years were included, with comparisons against no intervention, sedentary video games, or regular physical activity. Random-effects meta-analyses were conducted to estimate pooled effects. Subgroup analyses explored potential moderators. Risk of bias was assessed using the Cochrane Risk of Bias 2 tool (RoB 2; Cochrane), sensitivity analyses examined robustness, and small-study effects were evaluated when feasible. Certainty of evidence was assessed using GRADE (Grading of Recommendations Assessment, Development and Evaluation).

Results: A total of 14 RCTs involving 942 children and adolescents were included. AVG were associated with a small but significant reduction in BMI (Hedges g=−0.23, 95% CI −0.35 to −0.10; 95% prediction interval [PI] −0.43 to −0.01; P=.002). SBP (Hedges g=−0.18, 95% CI −0.36 to −0.001; 95% PI −0.43 to 0.07; P=.0497) showed a small statistically significant reduction, although the 95% PI crossed the null. No significant effects were observed for diastolic blood pressure (DBP) (Hedges g=−0.11, 95% CI −0.86 to 0.63; 95% PI −2.09 to 1.75; P=.59), high-density lipoprotein cholesterol (HDL) (Hedges g=0.05; 95% CI −0.21 to 0.31; 95% PI −0.54 to 0.57; P=.65), low-density lipoprotein cholesterol (LDL) (Hedges g=−0.26, 95% CI −0.64 to 0.13; 95% PI −1.18 to 0.69; P=.15), total cholesterol (TC) (Hedges g=−0.96, 95% CI −3.79 to 1.88; 95% PI −5.71 to 3.86; P=.37), triglycerides (Hedges g=−0.20, 95% CI −0.70 to 0.31; 95% PI −1.41 to 0.99; P=.38), heart rate (HR) (Hedges g=−0.14, 95% CI −1.74 to 1.46; 95% PI −4.23 to 5.38; P=.47), or glucose (Hedges g=−0.17, 95% CI −0.37 to 0.02; 95% PI −0.42 to 0.07; P=.07) following AVG. No significant BMI subgroup differences were observed by gender, intervention type, or nutritional status.

Conclusions: This review extends previous evidence by providing an updated RCT-only evaluation of a broader pediatric population and a wider range of cardiometabolic outcomes. AVG were associated with small reductions in BMI and systolic blood pressure (SBP), although evidence for other cardiometabolic outcomes remains uncertain. By clarifying both potential benefits and remaining evidence gaps, this review provides a broader basis for future research and intervention development. AVG may serve as an engaging adjunct to support physical activity participation among children and adolescents.

Introduction

Rationale

Insufficient physical activity and prolonged sedentary behavior are considered important adverse factors affecting cardiometabolic health in children and adolescents [1-3], and may be associated with reduced insulin sensitivity, abnormalities in glucose and lipid metabolism, elevated blood pressure, and an increased risk of obesity [4-6]. Existing evidence indicates that higher levels of physical activity are associated with lower cardiometabolic risk in children and adolescents [7]. In addition, childhood overweight and obesity warrant particular attention, as children who are overweight or obese are more likely to have abnormal levels of triglycerides, total cholesterol (TC), low-density lipoprotein cholesterol (LDL), and high-density lipoprotein cholesterol (HDL) than children of normal weight [8,9]. Friedemann et al [10] found that higher BMI was associated with adverse cardiovascular risk markers, including blood pressure, lipids, and insulin. Without effective intervention, these adverse lifestyle behaviors and early cardiometabolic risk factors may persist into adulthood and increase the future risk of cardiovascular diseases and type 2 diabetes [11].

Regular physical exercise has been repeatedly shown to be highly effective in improving cardiovascular function and metabolic markers [12-15]. However, approximately 80% of adolescents worldwide have insufficient levels of physical activity, and many adolescents spend 2 hours or more per day engaging in recreational screen time [16]. In practical situations, especially among children and adolescents who are overweight or obese, weight stigma, lack of enjoyment, and lower motor competence may reduce their willingness to participate in physical activity [17-19]. These factors may further limit sustained participation in physical activity and thereby adversely affect cardiometabolic health. These practical barriers highlight the need for interventions that can both increase physical activity and provide sufficient engagement to promote sustained participation and exercise adherence. Against this backdrop, active video games (AVG), also known as exergaming, have developed into an intervention model that integrates digital entertainment with physical activity and can significantly enhance children's and adolescents' interest in physical activity [20,21]. By using bodily movements to control virtual characters or advance game progress through a screen [22], these games can transform some traditionally sedentary screen-based activities into movement-based gameplay, thereby increasing energy expenditure and helping children and adolescents break sedentary habits and increase their physical activity levels [23,24].

Previous systematic reviews and meta-analyses of AVG have primarily focused on physical activity, weight management, and anthropometric outcomes. Ho et al [23], Oliveira et al [25], and Bourke et al [26] mainly evaluated physical activity levels, BMI, body weight, body fat, or other weight management-related outcomes, with limited attention to broader cardiometabolic outcomes such as blood pressure, lipid profiles, and glucose metabolism. Some reviews have begun to extend their scope to cardiometabolic outcomes, but important limitations remain. Comeras-Chueca et al [27] primarily evaluated body composition, health-related physical fitness, and motor competence in children and adolescents with overweight or obesity, whereas Erçelik et al [28] focused mainly on a limited range of outcomes, including BMI and TC, in adolescents with overweight or obesity. More recently, Hernandez-Martinez et al [29] comprehensively evaluated morphological variables, blood pressure, and biochemical parameters in children and adolescents with overweight or obesity; however, the study population was restricted to those with overweight or obesity. Zhu et al [30], in contrast, specifically evaluated blood pressure outcomes in children and young adults aged 6 to 25 years without simultaneously synthesizing other metabolic outcomes.

Objectives

Therefore, there remains a need for a systematic review and meta-analysis based on RCTs that includes children and adolescents across a broader range of weight status and evaluates anthropometric, cardiovascular, and metabolic outcomes within a unified framework. In addition, whether intervention type and participant characteristics are associated with the effectiveness of AVG has not been consistently or sufficiently evaluated across different cardiometabolic outcomes. With the publication of additional RCTs, an updated synthesis of the available evidence is warranted to clarify the potential cardiometabolic effects of AVG and the remaining uncertainties in the current evidence base.

Methods

Overview

This systematic review strictly adheres to the 2020 PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [31]. The completed PRISMA 2020 checklist is available in Appendix S1 of Multimedia Appendix 1. Additionally, this review protocol has been registered in the PROSPERO International Registry of Systematic Reviews under registration number CRD420261303390.

Eligibility Criteria

Inclusion and exclusion criteria were established based on the population, intervention, comparison, outcomes, and study design (PICOS) framework as follows: (1) study participants were children and adolescents aged 4 - 18 years; (2) participants who were able to safely engage in physical activity or interact with the intervention equipment were included, regardless of their baseline weight status or cardiometabolic health condition; (3) the intervention consisted of AVG or virtual reality (VR)-based exercise involving physical interaction with screen-based technology; (4) the control group (CG) consisted of participants who received no intervention, played sedentary video games, or maintained their regular physical activity; (5) studies reported at least 1 prespecified cardiometabolic outcome, including anthropometric measures, blood pressure, cardiorespiratory fitness, cardiac function-related measures, or metabolic biomarkers. The outcomes included in the quantitative syntheses were BMI, systolic blood pressure (SBP), diastolic

XSL•FO
RenderX

blood pressure (DBP), TC, triglycerides, HDL, LDL, heart rate (HR), and glucose, as detailed in the Data Items subsection; (6) study designs were randomized controlled trials (RCTs).

Exclusion criteria included (1) studies involving adult participants outside the child and adolescent age range, and animal studies were excluded during title and abstract screening; (2) qualitative research, systematic reviews, meta-analyses, study protocols, gray literature, and abstracts only; (3) ongoing or incomplete trials without outcome data, studies lacking sufficient numerical data for effect-size calculation, and reports for which the full text could not be obtained were excluded.

Data Items

Data were sought for all cardiometabolic outcomes prespecified in the registered protocol. The predefined outcome domains included anthropometric outcomes (BMI and body mass index z score [BMI-z]), blood pressure outcomes (SBP and DBP), cardiac and cardiorespiratory outcomes (HR, cardiorespiratory fitness, and cardiac function-related measures), and metabolic biomarkers (TC, triglycerides, HDL, LDL, glucose, insulin, and glycated hemoglobin [HbA_{1c}]). The assessment conducted at the end of the intervention was used for quantitative synthesis. Outcomes were pooled when numerical data were available from at least 2 independent studies and the outcome definitions and measurement methods were sufficiently comparable. On this basis, the quantitative syntheses included BMI, SBP, DBP, TC, triglycerides, HDL, LDL, HR, and glucose.

Other extracted variables included study author and publication year, participant sample size, age, sex distribution, intervention and comparator characteristics, intervention frequency, session duration, total intervention duration. When information was missing or insufficiently reported, it was recorded as not reported unless it could be derived directly from the published numerical data using standard statistical conversions. Unreported values were not imputed.

Information Sources

The databases searched were PubMed, Web of Science, the Cochrane Library, and Embase. Eligible studies were required to be peer-reviewed, published in English, accessible in full text, and without restrictions on publication date or sample size. Searches were conducted in July 2026.

Search Strategy

The search strategy was developed and reported in accordance with the PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search) extension for reporting literature searches in systematic reviews [32]. The search strategy was developed based on 3 key concepts: children and adolescents, AVG, and cardiometabolic outcomes. Controlled vocabulary terms were used, including MeSH in PubMed and Emtree terms in Embase, combined with free-text terms. The full search strategies are provided in Supplementary Material S2 of Multimedia Appendix 1. Additional searches included backward and forward citation searching of included studies. PROSPERO and the Cochrane Library were also searched to identify relevant registered or published systematic reviews.

Selection Process

The retrieved literature was first manually deduplicated by an independent researcher (LWQ) using EndNote 21 (Clarivate). After deduplication, 2 independent researchers (LWQ and WYX) screened the titles and abstracts against the predefined inclusion and exclusion criteria. In case of disagreement, the 2 researchers discussed the matter; if consensus could not be reached, a third independent researcher (WTL) made the final decision. Subsequently, the 2 researchers reviewed the full texts of the potentially eligible studies to determine the final included studies. Any disagreements arising at this stage were resolved using the same discussion and arbitration process. Other potentially eligible studies included those mentioned in previous relevant systematic reviews but not initially identified, or studies known to the research team through professional experience that met the inclusion criteria.

Data Collection Process

Data were independently extracted by 2 researchers (LWQ and WYX) using a predesigned Excel (Microsoft) data extraction form. Any disagreements were reviewed by a third researcher (WTL), and unresolved disagreements were adjudicated by a fourth independent researcher (LJ). If data were missing or presented only in graphical form, authors were contacted to obtain raw data; if contact was unsuccessful, data were extracted from the figures using Web Plot Digitizer 4.1 (Automeris). The reliability and validity of this software have been previously demonstrated [33]. Studies without sufficient data for effect size calculation were excluded. Extracted data included the mean, SD, and sample size for each group before and after the intervention. During data synthesis, when multiple eligible intervention groups shared a common CG, the eligible intervention groups were combined where appropriate to avoid double counting of the control participants, in accordance with the Cochrane Handbook [34].

When weight status classifications were not explicitly reported, BMI or BMI-z scores were used to determine whether participants met the criteria for overweight or obesity. BMI-z scores were not pooled with BMI values in the main meta-analysis. Although BMI is expressed in kg/m^2, its clinical interpretation varies according to age, sex, and developmental stage in children and adolescents. Therefore, BMI outcomes were analyzed using Hedges g to standardize effects across studies, and the pooled BMI effect was interpreted as a standardized difference rather than a direct change in BMI values.

Study Risk of Bias Assessment

The Cochrane Risk of Bias 2 tool (RoB 2) was used to assess the risk of bias in RCTs [35], examining the following domains: bias arising from the randomization process; bias due to deviations from intended interventions; bias due to missing outcome data; bias in measurement of the outcome; and bias in selection of the reported result. RoB 2 judgments were categorized as “Low risk of bias,” “Some concerns,” or “High risk of bias” in accordance with the official RoB 2 terminology. Any disagreements were resolved through discussion and, if necessary, by third-party arbitration.

XSL•FO
RenderX

Additionally, the Physiotherapy Evidence Database (PEDro) scale was used to assess methodological quality [36], with a scoring range of 0 - 10 points: ≥6 points indicated high quality, 4 - 5 points indicated moderate quality, and ≤3 points indicated low-quality studies. PEDro scores were used only as supplementary descriptive information on methodological quality and were not used as the basis for GRADE (Grading of Recommendations Assessment, Development and Evaluation) downgrading.

Sensitivity Analyses

Sensitivity analyses were conducted to assess the robustness of the pooled estimates, following established guidance for meta-analytic sensitivity and influence analyses [34]. Using a leave-one-out approach [37], each study was sequentially excluded, and the restricted maximum likelihood (REML)–based random-effects model with the Hartung-Knapp adjustment [38] was re-estimated. For each iteration, the pooled Hedges *g*, 95% CI, I^2, and τ^2 were recalculated. Robustness was assessed by examining whether omission of any single study materially altered the direction, magnitude, precision, heterogeneity, or overall interpretation of the pooled effect. Changes in statistical significance were considered but were not used as the sole criterion for judging robustness.

Synthesis Methods

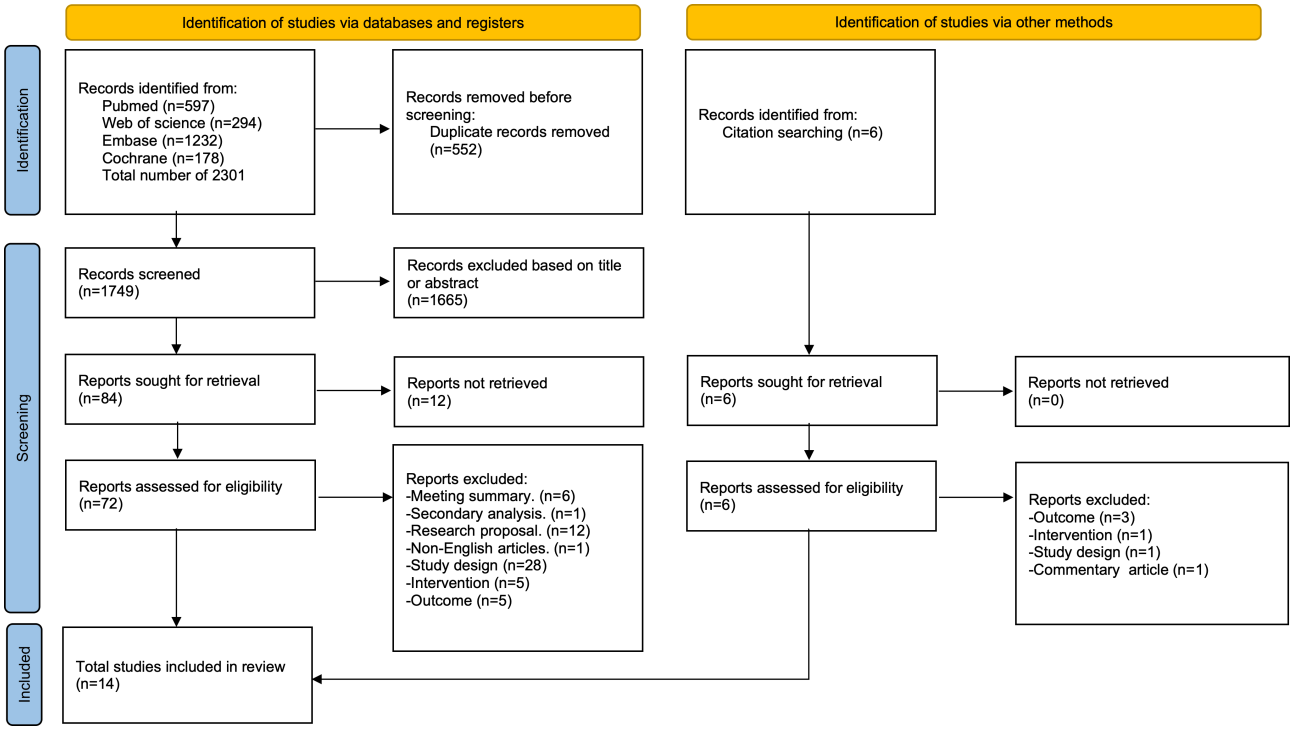
A random-effects model was applied because clinical and methodological heterogeneity among studies was anticipated, consistent with current recommendations for rigorous meta-analysis methodology [39]. Between-study variance (τ^2) was estimated using the REML method, 95% CI for the pooled effects were calculated using the Hartung-Knapp-Sidik-Jonkman adjustment [38], and 95% prediction intervals (PIs) were obtained using the Nagashima-Noma-Furukawa method [40]. Since the outcome measures in this study involved various units, and previous studies had recommended prioritizing standardized effect sizes, standardized mean differences (Hedges *g*) were used. Given that most included studies have small sample sizes, Hedges *g* was calculated using a bias-corrected exact formula as the effect size measure. Hedges *g* is interpreted as follows: 0.2 indicates a small effect, 0.5 indicates a moderate effect, and 0.8 indicates a large effect. Statistical heterogeneity was characterized using Cochran's Q, τ^2, and 95% PI, while I^2 was used as a relative measure of inconsistency among study estimates. I^2 was interpreted in relation to sampling error rather than as an absolute measure of between-study heterogeneity. Accordingly, fixed thresholds were not used to categorize I^2 values; instead, I^2 was interpreted descriptively in conjunction with τ^2, the *P* value from Cochran's *Q* test, and PI [41]. Outcomes were quantitatively synthesized when numerical data were available from at least 2 independent studies and the outcome definitions and measurement methods were sufficiently comparable [34]. Forest plots were used to display the individual study estimates and pooled effects, including for outcomes supported by few studies. These results were interpreted cautiously because of the limited precision of the available evidence.

Prespecified subgroup analyses were considered only when at least 10 studies were available for an outcome and were regarded as exploratory [34]. Accordingly, subgroup analyses were conducted only for BMI. No formal subgroup inference was made when a subgroup contained only one study.

Small-study effects were examined using funnel plots and Egger's regression test only when at least 10 studies were available for an outcome [42]. Accordingly, these analyses were performed only for BMI. A nonsignificant test result was interpreted as indicating no statistical evidence of small-study effects, rather than evidence that small-study effects were absent. Subgroup analyses and small-study effects tests were interpreted cautiously when only a limited number of studies or effect sizes were available, to reduce the risk of low statistical power and unstable inferences due to an insufficient number of studies. Statistical analysis and visualization were performed using the "meta" and "metafor" packages in R software (R Foundation for Statistical Computing) (version 4.2.0). Statistical significance was set at $P<.05$.

Certainty Assessment

The certainty of evidence for each outcome was assessed using the GRADE approach [43]. The GRADE approach classifies the certainty of evidence as high, moderate, low, or very low. Evidence certainty was rated based on 5 domains: risk of bias, inconsistency, indirectness, imprecision, and publication bias. The initial assessment was conducted by 1 reviewer (LWQ) and independently cross-checked by a second reviewer (WYX).



Results

Study Selection

The database search identified a total of 2307 records. Among these, 2301 were imported from PubMed, Web of Science, Cochrane Library, and Embase, while the remaining 6 records were identified through forward and backward citation searching within the final literature. After removing duplicate studies and screening titles or abstracts, 72 full-text articles were assessed for eligibility, and ultimately 14 RCTs were included in this systematic review and meta-analysis [44-57]. The study selection process is shown Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for the search strategy.

Study Characteristics

A total of 14 RCTs were included, with publication years ranging from 2009 to 2026. The included studies were conducted in Turkey (n=1) [47], New Zealand (n=1) [52], China (n=2) [50,57], Spain (n=1) [48], the United States (n=6) [46,49,51,54-56], Tunisia (n=1) [44], Norway (n=1) [45], and Italy (n=1) [53]. The total sample size was 942 participants, with individual study sample sizes ranging from 22 to 231 participants. Five studies [45,46,52,55,56] reported the sex distribution at baseline but did not report the sex distribution of the final analyzed sample. The mean age of participants ranged from 4 to 16 years. Participants included children and adolescents with normal weight, overweight, or obesity; one study included participants with endothelial dysfunction (EDF) [54]. BMI values ranging from 15 to 38 kg/m² across studies.

Interventions primarily included AVG and VR exercise, the CG mostly engaged in usual physical activity or received no intervention. Training frequency was typically 3 - 5 times per week, with intervention durations ranging from 4 - 24 weeks. Outcome measures included BMI, HR, SBP, DBP, HDL, LDL, TC, triglycerides, and glucose (Table 1).

Results of Individual Studies

In the pooled analysis of 14 studies [44-57], AVG were associated with a small but statistically significant reduction in BMI (n=899; Hedges g=−0.23, 95% CI −0.35 to −0.10; P=.002). The PI (95% PI −0.43 to −0.01) remained entirely below the null, indicating that the direction of the estimated effect was consistent across the range of plausible true effects (Figure 2). SBP (n=243; Hedges g=−0.18, 95% CI −0.36 to −0.001; P=.0497) showed a small statistically significant reduction; however, the PI (95% PI −0.43 to 0.07) crossed the null, indicating uncertainty regarding whether a similar effect would be observed across different future settings (Figure 3). The pooled estimate did not show a significant reduction in TC (n=208; Hedges g=−0.96, 95% CI −3.79 to 1.88; P=.37), the estimate was highly uncertain, with I^2=87% (Figure 4).

No statistically significant effects were observed for HR (n=186; Hedges g=−0.14, 95% CI −1.74 to 1.46; P=.47), DBP (n=195; Hedges g=−0.11, 95% CI −0.86 to 0.63; P=.59), TG (n=342; Hedges g=−0.20, 95% CI −0.70 to 0.31; P=.38), HDL (n=342; Hedges g=0.05, 95% CI −0.21 to 0.31; P=.65), LDL (n=342; Hedges g=−0.26, 95% CI −0.64 to 0.13; P=.15), or glucose (n=180; Hedges g=−0.17, 95% CI −0.37 to 0.02; P=.07). See Figures 5-10.

XSL•FO
RenderX

I^2 values ranged from 0% to 87% across outcome measures, while PI provided additional information regarding the range of plausible effects in future similar settings. The highest I^2 value was observed for TC (I^2=87%), whereas I^2 was 0% for BMI, HR, SBP, HDL, and glucose.

Figure 2. Forest plot of the effects of AVG on BMI in children and adolescents [44-50,52-54,57]. Hedges *g*: standardized mean difference corrected for small-sample bias. I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; NNF: Nagashima-Noma-Furukawa; REML: random-effects model.

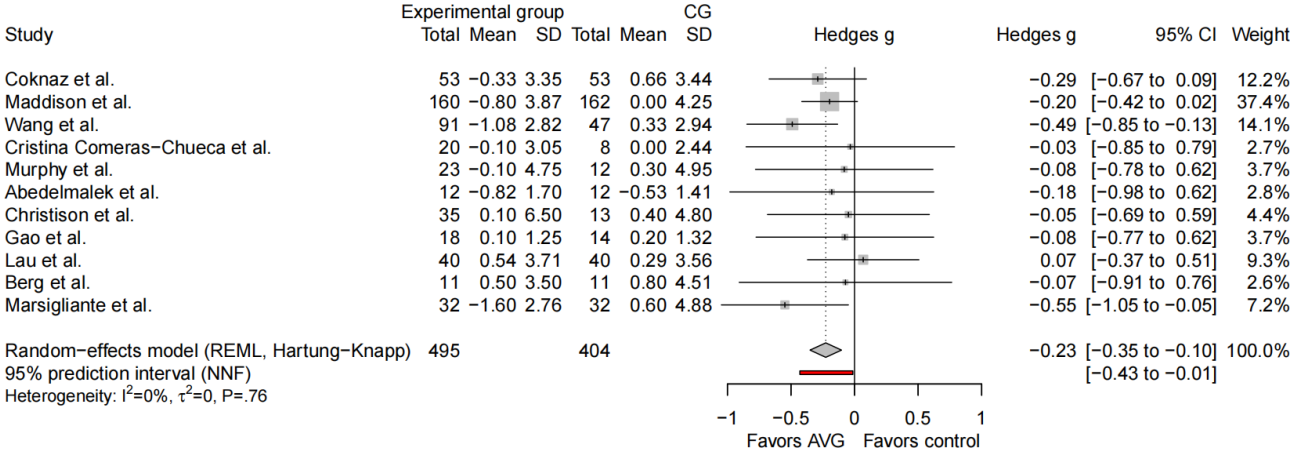

Figure 3. Forest plot of the effects of AVG on SBP in children and adolescents. Hedges *g*: standardized mean difference corrected for small-sample bias. Estimates in the forest plot are presented to 2 decimal places. For SBP, the upper 95% CI limit (−0.001) and *P* value (*P*=.0497) are reported with additional precision in the main text because rounding would yield −0.00 and *P*=.05, which could obscure the inferential result [45,46,54,57]. I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; NNF: Nagashima–Noma–Furukawa; REML: random-effects model; SBP: systolic blood pressure.

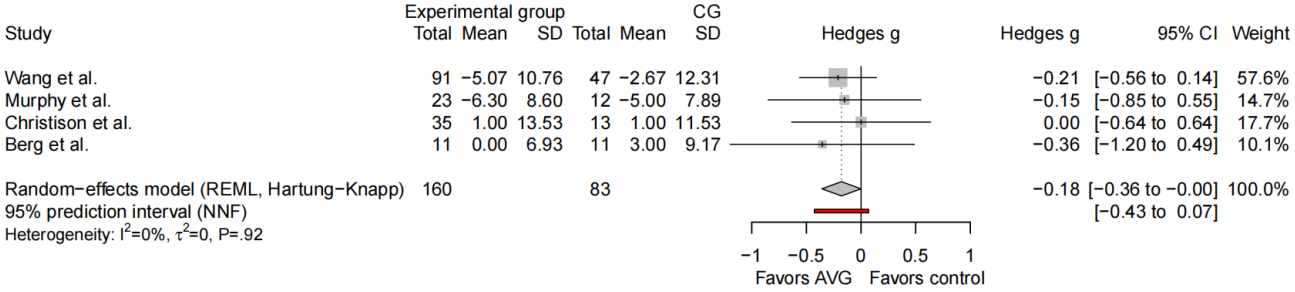

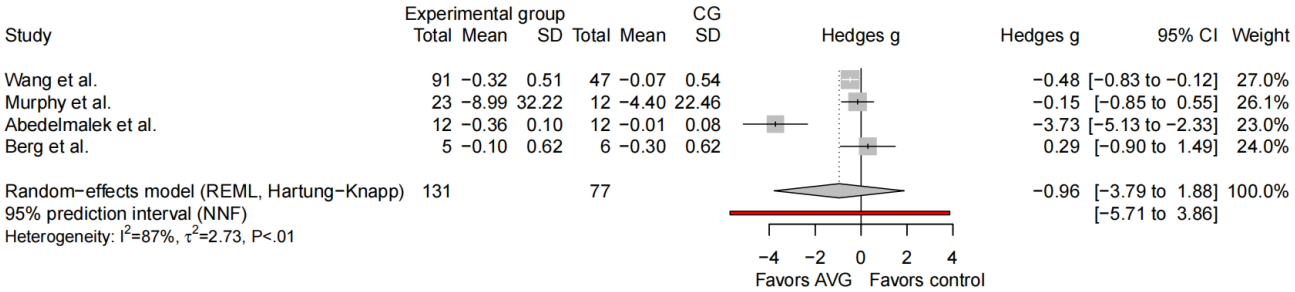

Figure 4. Forest plot of the effects of AVG on TC in children and adolescents [44,45,54,57]. Hedges *g*: standardized mean difference corrected for small-sample bias. I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; NNF: Nagashima–Noma–Furukawa; REML: random-effects model; TC: total cholesterol.

Figure 5. Forest plot of the effects of AVG on HR in children and adolescents [46,57]. Hedges *g*: standardized mean difference corrected for small-sample bias []. I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; HR: heart rate; NNF: Nagashima–Noma–Furukawa; REML: random-effects model.

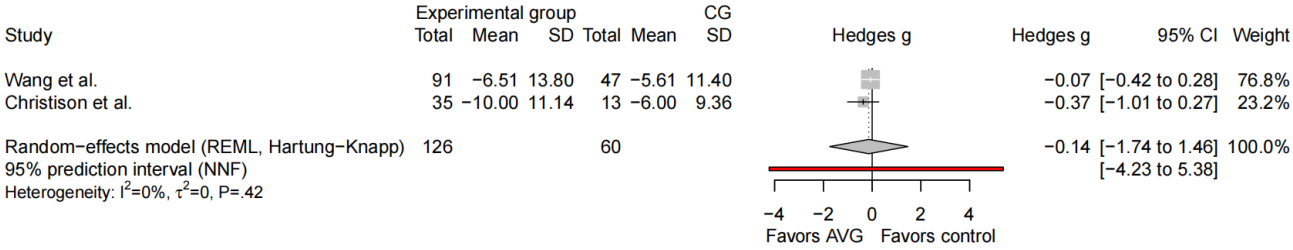

Figure 6. Forest plot of the effects of AVG on DBP in children and adolescents [45,54,57]. Hedges *g*: standardized mean difference corrected for small-sample bias; I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; DBP: diastolic blood pressure; NNF: Nagashima-Noma-Furukawa; REML: random-effects model.

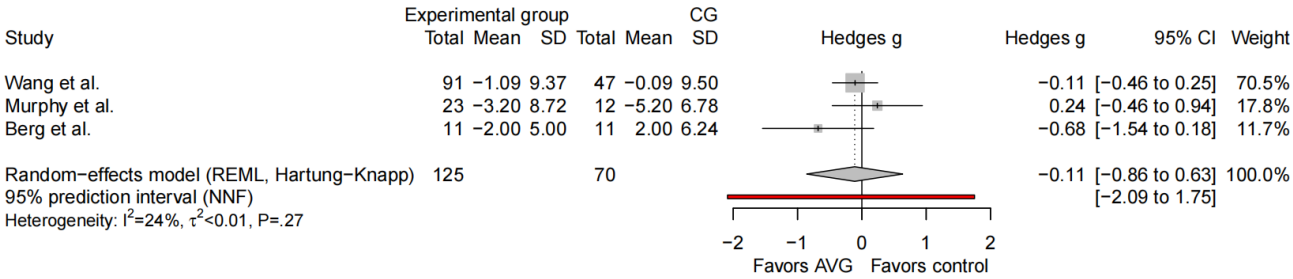

Figure 7. Forest plot of the effects of AVG on triglycerides in children and adolescents [44,45,51,54-57. Hedges *g*: standardized mean difference corrected for small-sample bias. I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; NNF: Nagashima-Noma-Furukawa; REML: random-effects model.

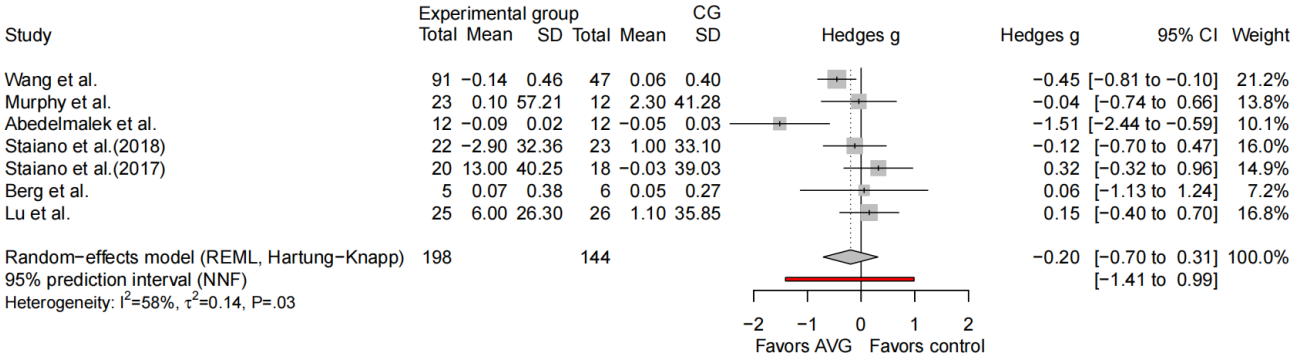

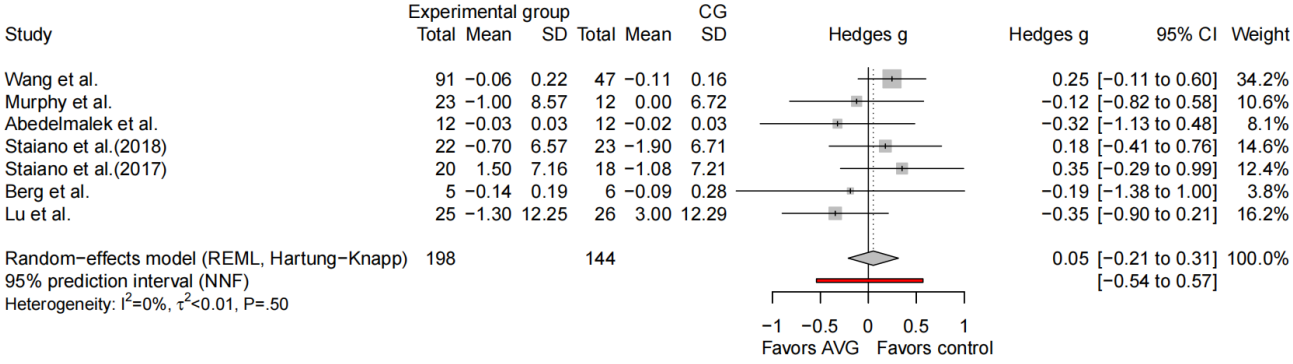

Figure 8. Forest plot of the effects of AVG on HDL in children and adolescents [44,45,51,54-57]. Hedges *g*: standardized mean difference corrected for small-sample bias. I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; HDL: high-density lipoprotein cholesterol; NNF: Nagashima-Noma-Furukawa; REML: random-effects model.

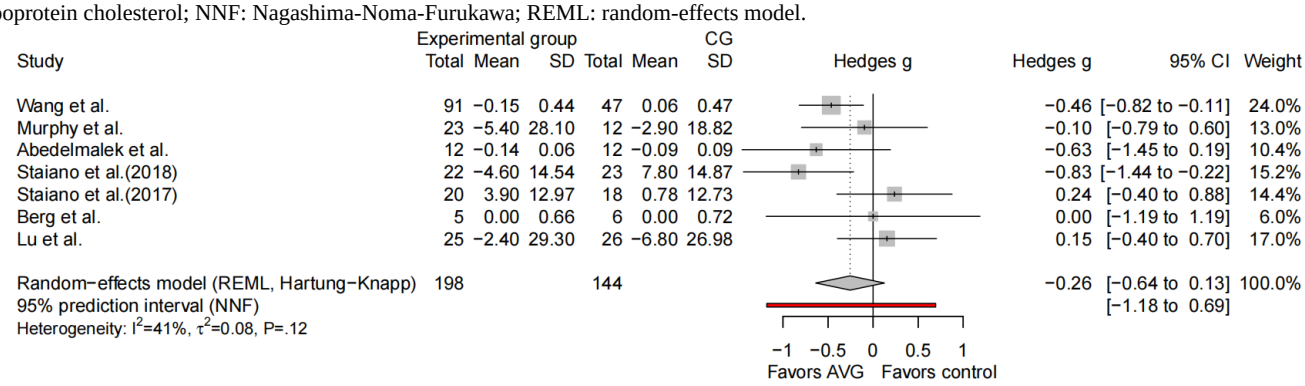
XSL•FO
RenderX

Figure 9. Forest plot of the effects of AVG on LDL in children and adolescents [44,45,51,54-57]. Hedges *g*: standardized mean difference corrected for small-sample bias; I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; LDL: low-density lipoprotein cholesterol; NNF: Nagashima-Noma-Furukawa; REML: random-effects model.



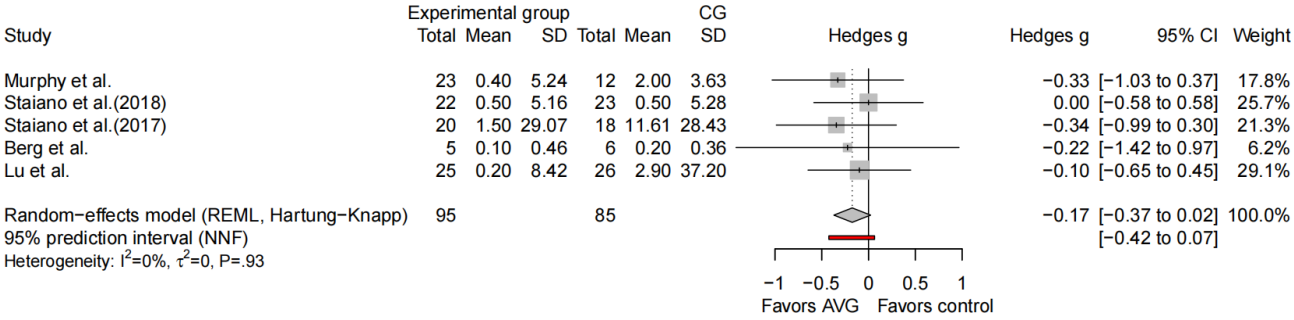


Figure 10. Forest plot of the effects of AVG on glucose in children and adolescents [45,51,54-56]. Hedges *g*: standardized mean difference corrected for small-sample bias; I^2: relative measure of inconsistency; τ^2: between-study variance; AVG: active video games; CG: control group; NNF: Nagashima-Noma-Furukawa; REML: random-effects model.

Subgroup Analysis

To further explore potential sources of heterogeneity and examine whether participant characteristics and intervention-related factors may modify the effects of AVG on cardiometabolic health in children and adolescents, subgroup analyses were conducted for BMI according to 3 dimensions: sex, intervention type, and nutritional status. These findings should be interpreted cautiously due to the limited number of studies within some subgroups.

Subgroup analysis revealed a small but statistically significant effect favoring BMI reduction in the mixed-sex group (Hedges *g*=−0.20), whereas it was not statistically significant in the male group (Hedges *g*=−0.45), likely reflecting the limited number of included studies (*K*=2) and the imprecision of the estimate (95% CI −2.55 to 1.66). The subgroup differences by sex were not statistically significant (*P*=.17). See Figure 11. Both the AVG group (Hedges *g*=−0.18) and the VR group (Hedges *g*=−0.49) showed effects favoring BMI reduction. See Figure 12. Because the VR category comprised a single study, this estimate should be regarded as a single-study observation, and no formal inference regarding differences between AVG and VR interventions can be made. Regarding nutritional status, the pooled effects were similar across normal weight (Hedges *g*=−0.24), overweight (Hedges *g*=−0.22), and obesity subgroups (Hedges *g*=−0.22), with no significant subgroup differences (*P*=.99). See Figure 13. Overall, no statistically significant subgroup differences were observed according to sex, intervention type, or nutritional status.

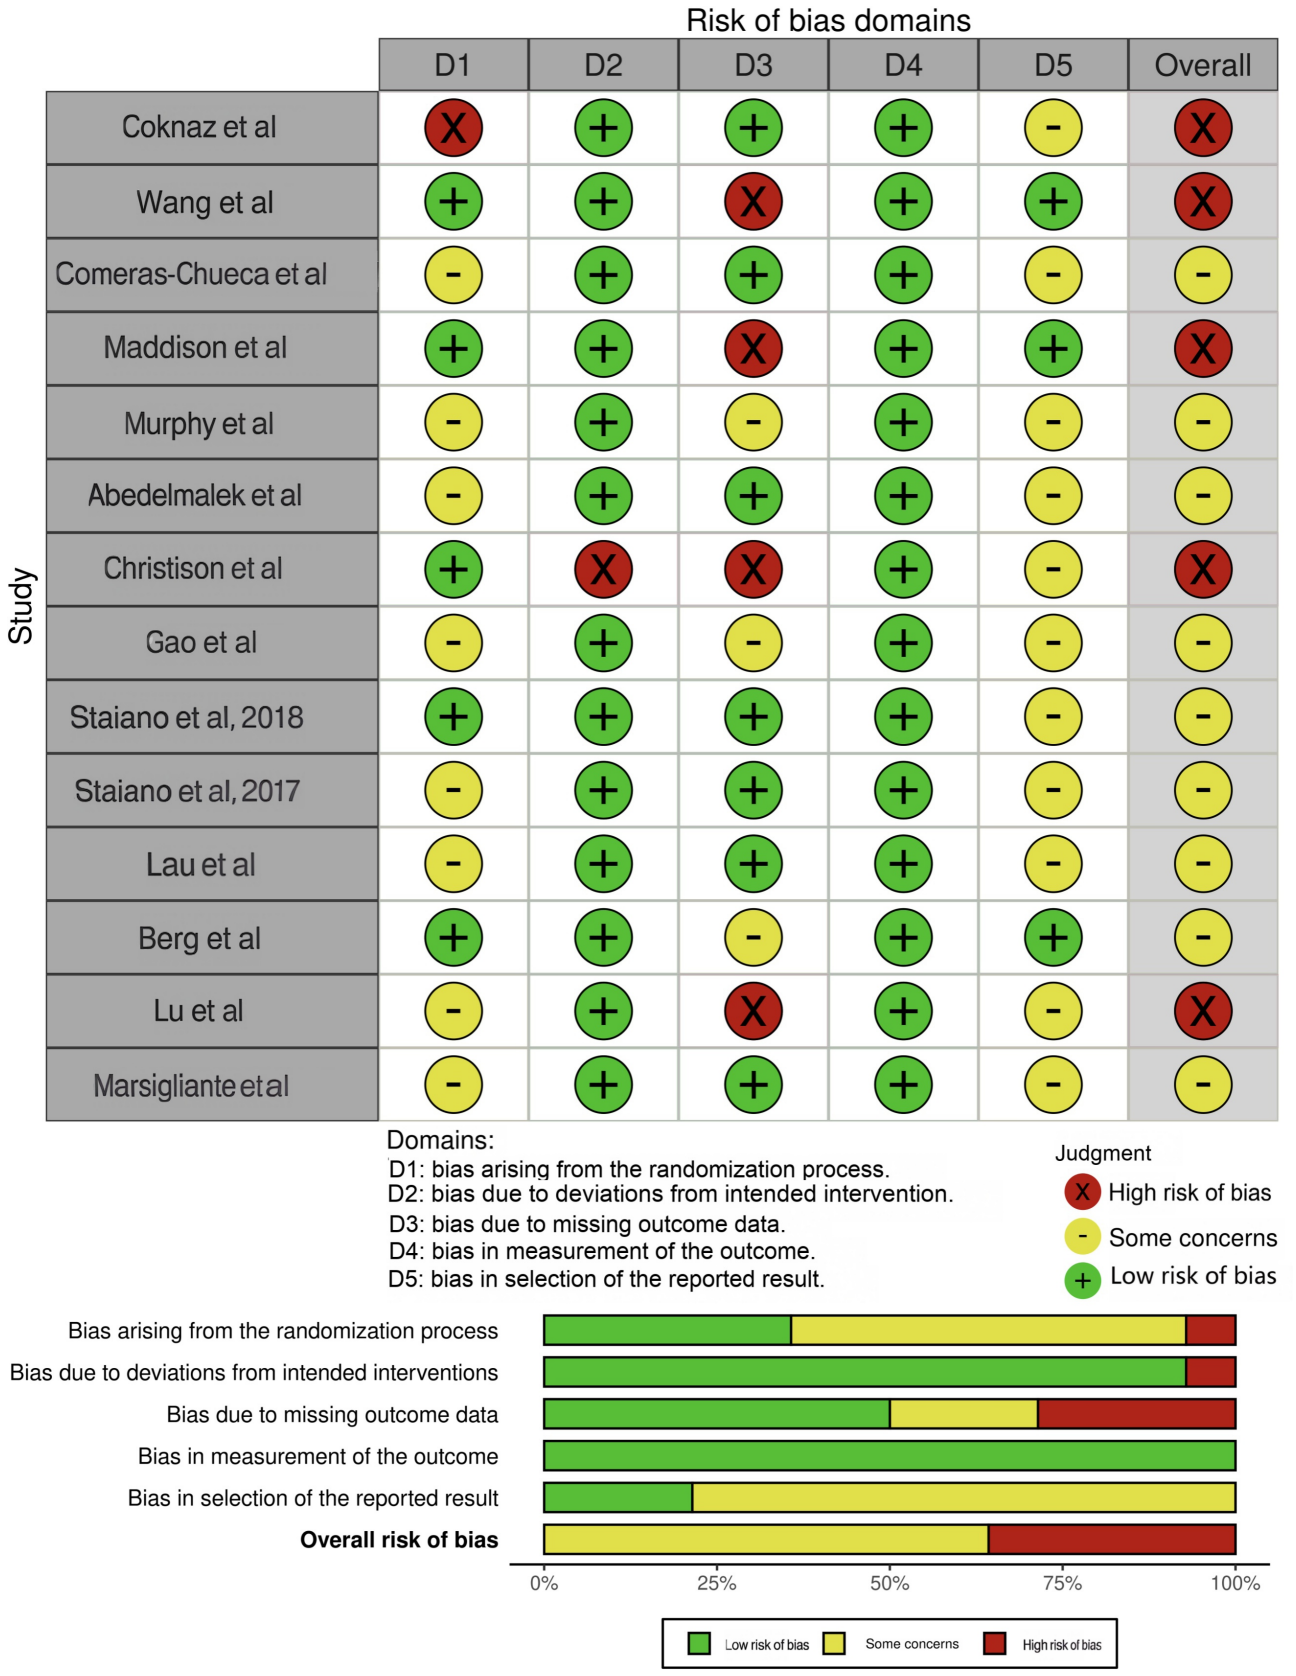
Risk of Bias in Studies



Overall, none of the included studies were judged to have a low risk of bias; 9 studies [44,45,48-50,53-56] were classified as having some concerns, and 5 studies [45,46,52,55,57] were judged to have a high risk of bias. Bias in measurement of the outcome (D4) was consistently rated as low risk of bias, with all studies judged as low risk of bias in the domain. Bias due to deviations from intended interventions (D2) was generally rated as low risk of bias, with only Christison et al [46] being judged as having a high risk of bias. This judgment was mainly due to potential deviations from the intended intervention, including additional physical activity opportunities beyond the prescribed exergaming sessions and limited control over intervention exposure. Bias in selection of the reported result (D5) was predominantly rated as some concerns, mainly due to insufficient information regarding trial registration or prespecified analysis plans, though no study was judged high risk of bias in this domain. Bias arising from the randomization process (D1) was rated as low risk of bias in 5 studies, with 8 studies having some concerns and 1 study judged as having high risk of bias, generally reflecting incomplete reporting of allocation concealment. Among the assessed domains, missing outcome data (D3) represented the main source of high risk of bias, which was judged high risk of bias in 4 studies, mainly due to substantial missing outcome data or insufficient reporting of participant attrition during follow-up. Among the 5 studies judged to have a high overall risk of bias, four were primarily driven by concerns in D3, suggesting that missing outcome data was an important contributor to overall risk judgments. See Figure 14.

A funnel plot combined with Egger's regression test was used to assess small-study effects for the BMI outcome (Appendix S3 in Multimedia Appendix 1). Due to the limited number of studies available for the other outcomes, small-study effects were only examined for BMI. Egger's regression test showed no evidence of small-study effects for BMI (*P*=.46).

The average PEDro score across all studies was 5.4, indicating that the methodological quality of the included studies was generally moderate (Appendix S6 in Multimedia Appendix 1).

RenderX

Figure 14. Summary of the risk of bias [44-57].

Sensitivity Analysis

Sensitivity analyses were conducted using the leave-one-out method to examine the stability of the pooled estimates. For BMI, the overall effect was significant (Hedges g=−0.23, 95% CI −0.35 to −0.10; P=.002; I^2=0%), the direction and significance of the results remained unchanged after excluding any single study, indicating that BMI demonstrated the highest robustness across all outcomes. The pooled effect for SBP showed a small statistically significant reduction (Hedges

XSL•FO
RenderX

g=−0.18, 95% CI −0.36 to −0.001; P=.0497). After excluding the study by Christison et al [46], the reduction became statistically stronger, suggesting that the magnitude of the SBP effect was influenced by this study. One possible explanation may be the substantial loss to follow-up reported in this study, which could have influenced the pooled estimate.

The pooled effects for HR (Hedges g=−0.14, 95% CI −1.74 to 1.46; P=.47) and HDL (Hedges g=0.05, 95% CI −0.21 to 0.31; P=.65) were all nonsignificant, and given the limited number of included studies, the evidence was limited due to the small number of available studies. Similarly, the effects for DBP (Hedges g=−0.11, 95% CI −0.86 to 0.63; P=.59), LDL (Hedges g=−0.26, 95% CI −0.64 to 0.13; P=.15), TC (Hedges g=−0.96, 95% CI −3.79 to 1.88; P=.37), and TG (Hedges g=−0.20, 95% CI −0.70 to 0.31; P=.38) remained nonsignificant after removal of individual studies. I^2 values ranged from 24% to 87% across these outcomes. For TC, I^2 decreased from 87% to 0% after excluding Abedelmalek et al [44], suggesting that this study contributed to the observed inconsistency among study estimates; however, the magnitude of the pooled effect was reduced. The pooled effect for glucose (Hedges g=−0.17, 95% CI −0.37 to 0.02; P=.07) remained nonsignificant after excluding any single study.

Overall, the results of the sensitivity analysis suggest that the improvement in BMI is robust. The evidence regarding blood pressure, glucose, and other lipid markers is insufficient. Future studies of higher quality are needed to validate these findings. Refer to Appendix S4 in Multimedia Appendix 1 for details.

Certainty of Evidence

The quality of evidence was assessed using the GRADE framework. Detailed results are presented in Supplementary Material S5 of Multimedia Appendix 1. Overall, the quality of evidence ranged from low to very low primarily due to factors such as risk of bias, inconsistency, and imprecision. Specifically, the certainty of evidence for BMI and SBP was rated as low, primarily due to serious risk of bias, whereas no serious concerns were identified regarding inconsistency, indirectness, or imprecision. The certainty of evidence for DBP was also rated as low, downgraded mainly because of concerns regarding risk of bias and imprecision. For HR, HDL, LDL, and glucose, the certainty of evidence was mainly downgraded due to serious risk of bias and imprecision. For TC and TG, additional downgrading was applied due to inconsistency and imprecision. For several cardiometabolic outcomes, the CI included the null value, indicating substantial uncertainty in the estimated effects. Risk-of-bias downgrading was based on RoB 2 judgments, whereas PEDro scores were retained only for descriptive methodological context.

Discussion

Principal Findings

This systematic review and meta-analysis aimed to evaluate the effects of AVG on cardiometabolic health in children and adolescents, and to explore potential moderators through subgroup analysis. The main findings indicated that AVG were associated with a small but statistically significant reduction in BMI. Subgroup analyses suggested that sex, intervention type, and nutritional status did not significantly modify the effect of AVG on BMI. Sensitivity analyses supported the robustness of the pooled BMI estimate. The certainty of evidence was rated as low due to concerns regarding risk of bias.

AVG were associated with a small reduction in SBP. No statistically significant effects were observed for HDL, LDL, TC, triglycerides, DBP, HR, and glucose. The certainty of evidence for most cardiometabolic outcomes was rated as very low, while evidence for SBP and DBP was rated as low, primarily due to concerns regarding risk of bias and imprecision. Therefore, these findings should be interpreted cautiously, particularly given the limited number of available studies for individual outcomes.

BMI

Regarding BMI outcomes, the reduction in BMI remained consistent across studies, and the PI remained entirely below the null effect. Nevertheless, the certainty of evidence was rated as low due to concerns regarding risk of bias, suggesting that the magnitude of the observed effect should be interpreted cautiously. The absence of significant differences among the normal weight, overweight, and obesity subgroups suggests that the favorable direction of the BMI effect may not be limited to a particular nutritional status.

The findings of the present review were generally consistent with previous systematic reviews and meta-analyses. Unlike previous reviews that mainly focused on children and adolescents with overweight or obesity, this review included participants with different baseline weight statuses and cardiometabolic health conditions, providing evidence from a broader pediatric population. Hernandez-Martinez et al [29] reported a small but statistically significant reduction in BMI following exergaming interventions among children and adolescents with overweight or obesity. Oliveira et al [25] similarly found small reductions in BMI or BMI z-score at short and intermediate term follow-up, while Comeras-Chueca et al [27] reported favorable effects on both BMI and BMI z-score. Bourke et al [26] reported a significant reduction in BMI z-score among children and adolescents with overweight or obesity, although the pooled effect on absolute BMI did not reach statistical significance. Collectively, these findings suggest that AVG may produce modest improvements in weight-related outcomes, although the magnitude and statistical significance of the effects vary according to the outcome measure and study population.

A network meta‐analysis by Ho et al [23] reported that AVG were more effective than no-AVG comparators in reducing BMI among children and adolescents. A recent umbrella review by Singh et al [58] also found modest improvements in BMI following digital health interventions, which included AVG and serious games. Singh et al [58] also examined whether BMI effects differed according to intervention type. In this review, however, only one study contributed to the VR category [57]. The VR estimate should therefore be regarded as a single-study observation, and the available evidence does not support conclusions regarding the comparative effectiveness of VR and conventional AVG. Singh et al [58] also found that interventions

XSL•FO
RenderX

lasting at least 12 weeks produced greater improvements in BMI than shorter interventions, suggesting that intervention duration may be more important than the specific intervention type. Earlier evidence from Biddiss et al [59] showed that AVG could elicit light to moderate intensity physical activity but was insufficient to establish their long-term effectiveness. Together, these findings suggest that intervention dose, sustained engagement, and long-term adherence may be important determinants of BMI-related outcomes.

Several mechanisms may explain the observed effect on BMI. The interactive and enjoyable characteristics of AVG may encourage children and adolescents to participate in physical activity [21]. By increasing energy expenditure during gameplay, repeated AVG participation could contribute to greater overall energy expenditure and a more favorable energy balance [60]. From a practical perspective, AVG may serve as an accessible and engaging adjunct to broader physical activity and weight-management strategies for children and adolescents, rather than as a stand-alone treatment for obesity. Future studies should determine how intervention duration, exercise intensity, game design, behavioral engagement, and adherence support can be optimized to produce larger and more sustainable effects. Longer follow-up periods are also required to establish whether the small changes in BMI observed after AVG translate into meaningful long-term benefits for obesity prevention and weight management.

Lipid Metabolism and Glucose

LDL

The present meta-analysis did not provide clear evidence that AVG reduced LDL in children and adolescents. This finding is consistent with the meta-analysis by Hernandez-Martinez et al [29], which likewise reported no statistically significant improvement in LDL among children and adolescents with overweight or obesity. According to the National Heart, Lung, and Blood Institute (NHLBI) guidelines [61], normal LDL levels for children and adolescents should be below 110 mg/dL. Among the studies included in this analysis, baseline mean LDL levels ranged from 86.4 to 131.6 mg/dL, generally falling within the normal range. But the study by Abedelmalek et al [44] reported a mean baseline LDL level of 131.2 - 131.6 mg/dL, which constitutes a high LDL level. And the baseline LDL level in the intervention group of Murphy et al [54] was 111.2 mg/dL, indicating borderline elevation. Some studies may have limited room for improvement, which could attenuate the overall intervention effect of AVG on LDL levels. Dietary intake may also have influenced the observed effects because LDL is sensitive to dietary composition and overall dietary patterns [62]. Most included trials did not consistently control or report participants' dietary intake during the intervention, making it difficult to distinguish the effects of AVG from those of concurrent dietary changes.

HDL

The present analysis found no evidence that AVG significantly improved HDL levels in children and adolescents. This finding is consistent with the meta-analysis by Hernandez-Martinez et al [29], which likewise reported no statistically significant overall improvement in HDL following exergaming interventions among children and adolescents with overweight or obesity. Sensitivity analyses did not alter this conclusion. Several factors may explain the absence of a clear HDL response, including exercise dose, dietary intake, and pubertal development [63-66]. The exercise dose provided in some included trials may have been insufficient to induce measurable changes in HDL, as recent pediatric evidence [66] suggests that lipid responses may depend on session duration, weekly frequency, and total intervention duration. In addition, the age range across the included studies covered different stages of growth and puberty, during which HDL levels may vary physiologically [63,64]. Dietary intake may also have contributed to variation in HDL, as dietary interventions have been shown to modify HDL levels in children and adolescents [65]. However, reports in the included studies regarding pubertal status and dietary intake are relatively scarce, which may obscure the subtle effects of interventions on HDL.

Triglycerides

This study found no evidence of improvement in triglycerides levels among children and adolescents following AVG. Similarly, Hernandez-Martinez et al [29] did not observe a significant improvement in triglycerides levels following an AVG in children and adolescents. Exercise training has been shown to increase skeletal muscle lipoprotein lipase (LPL) activity, and exercise-induced changes in muscle LPL activity were inversely associated with changes in plasma triglycerides concentrations [67]. More recent evidence further supports this mechanism, suggesting that skeletal muscle LPL helps break down circulating triglycerides during exercise and facilitates the uptake of triglycerides-derived fatty acids by muscle [68]. Adequately dosed traditional aerobic exercise has been shown to improve triglycerides levels [69]. Whether AVG provide a sufficient exercise stimulus to induce a comparable LPL-mediated adaptation in children and adolescents remains unclear. AVG may provide a relatively modest exercise stimulus [70], which may limit metabolic adaptations related to lipid clearance. The intensity and volume of exercise achieved through AVG may be insufficient to elicit similar metabolic adaptations, which could explain the lack of significant effects observed in our analysis. Additionally, triglycerides responses are sensitive to acute dietary intake, with the type and composition of foods consumed influencing the magnitude of the response [71]. In children and adolescents, Park et al [72] similarly showed that triglycerides concentrations increased significantly after a high-fat meal, whereas a single AVG session did not significantly attenuate the triglycerides response. Therefore, improvements in triglycerides levels may depend on multiple factors, including intervention dosage, baseline triglycerides levels, and dietary habits. This analysis included a limited number of studies, and the study estimates showed some inconsistency (I^2=58%), these findings should be interpreted with caution.

TC

This study found that the TC did not show a significant change. The wide prediction interval and the observed inconsistency among study estimates (I^2=87%) suggest considerable

XSL•FO
RenderX

uncertainty regarding the effect of AVG across different settings. In the sensitivity analyses, I^2 decreased from 87% to 0% after excluding the study by Abedelmalek et al [44]. This heterogeneity may partly be attributable to differences in participant characteristics, as Abedelmalek et al [44] included participants with severe obesity. Additionally, the intervention in Abedelmalek et al [44] was conducted during Ramadan, and dietary patterns during this period may have influenced participants' blood lipid levels, causing the effect size for TC to deviate from that of other studies. The intervention period in the study by Abedelmalek et al [44] was also the shortest among all studies, lasting only 4 weeks. The relatively short intervention duration may have limited the potential to detect changes in TC levels. A review by Erçelik et al [28] indicated that AVG can significantly reduce TC levels in overweight or obese children. However, the results of this meta-analysis showed no significant change in TC, which contradicts the conclusions of that review. Differences in study selection criteria, included populations, and the limited number of available trials may partly explain the discrepancy between findings. Because TC reflects the combined contribution of LDL, HDL, and very-low-density lipoprotein cholesterol (VLDL) [73], the absence of significant changes in LDL and HDL may have contributed to the lack of improvement in overall TC levels. Furthermore, the number of studies included in this analysis was too small to support definitive conclusions, limiting the study to an exploratory nature.

Glucose

The number of studies and participants included in the analysis of glucose was insufficient, resulting in limited statistical power. No significant improvement was observed, and the interpretation of the current evidence remains subject to considerable uncertainty. Furthermore, the glucose-regulating effect of exercise is primarily achieved through increased glucose uptake by skeletal muscle and improved insulin sensitivity [74]. During exercise, skeletal muscle contraction activates the glucose transporter type 4 (GLUT4) [75], facilitating its translocation from intracellular storage sites to the cell membrane, thereby promoting glucose entry into muscle cells [76,77]. Yin et al [78] suggested that repeated muscle activation throughout the day may contribute to improved glycemic regulation. However, the magnitude of exercise-induced glucose uptake is highly dependent on exercise intensity, frequency, and duration [79]. Although AVG can increase energy expenditure and physical activity levels [80,81], the exercise stimulus may not consistently reach the intensity or duration required to induce substantial metabolic adaptations. Current evidence remains insufficient to confirm a significant beneficial effect of AVG on glucose levels. Further exploration is needed through high-quality studies with larger sample sizes.

Blood Pressure and Heart Rate

AVG resulted in a small reduction in SBP, suggesting a potential beneficial effect on blood pressure regulation. However, the magnitude of the effect was limited, and the CI approached the null value, indicating uncertainty regarding the clinical relevance of this finding. This influence may partly reflect the methodological limitations of Christison et al [46], including substantial missing outcome data and reduced completeness of cardiovascular measurements, which may have increased uncertainty in the estimated intervention effect. Zhu et al [30] reported significant reductions in SBP following AVG among children and adolescents under 18 years of age; our findings showed only a marginal reduction. This discrepancy may be explained by differences in the number of included studies, participant characteristics, intervention protocols, and comparator conditions. In contrast, AVG did not significantly affect DBP. The wide CI indicates considerable uncertainty around the estimated effect, which may be attributed to the small number of included studies and limited statistical power rather than the absence of a true effect.

Exercise intensity may be an important determinant of blood pressure responses, although the overall effect may also depend on session duration and accumulated exercise dose [82,83]. The review by Hernandez-Martinez et al [29] also indicates that intensity is a key factor in improving blood pressure. Yin et al [84] found that low-volume high-intensity interval training (LV-HIIT) significantly reduced SBP and DBP compared with nontraining control conditions, despite requiring substantially less exercise time than traditional training modalities. These findings suggest that brief high-intensity exercise may elicit blood pressure adaptations even when total exercise volume is limited. However, LV-HIIT did not produce significantly greater reductions in SBP or DBP than moderate-intensity continuous training or higher-volume HIIT, and these findings therefore do not establish a specific intensity threshold for blood pressure improvement. A review by Tozo et al [85] also indicates that high-intensity interval training (HIIT) interventions with the highest intensity yield the greatest reductions in blood pressure, specifically 3 sessions per week, each lasting 60 minutes, for at least 12 weeks. Previous evidence from broader digital interventions [86], including AVG and exergaming, has shown limited efficacy in improving cardiometabolic health, particularly regarding blood pressure and blood lipids. AVG may provide a modest stimulus for SBP reduction, but the available evidence remains insufficient to determine the intervention intensity, session duration, or accumulated dose required to produce consistent blood pressure adaptations. Future trials should therefore report and systematically evaluate intervention intensity, minutes per session, weekly frequency, adherence, and baseline blood pressure in children and adolescents.

Neither of the 2 studies included in this HR analysis showed a significant between-group effect of HR. In Christison et al [46], HR decreased in both the exergaming and CGs, resulting in no significant between-group difference. Similarly, Wang et al [57] observed reductions in HR in both the REVERIE and CGs after the 8-week intervention, without a significant difference between groups. Thus, the absence of a significant pooled effect may reflect a small AVG-specific effect combined with the very limited evidence base rather than clear evidence that AVG do not influence HR.

The effect of AVG on HR remains uncertain. Only 2 studies contributed to this outcome, and the extremely wide CI and PI indicate considerable uncertainty regarding the magnitude and direction of the effect. The certainty of evidence was rated as

XSL•FO
RenderX

very low due to concerns regarding risk of bias and imprecision. Further high-quality trials with larger samples and longer intervention periods are needed to clarify whether AVG can induce meaningful adaptations in cardiac autonomic regulation.

Limitations and Future Research

The limitations of this systematic review and meta-analysis include: (1) Several outcomes were supported by small numbers of studies and participants, resulting in imprecise effect estimates and limited statistical power. In addition, the small numbers of studies and participants within some BMI subgroups restricted the robustness of the findings regarding potential moderator effects, including sex, intervention type, and nutritional status; (2) The included studies differed in terms of intervention equipment and game scenarios, which may also have influenced the effectiveness of the interventions; (3) Due to the limited number of studies included in this review and the lack of clear reporting on exercise protocols and exercise intensity, meta-regression analysis was not conducted; (4) Inconsistencies in intervention dose across the included studies may have led to between-study variability in results; (5) This review included only published studies with accessible full−text articles, and it did not search for gray literature or unpublished data, which may have led to publication bias in the results. This concern is particularly relevant because few studies contributed to most outcomes, limiting the reliability of formal assessments of small-study effects; (6) Although BMI was the most consistently reported anthropometric outcome across the included studies, raw BMI does not fully account for age, sex, and maturation-related changes in children and adolescents, which may limit the accuracy of weight-status interpretation.

Therefore, future research should include more high-quality, large-scale studies to validate these findings. These studies should explicitly report exercise intensity parameters and appropriately extend the intervention duration to determine whether AVG can effectively improve cardiometabolic health in children and adolescents when administered at a higher intervention dose. The interactivity and fun elements of AVG may help promote initial engagement and intervention adherence. However, existing studies report inconsistent findings regarding the assessment of engagement-related indicators, and the impact of AVG on long-term engagement behavior remains unclear. Future research should use standardized, objectively measurable tools for assessing engagement, and prospectively evaluate whether perceived fun translates into sustained engagement behavior.

Conclusion

This systematic review and meta-analysis provide an updated and broader RCT-only evaluation of the effects of AVG on cardiometabolic health in children and adolescents, including anthropometric, cardiovascular, and metabolic outcomes. In contrast to previous reviews that have focused on selected populations or narrower outcome domains, this review evaluates a broader pediatric population and a wider range of cardiometabolic outcomes within a unified framework. The findings suggest that AVG may be associated with small reductions in BMI and SBP, although the SBP effect was less consistent across potential future settings, and evidence for other cardiometabolic outcomes remains uncertain. By clarifying both the potential benefits and the remaining evidence gaps, this review provides a more comprehensive basis for future research and intervention development. From a practical perspective, AVG may serve as an engaging adjunct to support physical activity participation among children and adolescents. Further high-quality RCTs are needed to determine the optimal intervention characteristics and clarify their long-term cardiometabolic effects.

Abbreviations

AVG: active video games
BMI-z: body mass index z score
CG: control group
DBP: diastolic blood pressure
DTC: delayed-treatment control group
EDF: endothelial dysfunction
EX: experimental group
GLUT 4: glucose transporter type 4
GRADE: Grading of Recommendations Assessment, Development and Evaluation
HBA_{1c}: glycated hemoglobin
HDL: high-density lipoprotein cholesterol
HIIT: high-intensity interval training
HR: heart rate
LDL: low-density lipoprotein cholesterol
LPL: lipoprotein lipase
LV−HIIT: low-volume high-intensity interval training
NHLBI: National Heart, Lung, and Blood Institute
PEDro: Physiotherapy Evidence Database
PI: prediction interval
PICOS: Population, intervention, comparison, outcomes, and study design
PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses
PRISMA-S: Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search extension
PROSPERO: International Prospective Register of Systematic Reviews
RCTs: randomized controlled trials
RoB 2: Cochrane Risk of Bias 2 tool
SBP: systolic blood pressure
TC: total cholesterol
VLDL: very-low-density lipoprotein cholesterol
VR: virtual reality

Abstract

Background: Combined spinal-epidural (CSE) anesthesia is a complex psychomotor skill requiring precise tactile discrimination. Traditional manikin-based training may be limited by degraded haptic fidelity and inconsistent tissue feedback. Whether skills acquired through haptic virtual reality (VR) training transfer to supervised clinical procedures remains uncertain.

Objective: This study assessed the feasibility and early clinical application of CSE skills after high-fidelity haptic VR training in junior anesthesiology trainees vs traditional manikin-based training.

Methods: We conducted a single-center, prospective, parallel-group, randomized, and outcome assessor-blind pilot trial. A total of 20 fifth-year anesthesiology interns with minimal neuraxial experience were randomly assigned (1:1) by an independent investigator using a card draw to a standardized 7-day curriculum with either a traditional manikin (control group [CG], n=10) or a haptic-VR simulator (simulator group [SG], n=10). SG trainees performed repeated punctures on the haptic-VR CSE Teaching Platform, whereas the CG trainees practiced the CSE procedure on a lumbar puncture manikin. Both interventions were delivered face-to-face in a simulation laboratory by experienced instructors. During training, each trainee performed 1 supervised CSE on a patient. Clinical performance was video recorded and assessed by blinded experts. The primary outcome was the 0 to 100 total clinical performance score, rated by 2 assessors. Secondary outcomes included domain-specific scores, procedural time, puncture-angle adjustments, first-attempt success rate, and adverse events within 24 hours.

Results: All 20 trainees completed training and clinical assessments and were included in the intention-to-treat analysis. Overall scores were higher in the SG than in the CG (mean difference 4.50 points, 95% CI 1.85-7.15; *P*=.002). The SG had higher scores for tactile-dependent skills, including recognition by bubble compression (mean difference 1.90 points, loss of resistance 95% CI 1.14-2.66; *P*<.001) and ligamentum flavum penetration (mean difference 1.90 points, 95% CI 1.18-2.62; *P*<.001), but lower aseptic technique compliance (mean difference −1.40 points, 95% CI −2.00 to −0.80; *P*<.001). The SG trainees had a shorter time to ligamentum flavum breakthrough, fewer passive angle adjustments, and more active adjustments. The first-attempt success rate was higher but imprecisely estimated. Primary-outcome interrater reliability was excellent (average-measures intraclass correlation coefficient of 0.977). No significant adverse events occurred.

Conclusions: Compared with traditional manikin training, haptic-VR training yielded higher overall clinical performance and better tactile-dependent CSE skills during the first supervised patient procedure, whereas manikin training better supported aseptic practice. By evaluating posttraining performance in patients rather than only in simulation, this study extends VR research toward early clinical skill transfer and suggests that the 2 modalities may develop complementary components of procedural competence. In practice, these findings support a blended CSE curriculum in which VR is used for repeated tactile and needle-control training and manikin-based simulation for aseptic preparation and procedural workflow; this approach should be evaluated in larger trials.

Introduction

Combined spinal-epidural (CSE) anesthesia is widely used in anesthesiology, especially for obstetric and lower-limb orthopedic surgeries [1,2]. This technique pairs the rapid onset of spinal anesthesia with the option of epidural catheterization when prolonged analgesia is needed [3,4]. In practice, CSE is demanding for less experienced operators. Before advancing the spinal needle through the epidural needle, the operator must identify surface anatomical landmarks and recognize the epidural space through tactile feedback, most often by detecting loss of resistance (LOR) [5,6]. Although the needle-through-needle approach is commonly used, it adds technical difficulty because problems such as failed dural puncture or paresthesia may occur, particularly when the operator has limited procedural experience [5,7-9].

For many residents, CSE is traditionally learned through supervised procedures on patients [10-12]. That route remains part of training, but patient safety concerns, ethical constraints, and reduced clinical training time have made simulation-based medical education a larger part of procedural teaching [13,14]. Physical manikins are commonly used for this purpose, but their tactile feel can change with use. When a silicone or rubber model is punctured repeatedly, the needle may leave tracks in the material and create an easier route for later attempts. Trainees may then practice on resistance that no longer matches what they are expected to feel during the epidural space identification, especially when learning the LOR technique [15,16]. For CSE training, an effective simulator should do more than allow trainees to repeat the steps. It should give them similar resistance cues each time they advance the needle, including the tissue-layer resistance and LOR cues used to identify the epidural space.

Virtual reality (VR) and extended reality (XR) offer one way to build this type of practice into anesthesiology training. By linking 3D visualization with biomechanical models and haptic devices, these systems allow trainees to rehearse complex procedures under controlled conditions before working with patients [17-19]. In anesthesiology, VR-based simulation has been applied to airway management, regional anesthesia, and neuraxial procedures; studies in these areas have described improvements in technical performance, spatial understanding, and training efficiency [18-21]. Work focused on neuraxial procedures, including scoping reviews and experimental studies, also suggests that XR can reproduce several procedural elements that matter for training and guidance [17]. What remains less clear is what happens after simulator-based practice. Much of the literature still reports simulator scores, learner satisfaction, or cognitive workload [22,23], whereas only a few studies have examined VR-based training in clinical settings. Whether skills acquired in VR carry over to patient care is still uncertain [17,24].

In CSE, this question is not only theoretical. During needle advancement, trainees must detect small changes in resistance, but the same procedure also requires sterile preparation, correct sequencing of each step, and decisions about when to redirect the needle or continue. A VR program may improve the haptic part of CSE without producing the same gain in workflow or aseptic performance. Examining these domains separately can show where VR adds value in anesthesia training and where physical simulation may still be needed. In this study, the haptic-VR platform was evaluated as a supervised procedural training tool within simulation-based anesthesiology education rather than as a stand-alone patient-care intervention.

Therefore, we conducted a prospective, randomized pilot trial comparing a haptic-feedback VR platform with traditional high-fidelity manikin training. The trial had 2 main aims. First, we assessed whether puncture skills learned in VR could transfer to an early, supervised CSE procedure in an eligible patient, with the total clinical performance score as the primary outcome. Second, we examined whether VR and manikin-based training affected different parts of procedural performance in different ways.

Methods

Trial Design

This study was a single-center, prospective, parallel-group, randomized, and outcome assessor-blind exploratory pilot trial, with individual trainees as the unit of randomization and a 1:1 allocation ratio, designed to evaluate the feasibility and preliminary educational effects of VR-based CSE training compared with traditional manikin-based training. The trainees underwent training in a dedicated simulation laboratory, and clinical assessments were conducted in the operating room. The trial was registered with the Chinese Clinical Trial Registry (registration: ChiCTR2100043952) on March 6, 2021. Trainee enrollment began after trial registration, and the first trainee participant was enrolled on March 7, 2021. Clinical patient enrollment for the supervised procedural assessment began on March 10, 2021. The last participant was enrolled on March 31, 2021. No trainee or patient participant was enrolled before trial registration. The study protocol, including the eligibility criteria, intervention design, and outcome measures, was finalized prior to participant screening and remained unchanged throughout the study. A separate formal statistical analysis plan was not published before the trial. The trial ended as planned after completing the prespecified pilot sample. This study was reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2025 statement for randomized controlled trials [25]. Completed CONSORT 2025 and CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklists [26] are provided as supplementary files (Checklists 1and 2). The intervention evaluated in this trial was a haptic-VR training simulator and did not include an AI

XSL•FO
RenderX

component, such as automated diagnosis, prediction, clinical decision support, adaptive training recommendations, or algorithm-generated feedback. Therefore, the CONSORT-AI (Consolidated Standards of Reporting Trials–AI) extension was not applicable to this study. This was not an open web-based or mobile-app trial. Recruitment and written informed consent were conducted offline at the hospital, training was delivered face-to-face in a dedicated simulation laboratory, and clinical assessments were conducted in the operating room. The VR platform was used as an offline supervised training simulator and did not require public web access, user accounts, logins, online questionnaires, automated email/SMS prompts, or remote self-directed use.

Ethical Considerations

This study was approved by the Ethics Committee of Fujian Provincial Hospital (approval K2020-12-018) and was conducted in accordance with the Declaration of Helsinki. All participating trainees and patients provided written informed consent before enrollment. Consent was obtained offline using written consent forms after trainees and patients had been informed of the study purpose, procedures, the voluntary nature of participation, privacy protection, and the planned use of deidentified research data. For patients undergoing clinical procedures, consent included permission to use deidentified procedural data for research purposes. All study data were anonymized before analysis, and video recordings were used solely for blinded expert assessment and deidentified before evaluation. No identifiable personal information was included in the analytic dataset, reported in the manuscript, or included in the supplementary materials. Participation was voluntary, and participants received no financial compensation. No images or materials in the manuscript or supplementary files contained identifiable participant information.

Patient and Public Involvement

The patients or the public were not involved in the design, conduct, reporting, or dissemination of this study.

Participants

Trainees

A total of 20 fifth-year anesthesiology interns undergoing clinical internships at Fujian Medical University with limited prior experience in neuraxial anesthesia were enrolled. Prior experience was defined as any attempt at needle manipulation in a patient, whether successful or unsuccessful. The inclusion threshold was set at fewer than 10 prior supervised neuraxial procedures to capture early learners. In practice, all enrolled participants met our operational definition of “true novices,” defined as trainees with no more than 3 prior supervised neuraxial needle-manipulation attempts. Computer, internet, or eHealth literacy was not an eligibility criterion and was not separately assessed because trainees used the VR platform only during supervised face-to-face sessions with instructor support in the simulation laboratory.

Patients

Twenty patients with lower-limb fractures scheduled to undergo lower-limb arthroplasty under CSE anesthesia were enrolled. All patients were screened before enrollment according to predefined inclusion and exclusion criteria to reduce patient-related variability in procedural difficulty. Inclusion criteria for the study were as follows: indication for neuraxial puncture; age 35 to 65 years, inclusive; BMI 18 to 25 kg/m^2; American Society of Anesthesiologists physical status I to II; no contraindication to neuraxial anesthesia; no history of spinal deformity or spinal surgery; no skin infection at the puncture site; and provision of written informed consent. Exclusion criteria were allergy to amide local anesthetics, central nervous system disease, abnormal function of the heart, lungs, kidneys, or other major organs, lower-limb motor or sensory abnormalities, and mental disorders or communication disorders. Only patients who met all eligibility criteria were included in the clinical assessment phase.

Randomization and Blinding

Trainees were randomly assigned in a 1:1 ratio to either the control group (CG, n=10) or the simulator group (SG, n=10) using a lottery-based (card-draw) method without blocking or stratification. An investigator, independent of participant recruitment, training delivery, clinical supervision, and outcome assessment, prepared 10 red cards and 10 yellow cards in advance and placed them in an opaque container; red cards corresponded to the CG and yellow cards corresponded to the SG. Each trainee drew 1 card at random from the container, and the allocation was revealed and recorded immediately. Group assignment was disclosed only after trainee enrollment and before the assigned training intervention began. The outcome assessors remained blinded to the trainee group assignment throughout the video-based assessment.

Before the clinical assessment, a separate randomized trainee procedure order was generated using the RAND() function in Microsoft Excel. Each trainee was assigned a random number, and trainees were sorted by these numbers to create a prespecified procedure order from 1 to 20.

All patients were screened according to predefined inclusion and exclusion criteria. Eligible patients entered the clinical assessment sequence consecutively according to the order in which their surgeries were scheduled. The trainee who performed the CSE procedure for each patient was determined by the prespecified randomized trainee order from 1 to 20. In other words, the first eligible surgical patient was treated by the trainee ranked first in the random order, the second eligible patient by the trainee ranked second, and so forth. Therefore, patients were not selectively matched to trainees based on training group or anticipated procedural difficulty.

This study used an outcome assessor-blind assessment design. The 2 senior anesthesiologists who assessed clinical performance from the deidentified videos were blinded to the trainee group allocation. Patients were not informed about the trainees’ training modality. Supervising anesthesiologists were not involved in outcome scoring and intervened only when necessary for patient safety. Because the VR platform and manikin training were visually and operationally distinct, trainees and instructors could not be blinded to the training allocation; however, neither trainees nor instructors participated in video-based outcome scoring. To ensure fairness after

XSL•FO
RenderX

outcome assessment, trainees were offered the opportunity to receive training with an alternative modality after completing all study procedures and evaluations.

Interventions

General Training Procedures

The interventions were described with reference to the Template for Intervention Description and Replication (TIDieR) framework to improve replicability. The participants were assigned to either a VR-based training group (SG) or a traditional manikin-based training group (CG). Both groups received structured training designed to teach CSE anesthesia techniques. Training in both groups was delivered face-to-face in a dedicated simulation laboratory by experienced anesthesiology instructors using standardized teaching scripts and feedback principles. Each participant completed a standardized 7-day intensive training curriculum, consisting of five 45-minute training sessions per day, with a 15-minute interval between consecutive sessions. No modifications were made to the intervention protocols during the trial, and all randomized participants completed their assigned training sessions. No additional simulation-based training related to CSE anesthesia was provided during the study period. Patients received routine perioperative care according to institutional practices. Use of the assigned intervention was operationalized as completion of the standardized 7-day curriculum, consisting of 35 supervised training sessions. Because training was conducted only during scheduled face-to-face laboratory sessions, intervention use was monitored by session completion rather than by web logins, logfile analysis, or automated session analytics.

SG

Trainees used the Haptic-VR CSE Teaching Platform. The system hardware included an Oculus Rift S headset (Meta Platforms, Inc) for 3D visualization and a customized Geomagic Touch haptic device (3D Systems, Inc) to render force feedback. The platform reproduced the layered resistance of anatomical structures encountered during neuraxial procedures, including the supraspinous ligament, interspinous ligament, and ligamentum flavum, as well as the characteristic LOR sensation. The purpose of this intervention was to allow trainees to repeatedly practice needle advancement, trajectory control, tissue-layer discrimination, and tactile recognition of LOR in a controlled and reproducible environment. For this trial, the hardware and software configuration, training tasks, and instructional content were set before participant enrollment. No functional changes, content updates, major bug fixes, system failures, or downtime occurred during the trial.

Training tasks included repeated virtual punctures under two modes: (1) a visualization-assisted mode with transparent anatomical overlays to facilitate understanding of 3D spatial relationships, and (2) a blinded mode without visual guidance to enhance reliance on tactile feedback. Aseptic procedural steps (eg, disinfection and draping) were represented through interface-based interactions rather than physical manipulation. In contrast, the manikin group allowed physical rehearsal of the aseptic workflow. This design allowed the VR curriculum to focus primarily on haptic skill acquisition and spatial-technical performance. During each session, experienced anesthesiology instructors provided standardized guidance and feedback. The platform displayed procedural information, including puncture depth and angular deviation, during puncture training, but it did not provide automated clinical decision support, adaptive training recommendations, or algorithm-generated feedback. Therefore, instructor guidance and feedback were part of the trial intervention rather than an automated platform function.

CG

Trainees practiced using a standard lumbar puncture manikin (Tuoren Medical). The manikin-based curriculum emphasized patient positioning, surface landmark palpation, identification of the puncture interspace, aseptic preparation, draping, procedural workflows, and needle manipulation. In contrast to the VR curriculum, manikin-based training allowed for physical rehearsal of sterile preparation and procedural sequencing. During each session, the same instructor team provided standardized feedback on positioning, sterile workflow, puncture mechanics, and needle handling. The training dose was identical to that used in the SG.

Clinical Assessment and Procedure Evaluation

After completing the training curriculum, each trainee performed 1 supervised CSE anesthesia procedure on an eligible patient according to the prespecified clinical assessment sequence defined in the randomization procedure. The procedure was conducted under the direct supervision of an attending anesthesiologist, who intervened only when necessary for patient safety. The entire procedure was video-recorded. Videos were edited to remove audio or visual information that could reveal the trainees' training allocation. The camera angle was standardized to focus on the lumbar puncture field and the operator's hands, thereby minimizing the possibility of identifying trainees.

Clinical performance was assessed using the Modified Spinal-Epidural Puncture Assessment Scale (Multimedia Appendix 1). The core domains and scoring structure of this scale were adapted from established procedural assessment frameworks, including the Global Rating Scale (GRS), Direct Observation of Procedural Skills (DOPS), and prior anesthesia procedural assessment approaches that combine task-specific checklists with GRS [27-29]. Based on these frameworks and in accordance with standardized residency training requirements and institutional procedural teaching standards for neuraxial anesthesia, modifications were made to reflect the key procedural steps of CSE anesthesia. This approach is also consistent with recent neuraxial training literature emphasizing the structured assessment of lumbar puncture, epidural anesthesia, and spinal anesthesia skills [24]. These domains included patient positioning, disinfection scope and sequence, LOR recognition using the bubble compression test, ligamentum flavum penetration, avoidance of arachnoid membrane puncture, and aseptic technique compliance.

The scoring domains and point values were predefined before the outcome assessment and were based on the clinical importance of each procedural step for procedural success and

XSL•FO
RenderX

patient safety. Greater weight was assigned to critical CSE-specific technical steps, including LOR recognition, ligamentum flavum penetration, avoidance of arachnoid membrane puncture, and aseptic technique compliance. The total score ranged from 0 to 100, with higher scores indicating better procedural performance. To improve scoring transparency, operational scoring anchors for full, partial, and 0-score performance are provided in Multimedia Appendix 1. Although each item had a predefined maximum score, raters were allowed to assign partial scores, including half-point increments, when performance partially met the predefined criteria or reflected intermediate performance quality.

Two senior anesthesiologists, who were not involved in the training intervention, independently assessed all study videos and were blinded to group allocation. Before the formal assessment, the raters reviewed the scoring criteria together to standardize the interpretation of each domain. The final score for each performance domain was calculated as the mean of the 2 raters' scores.

Outcomes

Primary Outcome

Total clinical performance score on the Modified Spinal-Epidural Puncture Assessment Scale, ranging from 0 to 100.

Secondary Outcomes

Number of active/passive angle adjustments, time from puncture initiation to breakthrough of the ligamentum flavum, first-attempt success rate, and complications within 24 hours after the procedure. Complications assessed within 24 hours included postdural puncture headache, local bleeding, infection, nerve injury, and intracranial hypotension syndrome. All outcomes were obtained through video-based expert assessments, procedural records, and postoperative clinical follow-ups; no online questionnaires or participant self-assessments were used as outcome measures.

Harms were assessed during the supervised CSE procedure and within 24 hours postoperatively by the supervising anesthesiologist and study team. The prespecified harms included accidental dural puncture, postdural puncture headache, local bleeding or hematoma, infection, nerve injury, and intracranial hypotension syndrome. Intervention-related adverse events associated with the training procedures were also recorded. For the VR intervention, training-related adverse events included VR-related discomfort, privacy breaches, data security incidents, system failure, downtime, and other technical problems during platform use.

Sample Size

As this was a pilot feasibility study, the sample size was determined based on practical resource constraints and sample sizes used in recent pilot studies of simulation-based medical education [30,31]. Consistent with these pilot studies, a sample size of 10 participants per group was selected. This sample size was considered appropriate for a pilot study to estimate the variability of the primary outcome and generate preliminary effect estimates that could inform outcome selection and sample size planning for a subsequent adequately powered trial. No additional attrition allowance was applied to the pilot sample size because the sample size was determined by feasibility considerations, and all training and assessment sessions were scheduled and supervised. No interim analyses or stopping guidelines were planned or conducted because of the pilot nature and short duration of the study.

Statistical Methods

Statistical analyses were performed using SPSS software (version 25.0; IBM Corp). All randomized participants were included in the primary analysis according to the intention-to-treat principle and were analyzed in the groups to which they were originally assigned. Because all randomized participants completed the assigned training intervention and clinical outcome assessment, the intention-to-treat and per-protocol populations were identical.

Missing data were assessed at both the participant and item levels. Participant-level missing data were defined as attrition, withdrawal, loss to follow-up, or failure to complete clinical assessments. Item-level missing data were defined as incomplete or unavailable values for individual outcome measures or assessment items. Because no participant-level or item-level missing data occurred, the missing-data proportion was 0% at both levels. Therefore, a missing completely at random test, multiple imputation, or other missing-data handling procedures were not performed.

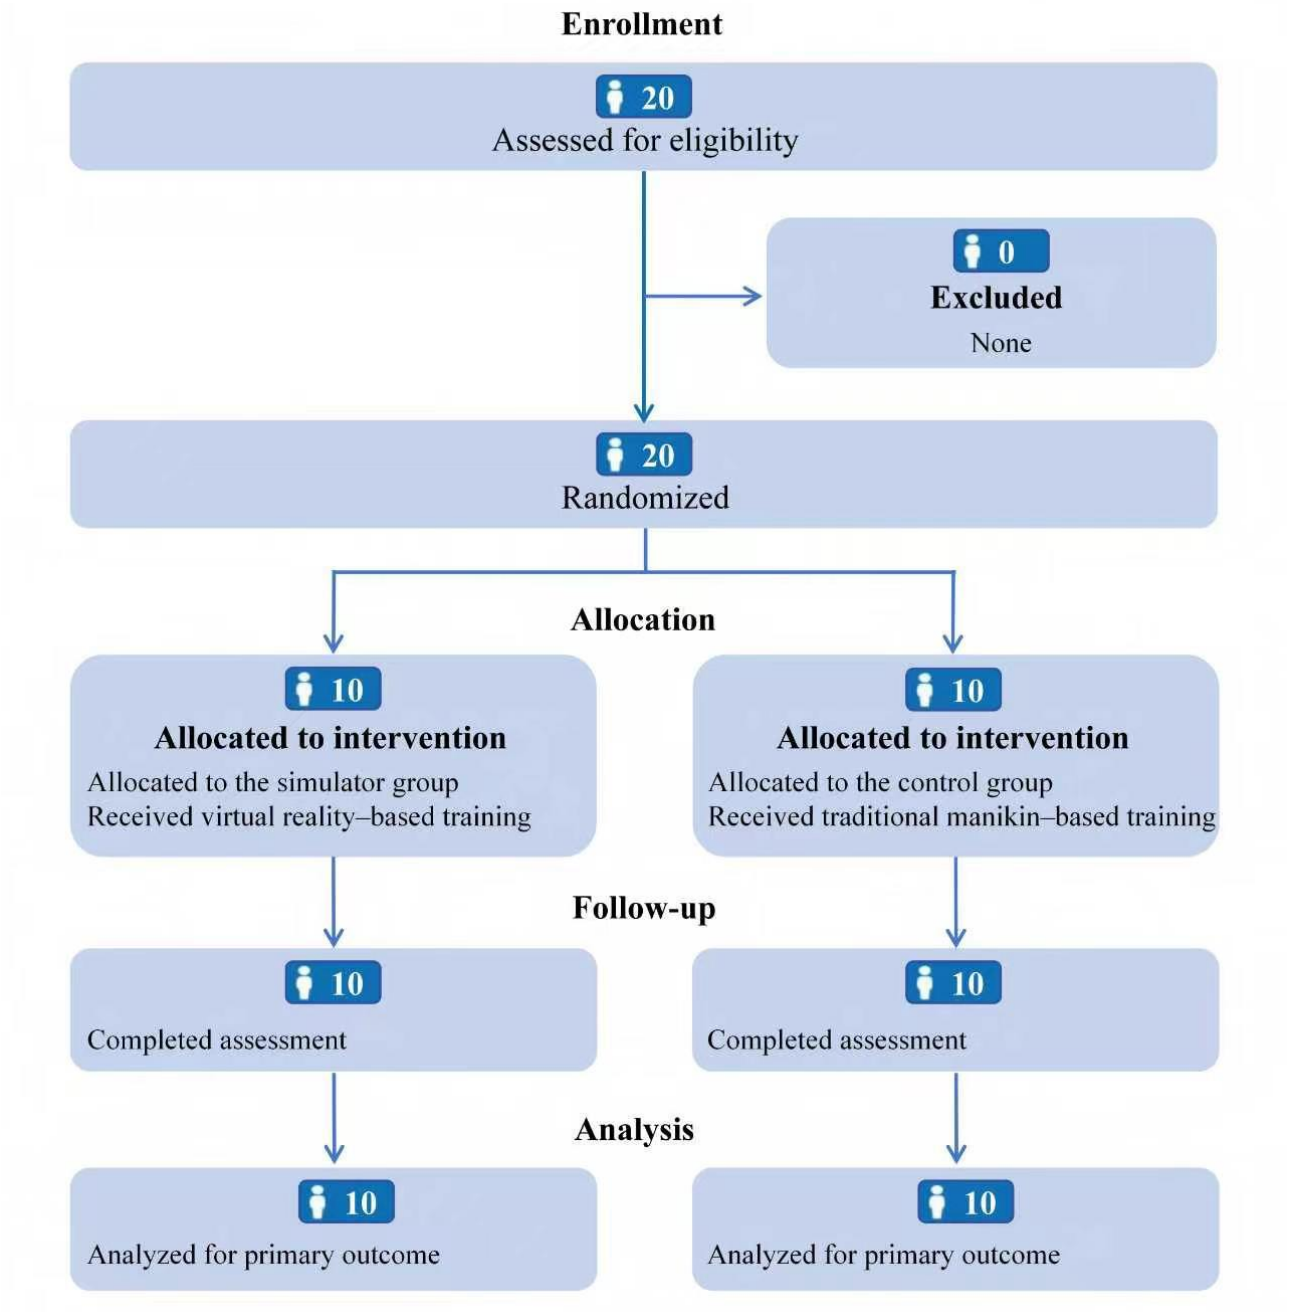
The interrater reliability for the total clinical performance score between the 2 blinded assessors was evaluated using a 2-way random-effects, absolute-agreement intraclass correlation coefficient (ICC). Because the final performance scores were based on the mean of the 2 raters' scores, the average-measures ICC was used to indicate the reliability of the final analyzed scores.

Baseline comparability between the 2 groups was assessed using absolute standardized mean differences (SMDs), where an SMD<0.25 was considered to indicate an adequate balance of covariates. In accordance with the CONSORT statement for randomized trials, significance testing (*P* values) was not performed for baseline characteristics, as any observed differences were due to chance following randomization. The Shapiro-Wilk test was used to assess the normality of continuous data. Normally distributed data were expressed as means (SD) and analyzed using Student's 2-tailed *t* test. Nonnormally distributed or ceiling-effect outcomes were summarized as medians with IQRs. Quartiles were calculated using Tukey hinges. Between-group comparisons for these outcomes were performed using the Mann-Whitney *U* test, with exact 2-sided *P* values reported because of the small sample size. Categorical data were presented as n (%), and comparisons were performed using Fisher exact test. Effect estimates were reported with corresponding 95% CIs where appropriate. For normally distributed continuous outcomes, between-group differences were expressed as mean differences with 95% CIs. For nonnormally distributed or ceiling-effect outcomes, between-group differences were expressed as Hodges-Lehmann median differences with 95% CIs. For categorical outcomes, between-group differences were expressed as risk differences

XSL•FO
RenderX

with 95% CIs where applicable. Cohen *d* was calculated for normally distributed continuous outcomes to inform interpretation and future sample size estimation but was not calculated for nonnormally distributed or ceiling-effect outcomes.

No formal adjustment for multiple comparisons was performed. Given the pilot and exploratory nature of this study, analyses of secondary outcomes were considered hypothesis-generating, and these findings should be interpreted cautiously. No subgroup, sensitivity, or ancillary analyses were prespecified or performed. A 2-sided *P* value of<.05 was considered statistically significant.



Results

Participant Flow

A total of 20 anesthesiology interns were assessed for eligibility and randomized in a 1:1 ratio to the CG (n=10) or the SG (n=10). All 20 randomized participants completed the assigned training intervention and subsequent clinical assessment. This corresponded to the completion of the full assigned training dose in both groups, defined as 35 supervised training sessions per trainee. No participants withdrew, were lost to follow-up, or were excluded from the analysis. No participant-level missing data or item-level missing data were observed; therefore, the missing data proportion was 0% at both levels (Figure 1).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) participant flow diagram of anesthesiology trainees in a single-center, prospective, parallel-group randomized pilot trial comparing haptic virtual reality–based training vs traditional manikin-based training for combined spinal-epidural anesthesia at Fujian Provincial Hospital, Fuzhou, China, March 2021.

Baseline Data

The baseline demographic characteristics and prior clinical experience are presented in Table 1. Socioeconomic status and computer, internet, or eHealth literacy were not collected as baseline variables because the intervention was delivered in supervised, face-to-face laboratory sessions rather than through remote, self-directed access. The 2 groups were comparable in terms of all measured variables. The absolute SMDs for the baseline characteristics are provided in Multimedia Appendix 2.

[a]CSE: combined spinal-epidural.

[b]CG: control group.

[c]SG: simulator group.

[d]SMD: standardized mean difference.

Primary Outcome: Technical Skill Acquisition

Interrater reliability for the primary outcome, the total clinical performance score, was excellent, with an average-measures ICC of 0.977. The SG had a higher total clinical performance score than the CG, with a mean difference of 4.50 points (95% CI 1.85-7.15; *P*=.002; Cohen *d*=1.59; Table 2). Exploratory domain-specific analyses showed higher SG scores in haptic-dependent components, including the bubble compression test (mean difference 1.90 points, 95% CI 1.14- 2.66; *P*<.001; Cohen *d*=2.37) and ligamentum flavum penetration (mean difference 1.90 points, 95% CI 1.18 to 2.62; *P*<.001; Cohen *d*=2.48). In contrast, the SG had lower aseptic technique compliance scores than the CG (mean difference −1.40 points, 95% CI −2.00 to −0.80; *P*<.001; Cohen *d*=−2.18), suggesting a domain-specific pattern of training effects.

Performance domain	CG[b]	SG[c]	Effect estimate, MD[d] (95% CI)	*P* value	Cohen *d*
Patient positioning (8 points), mean (SD)	5.00 (0.67)	6.40 (1.07)	1.40 (0.56 to 2.24)	.003	1.56
Scope and sequence of disinfection (5 points), mean (SD)	3.20 (0.42)	3.70 (0.82)	0.50 (–0.11 to 1.11)	.12	0.77
Bubble compression (LOR[e]; 10 points), mean (SD)	5.80 (0.92)	7.70 (0.67)	1.90 (1.14 to 2.66)	<.001	2.37
Ligamentum flavum penetration (10 points), mean (SD)	5.90 (0.74)	7.80 (0.79)	1.90 (1.18 to 2.62)	<.001	2.48
Epidural needle not penetrating the arachnoid membrane (10 points), median (IQR)	10.00 (10.00 - 10.00)	10.00 (10.00 - 10.00)	Hodges-Lehmann median difference 0.00 points (0.00-0.00)	.74	—[f]
Compliance with aseptic technique (10 points), mean (SD)	7.90 (0.57)	6.50 (0.71)	–1.40 (–2.00 to –0.80)	<.001	–2.18
Total score (100 points), mean (SD)	86.70 (2.87)	91.20 (2.78)	4.50 (1.85 to 7.15)	.002	1.59

[a]Data are from a single-center, prospective, parallel-group randomized pilot trial comparing haptic virtual reality–based training vs traditional manikin-based training for anesthesiology trainees at Fujian Provincial Hospital, Fuzhou, China, March 2021. Trainees were assessed during supervised procedures on real patients. For each domain, the final score was calculated as the mean of the 2 independent blinded raters' scores. Effect estimates were calculated as SG minus CG and are reported as mean differences or Hodges-Lehmann median differences, as appropriate. Exact 2-sided *P* values were reported for Mann-Whitney *U* tests. Cohen *d* was not calculated for the ceiling-effect outcome.

[b]CG: control group.

[c]SG: simulator group.

[d]MD: Mean difference.

[e]LOR: loss of resistance.

[f]Not applicable.

Secondary Outcomes

Efficiency and Safety Metrics

The procedural performance outcomes are shown in Table 3. The time from puncture initiation to breakthrough of the ligamentum flavum was shorter in the SG than in the CG, with a mean difference of −2.75 (95% CI −3.89 to −1.61; *P*<.001) minutes. For puncture-angle adjustments, the SG required more active adjustments than the CG (Hodges-Lehmann median difference 1.0 adjustment, 95% CI 0.0-2.0; *P*=.03), whereas passive adjustments due to bone contact were fewer in the SG (Hodges-Lehmann median difference −2.0 adjustments, 95% CI −2.0 to −1.0; *P*<.001). The first attempt success was numerically higher in the SG than in the CG (6/10, 60% vs 3/10, 30%); however, the CI was wide and crossed the null value (risk difference 30 percentage points, 95% CI −11.8 to 60.1; *P*=.37), indicating substantial imprecision. Given the pilot sample size and exploratory nature of these secondary outcomes, these procedural findings should be interpreted cautiously.

Table . Procedural performance outcomes of anesthesiology trainees during supervised combined spinal-epidural anesthesia procedures on real patients, by training modality[a].

Item	CG[b]	SG[c]	Effect estimate (95% CI)	*P* value
First attempt success, n (%)	3 (30)	6 (60)	Risk difference, 30 percentage points (95% CI −11.8 to 60.1)	.37
Number of active puncture-angle adjustments, median (IQR)	1.0 (1.0 - 2.0)	2.0 (2.0 - 3.0)	Hodges-Lehmann median difference 1.0 adjustment, (95% CI 0.0 to 2.0)	.03
Number of passive puncture-angle adjustments, median (IQR)	2.5 (2.0 - 3.0)	1.0 (0.0 - 1.0)	Hodges-Lehmann median difference –2.0 adjustments, (95% CI −2.0 to −1.0)	<.001
Time from puncture initiation to breakthrough of ligamentum flavum, mean (SD), min	8.66 (1.19)	5.91 (1.24)	Mean difference −2.75, min (95% CI −3.89 to −1.61)	<.001

[a]Data are from a single-center, prospective, parallel-group randomized pilot trial comparing haptic virtual reality–based training vs traditional manikin-based training for anesthesiology trainees at Fujian Provincial Hospital, Fuzhou, China, March 2021. Trainees were assessed during supervised procedures on real patients. Effect estimates were calculated as SG minus control group and are reported as risk differences, mean differences, or Hodges-Lehmann median differences, as appropriate. Exact 2-sided *P* values were reported for Mann-Whitney *U* tests.

[b]CG: control group.

[c]SG: simulator group.

Harms

No major complications, including accidental dural puncture, nerve injury, local bleeding or hematoma, infection, postdural puncture headache, or intracranial hypotension syndrome, were observed in either group during the supervised procedure or within the 24-hour postoperative follow-up period. No intervention-related adverse events were reported (0/10 and 0/10 in the control and SGs, respectively). No participants withdrew because of any harm. No VR-related discomfort, privacy breach, data-security incident, system failure, downtime, or other technical problem affecting training delivery was observed or reported during platform use.

Discussion

Key Findings

This randomized controlled pilot study aimed to investigate whether haptic-VR training can facilitate the early transfer of CSE anesthesia procedural skills to supervised procedures on real patients and whether the effects of this training differ across various procedural dimensions.

Compared with training using manikins, trainees who received haptic-VR training demonstrated better overall procedural performance, as assessed by the study's specific scale, during their first supervised clinical CSE procedure. Exploratory dimensional analysis suggested that the haptic-VR training group performed better at recognizing the LOR and ligamentum flavum penetration, while the manikin training group performed better in aseptic technique. Indicators related to puncture efficiency and needle trajectory adjustment were consistent in direction with the improved needle-path control observed after haptic-VR training; however, the precision of the effect estimates for first-attempt success rates was insufficient to draw definitive conclusions. Overall, these results provide stronger support for the notion that "different training methods have specific advantages across different skill dimensions" rather than indicating that any single simulation training method possesses a universal advantage.

Interpretation of Results and Comparison With Previous Studies

Most published studies on VR and XR in the fields of anesthesiology and intraspinal anesthesia education primarily evaluate learners' performance in simulated environments or rely on self-reported outcomes; therefore, it remains unclear whether these skills can be effectively transferred to clinical practice [17-24]. A recent systematic review on intraspinal anesthesia training also noted significant heterogeneity among studies in terms of teaching methods and assessment approaches, and high-quality evidence directly linking simulation training to performance in real patients remains limited [24].

Previous evaluations of the platform used in this study have shown that trainees are able to follow a certain learning curve with virtual patients, demonstrate a positive experience with repeated practice, as well as mastery of the puncture procedure steps; however, those studies did not compare different training modalities or further evaluate trainees' performance with real patients [32]. By using a randomized controlled design and having blinded evaluators score videos of the first supervised clinical CSE procedure, this study brought the outcome measures closer to performance in real clinical settings. However, a single, immediate, supervised clinical procedure represents only "near transfer" under relatively controlled conditions [33], and does not yet demonstrate that trainees have acquired lasting procedural competence, are capable of performing the procedure independently, or can improve patient outcomes.

The high overall clinical performance scores observed in this study should be interpreted with caution in light of the above.

XSL•FO
RenderX

A recent meta-analysis incorporating randomized studies found no significant overall difference in procedural skill outcomes between virtual simulation and training using manikins or live participants, and noted substantial heterogeneity among different interventions and assessment methods [34]. Therefore, the results of this study do not demonstrate that VR is superior to traditional simulation training overall. Rather, these results suggest that training outcomes may depend on whether the features of a particular simulator align with the specific skill components ultimately being assessed [34,35]. It is particularly important to note that the total scores in this study were derived from study-specific scales, and it has not yet been determined which score differences can be considered pedagogically or clinically meaningful.

The exploratory advantages observed in the recognition of the LOR and puncture of the ligamentum flavum are reasonable, as VR courses can repeatedly provide trainees with standardized force feedback cues while allowing them to control the needle trajectory within a 3D model [32]. In contrast, repeated puncture of physical models may alter the resistance characteristics of the material itself and create preexisting needle tracks, whereas digital force-feedback models can provide more consistent resistance feedback across multiple practice sessions [16,32]. However, the VR intervention in this study did not consist solely of haptic feedback; it also incorporated transparent anatomical displays, depth and angle information, and instructor guidance. Therefore, it is currently impossible to determine whether the observed advantages stemmed from haptic feedback, visual-spatial guidance, repeated practice, or a combination of these factors.

The results regarding procedure duration and needle angle adjustments are consistent with more efficient control of the needle trajectory, but this has not yet been proven. Fewer passive adjustments following bone contact may indicate that trainees were better able to anticipate the needle path; conversely, more active adjustments may reflect either conscious corrections by the trainees or greater uncertainty during the procedure. Since these process-based indicators in this study have not yet been validated as independent measures of procedural proficiency, nor have they been shown to correlate with patient outcomes, they should still be considered exploratory findings. Future research could evaluate these indicators in conjunction with objective trajectory parameters, the number of errors, the frequency of instructor interventions, and predefined criteria for successful needle insertion control.

The finding that the VR training group performed poorly in aseptic technique is also significant. In the VR environment, aseptic preparation and draping are primarily performed through interface operations, whereas the manikin training group physically practiced these steps. This illustrates a classic "training specificity effect." The closer a training method is to a real-world task, the more likely it is to facilitate the learning of that task [36]. A recent randomized study on central venous catheterization training also supports the complementary roles of VR and manikin training, although the areas of advantage across different skill dimensions differed from those in this study: the VR component of that study placed greater emphasis on standardized operating procedures, whereas manikin training was more beneficial for haptic-related operations and postoperative tasks [35]. These differences may stem from variations in the simulator design, haptic feedback capabilities, curriculum content, and assessment methods [34,35]. Taken together, these studies suggest that VR and manikin training should not be regarded as entirely identical or interchangeable interventions; rather, the "functional realism" of different simulation methods across specific skill components should be evaluated further [34-36].

The accuracy of the estimates of the first-attempt success rates was insufficient; therefore, it is not yet possible to determine whether either training method truly improved procedural success rates. Similarly, the absence of adverse events during the short-term follow-up period cannot be interpreted as evidence that the 2 training methods have comparable safety profiles. All procedures in this study were performed under supervision, and the patients were screened. Furthermore, the sample size of this trial was insufficient to detect low-incidence complications. Future confirmatory studies should predefine outcomes, such as clinical procedure success, instructor rescue interventions, patient-reported experiences, and procedure-related adverse events, and establish appropriate follow-up time frames based on the characteristics of the complications of interest.

Educational Implications and Implementation Insights

The primary educational implication of this study is not "replacement" but rather "sequential application." Haptic-VR may be more suitable for repetitive practice of specific procedural skills, such as identifying tissue resistance, spatial orientation, and needle-path control; this can be followed by training with physical manikins to integrate patient positioning, instrument manipulation, aseptic preparation, catheter insertion steps, and the complete procedural workflow, after which trainees can progress to the supervised patient procedure phase [34-36]. However, this sequential training model remains a hypothesis based on existing findings and should be validated through future research; it cannot be directly regarded as a proven best training approach. Future comparisons between hybrid "VR combined with manikins" training programs and single-manikin programs of equivalent duration will provide a more direct means of assessing whether this complementary training model offers added value.

Course design should also be based on the level of procedural competence achieved rather than solely on the duration or number of training sessions [37]. In the future, clear proficiency standards could be established; for example, trainees could first be required to demonstrate consistent haptic discrimination and needle trajectory control in a VR environment, followed by satisfactory performance of the complete procedure in a validated physical manikin assessment. Prior to routine implementation, training programs require further evaluation of instructor time commitments, hardware and maintenance costs, system availability, motion sickness or VR-related discomfort, and accessibility [38], as well as training performance under varying anatomical conditions. This study did not evaluate the aforementioned implementation outcomes. Furthermore, because the intervention used a centralized training

XSL•FO
RenderX

model under close instructor supervision, its feasibility in routine training environments or unsupervised self-directed training cannot be directly inferred.

Future multicenter studies should predefine clinically meaningful minimum differences [39] and use validated outcome assessment tools [40]; they should also include a more diverse cohort of trainees and patients and control for differences in case difficulty through stratification, balancing, or statistical adjustments. Furthermore, trainees' performance in completing multiple procedures on real patients should be assessed continuously over a defined time period rather than focusing solely on the first procedure. The study design should also clearly distinguish between primary and exploratory outcomes [25], appropriately control for multiple comparisons, and simultaneously evaluate skill retention and immediate performance [41]. Only such a study design can further determine whether the dimension-specific effects observed in this study are reproducible and whether these advantages ultimately translate into sustained clinical competence or patient benefits.

Limitations

This study had several limitations. First, as a small-sample, single-center pilot trial, the precision of the effect estimates for secondary and categorical outcomes was limited [42]. Although randomization can reduce allocation bias, differences in the baseline characteristics between the 2 groups of trainees may exist, given the small sample size. There is no guarantee that the baseline characteristics were evenly distributed across groups [43]. Furthermore, since each trainee was evaluated on different patients, variations in patient anatomy [44] and the complexity of the procedures may have influenced the trainees' performance. This study was not designed to assess rare adverse events.

Second, each trainee completed only 1 clinical assessment shortly after the training concluded; neither pretraining clinical performance data served as a baseline, nor was a follow-up assessment of skill retention conducted. Therefore, the study results primarily reflect the trainees' performance during their first supervised clinical procedure following training and cannot be used to evaluate the extent of skill improvement, consistency across cases, independent competence [33], or long-term retention of skills [41]. Furthermore, the patient population included in this study limits the generalizability of the findings to populations characterized by advanced age, high BMI, challenging anatomy, and other complex clinical cases.

Third, the modified scale was derived from an established assessment framework. Agreement between raters was high, but the modified version has not yet undergone formal psychometric validation. The present study also cannot determine what size of score difference would be clinically or educationally meaningful. Some domain-specific analyses and other secondary outcomes were exploratory, with no correction for multiple comparisons. Therefore, the differences seen in these analyses provide signals for hypothesis generation rather than confirmatory evidence [45].

Conclusions and Educational Implications

In this pilot trial, trainees who used haptic-feedback VR showed an early signal of transfer for selected tactile-dependent CSE skills during supervised patient procedures. Because the outcome was clinical performance rather than simulator scoring alone, the data are closer to early patient-care transfer than much of the existing simulation literature. This pattern was not a simple advantage for VR. Haptic-feedback VR appeared better aligned with tactile judgment and needle-path control, whereas manikin-based training remained important for workflow and aseptic practices. A practical curriculum would use the 2 tools for different purposes: VR for repeated exposure to resistance cues and physical simulation for the manual sequence and sterile steps of CSE. A larger multicenter trial would be a more appropriate test of this model, with repeated patient assessments, longer follow-up, validated scoring tools, and a prespecified approach to multiple testing.

Acknowledgments

The authors contributed equally as first authors. The authors thank the entire team from the Mechanical Engineering and Automation Institute of Fuzhou University for their assistance with the model reconstruction. According to the Generative AI Delegation Taxonomy (GAIDeT; 2025), proofreading and editing were delegated to generative AI (GenAI) tools under full human supervision. The GenAI tool used was ChatGPT (GPT-5.5). GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. The declaration was submitted by FG. The authors reviewed, edited, and verified all AI-assisted outputs and are fully accountable for the final content. No GenAI tool was used for the study design, data collection, data analysis, statistical analysis, interpretation of findings, reference selection, or figure creation. No confidential or identifiable data were provided to the tool.

Funding

This study was funded by the Startup Fund for Scientific Research of Fujian Medical University (2022QH1303), the general project of Fujian Provincial Education Department Middle-aged and Young Teachers Research Project (JAT241007), the Fujian Provincial Health Technology Project (2024GGA008), the joint funds for the innovation of science and technology, Fujian Province (2024Y9041), the Institute of Hospital Management, National Health Commission of China–clinical application research on medical AI (YLXX24AIA014), and the Guided Project of Social Development in Fujian Province (2025Y0009). The funders had no role in the study design, data collection, data analysis, data interpretation, manuscript preparation, or decision to submit the manuscript for publication.

Data Availability

All data generated or analyzed during this study are included in this article and its supplementary materials. Additional deidentified data are available from the corresponding author upon reasonable request, subject to institutional and ethical approval. Intervention materials are not publicly available because they include proprietary platform components. No public URL, demo account, archived web version, or source code is available for the platform; screenshots of the virtual reality interface and training platform are provided in Figure S1 in Multimedia Appendix 3 to support the description and replicability of the intervention.

Authors' Contributions

HX, WL, and YZ carried out the studies, participated in data collection, and drafted the manuscript. SM, ML, and XF performed the statistical analysis and participated in its design. XZ, DW, and FG participated in the acquisition, analysis, or interpretation of data and drafted the manuscript. All authors read and approved the final manuscript. FG and DW are co-corresponding authors.

Conflicts of Interest

Some members of the study team were involved in the academic development and previous application of the haptic virtual reality combined spinal-epidural teaching platform [32]. The platform included proprietary components, but the authors had no personal financial ownership of the platform and received no personal payments related to its use in this study. The engineering team assisted with model reconstruction but was not involved in trainee recruitment, training allocation, blinded outcome assessments, or statistical analysis.

Abstract

Background: Young people exposed to adverse childhood experiences (ACEs) are at risk of poor mental and physical health across the life course, yet many struggle to access timely help. Serious games offer an engaging, scalable, and stigma-reducing support, but few are co-designed with young people who have lived experience of ACEs, and methodological accounts of how participatory design is operationalized alongside software delivery are scarce.

Objective: We aimed to (1) develop and apply a novel methodological framework integrating experience-based co-design (EBCD) with agile game development to co-design a serious game with young people affected by ACEs, (2) describe the co-designed game prototype and the design decisions shaped by youth participation, and (3) examine the ethical and safeguarding considerations arising from co-designing digital mental health interventions with trauma-exposed young people.

Methods: We conducted a participatory co-design study comprising 12 workshops across 8 iterative co-design sprints, involving 18 diverse young people (aged 12 - 24 years) with lived experience of ACEs, 5 professional stakeholders, and a multidisciplinary game development team. Young people were recruited across England through partner youth organizations and regional Young People's Advisory Groups. Co-design ran from June 2022 to April 2024 in hybrid and online formats. Baseline characteristics include demographics, and mental health and well-being measures. EBCD activities were mapped onto agile practices (sprint planning, sprint reviews, and retrospectives); all feedback was logged in a "you said, we did" form. Analyses were descriptive, and reporting followed the GRIPP2-LF (Guidance for Reporting Involvement of Patients and the Public, long-form) checklist.

Results: The resulting prototype, ACE of Hearts, comprised a central "cozy den" hub and 4 mini-games addressing bereavement and caregiving, trauma and disability, gender dysphoria, and poverty. Youth feedback directly shaped 47 documented feedback and design decisions. Co-design participants (14 of 18 participants) were diverse in gender (8/14, 57% men or boys; 3/14, 21% women or girls; 1/14, 7% nonbinary; 2/14, 14% another identity; and 3/14, 21% transgender), ethnicity (5/14, 36% from minoritized ethnic backgrounds), sexuality (6/14, 43% bisexual or pansexual), and neurodivergence (7/14, 50% autistic), with elevated levels of depression (mean Patient Health Questionnaire 9-item scale 8.8, SD 4.5) and anxiety (mean Generalized Anxiety Disorder 7-item scale 8.4, SD 3.9). Mean posttraumatic stress symptom severity (Children's Revised Impact of Event Scale, 8-item; n=13) was 22.5 (SD 7.7). Design innovations included metaphoric storytelling, integration of narrative exposure therapy principles into gameplay, and an embedded ethics framework addressing representation, agency, and emotional safety.

Conclusions: Integrating EBCD with agile development is a feasible and transparent method for coproducing trauma-informed serious games with young people who have lived experience of ACEs. The approach is transferable to other participatory digital-health projects involving vulnerable populations. Future work would evaluate acceptability, feasibility, and clinical outcomes.

Introduction

Adverse childhood experiences (ACEs) refer to traumatic or stressful events in childhood, including abuse (emotional, physical, or sexual), neglect, and household challenges such as domestic violence, parental substance misuse, mental illness, incarceration, or separation [1,2]. ACEs tend to cluster in socioeconomically disadvantaged communities and have profound, long-term impacts on health across the lifespan [3,4]. In a meta-analysis of 253,719 participants, individuals with 4 or more ACEs showed elevated odds across 23 mental health and behavioral outcomes, including depression, posttraumatic stress disorder, self-harm, and suicide attempts [5]. Beyond individual suffering, ACEs confer substantial societal costs and are estimated to cost England and Wales £42.8 billion (a currency exchange rate of £1=US $1.35 was applicable) annually [6]. Mental health problems, one consequence of ACEs, cost society around £300 billion a year in 2022 [7]. Child and adolescent services across England are running at capacity with waiting lists, in some places as long as 6 years [8]. Those facing multiple disadvantages and identities of exclusion (by ethnicity, neurodiversity, and LGBTQ+ [lesbian, gay, bisexual, transgender, and queer] status), and/or living in rural or coastal areas experience additional barriers to accessing mental health support [9]. Even when seen in services, young people often fear stigma, harmful consequences, and being ignored or invalidated by practitioners who are increasingly pressed to provide short-term, discrete interventions [10,11]. Reducing waiting lists and providing more care and support at home, away from hospitals, is a global priority for prevention and mental health promotion [12].

Digital technologies and game-based interventions offer a novel avenue to meet this need. Video games are an integral part of youth culture and can deliver interactive experiences in a familiar, appealing format [13]. Serious games, designed for educational or therapeutic purposes beyond entertainment, have emerged as engaging mental health interventions for adolescents [14]. Serious games leverage playful interactions, narrative, and reward systems that are inherently appealing to young people, potentially increasing engagement and adherence to an intervention [15]. Recent meta-reviews have shown positive impacts of game-based interventions on anxiety, depression, and related symptoms in children and adolescents [16,17]. More recent syntheses report promising efficacy for serious games promoting mental health literacy and emotional regulation in young people [18]. Examples include MindLight, a biofeedback game for child anxiety, and SPARX, a fantasy role-playing game for adolescent depression, which demonstrated efficacy comparable to traditional therapies in controlled studies [19,20]. In randomized trials, MindLight reduced anxiety symptoms comparably to online cognitive behavioral therapy [21], and SPARX achieved remission rates superior to usual care among 187 adolescents seeking help for depression [22]. A game-based intervention was recently authorized by the US Food and Drug Administration for pediatric attention-deficit/hyperactivity disorder [23]. Serious games thus represent a novel modality for supporting young people's mental health, yet few have been designed specifically to address trauma- or adversity-related mental health needs [17].

How such games are designed is as critical as whether they work. Co-design, the meaningful involvement of end users as partners in intervention development, is increasingly recognized as essential for creating digital health innovations that are acceptable, relevant, and effective [24]. Recent reviews have begun to map how digital health technologies might screen for and mitigate the mental health consequences of ACEs in children and young people, while noting that few tools are designed with, rather than merely for, those affected [25]. Another systematic review of 41 co-design studies developing mental health interventions with young people found that one-third were assessed as low quality and that genuine youth participation was limited in two-thirds of studies [26]. To bridge this quality gap, future co-design studies need to prioritize theoretical grounding, methodological rigor, and transparent reporting of participant engagement [27].

This study addresses these gaps in the context of ATTUNE (Understanding Mechanisms and Mental Health Impacts of Adverse Childhood Experiences), an interdisciplinary, arts-science research program funded by UK Research and Innovation. We co-designed and developed ACE of Hearts, a novel serious digital game for young people (aged 12 - 24 y) who have experienced childhood adversities. The game is intended as a self-guided, supportive, and educational resource for use in community and home settings, complementary to, and not a substitute for, professional care. It may also be used with facilitation by practitioners in youth, school, and community settings. In particular, systematic accounts of how participatory engagement is operationalized alongside iterative software delivery, and how competing priorities such as youth preference, clinical safety, and technical feasibility are reconciled, remain scarce [28].

Situated within the development phase of the Medical Research Council framework for complex interventions [29], we integrated 2 complementary methodologies: experience-based co-design (EBCD) and agile development. Originating in health service improvement, EBCD centers the lived experiences of service users and systematically translates experiential data into design priorities [30,31]. In parallel, agile development, a software engineering framework characterized by iterative "sprints" with continuous feedback and adaptation [32], is the standard approach for digital product development but has rarely been formally integrated with participatory health research methodologies. The integration of these approaches addresses a fundamental tension in serious game design, the need to balance the deep participatory engagement of EBCD with the iterative technical fluency of agile [33].

In this paper, we present (1) a novel methodological framework integrating EBCD with agile game development, demonstrating how these complementary approaches can be combined; (2) the co-designed game prototype and a transparent audit trail tracing how youth participation shaped substantive design decisions; and (3) critical reflections on ethical safeguarding and the realities of power sharing when co-designing with trauma-exposed young people.

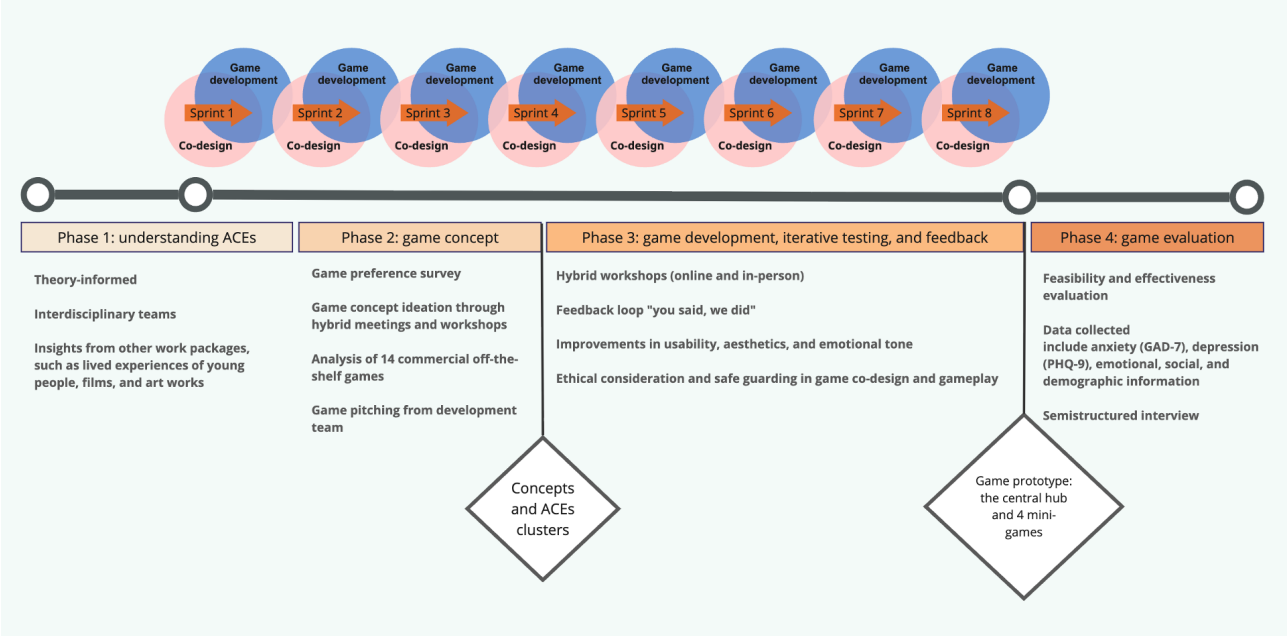
Methods



Research Design and Setting

This was a participatory co-design study integrating EBCD with agile software development, with a cross-sectional baseline survey characterizing participants. The method was designed to enable iteration and therefore facilitate deep co-design. This study was conducted within the UK Research and Innovation–funded ATTUNE program. In total, we conducted 12 sessions of co-design, 8 dedicated to general design and 4 to ethical dimensions. We collected qualitative co-design data throughout, supplemented by a baseline survey characterizing the co-design group. The game's acceptability and preliminary outcomes are evaluated in a separately reported study.

Overview of the Integrated EBCD-Agile Framework

The ACE of Hearts prototype was developed using an iterative EBCD approach integrated into an agile game development framework structured across 8 development sprints (Figure 1). Each sprint comprised defined goals at its start and evaluation at its end, with findings informing subsequent sprint goals. The 8 sprints of approximately 6 weeks each accounted for approximately 11 months of active development, and the remainder of the 12-month phase encompassed concept refinement, ethics review, participant recruitment, and scheduling around participants' school or work commitments. Agile practices comprised sprint planning (translating co-design outputs, such as prioritized emotional touchpoints, preference rankings, and storyboards, into sprint goals and a prioritized backlog of user stories), regular development within the game team, sprint reviews (in which young people played builds of the game and gave structured feedback), and retrospectives (in which the research and development teams reviewed process, safeguarding, and priorities). Where youth preferences, clinical safety, technical feasibility, and budget were in tension, clinical safety took precedence, followed by technical feasibility within the funded scope; youth suggestions that could not be implemented were documented in the "you said, we did" form with reasons and revisited where possible. The process was organized into four phases: (1) understanding ACEs, drawing on materials from earlier ATTUNE creative workshops [2]; (2) concept development, exploring game preferences and generating storylines, characters, and game mechanics; (3) game development, with iterative playtesting and feedback driving design refinements; and (4) game evaluation, involving a preliminary feasibility and acceptability study, which is reported separately. A summary of co-design sessions, stakeholders, and activities is provided in Table S1 in Multimedia Appendix 1.

Figure 1. Overview of the integrated experience-based co-design (EBCD) and agile development framework used to co-design the ACE of Hearts serious game with 18 young people (aged 12 - 24 y) with lived experience of adverse childhood experiences, United Kingdom, June 2022 to April 2024. ACE: adverse childhood experience; GAD-7: Generalized Anxiety Disorder 7-item scale; PHQ-9: Patient Health Questionnaire 9-item scale.

Inclusion and Exclusion Criteria

Inclusion criteria for young people were the following: being aged 12 - 24 years, self-identified lived experience of ACEs, living in the United Kingdom, and being able to provide informed consent. Young people were not eligible if they were unable to participate safely in group creative activities, if they were currently receiving acute crisis care, or if consent could not be obtained.

Participant Characteristics

Baseline survey data were available for 14 of the 18 young people (full details in Tables S2 and S3 in Multimedia Appendix 1). The mean age was 19.1 (SD 3.4; range 11 - 24) years. One participant was aged 11 years at the time of the baseline survey, which accounts for the observed range of 11 - 24 years against the 12 - 24 year eligibility criterion. Of 14 respondents, 8 (57%) identified as a man or boy, 3 (21%) as a woman or girl, 1 (7%) as nonbinary, and 2 (14%) with another gender identity; 3 (21%) reported being transgender; 6 (43%) identified as bisexual or

XSL•FO
RenderX

pansexual; 6 (43%) were White British and 5 (36%) from Black, mixed, or other ethnic backgrounds; and 7 (50%) reported at least one neurodivergent condition, most commonly autism (7, 50%) and attention-deficit/hyperactivity disorder (4, 29%). Nine (64%) participants lived in urban areas and 5 (36%) participants in rural or coastal areas. Participants presented with elevated mental health difficulties: mean Patient Health Questionnaire 9-item scale (PHQ-9) depression score was 8.8 (SD 4.5), with 7 (50%) participants meeting the threshold for moderate or higher severity; mean Generalized Anxiety Disorder 7-item scale (GAD-7) anxiety score was 8.4 (SD 3.9); mean loneliness (4-item UCLA Loneliness Scale [UCLA-4]) was 9.4 (SD 2.5); and mean PTSD (posttraumatic stress disorder) symptom severity (Children's Revised Impact of Event Scale, 8-item [CRIES-8]; n=13) was 22.5 (SD 7.7).

Sampling Procedures

The core co-design team brought together a multidisciplinary group comprising 18 young people (aged 12 - 24 years) with lived experiences of adversity and diverse backgrounds, 5 adult stakeholders comprising experts in clinical psychology, psychiatry, game studies, and medical ethics, and a game development team consisting of a game writer, a 3D artist, an animator, a programmer, and 2 creative arts practitioners. Co-design activities ran from June 2022 to April 2024 in hybrid and online formats to enable participation by young people across England, including rural and coastal regions. Young people were recruited purposively across the ATTUNE program through partner youth organizations and the regional Young People's Advisory Groups, with youth workers and organization leads supporting invitations. Adult professional stakeholders and the game development team were recruited by convenience sampling from researchers and professionals working within the program.

Sample Size, Power, and Precision

A priori power analysis was not performed, and no target sample size was calculated, because this was a participatory co-design study with descriptive aims rather than a hypothesis-testing design. The sample size was pragmatic, aiming for diversity of lived experience and sustained engagement across sprints. To indicate precision, 95% CIs were 8.8 (95% CI 6.2 - 11.4) for PHQ-9, 8.4 (95% CI 6.1 - 10.7) for GAD-7, 9.4 (95% CI 8.0 - 10.8) for UCLA-4, 22.6 (95% CI 20.2 - 25.0) for Short Warwick-Edinburgh Mental Well-Being Scale, 50.1 (95% CI 45.0 - 55.2) for Difficulties in Emotion Regulation Scale, short form (DERS-SF), and 22.5 (95% CI 17.8 - 27.2) for CRIES-8.

Measures and Covariates

Baseline sociodemographic measures included age, gender identity, transgender status, sexual orientation, ethnicity, neurodivergence, education and employment status, household composition, caregiver education and employment, and area of residence (urban, rural, or coastal). Mental health and well-being measures comprised depressive symptoms, anxiety symptoms, posttraumatic stress symptoms, loneliness, mental well-being, and difficulties in emotion regulation. Game-related measures comprised weekly play time, favorite games, and factors rated as important to the gaming experience, which informed the phase 2 concept development. These measures were used solely to characterize the co-design group and its starting point for design work. They were not treated as outcomes or predictors, and no covariates were specified or adjusted for because no modeling or inferential analysis was undertaken. The substantive study data were the qualitative co-design outputs and the "you said, we did" design decision log.

Data Collection

Co-design activities took place between June 2022 and April 2024, in online sessions and in hybrid sessions, enabling participation by young people in rural and coastal as well as urban areas. Baseline data and game preference data were collected through the online survey platform Qualtrics. Co-design data comprised facilitator and observer notes, workshop outputs (including collaborative whiteboards and questionnaires), and playtesting feedback captured during and after each session. All actionable feedback was logged in a "you said, we did" form recording the feedback received, the design response, and the rationale where suggestions were not taken forward.

Quality of Measurements

Sessions were cofacilitated by researchers trained in co-design facilitation, safeguarding, and trauma-informed practice, and at least 2 team members recorded observations independently at each session, providing multiple observations of the same activities. Self-report measures were completed directly by participants through an online survey platform. Formal interrater reliability was not calculated. The categorization of design decisions was reviewed by the wider research team, with disagreements resolved by consensus.

Instrumentation

All self-report instruments were previously validated measures used in their standard published form: the PHQ-9 for depressive symptoms [34]; the GAD-7 for anxiety symptoms [35]; the CRIES-8 for posttraumatic stress symptoms [36]; the UCLA-4 [37]; the Short Warwick-Edinburgh Mental Well-Being Scale [38]; and the DERS-SF [39]. Each was selected because it is brief, validated for adolescents and young adults, and already in use across the wider ATTUNE program, allowing consistency of measurement.

Masking

Masking was not applicable and was not attempted.

Psychometrics

Reliability and validity coefficients were not estimated within this study's sample. The self-report measures were used only to describe the composition of the co-design group.

Conditions and Design

Conditions and design were not applicable.

Data Diagnostics

No participants were excluded after data collection, and no criteria for postdata-collection exclusion were applied. A total of 4 of the 18 (22.2%) enrolled young people did not complete the baseline survey, so baseline characteristics are reported for

XSL•FO
RenderX

14 of 18 (14/18, 77.8%) participants. At the item level, all measures were complete except the CRIES-8 and the DERS-SF, each of which was completed by 13 of 14 respondents (13/14, 92.9%; 1/14, 7.1% missing). Noncompletion reflected scheduling and availability during the survey window rather than refusal or withdrawal, and these young people continued to take part in co-design activities.

Analytic Strategy

Quantitative baseline data were summarized descriptively, with means and SDs for continuous measures and counts, percentages, and explicit denominators for categorical measures. Qualitative co-design data were analyzed and categorized by design domain (narrative content and emotional tone; game mechanics and engagement; visual, audio, and interface design; ethics, emotional safety, and safeguarding; accessibility; and language and cultural fit) by the first author, with categorization reviewed by the wider research team and disagreements resolved by consensus.

Ethical Considerations

The project received ethics approval from the University Research Ethics Committee at the University of Oxford (23/WM/0105). At the start of the project, all participants (and guardians for those aged younger than 16 years) provided informed consent. Participation in any session or activity remained voluntary, and participants could decline or withdraw at any time without giving a reason. All study data were pseudonymized and stored on secure, access-controlled university systems in accordance with UK General Data Protection Regulation requirements. Participants' characteristics and quotations reported here are deidentified, and no information enabling identification of individual participants is presented. No images of individual participants or users appear in this paper or in the supplementary material. All in-game images are original artwork depicting fictional characters, and no photographs or other identifiable images of participants were used for publication. Young people received £15 per hour as reimbursement for their contribution. In addition to formal ethics approval, our method adopted an embedded ethics approach to game design, whereby ethically relevant issues were assessed and discussed with stakeholders throughout the co-design process, with the game adjusted to ensure responsible innovation. This included issues of representativeness, accessibility, emotional safety, responsible motivation, and responsible mental health and ACEs content.

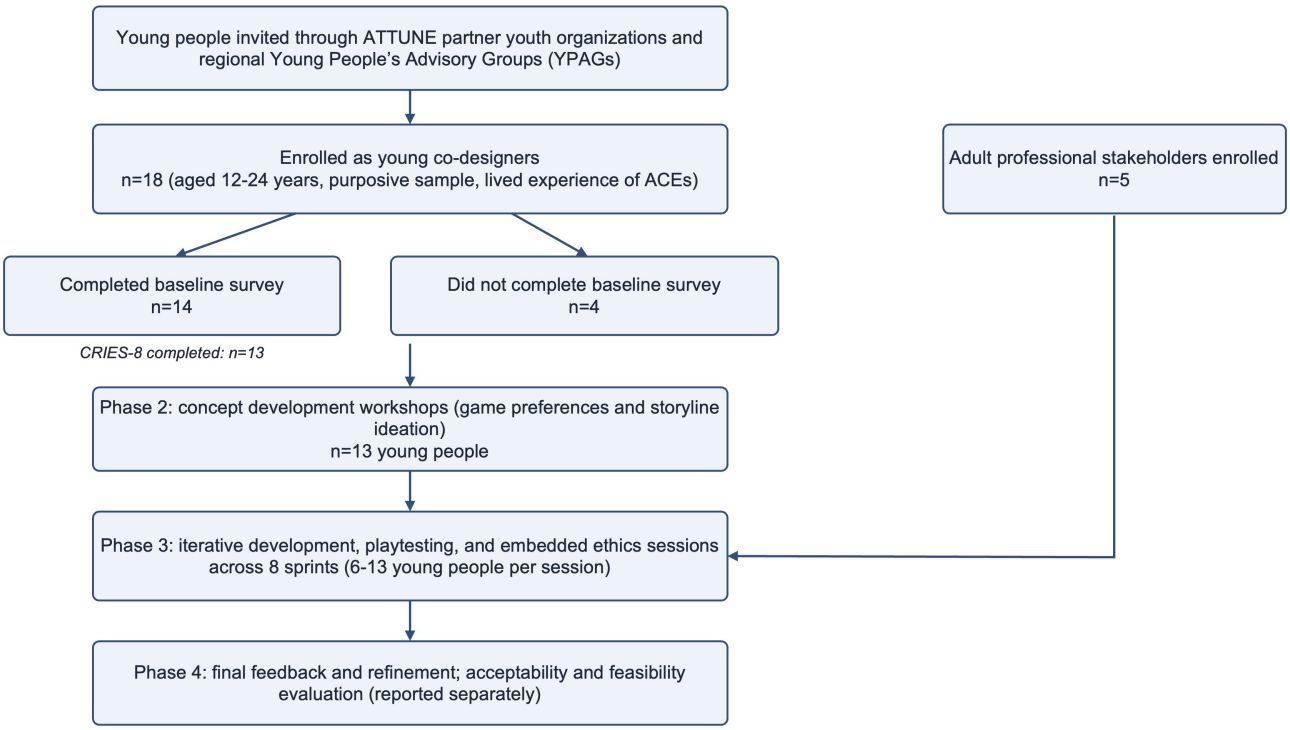
Given the elevated levels of depression, anxiety, and posttraumatic stress symptoms in the sample, safeguarding was planned into every session. Sessions were cofacilitated by researchers trained in safeguarding and trauma-informed practice, with a named safeguarding lead and an agreed distress protocol. Sessions began with ground rules co-developed with young people. Participants could pause, step out, or leave at any time without explanation, and creative activities were designed so that disclosure of personal trauma was never required. A youth worker or known professional from the partner organization was present or on call for sessions. Any participant showing or reporting distress was offered immediate support and a follow-up check-in and, where indicated, signposting or referral to local services. Escalation pathways to the clinical members of the team (including consultant psychiatrists and clinical psychologists) were available where needed, and sessions ended with a structured check-out and signposting to support resources. No adverse events were recorded during the co-design program.

Reporting Standards

We report patient and public involvement in accordance with the GRIPP2-LF (Guidance for Reporting Involvement of Patients and the Public, long form) checklist [40], given that co-design with young people with lived experience of ACEs is the primary focus of this study. We also draw on the adolescent and youth engagement reporting checklist to structure our account of the co-design process [41]. Young people were involved as co-designers throughout all phases of the research, from conceptualization through to game refinement.

Results

Overview



We present the results in 4 sections: the participant flow, the co-design process, and how youth participation shaped the game (phases 1 - 3), the resulting game prototype and its design innovations, and the ethical and safeguarding considerations that emerged.

Participant Flow

Figure 2 summarizes participant flow through this study: young people were invited through partner organizations and Young People's Advisory Groups; 18 enrolled as co-designers; 14 completed the baseline survey (4 young people did not, owing to scheduling and availability rather than refusal); and 6 - 13 young people participated per session across the 4 phases, alongside 5 adult professional stakeholders.

XSL•FO
RenderX

Figure 2. Participant flow through the ACE of Hearts co-design study with young people (aged 12 - 24 y) with lived experience of adverse childhood experiences (ACEs), United Kingdom, 2022 - 2024. ACE: adverse childhood experience; ATTUNE: Understanding Mechanisms and Mental Health Impacts of Adverse Childhood Experiences; CRIES-8: Children's Revised Impact of Event Scale, 8-item; YPAG: Young People's Advisory Group.

Phase 1: Understanding ACEs

This study was informed by earlier phases (corresponding to work packages 1 - 2) of the program, which explored the psychological and geo-socioeconomic mechanisms through which ACEs affect the mental health and lives of young people [42,43]. These studies used creative and participatory arts-based approaches to generate new, transformative experiential data, deepening understanding of key mechanisms and informing action for prevention and care. The outputs included resources such as magazines, short animations, and films, and neurodiversity considerations. These materials provided the research team with experiential understanding of ACEs from young people's perspectives, and they became direct inputs to game content. For example, the magazines became the digital magazine in the Cozy Den, while real-life accounts of young people's adverse experiences in accessing mental health services were incorporated into the dial it back mini-game.

Building on this foundation, a multidisciplinary research team comprising specialists in serious games, clinical psychology, psychiatry, and medical ethics conducted a game analysis study, playing and reviewing 14 commercial off-the-shelf games [44]. Using an autoethnographic approach, the team analyzed features and mechanics while reflecting on the player's role in meaning-making. These reflections informed the selection of game concepts and ACE-related themes for the development phase.

Phase 2: Game Concept Development

Early concept ideation activities explored game preferences and playing experiences related to mental health with 13 young people (Figure S1 in Multimedia Appendix 1). The most frequently named were Minecraft (6 mentions) and Apex Legends (5 mentions), followed by GTA 5 and Subway Surfers (4 mentions each). Most participants were unable to name any games that depicted mental health experiences. Participants found a variety of factors important for their playing experience, summarized as ranked frequencies. Excitement and playing with friends were rated most highly on average (mean 8.6 and 8.5 of 10), followed by engaging with a good story (mean 7.7) and taking time out (mean 7.5). Getting a high score (mean 6.4) and being part of a game community (mean 4.3) were rated lower and showed the greatest variation, with several participants rating them as unimportant (0-1) while others rated them maximally important (10). A recurring motif was that game worlds provide spaces of retreat from "the real world," offering relief and a sense of ownership, an insight that directly shaped the design of the cozy den hub as a safe, customizable home base.

Insights from phase 1 indicated several priority themes, including family loss, financial hardship, and disability, which became candidates for game storylines. During concept ideation, some participants emphasized the challenges of gender identity struggles and the lack of representation of transgender youth in mental health media. In response, the team agreed to develop a mini-game on this theme, which emerged unexpectedly from the workshops but filled an important gap identified by the young co-designers.

Phase 3: Game Development—Iterative Development, Play Testing, and Feedback Loops

Phase 3 encompassed the main development of the game prototype and multiple cycles of play testing with feedback. Participants played early builds of each mini-game and the hub, and provided detailed feedback on enjoyment, emotional impact, clarity, and areas for improvement. Their feedback directly

XSL•FO
RenderX

drove numerous design refinements. Table 1 presents an overview of key user feedback and the corresponding design actions taken. The full "you said, we did" table is provided in Table S4 in Multimedia Appendix 1.

Table . Selected examples of youth feedback and corresponding design decisions in the ACE of Hearts co-design study with young people (aged 12 - 24 y) with lived experience of adverse childhood experiences, United Kingdom, 2022 - 2024.

Mini-game	Domain	Key feedback	Design action
Horse and foal	Narrative pacing and emotional tone	"Shift to loss was too dramatic at the end"; "ending quite jarring but I think that helped to convey the loss"	Additional grief-processing chapter created; foreshadowing implemented; supportive messages and signposting added
Horse and foal	Visual design	Color palette described as too dark and cold	Revised palette with brighter seasonal backgrounds (spring/summer)
Dial it back	Narrative	Concern that visible physical trauma overshadowed less visible ACEs[a]; home environment "too big and tidy"	Clarified narrative to explicitly acknowledge multiple ACEs including neurodiversity; adjusted visuals for realism
Out of my shell	Metaphor	"I love the metaphor, an inventive way preventing themes from being too upsetting"; concerns about dragon misinterpretation	Expanded dragon metaphor with explicit narrative clarification; added breathing exercise mechanic and guardian NPCs[b]
Hard times	Realism	"Worried about trivialization" of poverty; requested systemic framing ("unfair system designed to keep people within margins")	Multiple endings implemented; reinforced message that systemic factors cause poverty; added practical support signposting
General	Cultural fit	Confusion about US cultural references (Kansas); colloquialisms felt "awkward"	Replaced references with universally recognizable content; reduced colloquialisms
General	Character	"Ordinary people can have mental health problems, not just green-haired weirdos"	Removed negative connotations from character descriptions; diversified representation across mini-games

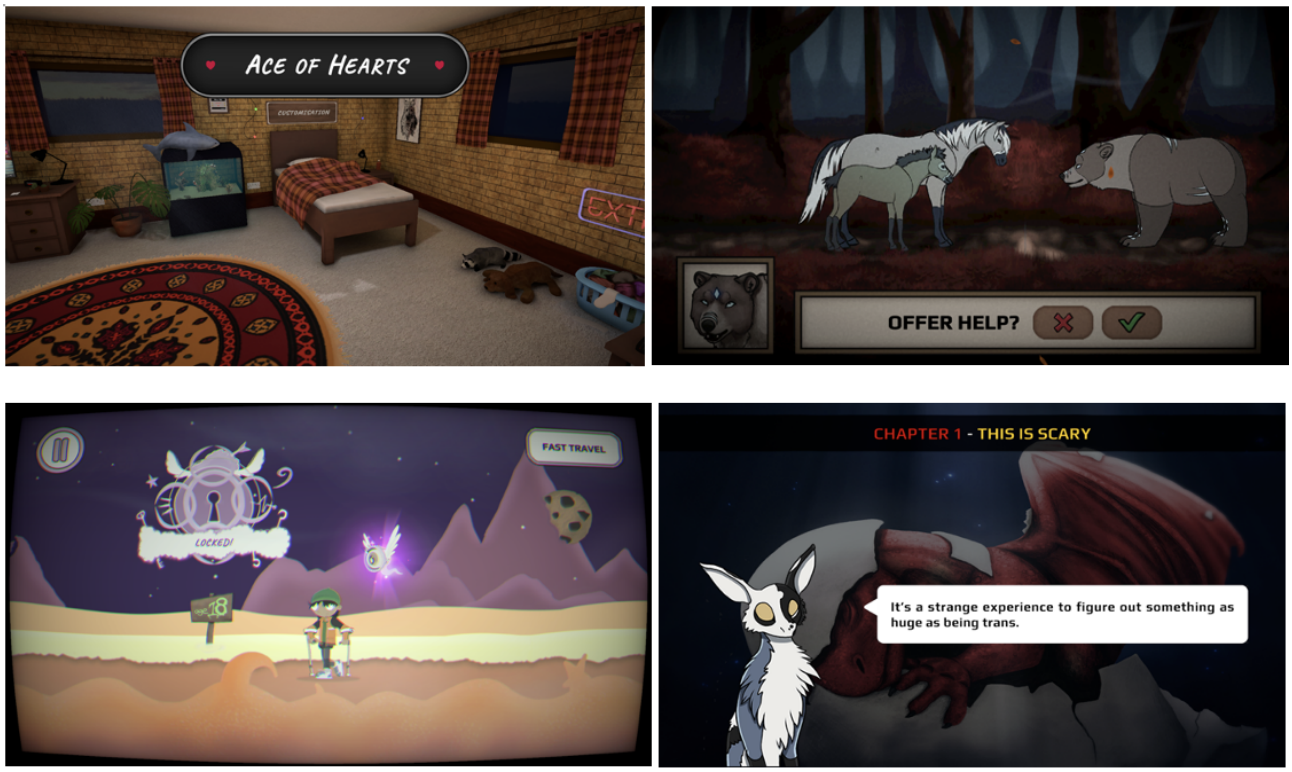
[a]ACE: adverse childhood experience.

[b]NPC: nonplayer character.

Considered in aggregate, the 47 logged decisions were distributed across 6 design domains: narrative content and emotional tone (n=27); game features, visuals, and engagement (n=8); ethics and safeguarding (n=7); accessibility (n=2); and language and cultural fit (n=3). A small number of suggestions (n=3) were not taken forward within the current prototype, most commonly because of technical feasibility or budget constraints (eg, multiplayer play) or scope; each is documented with its rationale in Table S4 in Multimedia Appendix 1 and was noted for future development.

Analysis of the documented design decisions reveals 3 patterns in how youth participation shaped the game. First, young people consistently pushed for emotional authenticity tempered by hope, acknowledging that "bad things happen and feelings such as anger or sadness are valid," while also reassuring players that "you're not alone and things can get better." This tension between realism and reassurance drove major narrative restructuring, including the addition of a grief-processing chapter in horse and foal and multiple endings in hard times. Second, participants articulated a sophisticated preference for metaphorical rather than literal representations of trauma, consistently endorsing approaches that created enough proximity to validate experience, but enough abstraction to prevent retraumatization. Third, youth feedback frequently identified cultural assumptions embedded in the game content (eg, US cultural references and colloquialisms that felt inauthentic) that the adult design team had not recognized, demonstrating the irreplaceable value of genuine participatory design.

The ACE of Hearts Game Prototype



Overview

The resulting prototype (Figure 3) comprises a central hub space, the "cozy den," which connects 4 fully developed mini-games, addressing adversity-related themes: bereavement and caring for a younger sibling (horse and foal), financial hardship (hard times), living with disability and the aftermath of traumatic injury (dial it back), and the stigma, bullying, and lack of representation experienced by young people with gender dysphoria (out of my shell). Game details are presented in another publication [45]. The present paper is distinct in reporting the co-design methodology, the safeguarding and embedded ethics processes, and the game design decisions. The cozy den itself functions as a persistent, customizable home base: players personalize their virtual bedroom (eg, changing posters and music), interact with objects (eg, playing the guitar, feeding the fish, drawing, and reading the digital magazine derived from the ATTUNE magazines), and unlock each mini-game through the in-game phone and computer, returning

XSL•FO
RenderX

to the den between and after mini-games as a space for decompression and safety.

Figure 3. Screenshots of the ACE of Hearts game. Panels show the cozy den hub and the horse and foal, dial it back, and out of my shell mini-games. The game was co-designed with young people (aged 12 - 24 y) with lived experience of adverse childhood experiences, United Kingdom, 2022 - 2024. No identifiable individuals are shown; all artwork is original and depicts fictional characters.

Horse and Foal

This 2D side-scrolling narrative mini-game explores themes of sibling caregiving and bereavement. The player controls Carla, a young horse, who must take care of her little sister (a foal named Rhea) as they journey through pastoral landscapes symbolizing the progression of Rhea's illness and eventual loss. In early testing, youth players praised the use of animal characters and seasons but found the initial pacing too dark or abrupt. In response, the visuals were brightened, the chapter sequence was reordered to begin in spring, and an epilogue scene was added showing Carla remembering her sister but continuing forward (the final choice: "keep moving on").

Dial It Back

Inspired by narrative exposure therapy (NET) principles [46], this mini-game unfolds an interactive story about confronting memories. The protagonist, Oli, a 16-year-old boy who has experienced multiple adverse events and physical disability, is presented in the third person, a deliberate choice based on co-design feedback that some distance can make processing trauma safer. The player helps Oli reconstruct his life story by identifying significant memories and placing a flower or a stone to mark each as good or bad, drawing directly from NET's life-line technique. During playtests, a journal feature was added, and the narrative was adjusted so that Oli chooses to seek counseling, framing help-seeking as a positive resolution.

Out of My Shell

This tower-defense mini-game uses a fantasy metaphor to explore identity, stigma, and finding one's true self, drawing on experiences of gender dysphoria and bullying. The protagonist, Flo, feels like a "dragon in disguise," a metaphor for having a hidden true identity. Flo must defend their "nest" (representing a sense of self) from "enemies" symbolizing bullies, rumors, and negative self-talk. Feedback led to a guided breathing exercise mechanic and 2 guardian nonplayer characters providing supportive messages. By the final wave, Flo can transform fully into a dragon, signaling resilience and self-acceptance. The dragon metaphor and the portrayal of Flo's experiences were reviewed with co-designers with relevant lived experience, including 1 game artist and 3 transgender participants, whose feedback shaped explicit dialogue acknowledging the diversity of transgender experiences, including a nuanced, nonstigmatizing treatment of detransition.

Hard Times

This 3D first-person scenario addresses financial hardship and family stress. The player steps into the shoes of Mina, a teenager struggling to pay rent in a small London flat. The core mechanic is managing scarce resources by making tough choices. Youth co-designers commented on how immersive and relatable the scenario felt but found the original eviction ending bleak. In response, multiple endings were implemented, ranging from hopeful (the family obtains assistance) to bittersweet (they move, but relationships strengthen), ensuring players retain agency and hope.

Design Innovations

Overview

Beyond the individual mini-games, 3 cross-cutting design innovations emerged from the co-design process that represent this study's contribution to serious game design methodology for trauma-exposed populations.

The Use of Metaphor and Multimodal Storytelling

A defining feature of ACE of Hearts is the systematic use of metaphor and multimodal storytelling. From the earliest design stages, we recognized that directly depicting real traumatic events might be triggering for some young players. Instead, inspired by techniques used in art therapy, we created a symbolic layer for each narrative. This design choice is grounded in therapeutic theory, which suggests that metaphors enable individuals to process trauma and express emotions indirectly [47,48]. Video games are particularly well-suited to convey such metaphors because they operate across visual, auditory, and interactive channels, creating an "ecosystem of meaning-making" [49]. Crucially, the metaphorical approach was not imposed by the design team but validated and refined by the youth co-designers, who consistently endorsed it as "an inventive way preventing themes from being too upsetting." A summary of the multimodal metaphor design is provided in Table S5 in Multimedia Appendix 1.

Drawing on NET

Another salient and critical design innovation is the integration of therapeutic techniques, specifically NET, in dial it back. NET is a short-term therapy in which individuals tell their trauma stories through unfolding memories within a biographical context [46]. Core elements of NET in the dial it back mini-game include the construction of a "lifeline" of events and recounting details of each traumatic memory. We worked closely with clinical advisors, including a psychiatrist experienced in NET, to gamify these elements. The game's memory constellation mechanic and lifeline timeline mirror the process of NET, engaging the player in the process of organizing life events. Another NET principle implemented was the emphasis on sensory cues: players unlock each memory by moving an "eyeglass" around a stylized brain to find 4 sensory details (smell, sound, touch, and an emotion) associated with that event [50,51]. We drew from narrative exposure therapy for children (KIDNET), the child adaptation of NET, which suggests using more visual aids and metaphors for younger audiences [52]. While dial it back incorporates elements of NET, it is important to note that it is not designed to serve as a standalone trauma therapy. Rather, the aim is to create a meaningful and supportive experience that may empower players, promote a sense of control, and encourage help-seeking.

Embedded Ethics Framework

Designing a mental health game for young people who have experienced distress or adversity required careful attention to ethical and safeguarding considerations throughout development [53]. Rather than treating ethics as a one-off review, we adopted an embedded ethics approach in which ethically relevant issues were assessed and discussed with stakeholders in 4 dedicated co-design sessions. By embedded ethics, we mean the continuous, in-process identification, discussion, and resolution of ethical issues during design, rather than a one-off ethics review. Before the co-design sessions, our research team, comprising clinical and ethics expertise, conducted a systematic review and critical appraisal of the ethical implications of digital gaming interventions for mental health [54]. Based on the findings, we provided comprehensive ethical considerations and related questions in the protocol, structured around 7 domains: representation, accessibility, agency, privacy, emotional safety, positive motivation, and responsible content. In practice, ethical concerns raised by any participant or team member in workshops or playtesting were logged as flagged entries in the design decision, discussed at dedicated embedded ethics review sessions. Table 2 summarizes the ethical dimensions, youth feedback, and actions taken (full details in Table S6 in Multimedia Appendix 1).

XSL•FO
RenderX

Table . Ethical dimensions, youth feedback, and safeguarding actions in the ACE of Hearts co-design study with young people (aged 12 - 24 y) with lived experience of adverse childhood experiences, United Kingdom, 2022 - 2024.

Ethical domain	Key concerns raised	Actions taken
Representation	Concerns about stereotyping; requests for ethnic/cultural markers; diverse transgender experiences	Diversified characters across games; culturally accurate elements in narratives; nuanced portrayal of gender identity experiences
Accessibility	Older devices excluded; small text for those who are visually impaired	Compatibility with older devices (iOS and Android); improved font sizes
Agency	Frustration when outcomes could not be influenced by choices; options to personalize or have visible impact	Personalization options in cozy den; clarified that some narratives reflect uncontrollable life events with explicit reassurance
Privacy and transparency	Youth asked about data handling and requested clear communication about development, purpose, and commercial interests; clear indication needed about the limits of the game's therapeutic value	Explicit in-game information about data use; clear communication about purpose
Emotional safety	Abrupt emotional content; need for external signposting and reporting mechanisms	Extended epilogues; foreshadowing; supportive dialogs; in-game resources and links to support organizations
Positive motivation	Suggested self-care and playtime reminders	Integrated self-care reminders and mindfulness exercises in-game
Responsible content	Concerns about trivialization or harmful portrayals of ACEs[a] and mental health (poverty, dysphoria, trauma)	Revised narratives and dialogues to responsibly portray mental health and ACEs; avoided stereotypes, and used diverse, respectful representations

[a]ACE: adverse childhood experience.

It was ethically important that the game's content respectfully represents the diverse experiences of young people with ACEs, who live in a range of geographic regions of England. In our co-design, we made conscious efforts to include youth collaborators of various identities (including diversity in ethnicity, gender identity, sexual orientation, neurodiversity, and region) so that the ideas generated reflected a broad spectrum of perspectives. This fed directly into the game narratives: each of the 4 mini-games features a distinct protagonist facing distinct adversities, intentionally broadening representation. Accessibility covered both technical accessibility and content accessibility, that is, the comprehensibility of narratives, metaphors, and visuals for diverse young players, including neurodivergent players. Key adjustments included providing compatibility with older and low-specification devices, increasing font sizes, and improving signposting for navigation and storylines.

Promoting a sense of agency and control for young players was central both in our co-design methodology and within the game itself. During the co-design sessions, young people were given real influence over decisions. Within the game, we designed the gameplay to give players meaningful choices and multiple pathways wherever feasible. Within our study, emotional safety refers to presenting emotionally challenging content in ways that validate experience while minimizing the risk of distress or retraumatization. Responsible and positive motivation refers to encouraging engagement without fostering overuse or dependence. Given the potential of the game to trigger distressing feelings, the realism of games can present a double-edged sword, in that it may increase engagement but also risks intensifying emotional responses or even retraumatizing young people [55]. The games were designed to balance the depiction of traumatic experiences enough to validate players' lived experiences while also incorporating positive messages, supportive characters, and moments of relief. Techniques such as gentle pacing, interactive coping activities (eg, breathing exercises in out of my shell and the "keep moving forward" option in horse and foal), and in-game resources and signposting to sources of real-world support were used to mitigate potential emotional burdens.

Discussion

Principal Findings

In this study, we combined EBCD and agile development to develop the ACE of Hearts game, one of the few serious games co-designed specifically with and for young people affected by ACEs. The integrated EBCD-agile framework produced a game prototype that was substantively shaped by the lived experiences and preferences of young people across 8 iterative sprints. Three principal findings emerge from this work. These findings correspond directly to the 3 objectives stated at the end of the Introduction section: the methodological framework, the co-designed prototype and feedback loop, and the ethical and safeguarding considerations.

First, the integration of EBCD with agile development proved both applicable and productive for serious game development with potentially vulnerable populations. EBCD's emphasis on foregrounding lived experience complemented agile's capacity for rapid iteration, creating a development process in which youth feedback could be gathered, discussed, and incorporated within sprint cycles. Systematic reviews of EBCD in health care

XSL•FO
RenderX

and of co-design in digital health have noted that participatory approaches are rarely coupled to iterative development, while agile-user experience hybrids seldom address power sharing or lived experience [27,28,56]. The resulting framework may serve as a transferable, well-documented model for future digital mental health innovation, whose replicability should be tested in other settings [57].

Second, young people's contributions substantively shaped the game's content, mechanics, and ethical safeguards. The transparent feedback and design decisions demonstrate how youth feedback led to concrete design changes, ranging from narrative restructuring (eg, the addition of a grief-processing chapter in horse and foal) to the emergence of entirely new game modules (eg, out of my shell, addressing gender dysphoria, which emerged from co-design discussions rather than the original research plan). This level of traceable participation addresses concerns raised in recent systematic reviews about the quality and depth of youth involvement in co-designed mental health interventions [26].

Third, the use of metaphor and multimodal storytelling, combined with therapeutic techniques adapted from NET, represents a novel approach to serious game design for young people with ACEs. The metaphorical framing—animal characters for bereavement, dragons for gender identity, and sensory constellations for memory processing—was not imposed by the design team but coconstructed with young people, who consistently advocated for approaches that were "real but not overwhelming." This aligns with therapeutic theory suggesting that metaphors can provide a "safe distance" for exploring difficult themes [44].

Comparison With Prior Work

This work extends the existing literature in several ways. While prior studies have described co-design of gamified mental health tools [33], few have formally integrated EBCD with agile methods. We do not claim primacy for the game itself: established serious games such as SPARX for adolescent depression [22] and MindLight for childhood anxiety [21], alongside scholarly analyses of commercial autobiographical titles addressing illness and grief, such as That Dragon, Cancer [44,49], demonstrate a maturing field; the contribution of this study is primarily methodological, namely the documented EBCD-agile integration and the transparent design decision audit trail. For example, a framework provides a 5-step model for theory-driven serious game development but does not incorporate EBCD's emphasis on lived experience [58]. The EBCD-agile synthesis also sits alongside adjacent design methodologies. Lean user experience combines agile cadence with user-experience research through rapid build-measure-learn loops but is commercially oriented and does not center lived experience or power sharing [56]. The Design Council's Double Diamond structures innovation through discover-define-develop-deliver phases, paralleling EBCD's discovery-to-co-design arc, but it is not intrinsically trauma-informed and specifies little about how to collaborate with vulnerable users [59]. Our framework differs in combining EBCD's experiential, touchpoint-based methods and explicit power-sharing commitments with agile's sprint cadence, while embedding clinical safeguarding and ethics review within the development loop itself. This current paper is also distinct from, and complementary to, 2 related outputs: a short demonstration paper describing the ACE of Hearts game artifact itself [45] and the separately reported study evaluating the game's acceptability and feasibility. The original contributions here are the integrated framework, the safeguarding and embedded ethics processes, and the aggregate analysis of the co-design feedback and game design decisions. Our work also contributes to the growing discourse on reporting quality in co-design research. By adopting the GRIPP2-LF checklist [40] and maintaining transparent communication of design decisions, we address concerns raised in the literature about the variable fidelity of EBCD adaptations and the quality of youth involvement reporting identified in recent systematic reviews [25-27].

Situating the prototype within the serious games literature clarifies the novelty of our game addressing ACEs. Systematic reviews of serious games for youth mental health report promising effects on mental health literacy, emotional regulation, and symptom outcomes, and consistently identify co-design and customization to diverse users as features associated with success [18-20]. Most established studies, however, target a diagnosis or symptom cluster, such as depression in SPARX [22] or anxiety in MindLight [21], rather than the experiences of adversity that cut across diagnoses. Games addressing childhood adversity directly remain uncommon, and where they exist, they have typically focused on prevention or disclosure, for example in child sexual abuse prevention [55], rather than on supporting young people already living with the consequences of ACEs. ACE of Hearts is distinctive in focusing on adversity-related themes nominated by young people themselves, and in treating those themes metaphorically rather than didactically.

Finally, our approach connects the serious games literature to trauma-informed and embedded ethics practice. Trauma-informed design has emerged as a distinct concern in human-computer interaction, emphasizing safety, choice, and control as design properties rather than as procedural safeguards [60]. A scoping review of ethical aspects of gamified mental health interventions for young people found that ethics is commonly interpreted narrowly as research ethics review, that co-design is frequently framed in instrumental terms, and that vulnerability is addressed pragmatically rather than systematically [61]. Work on participatory arts methods with young people affected by ACEs has raised parallel concerns about consent, representation, and emotional safety [53,54]. By running dedicated embedded ethics sessions inside the sprint cycle, and by documenting the resulting safeguarding decisions, our framework treats ethics as ongoing design work rather than as a gate passed before development begins, which is the practice these reviews call for.

Reflections on Youth Participation

Reflection on the limitations of participation is essential for advancing co-design methodology. The research and facilitation team brought perspectives from serious games and human-computer interaction, clinical psychology, psychiatry, medical ethics, and creative arts practice. We acknowledge that

XSL•FO
RenderX

these disciplinary lenses, and the inherent power asymmetry between adult researchers and young co-designers, shaped facilitation and interpretation. While young people were engaged as equal partners, power asymmetries inevitably remained. Such asymmetries are widely recognized in participatory work with young people, where involvement can slide toward tokenism unless decision-making influence is made explicit and visible [26]. The research team held decision-making authority over technical feasibility, budget allocation, and clinical safety considerations. Some design suggestions from young people (eg, multiplayer cooperative play) were noted for future development but could not be implemented within the current prototype due to resource constraints. We sought to mitigate these asymmetries through transparent communication about what was and was not feasible, and by documenting young people's rationales for suggestions that were not taken forward and revisiting them where possible.

Practical constraints also shaped the co-design process in ways that required ongoing negotiation. Most young participants were in school or college, meaning sessions had to be scheduled after school time to accommodate their availability. We conducted the majority of sessions online to enable participation from young people across England, enabling those in rural or coastal areas to contribute on equal terms. When it was necessary to bring young people and adult professionals together, we designed an accelerated EBCD day held online, in which participants were able to join and leave according to the specific mini-game under discussion as well as their own time constraints. This format was intensive but effective in maximizing reach, allowing us to gather feedback from a larger and more diverse group than a single in-person workshop would have permitted. Flexible and remote formats have similarly been reported to widen reach in co-design with young people, although they require deliberate attention to digital access and to sustaining engagement [57].

Implications

For research and development teams, the practical implication is that meaningful participation and iterative delivery can be run together, as work on agile-user experience integration and on participatory design in serious games has shown [33,56]. The transferable components of our study are concrete: co-design touchpoints tied to fixed sprint boundaries, a standing design decision log that records rejected as well as accepted suggestions, an explicit priority order when youth preference, clinical safety, technical feasibility, and ethics sessions are scheduled inside the development cycle. Co-design of this intensity requires facilitation time, payment for young people, safeguarding capacity, and practical constraints that are among the reasons co-design is often curtailed or reduced to consultation [26,28]. Where reporting standards for public involvement and for youth engagement increasingly expect demonstrable lived-experience involvement [40,41], an auditable "you said, we did" decision log also provides evidence that involvement shaped the product.

For services and practitioners, ACE of Hearts is designed as a self-guided resource for community and home use that can also be facilitated by a practitioner in youth, school, or community settings. Its plausible near-term roles are supportive rather than therapeutic, offering something to engage with while waiting for services, opening conversations about difficult experiences in a lower-stakes register, and modeling help-seeking through in-game signposting. Realizing any of this depends on implementation rather than on the artifact alone. Syntheses of real-world youth digital mental health delivery consistently find that embedding tools in existing services, sustaining engagement, and securing staff time and workflow fit are harder than building the technology [57]. Practitioners using the game with young people affected by ACEs would need clear guidance on the boundary between self-reflection and therapy [62,63].

Limitations

This work has several limitations. First, the current mini-games cover 4 ACE-related themes but do not encompass the full spectrum of adversities that young people experience. Second, our co-design participants, while diverse, were a relatively small group (N=18); thus, the narratives and characters may not fully capture the breadth of cultural backgrounds or individual differences [28]. Survey data were available for 14 of 18 participants, limiting the completeness of participant characterization. Third, there are potential risks associated with limited direct professional oversight in a standalone game. While in-game signposting to help-seeking was provided, we recognize that some players may require forms of support beyond the scope of the game. Future iterations should expand to include more adversities, involve a broader range of youth perspectives, and evaluate clinical and cost-effectiveness outcomes. Fourth, this study was conducted in England; the transferability of the game content and of the co-design framework to other cultural and linguistic contexts, age groups, health systems, and forms of adversity is untested. Finally, co-design preferences, however carefully documented, do not in themselves establish the safety, acceptability, or therapeutic value of the game for a wider population [60]. These require separately reported evaluation and future controlled studies.

Conclusions

In this paper, we presented the design and development of ACE of Hearts, a novel serious game that addresses ACEs through gameplay. By integrating EBCD with agile development and grounding the design in extensive co-design with young people, we created a prototype tailored to the perspectives and experiences of its target audience. The integrated EBCD-agile framework offers a transferable methodological model for future digital mental health innovation with vulnerable populations; its replicability should be tested in other settings. The transparent design decision audit trail demonstrates that meaningful youth participation can substantively shape serious game content, mechanics, and safeguards. The contribution of this study is primarily methodological, namely the documented EBCD-agile integration, within which the embedded ethics approach and the co-design feedback loop are design innovations. The resulting prototype illustrates how serious games may support awareness, self-reflection, and help-seeking, though its feasibility and effectiveness need further research. The game is not intended to replace professional care but to complement existing support systems by empowering young players to

XSL•FO
RenderX

explore their experiences and learn coping strategies in a safe, playful environment. We hope that the insights gained from this project will inform the future research and development of serious games for vulnerable populations, ultimately contributing to more creative and empathetic forms of mental health support for young people.

Acknowledgments

The authors wish to thank the participants who generously gave their time to take part in this research as well as the wider ATTUNE (Understanding Mechanisms and Mental Health Impacts of Adverse Childhood Experiences) team. We gratefully acknowledge the young people who co-designed ACE of Hearts and the Young People's Advisory Groups, whose insight and support were integral to the development of this work. We also wish to express our gratitude to the game development team, MSc Graham Smith, BA Flick Broadley, and BA Jamie Jones, for their creativity, commitment, and significant contribution to the design and development of ACE of Hearts. The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (2025; Generative AI Delegation Taxonomy), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing. The GenAI tool used was Claude Opus 5 (Anthropic PBC). Responsibility for this final paper lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the outcomes. Declaration submitted by HZ.

Abstract

Background: Exposure and response prevention is a first-line intervention for obsessive-compulsive disorder (OCD), yet many individuals with contamination concerns do not access care. Virtual reality exposure–based therapy (VRET) may improve scalability and acceptability.

Objective: This pilot study evaluated the feasibility and acceptability of a standardized single-session VRET protocol targeting contamination concerns and whether it elicited within-session anxiety and exploratory contamination symptom change at 1-month follow-up.

Methods: We conducted a single-arm pilot study in adults with elevated contamination concerns and no formal OCD diagnosis, recruited via convenience sampling. Participants completed a baseline survey, an in-laboratory VRET session using a standardized virtual public toilet environment, and a follow-up survey. Outcomes included momentary anxiety (Subjective Units of Distress Scale) during exposure, affect (positive and negative affect schedule) across time points, and contamination symptoms (Obsessive-Compulsive Inventory–Revised contamination subscale) at baseline and follow-up. Usability (System Usability Scale) and VR sickness were also assessed. Within-session outcomes used repeated-measures ANOVA or Friedman tests; symptom change used paired *t* tests (α=.05); point estimates include 95% CIs. Missing data were addressed using multiple imputation (random forest; m=5); 37.5% of participants did not complete the follow-up survey (overall missingness: 5.47%).

Results: Sixteen participants were included (aged 18 - 32 years). Anxiety increased during exposure tasks and decreased after virtual hand washing in both trials (Exposure 1 Friedman Test: χ^2_3=28.56; *P*<.001; W=0.6); Exposure 2 repeated measures ANOVA: $F_{1.85,\ 27.81}$=5.35; *P*=.01; Greenhouse-Geisser corrected=0.058. Negative and positive affect both changed significantly across time points (negative affect: Friedman Test: χ^2_3=13.76; *P*=.003; W=0.29 and positive affect: repeated measure ANOVA: $F_{3,\ 45}$=4.60 - 4.71; *P*=.006-.007; Greenhouse-Geisser corrected=0.07 - 0.073). Contamination symptoms did not significantly change from baseline to follow-up (mean change 1.30, SD 3.39; 95% CI –0.36 to 2.96; *P*=.12). Usability was adequate (System Usability Scale mean 69.5, 95% CI 62.79-76.21).

Conclusions: This study is among the first to systematically evaluate a standardized single-session contamination-focused VRET protocol in adults with elevated contamination concerns who did not meet diagnostic criteria for OCD, a subthreshold population underrepresented in prior VRET research, which has focused on clinically diagnosed samples and multisession protocols. The protocol proved feasible and acceptable, eliciting within-session anxiety and providing benchmarks in existing clinical literature. Contamination symptom change at 1-month follow-up was not statistically significant, and the effect size estimate was sensitive to the missingness assumption, underscoring the need for adequately powered multisession designs in future trials. The usability profile and VR sickness levels that did not prevent session completion suggest self-administered or minimally supervised delivery warrants evaluation, with implications for scalable early intervention in individuals with elevated contamination concerns who have not accessed formal treatment.

Introduction

Background

Obsessive-compulsive disorder (OCD) is a disorder characterized by intrusive thoughts, images, or urges, which are distressing and often result in repetitive physical or mental acts that the individual feels driven to perform to temporarily alleviate their distress [1]. It is associated with income loss, decreased quality of life, and substantial economic burden [2,3]. According to the National Comorbidity Survey Replication, the lifetime prevalence of OCD is approximately 2.3% [4], though this is thought to be an underestimate due to the stigma often experienced by those with OCD, leading to underreporting of symptoms [5]. The most widespread dimension experienced by people with OCD concerns contamination/washing, with up to 50% of people with OCD reporting contamination-related symptoms [1]. These fears often manifest as persistent and intrusive thoughts about being contaminated by germs, dirt, or other harmful substances [1], and typically drive compulsive washing or cleaning behaviors, which the individual performs repeatedly to reduce anxiety and prevent perceived contamination [6]. This cycle of obsessive fear and ritualistic behavior can significantly interfere with daily functioning and overall quality of life.

The prevalence of contamination-related OCD has increased since the COVID-19 pandemic [7]. Similarly, symptoms related to fear of contamination have also increased in nondiagnosed populations [7], although it remains unclear whether they will remain elevated. People with mild or undiagnosed OCD symptoms are often overlooked in treatment and research, despite evidence demonstrating that conditions falling below diagnostic cut-offs for anxiety-related disorders still have considerable clinical significance, and these early signs can often predict meeting full diagnostic criteria for OCD in the future [8-10]. This could be due to reasons such as not meeting the criteria for severity of symptoms, recurrence, presence of obsessions without compulsions, insufficient time consumption, or not causing significant day-to-day impairment. Undiagnosed individuals may include those who meet the criteria for diagnosis but have not sought or had the opportunity to receive a diagnosis, as well as those who do not meet diagnostic criteria (also called subclinical or subdiagnostic symptoms, but described in this paper as not meeting diagnostic criteria). As symptoms occur on a continuum [11], research into symptoms that do not meet diagnostic criteria is of clinical value. Symptoms of anxiety-related disorders, including OCD, exhibit significant comorbidity and sequential comorbidity with each other, even at levels below the clinical threshold [12,13]. Gaining a deeper understanding of OCD symptoms below the diagnostic threshold could pave the way for early intervention, reducing the risk of progression to clinical diagnosis.

Traditional Treatment

The traditional first-line gold-standard treatment for OCD is cognitive-behavioral therapy incorporating exposure and response prevention [14], which is considered a key active ingredient of this approach. Exposure-based therapy involves confronting a fear-provoking stimulus in a controlled environment, enabling anxiety habituation and/or belief disconfirmation. Its effectiveness as an intervention for fear and anxiety has been well-documented [15,16]. Nevertheless, exposure-based therapy is not for everyone. The majority of people with OCD cannot access evidence-based treatment [17]. Even among those with access to treatment, delays are common, with the average untreated illness lasting over 7 years [18]. These delays are concerning, as longer durations of untreated illness are associated with poorer treatment outcomes [19] and spontaneous remission is rare in OCD [20]. Hurdles to receiving treatment include cost, finding a relevant clinician, and taking time off from school/work for multiple sessions [21]. Thus, new intervention solutions are necessary to effectively address these evolving challenges.

Virtual Reality–Delivered Exposure-Based Therapy

Digital exposure therapy offers a promising solution to treatment access barriers, providing benefits such as scalability, personalization, and a lower refusal rate compared to traditional exposure-based therapy, suggesting individuals may be more open to it [22-24]. Virtual reality (VR) is an immersive technology in which a participant experiences and engages with a customized virtual environment other than the external physical environment around them [25]. It has been successfully used to deliver therapy for various conditions such as posttraumatic stress disorder, addiction, eating disorders, and acute and chronic pain, as well as for many anxiety-related disorders, such as generalized anxiety disorder, social anxiety disorder, and numerous phobias [26].

Meta-analyses suggest that virtual reality exposure–based therapy (VRET; also known as VRE) is effective for various anxiety-related disorders and is not inferior to traditional in vivo exposure therapy [27,28]. Due to its potential to encourage realistic behavior in the virtual environment, it is believed that the plausibility and sense of physical presence (ie, being physically present and immersed) in the VR environment enhance engagement, making exposure therapy more effective [29]. Additionally, the documented lower refusal rate may be especially beneficial for the treatment of OCD due to its typical high refusal and drop-out rates [30,31]. VRET can be conducted in a clinical setting, administered by a clinician, or self-administered at home. This flexibility enables individuals to receive treatment without necessarily needing to take time off work or school for travel.

Nevertheless, VRET is not without its limitations. Individuals may experience VR sickness (also called cybersickness), which presents as dizziness, nausea, and other similar motion sickness–related symptoms. While accessibility is a challenge for VRET, as VR technology is still in early stages of adoption by the general public, the global VR market is forecast to hit US $103 billion by 2027 [32]. The hope is that advancements will make it increasingly accessible, potentially even more so

XSL•FO
RenderX

than traditional treatment. Developing an optimal protocol for its operation and implementation to maximize effectiveness and safety remains a crucial challenge.

A modest but growing literature suggests that virtual reality can be used to provoke obsessive-compulsive-relevant distress and deliver exposure-based procedures, including contamination-focused paradigms [33-36]. Collectively, these reviews suggest increasing support for VR as a tool for symptom provocation and exposure delivery in OCD, while also highlighting heterogeneity in protocols and a need for more standardized approaches and clearer characterization of target populations. Recent systematic reviews and meta-analyses have summarized extended reality (XR)/VR applications for OCD and contamination-related concerns, including both clinical and nonclinical samples [37-40], and randomized studies have compared VR-based exposure and response prevention with in vivo exposure approaches [33,41]. Against this background, there remains limited work examining standardized single-session VR exposure protocols in individuals with elevated contamination concerns who do not meet diagnostic criteria for OCD, despite potential relevance for scalable early intervention and for improving treatment engagement. VR environments designed for exposure-based therapy have been validated in their ability to provoke OCD-relevant distress and compulsive behaviors, yet some findings [34] suggest they may not consistently sustain anxiety levels throughout exposure, which could affect fear extinction processes and optimization of exposure dose. However, an earlier study [35] suggested that repeated VR exposure can reduce contamination-related distress, demonstrating its potential as an intervention. Research in comparisons between VRET and in vivo exposure also indicates that VR can provoke similar anxiety responses during exposure, but protocol standardization and long-term effectiveness remain unresolved [42]. Additionally, while VR has been shown to effectively provoke contamination-related anxiety and disgust, its impact on symptom reduction has not been fully examined, limiting its clinical applicability [36]. These gaps highlight the need for systematic, carefully controlled VRET research that explores its efficacy in anxiety induction, symptom reduction, and participant acceptability.

In addition to this broader evidence base, early studies on VRET for contamination fear [35,36] established proof of concept but faced significant limitations. Variability in session lengths, number of sessions, and VR scenario content hindered protocol standardization, limiting the clinical relevance and reproducibility of findings [35]. Moreover, previous studies [35,36] offered limited exploration of user experience, such as how individuals perceive and respond to VR interventions, usability of the program, or whether the VRET program was deemed acceptable by participants as an intervention.

Prior VR exposure studies for contamination concerns have varied substantially in dose, including session length, number of sessions, and exposure structure, which complicates interpretation and replication across studies and limits the ability to identify which procedural elements are most responsible for observed effects. In the present study, we selected a single-session design to standardize intervention delivery and evaluate the feasibility, acceptability, and anxiety elicitation capacity of a clearly specified VR exposure protocol. This approach also aligns with broader work on single-session interventions that aim to increase scalability and reduce barriers to engagement, while generating preliminary parameter estimates to guide subsequent multisession and controlled trials [43]. The single-session format was therefore intended as an initial, low-burden step to test whether a standardized contamination-focused VR exposure session could reliably induce distress during exposure tasks and be tolerated by participants.

This Study

To address limitations of prior studies, this small-scale pilot study evaluated the feasibility and acceptability of a standardized single-session VR exposure protocol targeting contamination concerns and characterized within-session distress responding. Symptom outcomes were assessed exploratorily from baseline to 1-month follow-up to inform future controlled trials. This study sought to address the variability found in earlier research by using a standardized protocol with 2 identical exposures within a single session, modeled after Inozu et al [36], Schleider et al [44], and Schleider and Beidas [43], ensuring consistent conditions for all participants and enhancing the reliability of the findings. Additionally, by studying participant experience, including acceptability, VR sickness, and feedback for potential improvements, we aimed to advance understanding of the usability of VRET and inform future intervention design. As no prior studies have focused on this group, we did not formulate specific hypotheses. Instead, we explored the following research questions: (1) Can this single-session VRET intervention effectively induce anxiety to facilitate exposure? (2) How do participants rate their experience of the VRET, and do they find it acceptable as an intervention? (3) What preliminary changes in self-reported contamination symptoms are observed from baseline to 1-month follow-up?

Methods

Inclusion and Exclusion Criteria

Participants were recruited via Instagram (Meta) advertisements and posters placed around the main campus of Imperial College London, directing them to an online screening survey on Qualtrics. The advertisements and posters inquired if potential participants found public toilets stressful and invited them to participate in a VR study exploring discomfort around contamination. This recruitment approach reflects convenience sampling of volunteers responding to study advertisements.

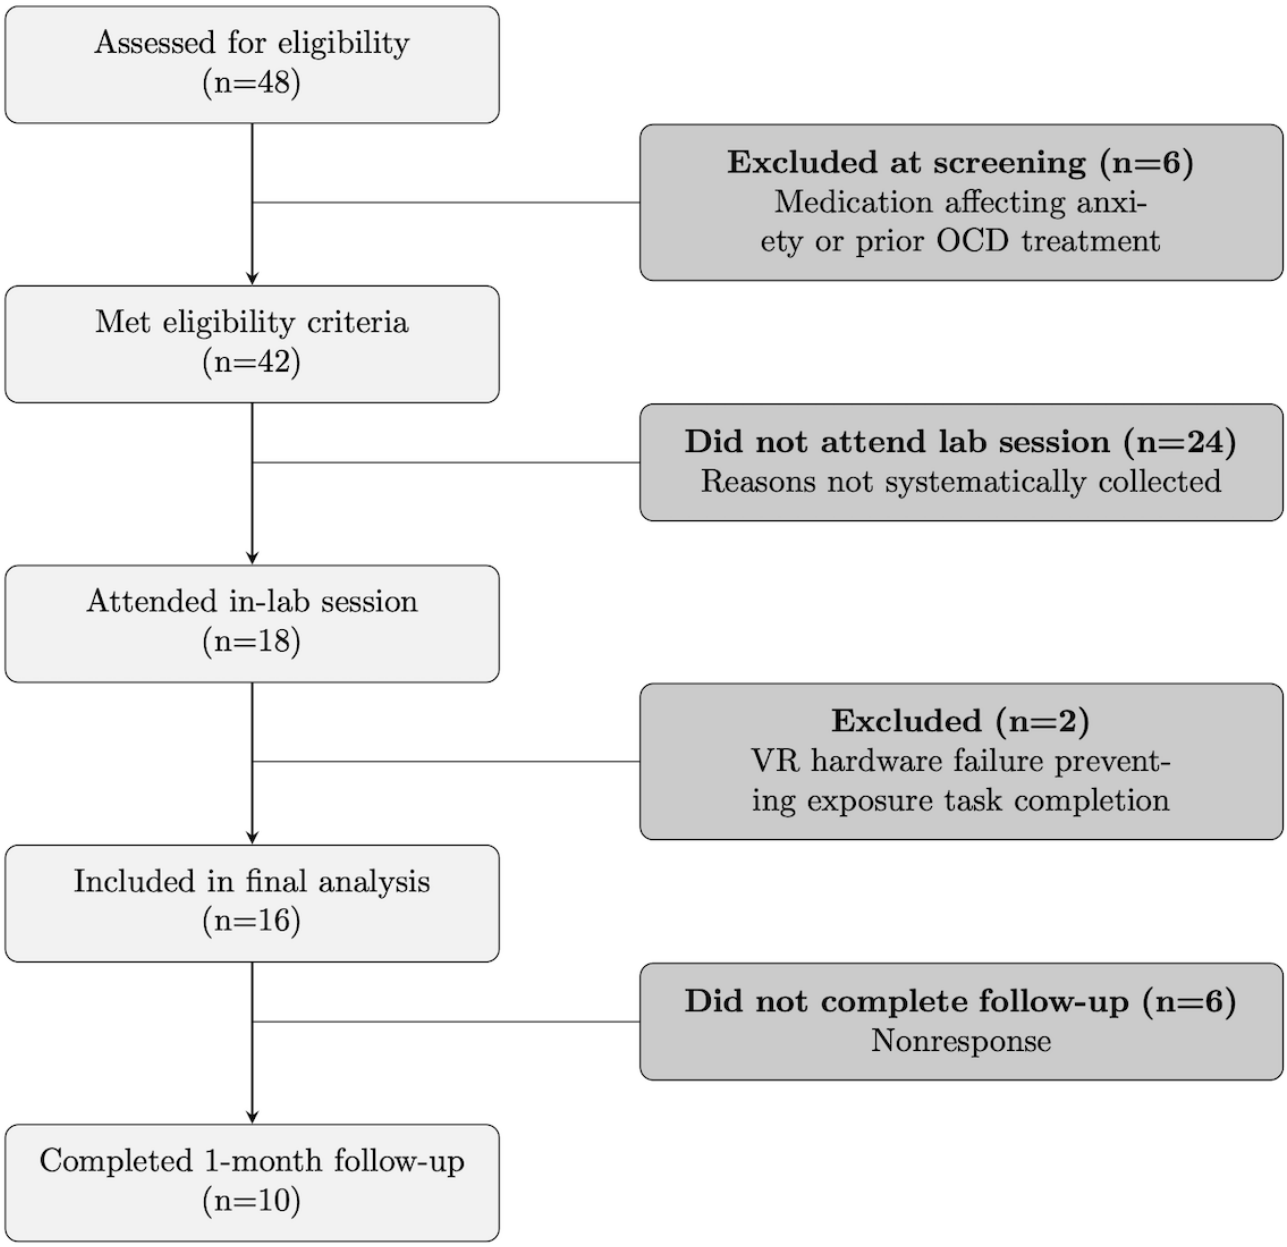
A total of 48 individuals opened the online screening survey. Of these, 6 were excluded at screening, primarily due to self-reported use of medication that could affect heart rate or anxiety responses and self-reported current or past treatment for OCD. Forty-two individuals met eligibility criteria and were invited to participate. Eighteen participants scheduled and attended the in-laboratory session.

Participants were required to be 18 years or older English speakers with contamination concerns. To capture a full range of contamination-related anxiety, these concerns were defined as either a score greater than 0 on the contamination subscale

XSL•FO
RenderX

of the Obsessive-Compulsive Inventory–Revised (OCI-R [45]) or a response of 3, 4, or 5 (indicating "sometimes," "often," or "always") to at least one of the following questions/statements constructed for the purposes of this study: (1) "I experience anxiety or distress when I see a dirty toilet," (2) "How often do you find yourself avoiding public toilets due to fear or worry that they might be too dirty?" and (3) "How often do you find yourself unable to use public toilets due to fear or worry that they might be too dirty?"

Exclusion criteria included reporting any condition precluding adherence to the measurement protocol (such as difficulty reading or writing), any uncorrected visual and/or auditory impairment affecting full participation in VR (use of corrective lenses or hearing aids was not a criterion for exclusion), current or past diagnosis of OCD (to target below-threshold OCD symptoms), current or past treatment for OCD (including psychological and pharmacological therapies), presence or history of epilepsy, and history of severe motion sickness or dizziness. Participants were also excluded if they self-reported taking medication at the time of this writing that affected heart rate, such as benzodiazepines. Eligibility and exclusion criteria were assessed entirely by self-report in the screening survey.



Sampling Procedures

A total of 18 participants signed up and gave informed consent. Data from 2 participants were excluded due to technical difficulties with the VR hardware, leaving 16 participants in the final analysis. Ten of these 16 (62.5%) participants completed the one-month follow-up survey.

Participant Characteristics

Participant characteristics are summarized in the Results section. The participant flow is illustrated in Figure 1.

Figure 1. Participant flow diagram for a single-arm, pretest–posttest, single-session virtual reality (VR) exposure pilot study in adults with subthreshold contamination concerns at Imperial College London (London, United Kingdom), February-June 2023. OCD: obsessive-compulsive disorder.

XSL•FO
RenderX

Procedure

We conducted a single-group, pretest-posttest pilot study with a one-month follow-up. Participants who met the inclusion criteria and consented to take part in the study were invited to an in-laboratory session where they were given an online Qualtrics (Qualtrics LLC) survey to collect baseline information on their OCD symptoms and factors that may influence their levels of anxiety (eg, medication taken, exercise today, and illness). Participants were then given a brief information sheet about exposure therapy and read a short script providing the context to the VR scenario they would experience shortly.

Before entering the VR environment, participants were asked to select the skin color of their avatar. This was done to enhance the experience of embodiment in the virtual environment. Participants then experienced 2 identical self-paced VR exposures and viewed a short neutral video between exposure sessions. Virtual hand-washing was included as the concluding element of each exposure trial. This was a deliberate design choice reflecting the ecologically valid sequence of behavior in a public toilet context, as washing hands is a normative response after toilet use, and it was supported by the structure of the Amelia by XR Health (XRHealth) environment. Consistent with the study's pilot aims, which centered on feasibility, acceptability, and anxiety elicitation rather than delivering a full exposure and response prevention (ERP) protocol, response prevention was not imposed. This design choice is acknowledged as a limitation when interpreting the anxiety reduction data (see Discussion). Participants were asked to rank their anxiety (Subjective Units of Distress Scale [SUDS]; [46]) 4 times during each exposure. They reported on their affect (Positive and Negative Affect Schedule [PANAS]; [47]) before, between, and after these VR sessions. They were then asked about VR presence and plausibility, with additional repeated measures taken on affect. One month later, an online follow-up survey was emailed to participants to assess OCD symptoms, attitudes relating to contamination, and positive and negative affect.

Ethical Considerations

Ethics approval was granted by the Imperial College Research Governance and Integrity Team (Reference number: 22IC7615). All participants provided informed consent prior to completing any study procedures, and participants could discontinue participation at any time without penalty. Data were collected using Qualtrics and stored in access-controlled systems; data were deidentified prior to analysis and reported only in aggregate form. Participants who completed the in-laboratory session were entered into a raffle to win a £30 (approximately US $36.22; conversion rate: 1 GBP=US $1.2073; February 2023 monthly average) Amazon e-voucher; compensation was not contingent on completion of the one-month follow-up survey. The manuscript figures and materials do not include identifiable images of participants.

Measures and Covariates

Demographics

Participants self-reported age, sex, and whether their gender identity matched their sex assigned at birth. They were also asked to self-report variables that could impact anxiety, including caffeine intake, exercise, medication, and illness. Additional demographics, such as ethnicity and education, were not collected to keep the protocol brief given the low-burden compensation and to minimize collection of potentially identifying information, consistent with ethics review guidance.

Psychiatric Diagnoses

Participants self-reported any past or current psychiatric diagnoses. Participants reported contamination-featured OCD symptoms using the Washing subscale of the OCI-R at baseline (α=.83; SE 0.07; 95% CI 0.68-0.97) and at one-month follow-up (α=.59; SE 0.19; 95% CI 0.22-0.95). The OCI-R is a widely used self-report measure of OCD symptoms, comprising 18 items that assess symptoms across 6 subscales. Each item is rated on a 5-point Likert scale ranging from 0 ("not at all") to 4 ("extremely"). The contamination subscale includes 3 items, with a total score range of 0-12, where higher scores indicate greater contamination-related distress.

Anxiety and Affect

Momentary anxiety was measured using the one-item SUDS rated on a scale from 0 to 10, administered verbally during each VR exposure. To measure positive and negative affect, the short form of the PANAS was administered at baseline (positive subscale: α=.82; SE 0.07; 95% CI 0.69-0.95; negative subscale: α=.71; SE 0.11; 95% CI 0.50-0.92), after the first VR exposure (positive subscale: α=.76; SE 0.09; 95% CI 0.58-0.93; negative subscale: SE 0.05; 95% CI 0.58-0.93), after the break between exposure sessions (positive subscale: α=.82; SE 0.07; 95% CI 0.70-0.95; negative subscale: SE 0.04; 95% CI 0.80-0.97), and after the second VR exposure (positive subscale: α=.83; SE 0.06; 95% CI 0.70-0.95; negative subscale: α=.95; SE 0.02; 95% CI 0.91-0.99). The PANAS consists of 2 scales (one for positive affect and one for negative affect), both on a 5-point Likert scale.

User Experience and Acceptability

VR presence and plausibility were measured by 2 questions each that were created for this study, adapted from Slater [29]. To measure VR plausibility, we asked participants to compare the virtual environment to (1) a real public toilet and (2) an imagined public toilet environment. The responses are on a 5-point Likert scale, where 1 is much more anxious in VR and 5 is much more anxious in the real or imagined public toilet environment. VR sickness was measured using the Simulator Sickness Questionnaire (SSQ [48]) at baseline (α=.86; SE 0.05; 95% CI 0.76-0.96) and postintervention (α=.77; SE 0.08; 95% CI 0.60-0.93). The SSQ is on a 4-point Likert scale. Acceptability was measured using the System Usability Scale (SUS [49]) on a 5-point Likert scale and an α of .81 (SE 0.07; 95% CI 0.68-0.95), as well as open-ended questions for descriptive analysis, such as "How did you feel while you were taking part in the virtual reality experience?" and "In your opinion, is there anything that could have been done differently to improve the software or create a better experience (in any aspect)?"

XSL•FO
RenderX

Equipment and Environment

We used Amelia by XR Health's public-toilet VR environment, which depicts a contaminated public toilet in a subway area (Figure 2). The scenario begins with the participant standing outside the door of a public toilet. The participant sees other individuals by the cubicles and the sink upon entering. The participant is able to enter the cubicle in front of them and interact with the toilet-related elements (eg, toilet lid, toilet paper, and toilet brush) and can sit down on the toilet (the participant can simultaneously sit in a chair in the real world to mirror their position in VR). The participant is then placed in front of the sink and able to wash their hands in the virtual scenario. The software was run on PICO G2 (Pico Interactive Inc) head-mounted display VR headsets.

The VR environments are controlled through Amelia by XR Health's online platform, where the following actions can be taken: open the entrance door, open the cubicle door, touch the wall while standing inside the cubicle, lower the toilet lid, flush the toilet, touch the wall while sitting on the toilet, take toilet paper, touch the toilet brush, and wash hands. In this study, participants completed the actions in the given order at their own pace. When asked to sit on the virtual toilet, a real-life chair was provided to heighten the sense of immersiveness in the virtual environment.

Figure 2. Screenshot of the Amelia by XR Health virtual public toilet environment used in a single-arm, pretest-posttest, single-session virtual reality exposure pilot study in adults with subthreshold contamination concerns at Imperial College London (London, United Kingdom), February-June 2023.

Sample Size, Power, and Precision

In this study, feasibility refers to whether the protocol could be successfully conducted, encompassing recruitment, retention, protocol adherence, and data completion, while acceptability refers to participant experience and willingness to engage with the intervention, indexed by usability ratings, VR sickness, and qualitative feedback. These constructs are treated as distinct throughout, consistent with pilot study reporting conventions [50,51]. This study was designed as a pilot to evaluate feasibility and acceptability of a standardized single-session VR exposure protocol and to characterize within-session distress responding. As a planning benchmark, prior VRET studies reported effect sizes ranging from Hedges g=0.88-1.08 [27,28], and a sample of 14-20 participants would be needed to detect effects in this range at α=.05 and power=0.95 using a 2-tailed Wilcoxon signed-rank test. However, these effect sizes derive from multi-session interventions in clinical samples and may not generalize to a single-session, subthreshold pilot; accordingly, this calculation should be understood as an approximate recruitment benchmark rather than a definitive power analysis for detecting symptom change in this design. The study was not powered to detect small-to-moderate changes in contamination symptoms.

Data Analysis

Pilot studies are commonly sized to support preliminary estimation (eg, variability and CIs) and to identify procedural issues relevant to scaling, rather than to provide definitive hypothesis tests of clinical efficacy [52]. Accordingly, we aimed to recruit approximately 15-30 participants, which is consistent with common recommendations for feasibility and pilot work and sufficient to yield stable estimates of feasibility and acceptability outcomes and to inform the design of future randomized trials [53].

The study was preregistered on AsPredicted (AsPredicted.org) [54]. After preregistration, we refined the analytic focus to prioritize outcomes directly related to the study's primary aims of feasibility, acceptability, and within-session distress responding, as well as exploratory symptom change at follow-up. Accordingly, several secondary measures that were collected (Patient-Reported Outcomes Measurement Information System, Work and Social Adjustment Scale, and Distress Tolerance Scale) were not analyzed in the present report because they were not central to these aims and would substantially expand the number of analyses in a small pilot sample. The Distress Tolerance Scale was included as a trait-oriented measure and was not designed to assess within-session change during exposure, which was the focus of the current analyses.

XSL•FO
RenderX

Physiological data were also collected but were not analyzed in this study.

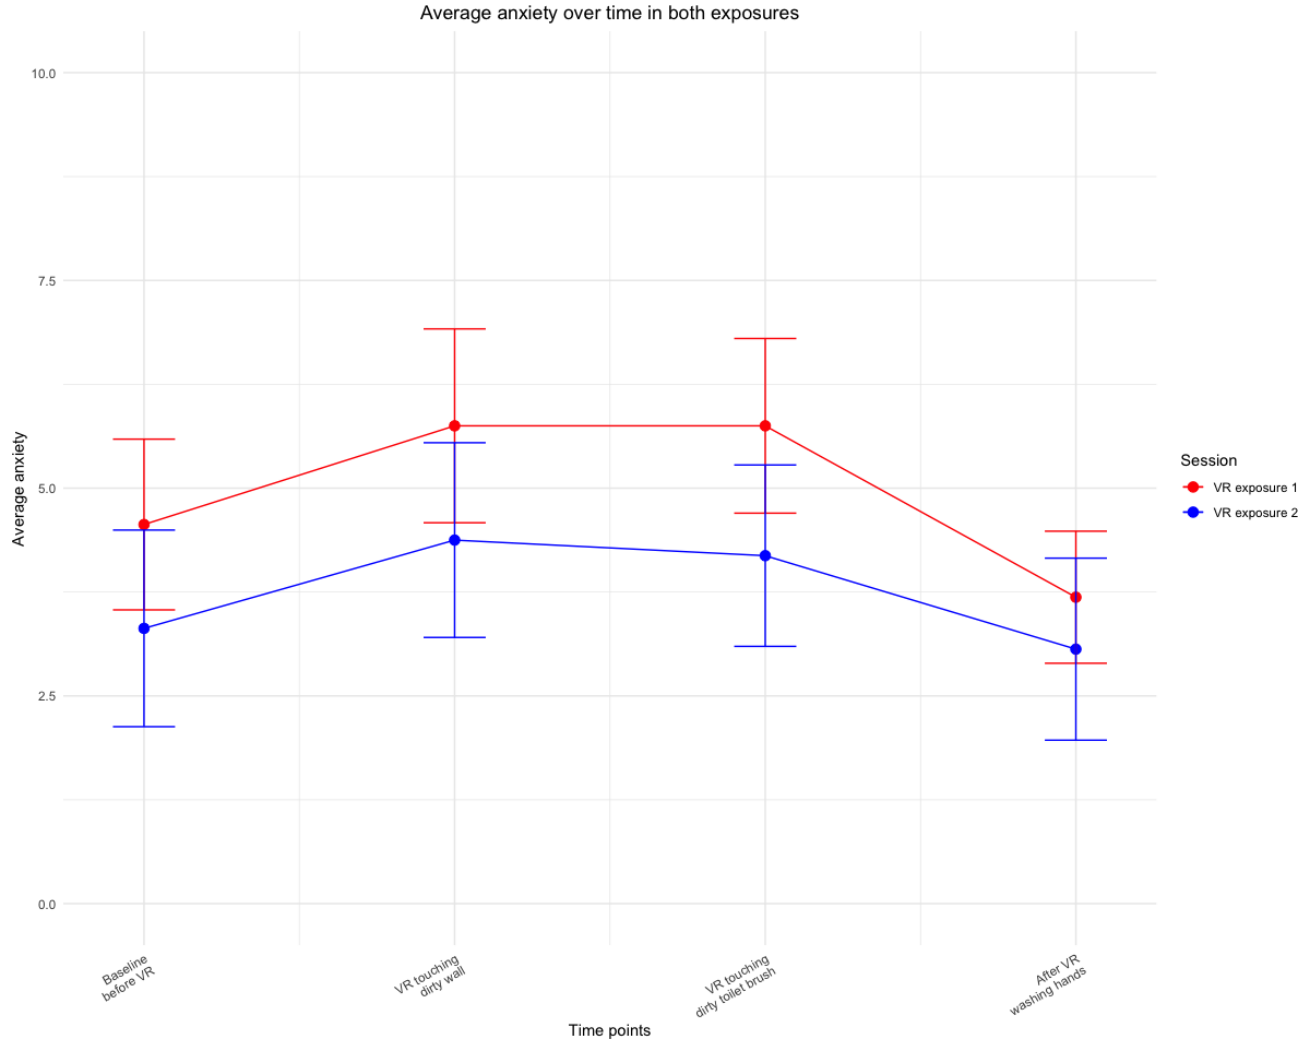
Although the preregistration noted an expected pattern of distress activation and reduction during exposure, the present report is framed around research questions consistent with the study's pilot aims rather than formal hypothesis testing. Two participants were excluded due to VR hardware issues that prevented completion of the exposure task and resulted in incomplete data.

Statistical analyses were performed in R (R Core Team). Data were analyzed to explore symptom outcomes, participant experience, and potential outcome predictors. To examine symptom outcomes, statistical analyses were selected based on normality assessments (Shapiro-Wilk tests). Repeated measures ANOVAs were conducted for variables meeting assumptions of normality (positive affect), while Friedman tests, a nonparametric alternative, were used for variables violating these assumptions (negative affect and anxiety levels). For within-session SUDS ratings, normality was evaluated separately for each exposure trial; Exposure 1 SUDS violated distributional assumptions and was analyzed using the Friedman test, whereas Exposure 2 SUDS met normality assumptions and was analyzed using a repeated-measures ANOVA (Greenhouse-Geisser corrected as needed). Given the pilot sample and the similarity of the 2 exposure trials, we interpret inferential results within each trial descriptively and avoid overinterpreting differences in statistical significance between trials. Paired *t* tests were additionally performed to compare pre- and postintervention scores for contamination symptoms, which met normality criteria. Results that were identical across the 5 imputed datasets (ie, did not use any imputed data) were reported based on a single calculation from one dataset, while results based on missing data were pooled using Rubin's rules if appropriate. For Friedman and ANOVA, a range was reported to show variation in results across datasets. Effect size calculations were conducted to investigate the magnitude of changes. To examine participant experience, descriptive data for virtual sense of presence and plausibility, descriptive data for intervention acceptability, frequency of item endorsement on the SUS, and open-answer participant feedback for areas of intervention improvement were examined. As an exploratory analysis, we examined whether baseline contamination severity (OCI-R contamination subscale) was associated with peak subjective distress during the VR protocol, indexed by the SUDS rating collected at the end of the first VR exposure, prior to virtual handwashing (following the highest-intensity contact task), which was expected to capture the highest distress response relative to the second exposure. Mixed effects models were considered but not emphasized due to limited precision in a small pilot sample.

Overall cell-level missingness was 5.47%. However, 6 out of 16 (37.5%) participants did not complete the 1-month follow-up survey, resulting in missing follow-up symptom data. Missingness was primarily due to follow-up nonresponse and occasional skipped questionnaire items. Because missingness could not be assumed, particularly for follow-up nonresponse, we addressed missing values using multiple imputation with chained equations (random forest) under a missing-at-random assumption conditional on observed variables included in the imputation model. Five imputed datasets were generated; estimates were pooled using Rubin's rules when appropriate, and for omnibus repeated-measures tests we report the range of results across imputations. Statistical significance was defined at $P<.05$.

Little's missing completely at random test was not feasible due to the perfectly monotone missing data pattern; the same 6 participants were missing all follow-up variables, as none of them returned the one-month follow-up survey. This rendered the covariance matrix required by the test rank-deficient. As an alternative diagnostic, we compared completers and noncompleters on baseline contamination scores and baseline negative affect using Mann-Whitney *U* tests. No statistically significant differences were found (contamination: W=39, $P=.35$; negative affect: W=37.5, $P=.44$), providing limited but consistent evidence that follow-up nonresponse was not strongly predicted by baseline symptom severity or affect.

Results



Overview

The sample comprised 6 females, 9 males, and 1 individual who preferred not to say; 87.5% of participants reported a gender identity that matched their sex assigned at birth. Participants were aged 18 - 32 (mean 21.75, SD 3.86) years.

Baseline contamination symptoms (as measured by the contamination subscale on the OCI-R) ranged from 0 to 11 (mean 5.75, SD 3.51), out of a maximum score of 12. One participant scored 0 on the OCI-R contamination subscale at baseline but met study eligibility criteria based on screening endorsement of contamination concerns and reported distress during the VR exposure tasks. Figure 3 presents responses from the 12 participants who completed the screening items. Responses to the question "How often do you find yourself avoiding public toilets for fear or worry that they might be too dirty?" were distributed as follows: always (n=1), often (n=7), sometimes (n=2), rarely (n=1), and never (n=1). Responses to the question "How often do you find yourself unable to use public toilets for fear or worry that they might be too dirty?" were always (n=0), often (n=5), sometimes (n=5), rarely (n=1), and never (n=1). For the statement "I experience anxiety or distress when I see a dirty toilet" responses were always (n=4), often (n=4), sometimes (n=2), rarely (n=2), and never (n=0). Four out of 16 participants (25%) reported having prior VR experience. Table 1 displays descriptive statistics for the main study variables. Correlations between primary variables of interest were examined and are presented in Table S1 in Multimedia Appendix 1. No unexpected associations were observed.

[a]OCD: obsessive-compulsive disorder.

[b]Perceived OCD 1: “I experience anxiety or distress when I see a dirty toilet.”

[c]Perceived OCD 2: “How often do you find yourself avoiding public toilets for fear or worry that they might be too dirty?”

[d]Perceived OCD 3: “How often do you find yourself unable to use public toilets for fear or worry that they might be too dirty?”

[e]Presence 1: “I had the sensation of being in the public toilet.”

[f]Presence 2: “I had the sensation that the scenario was really happening.”

[g]Plausibility 1: “Compared to a real public toilet, did you feel as uncomfortable and/or anxious in the virtual environment?”

[h]Plausibility 2: “Take a second to imagine that you are in a public toilet. Compared to this imagined public toilet, did you feel as uncomfortable and/or anxious in the virtual environment?”

Symptom and Anxiety Outcomes

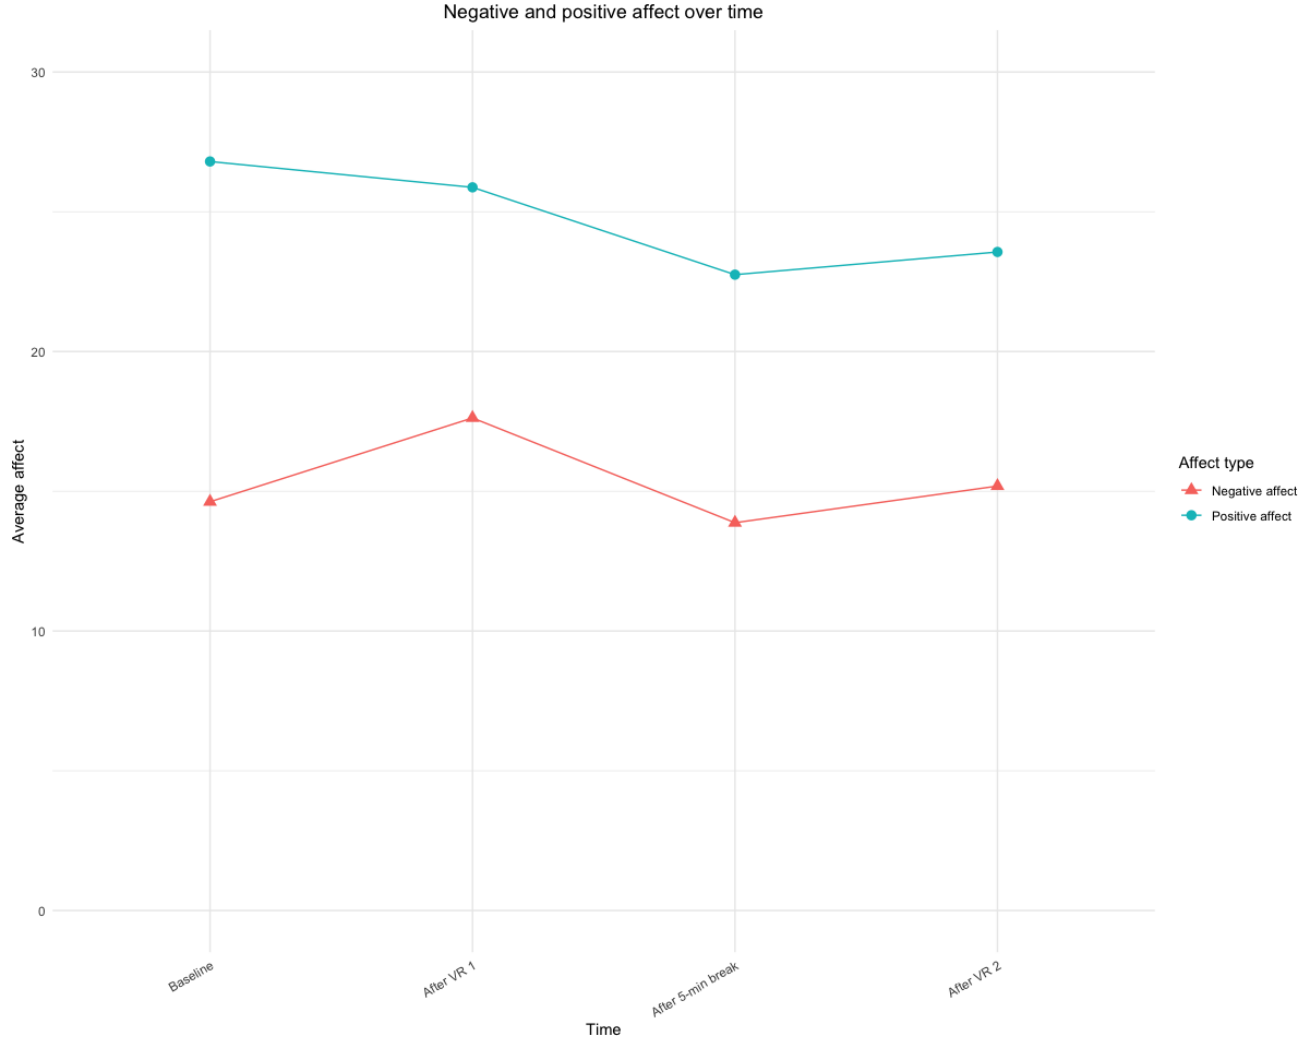
The Friedman test for negative affect indicated a statistically significant difference across session time points (χ^2_3=13.76; *P*=.003; W=0.29), with negative affect increasing after Exposure 1, returning toward baseline after the neutral break, and increasing again after Exposure 2. The repeated measures ANOVA for positive affect revealed a statistically significant difference during the VRET session (range across 5 imputed datasets: $F_{3,\ 45}$=4.60-4.71; *P*=.006-.007; generalized eta squared=0.070-0.073), with positive affect decreasing from baseline to the end of Exposure 1 and then increasing from the break to the end of Exposure 2. For anxiety in the first VR exposure, the Friedman test indicated a statistically significant difference in SUDS scores across time points (χ^2_3=28.56; *P*<.001; W=0.60), with anxiety increasing during exposure and decreasing following virtual handwashing. For the second VR exposure, a repeated measures ANOVA again indicated a significant difference in SUDS scores across time points (Greenhouse-Geisser corrected: $F_{1.85,\ 27.81}$=5.35; *P*=.01; generalized eta squared=0.058), with anxiety increasing during exposure and decreasing following virtual handwashing.

As an exploratory analysis, we examined whether baseline contamination severity (OCI-R contamination subscale) was associated with within-session distress during the VR protocol, indexed by the third SUDS during the first exposure trial (prior to virtual handwashing). Baseline contamination severity was not significantly correlated with peak distress (Spearman ρ=0.18; *P*=.51). Given the small sample size (n=16), the CI around this estimate is extremely wide and includes both strong positive and strong negative relationships; accordingly, no conclusions can be drawn from this analysis.

Figure 3 displays a graph of average anxiety levels over both VR exposures, including the 4 tasks that the participants experienced. Anxiety levels rose from baseline as participants interacted with the contaminated-looking VR environment and declined after exposure when they performed virtual handwashing. Highest levels of anxiety were reported when participants were engaging most directly with the contaminated environment (eg, touching the dirty-looking stall wall or toilet brush).

Figure 4 illustrates average negative and positive affect over time, showing an increase in negative affect from baseline after the first VR exposure, a return to baseline following a 5-minute break, and another rise after the second VR exposure. Positive affect declined after the 5-minute break, with a slight decrease from baseline to the end of the first VR exposure, followed by a small increase from the break to the end of the second VR exposure.

To explore changes in contamination symptoms from baseline to 1-month follow-up, we conducted a paired-samples *t* test comparing OCI-R contamination scores at baseline (mean 5.75, SD 3.51) and at one-month follow-up (mean 4.45, SD 2.38). The results were not statistically significant ($t_{349.57}$=1.54; *P*=.12; 95% CI –0.36 to 2.96), with an effect size of Hedges *g*=0.40. The large degrees of freedom reflect the multiple imputation



XSL•FO
RenderX

pooling approach and the low fraction of missing information for this estimate. However, the CI included 0, indicating uncertainty in the magnitude of symptom change.

A complete-case sensitivity analysis was conducted restricted to the 10 participants with observed follow-up data. The complete-case paired *t* test yielded a mean difference of 0.40 (95% CI −0.96 to 1.76; t_9= 0.67; *P*=.52; Hedges *g*=0.12), compared with the imputed estimate of 1.30 (95% CI −0.36 to 2.96; $t_{349.57}$=1.54; *P*=.12 Hedges; *g*=0.40). The divergence between these estimates, particularly the reduction in effect size from Hedges *g*=0.40 to Hedges *g*=0.12, indicates that the imputed contamination finding is sensitive to the missingness assumption. The PANAS outcomes showed greater consistency between imputed and complete-case estimates (positive affect: Hedges *g*=0.83 vs 0.98; negative affect: Hedges *g*=−0.39 vs −0.39), suggesting the imputation performed more reliably for outcomes with lower follow-up missingness.

Separately, effect size calculations were conducted to describe the magnitude of observed changes in symptom severity and affect at 1-month follow-up. The estimated effect size for baseline to one-month follow-up contamination scores, as measured by the contamination OCI-R subscale, was moderate (Hedges *g*=0.40). However, this estimate should be interpreted cautiously, given the small sample size and uncontrolled single-arm design. For affect outcomes, a moderate negative effect size (Hedges *g*=–0.39; lower negative affect at follow-up) was found for negative affect, while a large positive effect size (Hedges *g*=0.83) was found for positive affect, suggesting potential change over time. However, these effect sizes are descriptive and do not establish clinical or causal effects in this pilot study.

Figure 4. Mean positive affect and negative affect (Positive and Negative Affect Schedule [PANAS]) assessed at baseline, after Exposure 1, after the neutral break (5 minutes), and after Exposure 2 in a single-arm, pretest-posttest, single-session virtual reality exposure pilot study in adults with subthreshold contamination concerns at Imperial College London (London, United Kingdom), February-June 2023. VR: virtual reality.

Participant Experience

To assess participants' perception of the virtual environment, VR presence (sense of physical immersion and engagement) and plausibility were examined.

Participants varied in their sense of presence during the VR session. For the statement "I had the sensation of being in the public toilet," most participants rated their sense of presence at the midpoint or above. One participant selected 1 (strongly disagree), one selected 2, 3 selected 3, one selected 4, 4 selected 5, 4 selected 6, and 2 selected 7 (strongly agree). For the

XSL•FO
RenderX

statement "I had the sensation that the scenario was really happening," one participant selected 1 (strongly disagree), none selected 2, 3 selected 3, 3 selected 4, 5 selected 5, 2 selected 6, and 2 selected 7 (strongly agree). Together these responses indicate that most participants reported at least a moderate sense of presence in the virtual environment.

Responses to the 2 plausibility items showed that participants generally found the VR environment comparable to or less anxiety-provoking than real and imagined scenarios. For the comparison with a real public toilet, no participant selected 1 (much more anxious in VR), one selected 2, 2 selected 3, 6 selected 4, and 7 selected 5 (much more anxious in the real toilet). For the comparison with an imagined public toilet, no participant selected 1, 3 selected 2, 4 selected 3, 6 selected 4, and 3 selected 5 (much more anxious in the imagined toilet).

Participants reported adequate acceptability for the VRET intervention. On the SUS, participants scored between 30.0 and 87.5, with a mean of 69.50 (SD 13.70; 95% CI 62.79-76.21), where a score of 68 is typically considered average and acceptable [55]. A majority found the system easy to use, usable without technical support, felt confident using the system, and thought that most people would learn to use the system quickly. A participant described using the intervention as "...an enjoyable, fun experience and a good way for exposure therapy without causing too much distress." Another participant wrote, "...overall it was very good and well instructed. I can see how multiple sessions of this kind could help with this issue as it wouldn't feel so daunting to enter contaminated places of this kind." Complete participant feedback is listed in Table S2 in Multimedia Appendix 1.

Only 1 out of 16 (6.25%) participant reported VR sickness when asked directly at the end of the session. This reflects a global self-identification of sickness, which may differ from SSQ-measured symptom composites: the SSQ aggregates weighted ratings across multiple individual symptoms, including nausea, oculomotor discomfort, and disorientation, such that participants may endorse individual symptoms at meaningful levels without identifying themselves as experiencing VR sickness overall. SSQ scores are therefore reported separately as a more granular index of sickness-related symptoms. VR sickness scores were measured by the SSQ after each exposure. Disorientation was the highest reported symptom. Total VR sickness was much higher after the second (mean 105.89, SD 13.64; 95% CI 99.20-112.57) than after the first exposure (mean 25.25, SD 25.13; 95% CI 12.93-37.56). Total scores for VR sickness ranged from 0 to 78.54 for postfirst exposure and 78.54-130.90 for postsecond exposure.

Participants suggested several areas of improvement to the VR environment. One participant mentioned that, "...the avatar's body blocked the view of some elements, so perhaps adjusting the dimensions of the avatar could enhance the viewing experience." Participants also mentioned, "somehow trying to recreate the smell, though that might be quite gross," and

> *...maybe if the environment had been changing more, like someone banging on the door or sounds of other people defecating, it would've felt more real. I think those are the kind of experiences that the VR might actually make me more resilient to.* [Participant]

Participants frequently expressed a desire for changes in the avatar's body dimensions (ie, the amount of body seen from the first-person avatar perspective) to allow for a clearer view inside the toilet bowl, as well as multisensory enhancements (eg, sounds and smells) to increase plausibility and immersion. Table S2 in Multimedia Appendix 1 includes a full list of participant feedback.

Discussion

Principal Results

This pilot study evaluated the feasibility and acceptability of a single-session VRET contamination exposure protocol, characterized within-session affective responding, and exploratorily assessed contamination symptom change at 1-month follow-up. Addressing these aims in turn: the VR protocol successfully elicited within-session anxiety during contamination exposure tasks, and affect fluctuated in patterns consistent with emotional responding during exposure. The intervention was feasible and acceptable, with participants rating usability as adequate and VR sickness not preventing session completion. However, a single session was not associated with statistically detectable contamination symptom reduction at 1-month follow-up.

Comparison With Prior Work

Changes in anxiety across both exposures, increasing during interaction with the contaminated environment and decreasing following virtual hand-washing, demonstrated that the VR environment was capable of eliciting momentary anxiety. However, the postexposure anxiety decrease cannot be unambiguously attributed to extinction learning. A key design consideration concerns the inclusion of virtual hand-washing at the conclusion of each exposure trial. In standard ERP for contamination OCD, the therapeutic mechanism depends on preventing the compulsive response so that anxiety reduces without the reinforcing relief of completing a compulsion, thereby promoting extinction learning [56]. In the present protocol, virtual hand-washing was retained as an ecologically grounded feature reflecting normative post–toilet behavior, as washing hands after toilet use is typical in this context, and the study was not designed as a full ERP protocol. As a result, the observed postexposure anxiety decreases may equally reflect relief following completion of a compulsive washing behavior, which would be mechanistically opposite to the extinction learning process that ERP is designed to promote. This affects the degree to which the anxiety trajectory can be interpreted as consistent with exposure-based processes in the strict clinical sense [56], and future iterations should consider incorporating structured response prevention to test this more rigorously. Anxiety levels were slightly higher on average during the first exposure compared to the second. While this pattern could reflect habituation to the feared stimulus, it may also reflect reduced novelty, increased task familiarity, or boredom effects, given that participants had just completed an identical trial. The study design does not permit distinguishing among these explanations, and this should be considered when interpreting

XSL•FO
RenderX

the between-trial difference. The limited nature of the intervention may not have been sufficient to establish habituation or for habituation to become ingrained in real-life scenarios [56], and further research is needed to determine therapeutic benefits. This is consistent with Inozu et al [35], who found that significant reductions in contamination-related anxiety required a minimum of 3 VR-ERP sessions delivered across several weeks, suggesting that a single session is unlikely to produce lasting symptom change. Fajnerová et al [34] similarly found that overall anxiety levels did not significantly increase in patients with OCD following a single VR exposure session, raising questions about the dose of exposure required to produce meaningful affective change.

This is further supported by the observed changes in positive and negative affect. Figure 4 shows negative affect rising from baseline after the first VR exposure, returning to baseline following the 5-minute break, and increasing again after the second VR exposure. These fluctuations are consistent with within-session affective responding patterns described in the exposure therapy literature, in which negative affect is expected to increase during contact with feared stimuli and decrease during recovery intervals [56]. Positive affect decreased after the 5-minute break, with a slight drop from baseline to the end of the first VR exposure and a small increase from the break to the end of the second exposure. This pattern may reflect the novelty of the intervention and a sense of relief at the session's conclusion, though direct evidence for these explanations is not available in the present data.

Most participants felt a strong sense of VR presence but did not find the environment overly anxiety-provoking compared to real or imagined public toilet scenarios. The adequate usability profile and low distress burden observed here also raise the possibility of a role for VRET as a stepping stone within a treatment hierarchy, positioned between imaginal exercises and in vivo exposure, as suggested by comparisons of VRET and in vivo approaches [41], though this remains speculative and untested in the present design. VR offers a more realistic and immersive context than imaginal exposure while remaining more controllable and safer than in vivo contact with feared stimuli [41], potentially allowing individuals to build tolerance and self-efficacy before progressing to real-world exposures. However, this remains speculative on the basis of the present data, and direct evidence for the stepping stone hypothesis would require studies comparing outcomes in samples who receive VRET prior to in vivo ERP against those who proceed to in vivo ERP directly. While the VR environment successfully elicited anxiety, the single-session design may have limited the opportunity for habituation, which has been identified as a key process in exposure-based symptom reduction [56]. These results support the feasibility of delivering a standardized contamination-focused VR exposure protocol and provide acceptability and within-session responding data that can inform the design of future multi-session and controlled trials. Participants rated the system's usability as adequate, clearing the conventional threshold for acceptable usability by a modest margin [55], felt confident using the intervention, and found it manageable without technical support. These findings indicate that the protocol meets a basic threshold for usability, though there remains meaningful room for improvement, as also reflected in participants' qualitative feedback on avatar dimensions, multisensory limitations, and environmental realism. These findings are consistent with broader interest in scalable digital health interventions that can be delivered with reduced clinician involvement [22,43], though whether this protocol can be meaningfully deployed as homework or with minimal supervision requires direct evaluation. Usability findings also suggest that prior VR experience may not be a prerequisite for engaging with the protocol, though replication in samples with greater age diversity and varying levels of technological familiarity is needed.

Though only one participant identified themselves as experiencing VR sickness when asked directly, SSQ scores indicated that sickness-related symptoms were present across the sample, particularly after the second exposure. This discrepancy reflects the distinction between global self-identification of sickness and a multi-item symptom composite, as discussed in the Results. VR sickness did not prevent session completion for any participant, and the limited avatar movement likely contributed to the relatively contained symptom profile observed after the first exposure [57]. Disorientation was the most commonly endorsed symptom cluster, more so than nausea or oculomotor symptoms. This may be due to technical issues like latency, inconsistent frame rates, or unnatural field of view and depth perception [57]. It could also result from participant fatigue (spending too long in VR without breaks to reset proprioception) or inadequate embodiment (not feeling connected to the avatar as their own body), though these remain speculative explanations in the absence of direct measurement. The substantially higher SSQ scores after the second exposure suggest that symptom burden increased over the course of the session, which should be considered in future protocol design.

Our VR sickness scores after one exposure (mean 25.25, SD 25.13) were comparable to those of the healthy control group in Fajnerová et al [34], who reported median scores of 21.50 (SD 58.08). This is likely because the participants in this study had symptoms below the clinical threshold, making them more similar to healthy controls than to the diagnosed OCD group in Fajnerová et al [34]. However, the teleportation movement mechanic used in the VR environment of Fajnerová et al [34], which was not used in this study, likely contributed to higher VR sickness scores.

The present pilot study makes several specific contributions to the VR exposure literature. First, it extends prior work by evaluating a standardized single-session contamination-focused VR exposure protocol in adults with elevated contamination concerns who did not meet diagnostic criteria for OCD, a population underrepresented in VRET research despite clinical relevance for scalable early intervention [37,40], and establishes that the protocol is feasible and acceptable in this group specifically. Second, the study demonstrates that the VR environment reliably elicited within-session anxiety across both exposure trials in a subthreshold sample. Because fear activation during exposure is considered a prerequisite for therapeutic change [56], this finding is a meaningful indicator that the environment functions as intended and supports progression to

XSL•FO
RenderX

efficacy testing. Third, the finding that a single session was not associated with symptom change at 1-month follow-up, while exploratory, directly informs future protocol development by ruling out single-session dosing as a sufficient therapeutic dose for this population and pointing toward multisession designs. Finally, adequate usability ratings and VR sickness levels that did not prevent session completion suggest the protocol could potentially be delivered without live clinical supervision, with implications for scalable implementation among individuals with elevated contamination concerns who have not yet sought formal treatment.

Limitations

This pilot study is not without limitations. The study's sample size was limited, which could have potentially diminished its generalizability. In addition, ethnicity was not collected, which limits characterization of sample diversity and may further constrain generalizability. Accordingly, the nonsignificant symptom change finding should not be interpreted as evidence of a true null effect. The observed effect size was moderate, and a moderate effect in a sample of this size is consistent with insufficient statistical power to detect a real difference. The direction of the effect, suggesting a trend toward symptom reduction, provides a preliminary basis for sample size estimation in future adequately powered trials. Future studies targeting a similar population should be powered to detect effects in the small-to-moderate range. Even so, the study offers valuable preliminary data that will inform future research endeavors. The broad range of contamination scores (as measured by the contamination subscale on the OCI-R) represents a full spectrum of contamination-related anxiety. However, the inclusion of participants with relatively low contamination scores could have diluted the observed pre-post changes, potentially masking significant findings or underestimating the true magnitude of change among individuals with higher baseline symptoms. Nevertheless, a sensitivity analysis for contamination scores was not feasible due to the small sample size. The follow-up noncompletion rate of 37.5% (6/16) participants means that the primary symptom outcome was missing for a substantial proportion of the sample. Although multiple imputation with chained equations was applied under a missing-at-random assumption, this assumption may not hold because participants who did not return for follow-up may differ systematically from those who did in ways not fully captured by observed variables; for example, in terms of engagement with the intervention or symptom trajectory. Imputing 37.5% of follow-up data in a sample of n=16 is inherently substantial, and pooled estimates for the contamination outcome should be interpreted with particular caution. A complete-case sensitivity analysis is reported in the Results section. Briefly, the primary symptom finding was sensitive to the missingness assumption, with the complete-case and imputed effect size estimates diverging substantially, indicating that the imputed contamination finding should not be taken as a reliable estimate of the true effect. PANAS outcomes showed greater consistency between the 2 estimation approaches, suggesting the imputation performed more reliably for outcomes with lower follow-up missingness. Multiple imputation was conducted with m=5 imputations, consistent with common practice in small-sample pilot work, though this may introduce additional Monte Carlo error in pooled estimates. It is also worth noting that compensation was not contingent on completion of the one-month follow-up survey, which may have contributed to the 37.5% follow-up dropout rate and the resulting missingness in the primary symptom outcome data.

Another constraint is the lower internal consistency observed for the OCI-R subscale at the one-month follow-up compared to baseline. Since the OCI-R demonstrated strong reliability at baseline, this decline is unlikely due to flaws in the measure itself. Indeed, repeated exposure to tests can affect participant performance, and sample attrition can impact the consistency of measurements, potentially distorting reliability estimates [58]. Furthermore, while measuring contamination symptoms using the OCI-R subscale at the one-month follow-up may present limitations for detecting change following a single-session intervention, prior research has demonstrated that even single-session VRET interventions can produce measurable effects at one month or later [59,60]. Participant bias is another potential limitation, given the novel nature of the technology and the recruitment method. Specifically, self-selection bias may have led participants to be more motivated to address their contamination-related fears, possibly increasing the perceived benefit of the intervention. Additionally, individuals drawn to the pilot study may have had a preexisting interest in VR technology, which could have influenced engagement and overall perception of the intervention, regardless of its direct impact on symptoms.

Furthermore, participants were recruited via Instagram advertisements and campus posters at a single UK university, which may have introduced a bias toward individuals with above-average technology familiarity and engagement with digital platforms. This is directly relevant to the interpretation of usability and acceptability findings: the usability scores observed in a potentially technology-comfortable sample may not generalize to older or less technology-familiar populations who would be among the primary beneficiaries of a scalable, low-barrier intervention. Usability and acceptability findings should therefore be interpreted with this recruitment context in mind.

It should also be noted that because Exposure 1 and Exposure 2 SUDS data were analyzed using different test families, reflecting differences in distributional assumptions, formal statistical comparison of results between trials is not straightforward. Between-trial differences should therefore be interpreted descriptively rather than inferentially.

This study used a single-group, nonrandomized design without a comparison condition, which limits causal inference. As a result, changes observed from baseline to follow-up cannot be attributed definitively to the VR exposure protocol and may reflect nonspecific factors such as assessment effects, expectancy effects, or the novelty of engaging with VR. In addition, symptom change at follow-up may be influenced by regression to the mean, particularly given the subthreshold nature of the sample and the single-session format. Accordingly, symptom outcomes should be interpreted as preliminary and exploratory, and future studies should include randomized

XSL•FO
RenderX

controlled designs with appropriate comparator conditions to evaluate efficacy. Bayesian approaches may be useful in future larger-scale studies to quantify evidence for change versus no change, particularly when effects are expected to be small.

Although exposure-based treatment for OCD is typically delivered across multiple sessions [14], the goal of the present pilot was not to evaluate clinical efficacy but to establish whether a standardized single-session VR protocol was feasible, acceptable, and capable of eliciting distress during exposure tasks. The single-session design was selected to reduce participant burden and to support scalable early-stage testing of the protocol, particularly given the subthreshold nature of the sample and the study's emphasis on user experience. We view this study as a first step in developing a replicable VR exposure procedure, with future work needed to evaluate multisession dosing and to test clinical outcomes using randomized designs and diagnostically confirmed samples.

Despite these limitations, our pilot study has several strengths, as it offers a comprehensive analysis by examining both the program's usability and its acceptability as an intervention. Evaluating usability ensures that users can navigate the program effectively, which is crucial for maintaining engagement and optimizing the user experience [55]. In contrast, assessing acceptability illuminates how well the intervention is received by users, providing preliminary information relevant to future integration into clinical practice and informing efforts to optimize treatment engagement. In addition, by incorporating both quantitative study design elements and open-ended questions, we gain a nuanced, multifaceted understanding of critical factors, such as participant perceptions of usability, intervention acceptability, and subjective experiences during VR exposure tasks. Furthermore, rather than focusing solely on OCD symptom reduction, we explore additional dimensions such as anxiety, as well as positive and negative affect. This broader evaluation provides insight into the emotional processes during exposure, such as the temporary increase in negative affect and recovery during the break, supporting the VRET's ability to provoke and modulate anxiety.

These findings carry specific implications for future research and clinical translation. The adequate usability profile and tolerability observed here suggest that self-administered or minimally supervised delivery may be worth evaluating in future trials [22,43], with particular relevance for scalable early intervention among individuals with elevated contamination concerns who have not yet accessed formal treatment, including those in settings with limited access to specialist OCD care. Future research should prioritize multisession designs [56] with larger, diagnostically confirmed samples and appropriate control conditions to evaluate therapeutic efficacy, with attention to protocol parameters such as response prevention structure and exposure dose. Refinement of the virtual environment, including enhanced contamination cues and multi-sensory features such as spatial audio, will support development of a clinically optimized protocol. This line of work holds promise as a pathway to reducing barriers to early intervention in a population that remains largely underserved by current treatment pathways.

Conclusions

This study is among the first to systematically evaluate a standardized single-session contamination-focused VR exposure protocol in adults with elevated contamination concerns who did not meet diagnostic criteria for OCD, a subthreshold population largely underrepresented in prior VRET research, which has predominantly focused on clinically diagnosed samples and multisession protocols [27,28,38,39]. By directly targeting this underrepresented group, the study provides feasibility and acceptability benchmarks and within-session anxiety data not available from existing literature focused on clinical samples [37,40]. A single session was not associated with significant symptom change, and the effect size estimate for contamination symptom reduction was sensitive to the missingness assumption, indicating that a single session is unlikely to constitute an adequate therapeutic dose for this population and underscoring the need for adequately powered multisession designs in future efficacy trials. Nevertheless, the protocol reliably elicited within-session anxiety during exposure tasks, was rated as usable and manageable by participants, and was associated with VR sickness that did not prevent session completion, indicating that the protocol functions as intended in this population and supports progression toward efficacy testing.

Acknowledgments

No generative artificial intelligence (AI) tools were used in any part of the preparation of this manuscript.

Funding

This project was funded by the London Interdisciplinary Social Science Doctoral Training Partnership. XRHealth provided in-kind support by loaning equipment used for the virtual reality procedures. XRHealth had no role in the manuscript preparation, study design, protocol development, data collection, management, analysis, or interpretation.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to privacy considerations and the small sample size, but are available from the corresponding author on reasonable request, subject to ethics approval and institutional requirements. The R code used to reproduce the analyses and figures reported in this manuscript is available in the OSF repository [61].

Abstract

Background: Craving is a diagnostic criterion and predictor of relapse in patients with alcohol dependence (AD) and is induced in cue exposure therapy (CET) to prepare patients for real-life risk situations. The benefits of virtual reality (VR) as an innovative tool within treatment for this highly prevalent disorder include increased practicability, standardization, and personalization of CET. Accurate measurement of craving is essential to develop effective virtual reality cue exposure (VR-CE) scenarios. Despite being relevant for diagnostics and therapy, the psychophysiological reaction to alcohol cues and its relationship to subjective craving has not been sufficiently examined.

Objective: This study aimed to investigate the induction of subjective craving, its physiological correlates, and their relationship in patients with AD during an innovative VR-CE paradigm, including 2 alcohol-associated risk scenarios (bar and living room) and a neutral baseline scenario.

Methods: Craving was analyzed by measuring physiological reactions (electrodermal activity, including nonspecific skin conductance responses [NS-SCR] and skin conductance level [SCL]; heart rate [variability] [HR(V)]; brightness-corrected pupil diameter [BCPD]; and respiration rate [RR]) and subjective craving (visual analog scale) in 61 patients with AD. Linear mixed-effects models were conducted to estimate the effects of VR-CE. Correlations between subjective and physiological craving parameters were analyzed using Spearman correlations.

Results: Results showed that alcohol-associated VR scenarios had significant effects on subjective craving (β values between 9.48, 95% CI 6.02 - 12.95 and 15.93, 95% CI 12.47 - 19.40, with moderate effect sizes between *d*=0.56 and *d*=0.72) and on NS-SCR frequency (β values between 0.97, 95% CI 0.14 - 1.80 and 3.06, 95% CI 2.23 - 3.89, with small-to-large effect sizes

XSL•FO
RenderX

between *d*=0.31 and *d*=0.91), BCPD (β values between 0.03, 95% CI 0.01 - 0.06 and 0.05, 95% CI 0.02 - 0.07, with small effect sizes between *d*=0.21 and *d*=0.29), and RR (β values between 0.67, 95% CI 0.06 - 1.28 and 1.66, 95% CI 1.05 - 2.26, with small effect sizes between *d*=0.22 and *d*=0.45), but not on SCL and HR(V). Correlation analyses showed significant but weak correlations between subjective craving and electrodermal activity (SCL: *r*=0.20, *P*=.04; NS-SCR frequency: *r*=0.21, *P*=.03).

Conclusions: This study showed that subjective and physiological craving (NS-SCR, BCPD, and RR but not SCL and HR[V]) can be successfully induced by VR-CE in patients with AD. These outcomes add to research on the induction of craving using a wide range of psychophysiological and subjective parameters. Furthermore, this study expands the still-limited research on the relationship between subjective and psychophysiological craving in patients with AD. In the long term, this study informs the development of effective VR-CET, which could, by further building on psychophysiological parameters, lead to biofeedback VR-CET as an innovative treatment option for patients with AD.

Introduction

Problem

Craving, defined as the urge to consume a psychoactive substance, is a criterion for diagnosing alcohol dependence (AD) and alcohol use disorder according to the *International Classification of Diseases, 11th Revision* (*ICD-11*) and the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) [1,2] and a predictor of relapses [3]. One explanatory model, the "conditioned drug-like model," highlights the role of substance-associated stimuli that trigger psychological and physiological responses, promoting drug-seeking behavior [4]. In cue exposure therapy (CET), a component of cognitive behavioral therapy, patients are exposed to alcohol-associated stimuli to identify risk situations and practice coping strategies, potentially reducing conditioned responses over time [5]. The effectiveness of CET for AD remains debated because of insufficient evidence, with a small number of studies and small-to-moderate effects on outcomes, underscoring the need for more trials using innovative methods such as virtual reality (VR) [6]. VR-CET has gained attention because of its advantages: realistic and immersive simulations, individualized content, increased practicability, and better standardization [7,8]. These benefits could reduce the financial and time demands of traditional in vivo CET in clinical practice [8]. Accurate craving assessment is critical for developing effective VR-CET scenarios.

Review of Relevant Scholarship

Based on self-report data, Ghiță et al [9] identified common triggers for alcohol craving, such as being in social settings or specific environments such as bars, restaurants, or home, and found beer, red wine, and whiskey to be most commonly associated with craving. A recent study based on this research, which implemented these VR scenarios, showed no significant differences in relapse rates between the VR-CET and control groups but did show a tendency toward lower subjective craving and anxiety in the VR-CET group. Furthermore, several important limitations of the study were highlighted, underscoring the need for further research [10]. Beyond self-reports, studies have shown that physiological responses such as pupillometry, respiration rate (RR), heart rate (HR), and electrodermal activity (EDA) can also indicate craving [11-14]. These methods help address the limitations of self-reports, including social desirability bias, defined as the tendency to give socially desirable responses [15], and recall difficulties when using retrospective reports [16]. In line with this, correlations between subjective craving and physiological responses are rather weak [17,18], but studies are few and the relationship remains ambiguous, meriting further investigation. VR may help clarify this relationship and identify physiological biomarkers relevant for diagnostics and therapy, including biofeedback applications in VR-CET in the long term.

Several studies have demonstrated that VR exposure paradigms can effectively induce craving [19]. However, research on physiological cue reactivity in VR scenarios is limited. One study included electroencephalography as a potential correlate of craving during VR-CET and showed a decrease in craving for alcohol parallel to an increase in frontal α activity over the course of the therapy [20]. One recent study by Zhang et al [12] focused on the changes in HR, EDA, and RR after VR-CET and found significantly lower increases in HR and subjective craving after cue exposure in the group receiving VR-CET. Apart from these studies, to our knowledge, further research on craving induction through virtual reality cue exposure (VR-CE) in AD populations has relied on subjective craving measurements [19].

Hypothesis, Aims, and Objectives

In this study, we first investigated the induction and progression of craving through VR exposure using both subjective (questionnaires) and objective physiological measures (EDA, heart rate [variability] [HR(V)], brightness-corrected pupil diameter [BCPD], RR). We hypothesized that exposure to alcohol-associated VR scenarios would significantly increase (1) subjective craving and (2) physiological indicators of craving.

XSL•FO
RenderX

Additionally, we aimed to explore the relationship between subjective and objective measures, hypothesizing that (3) subjective and physiological measures of craving would show significant correlations. On an exploratory basis, we also examined the correlations between the individual psychophysiological parameters.

Methods

Conditions and Design

This prospective, exploratory, single-arm clinical study assessed subjective and physiological craving parameters in patients with AD. It followed a previously published study protocol with details on the study design, measures, and materials [21].

Ethical Considerations

The study was approved by the Charité–Universitätsmedizin Berlin Institutional Review Board (EA1/190/22; May 23, 2023) and was preregistered on ClinicalTrials.gov (NCT05861843). All participants provided written informed consent and received compensation of €30 (approximately US $34.80) for participation.

All study data were pseudonymized, and identification through images or supplementary material was not possible.

Sampling Procedures

Inpatients and outpatients diagnosed with AD were recruited at Charité–Universitätsmedizin Berlin and Salus Clinic Lindow, Germany. Patients were screened for eligibility, and they provided written informed consent and received compensation. Recruitment and data collection took place between September 23, 2023, and June 30, 2024.

Inclusion and Exclusion

Patients aged between 18 and 65 years who were diagnosed with AD according to *ICD-10* (F10.2) based on clinical consensus were included in the study. Further inclusion criteria were completion of inpatient withdrawal treatment during the last 3 months and a history of alcohol craving.

Exclusion criteria included other substance dependencies (except nicotine), less than 7 days of abstinence or current intoxication (randomly tested using breath alcohol concentration), severe neuropsychiatric disorders (eg, schizophrenia and bipolar disorder), cognitive impairment, acute suicidality or risk of endangering others, serious conditions affecting brain or heart function, current use of AD-targeting medication (eg, benzodiazepines and acamprosate), medications significantly affecting HR, or inability to understand study procedures.

Data Collection

Clinical Data and Questionnaires

Clinical data and questionnaires were collected using REDCap (Research Electronic Data Capture) tools hosted at Charité–Universitätsmedizin Berlin [22,23].

General baseline data included demographic information, medical history, comorbidities (assessed using Charlson Comorbidity Index [24] and patient information), and medication. Subjective craving was measured using a 0 to 100 visual analog scale (VAS) [25] at 3 time points (0:30, 2:30, and 4:30 min) in each VR scenario using verbal reports from participants [21]. The study workflow followed the previously published protocol [21].

VR Exposure

VR exposure was conducted according to the study protocol, for which a detailed description can be found in Multimedia Appendix 1 [21]. The hardware consisted of a VR head-mounted display (HTC VIVE Pro Eye) and a desktop PC based on the SCHENKER XR Station with Intel Core i5-12,500. Patients selected a preferred drink (schnapps, red wine, white wine, beer, or vodka) and a bar environment (wine bar or corner pub), and scenarios were personalized accordingly. In addition to the bar environment, a second risk scenario featured a living room setting with the drink of choice. All patients started with a VR acclimation session (1 - 5 min) consisting of a white waiting room for acclimatization to VR before proceeding to a neutral baseline scenario (5 min). This room was a black space with a grid for spatial orientation. Next, patients entered the first of 2 risk scenarios presented in randomized order (5 min each). After a 45-minute break, the second baseline-risk paradigm was conducted. After completing the final questionnaires following VR exposure, patients were asked to confirm that they could safely leave the study site without experiencing an increased risk of relapse. Immediate therapeutic support would have been provided if necessary, but it was not required in any case. The VR sessions were conducted by 2 medical doctors and 1 psychologist with experience in VR applications and treatment of psychiatric patients.

Psychophysiological Data

Psychophysiological data were collected using the Bionomadix wireless respiration and electrocardiography (ECG), photoplethysmography, and EDA amplifiers in combination with the Biopac MP160 data acquisition system (Biopac Systems). The system was connected to an acquisition computer running the AcqKnowledge 5.0 software (Biopac Systems). Signals were obtained using a 1000 Hz sampling rate.

Electrodermal Activity

Disposable Ag/AgCl dry electrodes were prepared with isotonic paste and placed on the volar surfaces of the medial phalanges of the index and middle fingers of the nondominant hand. EDA was measured by assessing the slow-varying skin conductance level (SCL) and the frequency of nonspecific skin conductance responses (NS-SCR) exceeding a threshold of 0.03 µS. We excluded participants who failed to show a peak above the threshold of 0.03 from the analysis of NS-SCR frequency ("nonresponders" according to established guidelines) [26,27]. The SCL and NS-SCR frequency were extracted from the EDA signal using continuous decomposition analysis via the Ledalab toolbox [28] for MATLAB (MathWorks), version 24.2.0.2712019 [29].

Heart Rate and Heart Rate Variability

HR and heart rate variability (HRV) were obtained via a 3-lead ECG. Electrodes were placed on the chest 1 cm below the sternum, left and right, along the midclavicular line, and 1 cm

XSL•FO
RenderX

left of the parasternal line, between the fifth and sixth left sternochondral joints. Before performing the analysis, each waveform was preprocessed within the AcqKnowledge HRV Suite, using the Biopac's HR detection algorithm. Applying Biopac's Classify Script—an automated ECG beat-detection and derivative-based QRS peak realignment algorithm—to the waveform within the AcqKnowledge environment, intervals between successive heartbeats (R-R intervals) were computed and labeled, flagging out-of-range values or significant deviations from neighboring values. Waveforms were visually inspected for artifacts and manually corrected by 2 medical experts to allow differentiation between artifacts and actual arrhythmias. Artifacts were replaced with an aligned R marker, calculating the midpoint between 2 existing QRS markers and inserting a new marker at the estimated equidistant position in the ECG signal. Using the preprocessed signal, various time-domain, frequency-domain, and nonlinear-domain parameters were extracted using the AcqKnowledge HRV Analysis Suite for the whole 5-minute duration of each VR scenario.

The time-domain parameters included the standard deviation (SD) of successive differences in R-R intervals (SDSD, ms), the root mean square of successive R-R differences (RMSSD, ms), and the percentage of successive R-R intervals differing by more than 50 ms (pNN50, %). The frequency domain included the power as measured in the following bands (ms^2): the very low frequency band (VLFB, 0.0033 - 0.04 Hz), the low frequency (LF) band (LFB, 0.04 - 0.15 Hz), the high frequency (HF) band (HFB, 0.15 - 0.40 Hz), and the very high frequency band (VHFB, 0.40 - 3.00 Hz). Additionally, total power (ms^2), LF/(LF+HF), HF/(LF+HF), and LF/HF ratios were calculated. For the nonlinear domain, the SD of each point from the y=x axis (SD1), the SD of each point from the y=x+average R-R interval (SD2), and the SD1/SD2 ratio were calculated. The cleaned R-R intervals were processed using Python 3.9.20 with the pandas, NumPy, and regex packages [30-32], extracting the SD of R-R intervals (SDRR, ms, time-domain parameter) and obtaining HR by averaging the R-R intervals within each 1-minute segment of the exposure period.

Brightness-Corrected Pupil Diameter

Pupil diameter and scene brightness in VR were recorded continuously during the paradigm using the built-in eye-tracking device within the VIVE Pro Eye Headset (120 Hz binocular data output frequency, 110° trackable field of view). Data were processed using the Soma Reality algorithm (Soma Reality GmbH), which differentiates between illumination-induced and cognitive-induced ("cognitive load") components of pupil diameter variation, as shown by Gollan [33] and based on Beatty et al [34]. The approach combines (1) a brightness measure of the content displayed in the VR headset, (2) an empirical model of the pupillary light reflex, and (3) a temporal modeling of the delay of the pupillary response to model how the pupil size reacts to perceived brightness. This allows for the separation of light-induced effects from cognitive effects in pupillary behavior and the extraction of BCPD. Preprocessing was conducted in Jupyter Notebook, version 7.0.8 [35], using the Anaconda Python distribution, version 24.11.3 [36], and the pandas and NumPy packages [30-32]. Confidence scores for BCPD values were calculated.

Respiration Rate

The respiratory transducer was attached to the chest or abdomen using a fully adjustable nylon strap, depending on the primary breathing pattern. The respiratory signal was filtered using a bandpass finite impulse response filter between 0.05 and 1 Hz. Breaths per minute were then extracted for further analysis of RR.

Analytic Strategy

All analyses were performed using R software (version 4.3.2, Eye Holes; R Foundation for Statistical Computing) [37] and RStudio (version 2024.4.0.735, Chocolate Cosmo; Posit) [38]. Demographic and baseline characteristics are reported as mean, SDs, and ranges.

EDA, HR, BCPD, and RR data were divided into 5 equal segments for each 5-minute exposure period (baseline: B1, B2, B3, B4, and B5; risk scenario: R1, R2, R3, R4, and R5). HRV parameters were calculated across each entire VR scenario (5 min; baseline: B, risk scenario: R). Each exposure combined a baseline and a risk scenario into 1 data frame. Because each participant underwent 2 exposures, each participant produced 2 data frames (N=61 participants, N=122 data frames). Because of recording problems, some data were unavailable: one participant lacked all physiological recordings, resulting in 2 missing data frames for BCPD, RR, EDA parameters, HR, and HRV. In addition, 4 BCPD data frames from 3 participants were missing, leaving 116 data frames for BCPD analysis. For HRV, 1 additional data frame with partial missing values (segments R4 and R5) was excluded, resulting in 119 data frames for HRV analysis. NS-SCR frequency was calculated from 116 data frames, with 2 participants excluded as nonresponders.

Subjective craving, measured using VAS, was assessed during first (B1 and R1), third (B3 and R3), and fifth (B5 and R5) segments, with one missing data frame, resulting in 121 data frames.

The main analyses were conducted using linear mixed-effects models fitted with the nlme package (version 0.3.2) [39] to estimate the effects of VR-CE. Models were specified with a categorical variable for craving assessment as a fixed effect, indicating exposure to baseline (B1-B5) and risk scenarios (R1-R5). A random intercept was included to account for individual variability, whereas a fixed slope was used to estimate the overall effect across all participants. The mean baseline value (B) was included as the reference category. Accordingly, the estimated fixed effects (β) from the linear mixed-effects models are reported as model-based mean differences between each craving assessment and the baseline assessment, as estimated by the nlme package. Models are reported in adjusted form, using covariates with influence on the psychophysiological parameters identified a priori. These covariates were selected individually based on guidelines and prior research and were centered within cluster. Covariates for EDA included gender, age, ambient temperature, and medication [27]. In addition to these covariates, BMI, smoking status, and health status (Charlson Comorbidity Index score) were incorporated for HR,

XSL•FO
RenderX

HRV [40], and RR [41-45]. Medication and age were also included for BCPD [46-51]. Ambient temperature for 1 participant was interpolated because of a missing value. Post hoc calculations of *t* statistics and *P* values were performed using the Satterthwaite approximation [52]. Missing data were handled using linear mixed-effects models, which incorporate all available data from each participant into the analysis. Effect sizes were estimated as standardized mean differences, that is, approximations of Cohen *d* based on mixed-effects modeling following Pustejovsky et al [53], using the *lmeInfo* (version 0.3.2) [54] and *nlme* (version 0.3.2) [39] packages. Plots of the estimated model effects were generated using the *effects* package (version 4.2.4) [55]. Correlations between subjective and physiological craving parameters were analyzed using Spearman correlations on calculated difference scores of the parameters between baseline and risk scenarios (first segment: R1-B1; second segment: R2-B2; third segment: R3-B3; fourth segment: R4-B4; and fifth segment: R5-B5). Correlation analyses could only be conducted using complete data frames, leading to 111 data frames for analysis. To correlate subjective and physiological parameters at the same time points, physiological measures during the first, third, and fifth segments of the exposure were selected, during which subjective craving was assessed. Additional correlation analysis was conducted for psychophysiological craving parameters (EDA, HR, RR, and BCPD), excluding HRV because of the longer time frames for analyses. Effect sizes are reported as Cohen *d*, with 0.2 considered as small, 0.5 as moderate, and 0.8 as large [56]. The predetermined α level was .05. This study was reported in accordance with the American Psychological Association Reporting Standards for quantitative research [57].

Results

Descriptive Analysis

Baseline demographic and medical characteristics are presented in Table 1. Participants (49/61, 80% male and 12/61, 20% female) had a mean age of 48.16 (SD 9.82; range 31 - 65) years, with a mean duration of 20.64 (SD 22.42; range 7 - 109) days since their last alcohol consumption on the day of the experiment.

[a]CCI: Charlson Comorbidity Index.

Mean craving was 9.03 (SD 17.96) during the VR-CE baseline and 22.77 (SD 26.49) during the risk scenario, as assessed using a VAS ranging from 0 to 100 (Figure 1). Cybersickness, including any sign of discomfort, nausea, and dizziness, during the VR-CE was reported by 67.2% (41/61) of patients on the Fast Motion Sickness Scale.

XSL•FO

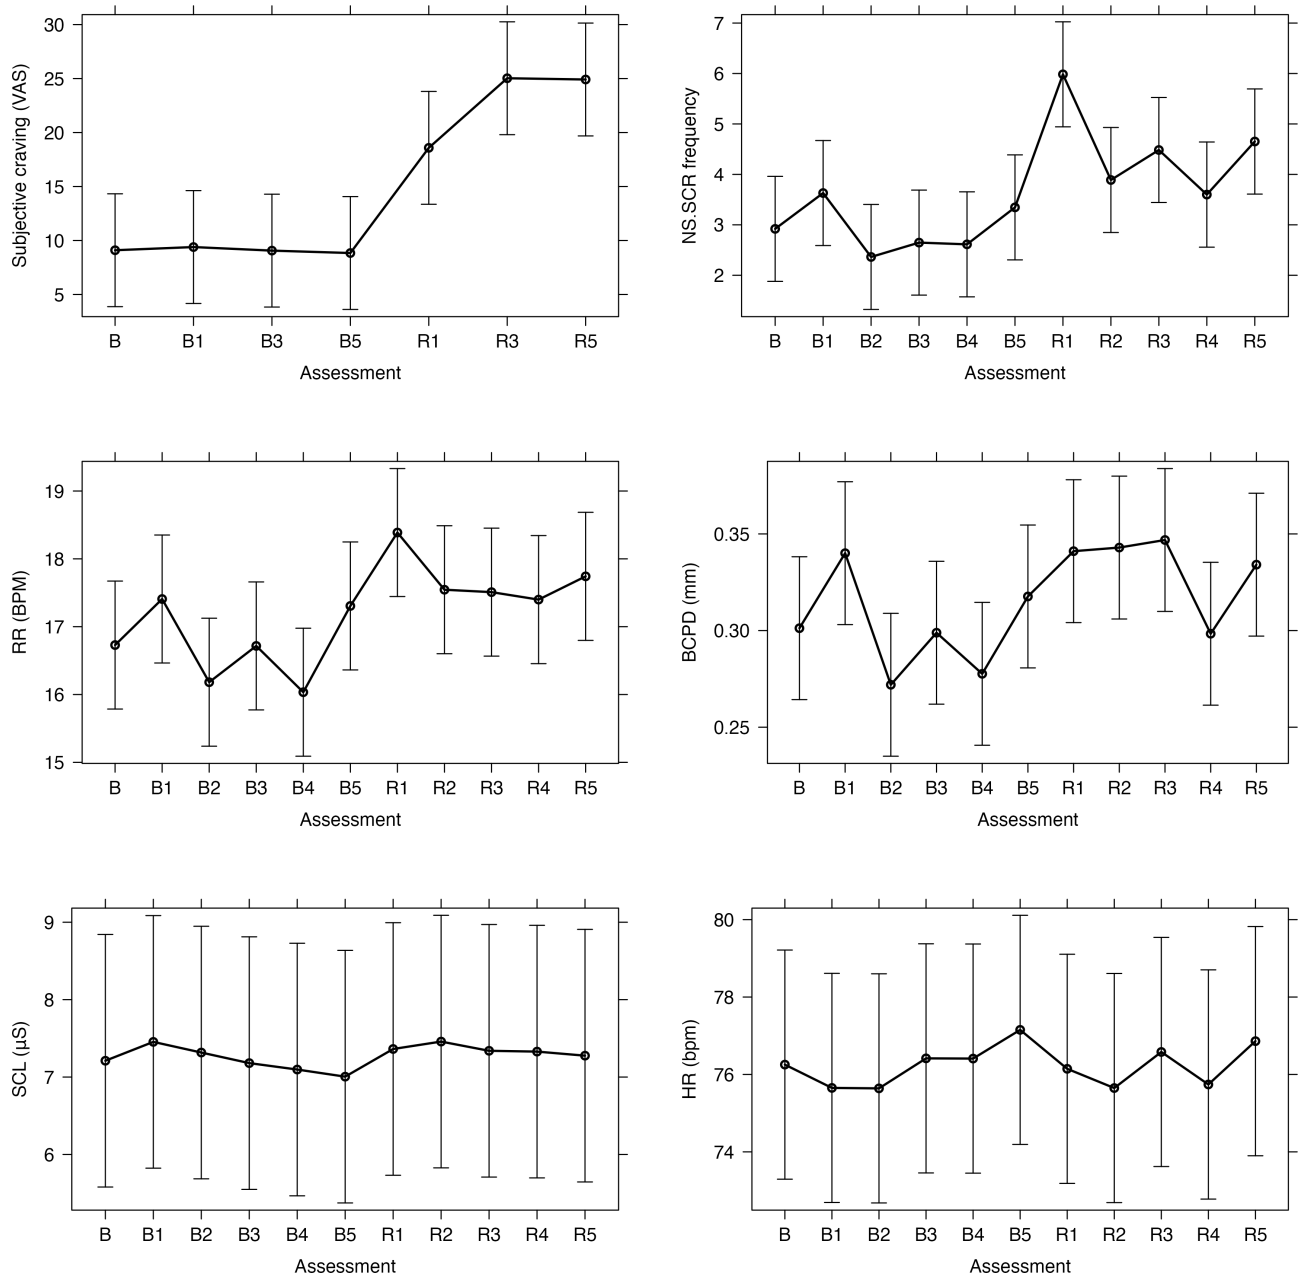
Figure 1 shows subjective craving measured by VAS during VR-CE baseline and risk scenarios, displayed using a combination of boxplots and spaghetti plots. The boxplots display the mean (dotted line), median (horizontal line), IQR (box), whiskers (1.5 × IQR), and outliers marked as crosses.

Figure 1. Subjective craving measured using the visual analog scale (VAS) during virtual reality cue exposure (VR-CE).

Statistics and Data Analysis



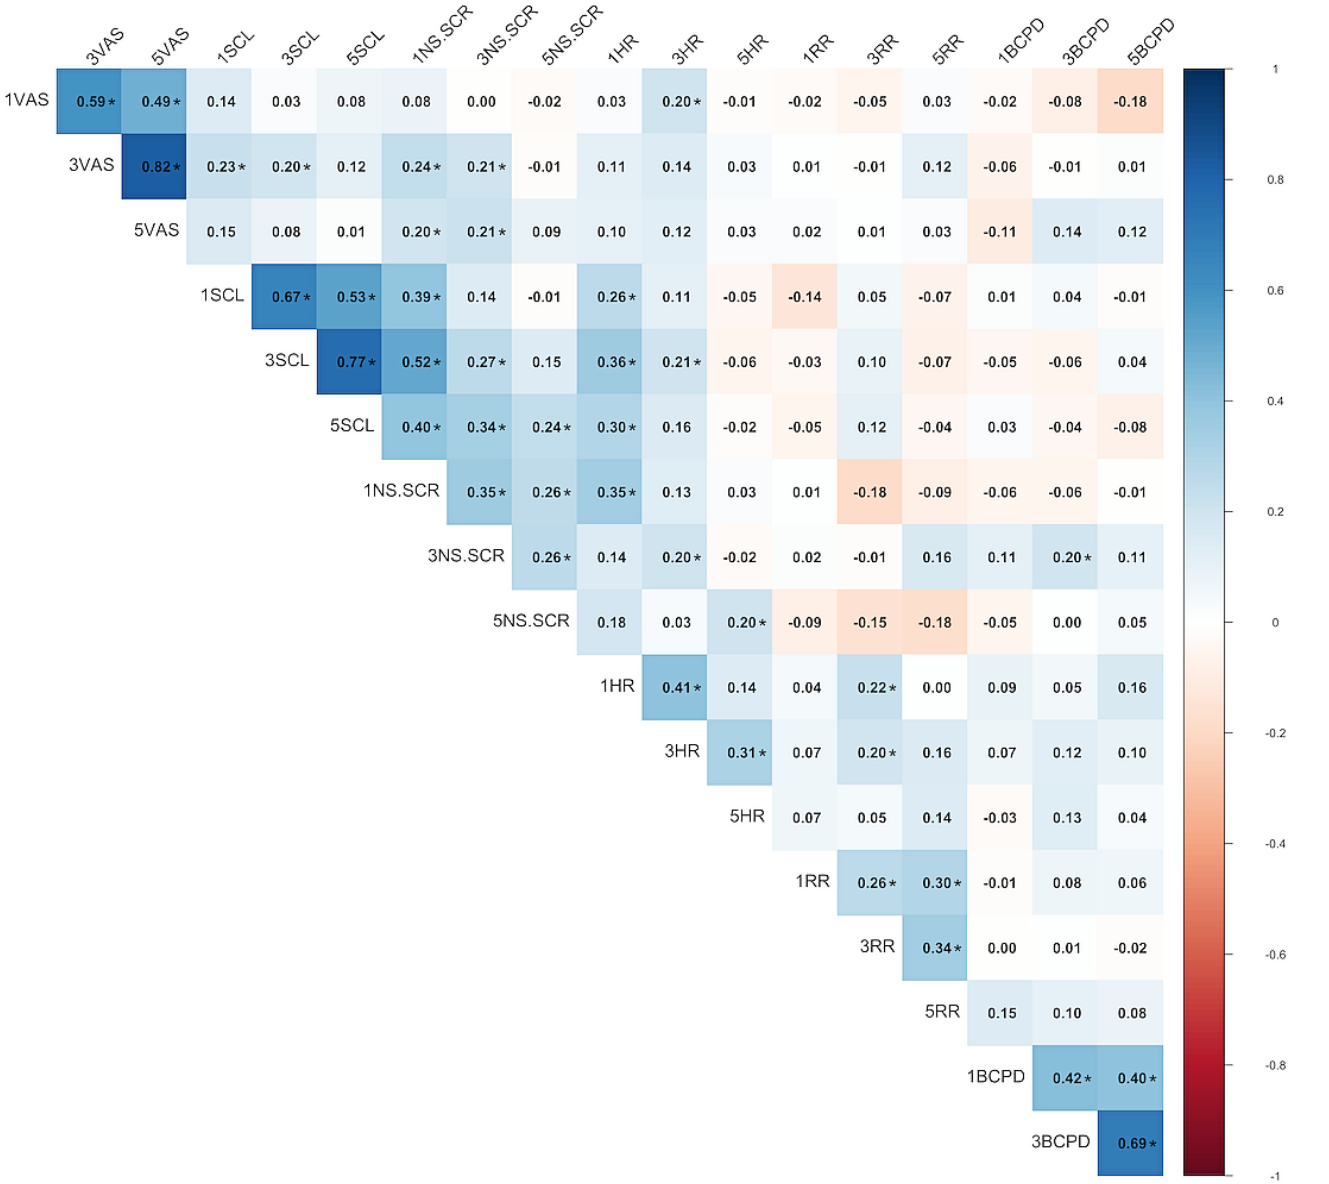
Effects of VR-CE on Subjective and Physiological Parameters

The linear mixed-effects model analysis showed an overall significant main effect of the VR-CE on subjective craving as indicated by the VAS, indicating significantly higher craving observed in the risk scenarios, with a mean difference to baseline of 9.48 (95% CI 6.02 - 12.95; R1) during the first segment, 15.93 (95% CI 12.47 - 19.40; R3) during the third segment, and 15.82 (95% CI 12.35 - 19.28; R5) during the fifth segment of the risk scenarios. This corresponds to moderate effect sizes between *d*=0.56 (R1) and *d*=0.72 (R3) for the VR-CE. Further results are displayed in Table S1 in Multimedia Appendix 1.

For the physiological craving parameters, the analyses showed an overall significant effect of the VR-CE on NS-SCR frequency, with a mean difference to baseline between 0.97 (95% CI 0.14 - 1.80; R2) and 3.06 (95% CI 2.23 - 3.89; R1), with small-to-large effect sizes between *d*=0.31 (R2) and *d*=0.91 (R1). However, the fourth segment of the risk scenarios did not show statistical significance (0.68, 95% CI −0.15 to 1.51; R4). Furthermore, analyses showed an overall significant effect of the VR-CE on RR, with a mean difference to baseline between 0.67 (95% CI 0.06 - 1.28; R3) and 1.66 (95% CI 1.05 - 2.26; R1), indicating small effect sizes between *d*=0.22 (R3) and *d*=0.45 (R1). We also observed an overall significant effect of the VR-CE on BCPD, with a mean difference to baseline between 0.03 (95% CI 0.01 - 0.06; R5) and 0.05 (95% CI 0.02 - 0.07; R3) and small effect sizes between *d*=0.21 (R5) and *d*=0.29 (R1), except for the fourth segment of the risk scenarios (−0.00, 95% CI −0.03 to 0.02; R4). The result for the main effect of the VR-CE on BCPD during the risk scenarios remained consistent after excluding datasets of BCPD in which confidence levels fell below 0.3 for phases exceeding 30 seconds or in which more than 20% were below this threshold. No significant effect of the VR-CE on SCL, HR, or any of the HRV parameters was detected (for details see Figure 2; Tables S1-S3 and Figure S1 in Multimedia Appendix 1). Figure 2 shows plots of estimated marginal means and 95% model-based CIs displaying main effects of the VR-CE over time on subjective craving and physiological craving parameters. The figure depicts the segments for baseline (B1-B5) and risk scenario (R1-R5), with the mean of baseline as the reference category for this analysis.

XSL•FO
RenderX

Figure 2. Effects of virtual reality cue exposure on subjective and physiological parameters. BCPD: brightness-corrected pupil diameter; bpm: beats per minute; BPM: breaths per minute; HR: heart rate; NS-SCR: nonspecific skin conductance responses; RR: respiration rate; SCL: skin conductance level; VAS: visual analog scale.



Correlation of Subjective and Physiological Craving Parameters

The correlation analysis revealed no significant relationships between subjective and physiological craving parameters during simultaneous segments of the assessments (P>.05; Figure 3 and Table S3 in Multimedia Appendix 1), except for the third segment of the assessment of subjective craving and the EDA parameters SCL (r=0.20, P=.04; see Table S4 in Multimedia Appendix 1) and NS-SCR frequency (r=0.21, P=.03). Significant correlations with small effect sizes were also observed between nonsimultaneous assessments of subjective craving and NS-SCR frequency.

XSL•FO
RenderX

Figure 3. Correlation heatmap of subjective and physiological craving parameters. BCPD: brightness-corrected pupil diameter; HR: heart rate; NS-SCR: nonspecific skin conductance responses; RR: respiration rate; SCL: skin conductance level; VAS: visual analog scale.

Significant correlations of time-corresponding segments of the assessment between the physiological craving parameters were identified *(P*<.05; see Figure 3 and Table S3 in Multimedia Appendix 1). The parameters of EDA, SCL and NS-SCR frequency showed significant correlations for all segments of the assessment between *r*=0.24 (*P*=.01; fifth segment) and *r*=0.39 (*P*<.001; first segment). EDA parameters further showed significant correlations with HR: in segments 1 to 3 of the assessment of SCL and HR, ranging between *r*=0.21 (*P*=.03; third segment) and *r*=0.29 (*P*=.002; second segment), and in the first segment as well as segments 3 to 5 of the assessment of NS-SCR frequency and HR, ranging between *r*=0.20 (*P*=.03, third segment and *P*=.04, fifth segment) and *r*=0.35 (*P*<.001; first segment). NS-SCR frequency further showed a correlation with RR during the second segment of the assessment (*r*=−0.19, *P*=.04) and with BCPD during the third segment of the assessment (*r*=0.20, *P*=.04), whereas SCL showed no significant correlations with RR and BCPD (*P*>.05). Furthermore, HR and RR showed significant correlations during the third (*r*=0.20, *P*=.04) and fourth (*r*=0.21, *P*=.03) segments of the assessment. There were no significant correlations with BCPD and HR as well as RR (*P*>.05). Significant correlations of time-corresponding segments of the assessment all corresponded to small effect sizes. Figure 3 shows a correlation heatmap of subjective craving measured and physiological craving parameters (NS-SCR, RR, and BCPD). Significant correlations are labeled with an asterisk. HRV parameters are not depicted because of the longer analysis time frames.

Discussion

Principal Findings

This study demonstrates that exposure to alcohol-associated VR scenarios significantly induced subjective craving. VR-CE had significant effects on NS-SCR as one measure of EDA, on BCPD, and on RR. No significant changes were observed in SCL, as a second EDA parameter, HR, or HRV. Our first hypothesis was thus confirmed and our second hypothesis partially confirmed. Correlation analyses focusing on

XSL•FO
RenderX

simultaneous time segments revealed significant but weak correlations between subjective craving and EDA measures. Subjective craving was not significantly correlated with other physiological parameters. Additionally, significant correlations were found in simultaneous assessments between several physiological craving parameters, leading to a partial confirmation of our third hypothesis.

Subjective Craving

This study confirms that VR effectively induces subjective craving, consistent with positive results from previous studies [9,58,59]. A recent scoping review from our group once again confirmed that the majority of studies report significant changes in craving [60]. The current study builds on a prior feasibility study [61], adding comparisons to baseline scenarios and physiological measures. Observed effect sizes (d=0.56 - 0.72) indicate moderate effects, higher than those reported in the meta-analysis by Carter and Tiffany [62] (d=0.53). This may be due to the higher ecological validity of VR compared with more conventional stimuli (eg, images, sounds, or in vivo cues) used in prior studies [62].

Psychophysiological Craving

The results of our study indicate that measures of EDA (NS-SCR), BCPD, and respiration could serve as sensitive biomarkers of craving in patients with AD exposed to high-risk scenarios in VR. These measures provide objective insight into a subjective, bias-prone construct and may support more effective VR-CET, including biofeedback integration. Providing patients with feedback on their physiological data may help them better recognize and manage personal risk cues [63].

To date, we are aware of only 2 other VR craving studies that include psychophysiological measures of craving in patients with AD. However, their designs differed from ours: Lee et al [20] reported an increase in electroencephalography α power and a greater craving reduction through 10 sessions of VR-CET compared with patients receiving cognitive therapy. Zhang et al [12] compared 2 groups (n=23 vs n=21) of male patients with AD, one group receiving treatment as usual and the other group receiving additional VR-CET sessions. Comparing these 2 groups regarding their cue reactivity in VR assessments, the VR group exhibited significantly lower changes in subjective craving and HR, but not in EDA and RR, after treatment [12]. Notably, in the study by Zhang et al [12], skin conductance was averaged across the whole signal and not evaluated separately (eg, SCL, SCR, or NS-SCR), which could artificially elevate the parameter [12,26,27]. Although we employed a different analysis approach, we also found no significant effects of VR-CE on SCL. In contrast to Zhang et al [12], we did not observe significant changes in HR but did note changes in RR. Additionally, we used HRV and BCPD, expanding the physiological scope. While VR-CE had significant effects on BCPD, this was not the case for HRV parameters. Previous studies have reported inconsistent conclusions on this matter: Wang et al [64] observed higher RMSSD in patients with AD during exposure to alcohol cues compared with neutral cues. High-frequency HRV, a marker of parasympathetic activity, has been shown to react to alcohol-associated cues and is associated with relapse in patients with AD [65,66]. It may be worth considering that VR itself may elevate HR and SCL because of sensory stimulation, potentially obscuring craving-specific responses.

Relation Between Subjective and Physiological Craving

Similar to our study, several studies indicated that subjective craving is only weakly associated with physiological parameters. For instance, a meta-analysis conducted by Field et al [18] on craving in various substance-use disorders found low correlations (r=0.19) between subjective craving and attentional bias. Similarly, Witteman et al [67] reported low-to-moderate correlations between HRV and subjective craving (r=0.33, P=.004). Interestingly, Szegedi et al [68] identified 3 groups of patients with AD: one with both subjective and physiological craving responses, another group with only physiological craving responses, and a third group with no response at all. In contrast, Ooteman et al [17] found only a few patients with or without physiological craving responses who also reported subjective craving, suggesting a need to explore possibilities to help patients become more aware of these sensations. Analyses by Bollen et al [69,70] and Field et al [71] showed that patients with AD who report only low subjective craving and high abstinence motivation tend to avoid alcohol-associated cues when presented. Based on these findings, future studies should include fixation analyses as a measure of attentional bias to better understand the relationship between subjective craving and physiological parameters and why these sometimes differ from one another.

Limitations

The single-arm design of this study does not allow comparisons between patients with AD and healthy controls, which would have shifted the study's focus but should be reconsidered in further studies. Regarding the physiological measurements, we did not assess nicotine or caffeine consumption directly before study participation, which could have influenced both the baseline and risk scenario results. Additionally, while gender and age were shown to influence physiological parameters such as EDA, our sample's gender distribution reflects AD prevalence and was adjusted for in the models. Further studies should include additional nonalcohol cue exposure scenarios that are comparable in complexity to the alcohol cue exposure scenarios because the complexity might, for example, influence BCPD. This will strengthen confidence in the ability of specific physiological parameters to indicate alcohol craving. A further control group exposed to alcohol-associated stimuli outside VR (eg, photographs) could be used to correct for the potential sensory stimulation of VR described above.

Conclusions

We demonstrated that subjective craving can be successfully induced by VR-CE in patients diagnosed with AD. NS-SCR, RR, and BCPD were significantly altered, reflecting a physiological craving response, whereas HR, HRV, and SCL did not react significantly to alcohol-associated cues. Correlation analyses indicated significant but weak correlations between subjective craving and EDA. Based on high methodological standards and a wide range of psychophysiological craving parameters, this study complements the ambiguous research

XSL•FO
RenderX

situation regarding the induction of subjective and physiological craving and the relationship between subjective and psychophysiological parameters, offering guidance for future research on craving in VR-CE. In the long term, this will inform the development of effective VR-CET, and through further focus on psychophysiological craving signatures, possibly also biofeedback-based VR-CET in patients with AD, a disorder for which innovative treatment options are urgently needed.

Acknowledgments

We sincerely thank Dr Adam Streck and Philipp Stepnicka for their expertise in the implementation of virtual reality and continuous technical support. We also thank Edwin Schenkel for his assistance with recruitment and conducting the experiments at Salus Klinik Lindow. The authors disclose that generative artificial intelligence was not used in writing this manuscript.

Funding

The development of the virtual reality software used for the applied intervention was supported through the VirtuCueR project, which was funded by the Berlin Institute of Health and Charité–Universitätsmedizin Berlin. The Berlin Institute of Health provided protected time for NT, SG, and AL and partially funded the hardware. This project was supported by the Sonnenfeld Stiftung. The work was in part supported by the German Research Foundation (DFG: Project-ID 402170461 – TRR 265 [AB, FB, and AH]) and the Innovation Fund of the Joint Federal Committee (GBA: Project-ID 01NVF22102 [AB]). AL and IN are participants in the BIH Charité Digital Clinician Scientist Program funded by Charité–Universitätsmedizin Berlin and the Berlin Institute of Health at Charité.

Authors' Contributions

AL, SG, AB, NT, and MS designed the study. AL, NR, AT, and JT conducted the experiments with assistance from NT and RS. AL, NR, and AT analyzed the data under the supervision of DS, AB, and SG. AL, NR, AT, AB, and SG wrote the manuscript. MS, FB, AH, TW, SMLM, IN, and JZF contributed to the interpretation of the findings and provided feedback and editing of the manuscript. All authors approved the final manuscript.

Conflicts of Interest

NT, SG, AB, SMLM, and AL cooperate with neomento GmbH without financial interests in the development of virtual reality (VR) software for VirtuCueR, a VR treatment for patients with alcohol use disorder, developed and supported by the Berlin Institute of Health (Digital Health Accelerator Program) and Charité-Universitätsmedizin Berlin. TW is a shareholder of neomento GmbH. SG received funding from Welt Co and Lindus Health with no relation to the study. NR, AT, JT, JZF, DS, IN, MS, RS, FB, and AH have no competing interests to declare.

Abstract

Background: Adolescents and young adults account for a disproportionate number of new HIV diagnoses in the United States due to missed opportunities for education, testing, and prevention.

Objective: We tested the efficacy of an interactive life-simulation gaming intervention to provide HIV education and improve HIV testing uptake and preventive services among youths ages 13 - 24 years in the Washington, DC area.

Methods: We conducted a parallel randomized controlled trial testing the efficacy of an HIV-focused gaming intervention app to a control app in increasing HIV testing uptake. Participants were recruited via social media and peer referral. Eligible participants were randomized 1:1 by age (13 - 17 vs 18 - 24 years) and sexual orientation (lesbian, gay, bisexual, or "other" vs heterosexual). Participants accessed their assigned app for 3 months and completed baseline, 1-, 3-, and 6-month surveys. The primary outcome was self-reported HIV testing within 6 months after enrollment; secondary outcomes included intent to test for HIV, HIV knowledge, and intention to start pre-exposure prophylaxis (PrEP). Analyses were conducted as intent-to-treat and stratified by sexual orientation.

Results: From November 2023 to May 2024, we randomized 309 participants (intervention: n=156; control: n=153) with 80% and 88% retention at 6 months, respectively. Among the analyzed participants (intervention: n=150; control: n=149), the mean age was 20.7 (SD 1.84) years, 49% (145/299) were women, and 34% (103/299) were non-Hispanic White. Overall, 53% (158/299) self-reported as gay, lesbian, bisexual, or "other" sexual orientation. A total of 48% (144/299) had previously tested for HIV. Compared to the control app, game participants were 32% less likely to test for HIV within 6 months (relative risk 0.68, 95% CI 0.47 - 0.98). The two groups showed no statistically significant differences regarding their intention to get tested for HIV or to start PrEP. A significantly higher difference in mean HIV knowledge scores at 3 months (0.99, 95% CI 0.33 - 1.65; *P*<.01) and 6 months (0.81, 95% CI 0.14 - 1.48; *P*=.02) was observed in the game arm compared to the control arm. Additionally, heterosexual participants in the game arm had statistically significant increases in PrEP intention (0.53, 95% CI 0.05 - 1.00; *P*=.03) across all time points compared to controls.

Conclusions: Our interactive gaming app was less effective than an information control app in increasing HIV testing and changing testing and prevention intentions among adolescents and young adults. In the game arm, we did observe increased HIV knowledge and increased PrEP intention among heterosexual adolescents and young adults. Few life-simulation apps integrating HIV testing and prevention features have been rigorously tested among adolescents and young adults. Our efficacy findings suggest that while these interventions are feasible and acceptable to adolescents and young adults, they require additional tailoring to improve their reach, use, and potential effectiveness in real-world settings.

Introduction

Background and Rationale

Adolescents and young adults ages 13 - 24 years account for 18% of new HIV infections in the United States, with racial and ethnic minority groups and men who have sex with men being disproportionately impacted [1]. Additionally, an estimated 50% or more of youths in the United States are unaware they are living with HIV, indicating that there are critical gaps in getting adolescents and young adults tested for HIV [2,3]. Accordingly, national initiatives such as the US National HIV/AIDS Strategy and the Ending the HIV Epidemic initiative have focused on reducing HIV incidence in this key population through efforts such as improved self-assessment of HIV risk, increased uptake of HIV prevention efforts, and use of routine HIV testing [4-6].

In Washington, DC, a priority jurisdiction for Ending the HIV Epidemic efforts, in 2023, 36% of new HIV diagnoses were among persons ages 13 - 29 years, making this the leading age group for new diagnoses [7]. Adolescents and young adults in DC have high rates of gonorrhea and chlamydia with 29% and 45% of diagnoses in 2023, respectively, occurring among persons ages 13 - 24 years [7]. These high rates of sexually transmitted infections (STIs) are likely a result of engaging in condomless sex; thus, adolescents and young adults may also be exposing themselves to HIV [8]. Data from the 2023 Youth Risk Behavioral Survey conducted in DC among high school students further support these risky behaviors, with 82% - 84% of sexually active youths reporting never being tested or not sure if they were ever tested for an STI and 76% - 80% never being tested or not sure if they were ever tested for HIV [9]. Finally, these data highlight the need for increased education around HIV prevention, with as many as 39% of heterosexual and 48.9% of lesbian, gay, and bisexual high school students not receiving HIV education at school [9].

Despite engaging in these risky behaviors, and initiatives focused on routine testing among adolescents and young adults, adolescents and young adults do not partake in routine HIV testing, which results in missed opportunities for HIV education, prevention, and possibly early diagnosis [10-16]. Barriers to testing include lack of provider screening, lack of self-perceived risk, lack of knowledge regarding HIV and HIV prevention services such as pre-exposure prophylaxis (PrEP), and difficulty identifying and accessing HIV testing sites [16-21]. These data suggest that there are significant gaps in our ability to educate youths on how to prevent HIV, engage in safe sexual behaviors, and access resources such as HIV testing and PrEP [12,17,22].

The use of technology-based interventions to address HIV among adolescents and young adults has emerged over the last decade [23-25]. Moreover, with the pervasiveness of mobile phones and use of social media among adolescents and young adults, digital gaming is a promising approach to facilitate the delivery of health-related information, particularly as it relates to HIV. A systematic review conducted in 2015 identified 55 smartphone, internet, and web-based interventions addressing the HIV care continuum, of which only 5 used gaming approaches [24]. More recent reviews have identified more than 30 game-based interventions focused on HIV prevention [26]. For example, an increasing number of digital game–based interventions, or serious games, have been developed to address various steps along the HIV care continuum, including to promote sexual health literacy [27,28], HIV risk assessment and reduction [29-31], HIV prevention and testing [32-34], as well as PrEP adherence [35]. Although some of these programs have demonstrated preliminary acceptability and feasibility, results from several of these trials are forthcoming, and there is limited research on their efficacy in increasing HIV testing among adolescents and young adults [33,36-39].

Evidence also suggests that when people practice new behaviors in virtual environments, they acquire new skills that they are more likely to apply in real-life situations [30,31,40-43]. Additionally, these games can be used to assess varying levels of exposure to an intervention and have the potential for sustained exposure [30,31].

Objectives

Given the high rates of HIV among adolescents and young adults, the need to increase HIV testing and access to prevention interventions, and the pervasive use of technology, more specifically gaming, we sought to test the efficacy of a theoretically based interactive and entertaining dating-and-life simulation game with the goal of increasing HIV knowledge and risk assessment and facilitating access to HIV testing and PrEP. Our intervention was grounded in social cognitive theory [44] and the health belief model [45] and iteratively informed and designed through focus groups and pilot testing by adolescents and young adults [46]. The final intervention product was designed to offer adolescents and young adults personally tailored risk messages and support their accessibility to HIV testing and prevention services through an innovative gaming approach [47]. In this analysis, our objective was to assess the efficacy of the interactive, life-simulation game to increase HIV testing, knowledge, and prevention, and reduce risk behaviors among adolescents and young adults ages 13 - 24 years compared to a control app that provided static information on HIV prevention, care, and treatment.

Methods

Participant Recruitment

Between November 2023 and May 2024, participants were recruited using a combination of community-based outreach and social media advertisements. Targeted advertisements were developed and placed on social media sites (ie, Facebook,

XSL•FO
RenderX

Instagram, Twitter, Snapchat, and YouTube). In addition, advertisements were placed at local community-based organizations, local colleges and universities, and 2 local public health clinics (DC Health and Wellness Center and the Montgomery County Maryland Health Center). Potential participants were able to scan a QR code or click on an advertisement to complete an online screener that assessed their age, gender, sexual behaviors and orientation, state of residence, and availability of a reliable cell phone. Peer referral was also used, where eligible participants were provided with unique links to share with up to 3 of their peers. Participants received an additional US $10 incentive for each peer recruited who participated in the trial. REDCap was used to generate peer referral links, screen potential participants, and record and manage the eligibility screener surveys for peer-recruited participants [48,49].

Eligible participants were ages 13 to 24 years, self-reported being HIV negative or unknown status, self-reported ever being sexually active (inclusive of oral, anal, or vaginal sex), were residents of the DC metropolitan region (DC, Southern Maryland, and Northern Virginia) for at least the next 6 months, were able to provide informed consent, were able to complete all study procedures in English, and had their own mobile phone to be used for the study duration. To reduce the risk of fraud due to online screening, all participants meeting eligibility criteria were contacted by telephone by a member of the study team to confirm their responses and eligibility for the study.

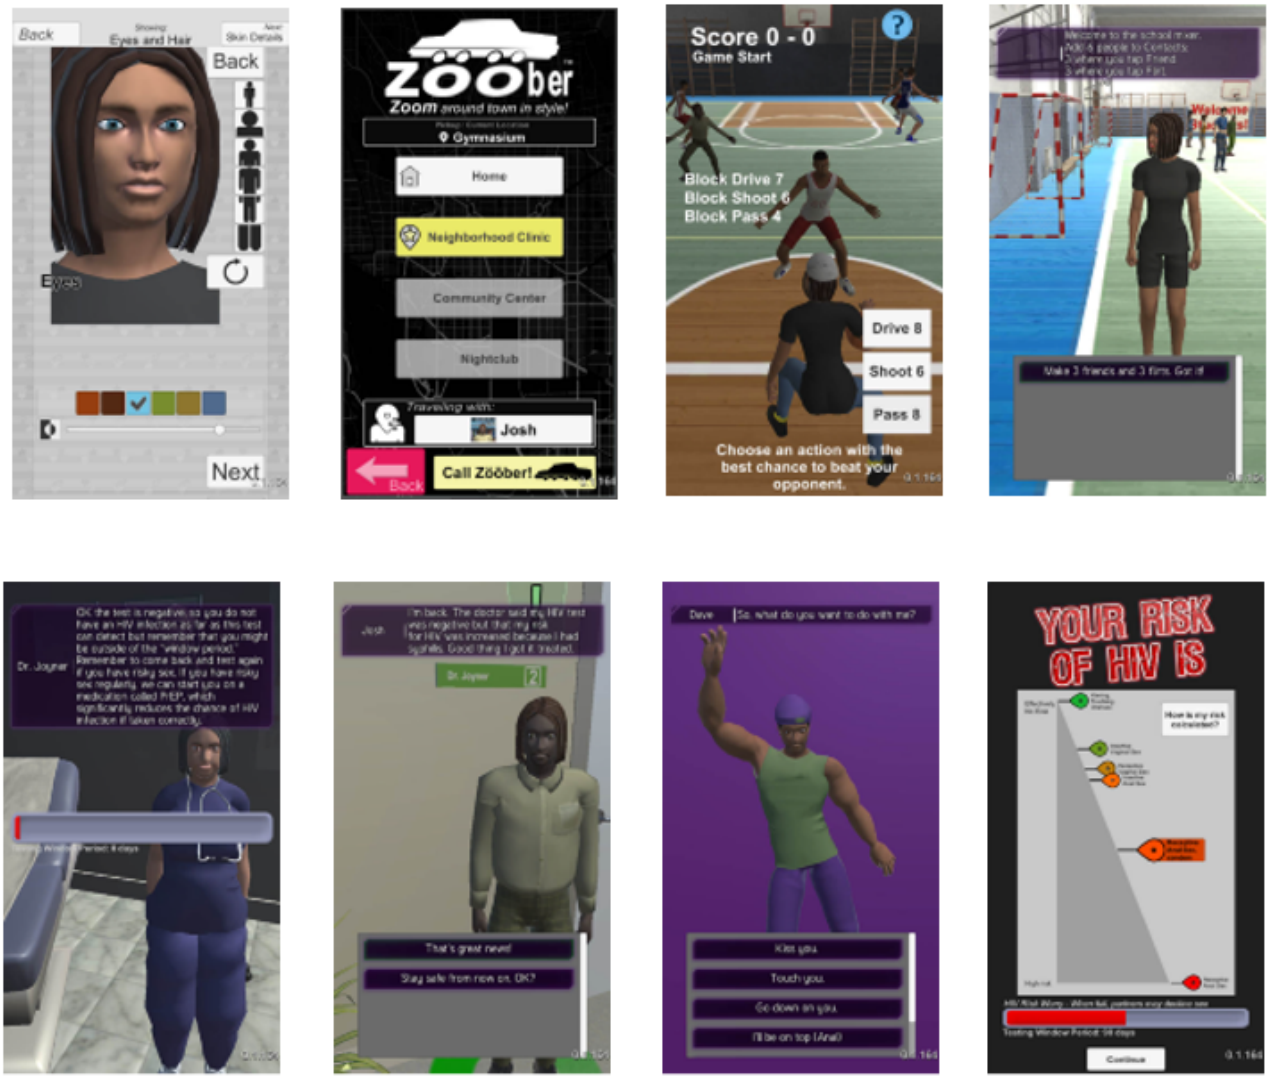
A waiver of parental consent was obtained for participants aged 13 to 17 years as well as a waiver of written informed consent. After participants were screened for eligibility and fraud, they were provided with a link to REDCap to provide electronic consent or assent.

There was no public involvement in the design or reporting of the trial. A separate group of adolescents and young adults helped inform the intervention but were not involved in the conduct of the trial [47].

Trial Design

This study has been reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2025 checklist (Checklist 1) and the CONSORT-eHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist for randomized controlled trials [50,51].

Study Arm Randomization



Once verified and consented, participants were randomized 1:1 to 1 of 2 study arms for a 3-month period: (1) the intervention arm, in which participants had unlimited access to the interactive game, as well as a Centers for Disease Control and Prevention (CDC)–supported HIV risk estimator tool [52], and HIV and PrEP locators [53], both of which were embedded within the game; or (2) the control arm, in which participants had access to a static HIV educational app curated from existing resources including the U.S. CDC website on HIV, the CDC HIV risk estimator tool, and the HIV and PrEP locator websites. Participants were randomized in blocks of 8, stratifying by age (13-17 and 18-24 years) and sexual orientation (lesbian, gay, bisexual, or “other” vs heterosexual), using a random number generator for assignment. Randomization blocks were set up using R (R Foundation for Statistical Computing) by the study biostatistician (AC) and applied through REDCap by the study research coordinators (CC and LK). The research coordinators did not have access to the randomization allocation sequence. Once enrolled, participants completed a baseline survey through REDCap and received a link to download either the game or control app to their personal smartphone. There was no blinding after assignment or allocation concealment.

Intervention Condition and Delivery

The game intervention included a dating and life simulation game that offered a personalized avatar and multiple mini scenes in which participants could complete mini-games or quests (eg, basketball gymnasium, community center, neighborhood clinic waiting room, and nightclub), meet and interact with friends, engage in interactive virtual dating, and identify potential sexual partners. After downloading the app to their personal mobile phones, participants had the opportunity to create their personal avatar. They were able to progress through the game at their own pace, playing the game for as little or as long as they desired. They had 18 opportunities to learn about HIV prevention (eg, condom use, postexposure prophylaxis, PrEP, and STI testing), HIV testing and treatment (eg, routes of transmission and how and where to get testing), stigma, risk reduction, and how PrEP works (“HIV learning content”) through interactions with in-game characters (Figure 1). Participants could engage in in-game dialogue with characters in the game to facilitate their ability to learn about HIV. Through prespecified dialogue, the participant could choose to engage in a hypothetical virtual sexual encounter. Anytime a participant had a hypothetical virtual sexual encounter (not graphically depicted) with an in-game sexual partner, they could make choices regarding their sexual behaviors and risks (eg, oral, anal, or vaginal sex, use of condoms, or PrEP). Once their choices were made, their risk for HIV was calculated using an integrated version of the CDC HIV risk estimator, and a link to an HIV testing and PrEP locator was available. Participants could choose to click on a link to be connected to a real-life HIV testing or PrEP site of their choice. Once downloaded, participants had access to the game for a 3-month period, with up to 30 hours of content available. Participants were asked to opt in to receive up to 4 notifications to encourage them to engage with the game. Notifications occurred after the first 7 days of no game activity and at 30, 60, and 90 days after enrollment.

XSL•FO
RenderX

Figure 1. Sample images of life-simulation gaming app intervention.

Control Condition Development and Delivery

Prior to the rollout of the intervention, the game development team (Media Rez), along with the clinical research team, developed a control app that included the same basic HIV content included in the game intervention, as mentioned earlier (eg, data on HIV transmission, prevention information, and information on HIV testing and PrEP). It also included links for additional information as well as a link to the CDC HIV risk estimator and HIV testing and PrEP locators (Figure 2). After providing informed consent and completing a baseline survey through REDCap, participants randomized to the control arm received a link to download the informational app (both iOS and Android compatible) and had unlimited access to the app for a 3-month period. Participants were asked to opt in to receive up to 4 notifications to encourage them to engage with the control arm app. Notifications occurred after the first 7 days of no control app openings and at 30, 60, and 90 days after enrollment.

XSL•FO
RenderX

Figure 2. Sample images of HIV informational app content.

Data Collection and Management

The primary outcome for the study was being tested for HIV within the 6-month period after enrolling in the study. HIV testing was measured by participant self-report at the 6-month behavioral survey. Secondary outcomes included participant self-reported HIV and PrEP knowledge, intention to test for HIV, intention to start PrEP, condom self-efficacy, and self-perceived risk. These outcomes were measured using previously validated scales at each time interval.

Data were collected through REDCap surveys at baseline, 1, 3, and 6 months after enrollment. Surveys included questions regarding self-reported sexual and HIV risk behaviors, self-perceived risk for HIV [54], barriers to HIV testing, reported HIV testing and PrEP uptake, behavioral intentions, which included intent to test for HIV [55], intent to start PrEP [56], and reduce risky behaviors, self-efficacy [57], game use, interest, acceptability, and usability [58].

To minimize nonresponse rates and social desirability bias with respect to self-reported data, all surveys were sent to participants via a web link using the REDCap system. Participants received US $30 for completion of the baseline survey, US $25 for the 1-month, US $25 for the 3-month, and US $40 for the 6-month survey.

Game and Control App Paradata and Game Usability, Acceptability, and Satisfaction

We monitored the intervention and control arm apps in real time using game data and paradata, that is, supplementary data to quantify technology use [59,60]. Paradata collected for participants in the intervention arm included length of time using the game, HIV-related game content accessed, and use of locators. For those in the control arm, use of the app, including the number of times the app was opened, and clicks on external content were collected for each participant. We also assessed game and control app usability, acceptability, and satisfaction. The System Usability Score (SUS) was used to measure game usability, with possible scores ranging from 0 to 100, with a mean score of 68 or higher indicating above-average usability [53]. Selected items from the MAKE (Motivation, Attitude, Knowledge, and Engagement) measure were used to

XSL•FO
RenderX

assess game acceptability, which included domains to measure participants' motivation, attitude, knowledge, and engagement with the game or control arm [61]. Each domain was scored with a total possible score of 160. Game satisfaction was measured using an 8-item scale with responses ranging on a Likert scale of 1 to 4, with a total possible range of scores from 8 to 32 [62].

Retention Protocol

The study research assistants and coordinators (JB, SB, CC, LK, and TM) were in contact with participants throughout the follow-up period to support downloading of the app or game, provide technical support, and provide study reminders and updates. Participants were sent a reminder of an upcoming survey 2 weeks and 1 week prior to their survey date. If participants did not complete the follow-up survey, the link was resent, and the participant was contacted via email or text message 24, 48, and 72 hours after being sent the initial email or text notification to remind them to complete it. If there was no response, the study research assistants and coordinators (JB, SB, CC, LK, and TM) contacted the participant to confirm receipt of the link and to assist them in completing it. Participants had up to 2 weeks to complete each survey. If a participant was nonresponsive after 10 attempts, the participant was considered lost to follow-up.

Statistical Methods

We described the study sample's clinical, demographic, and sexual behavior characteristics at baseline, both overall and stratified by treatment arm. We reported mean (SD) or median (IQR) for numerical variables and frequency (proportion) for categorical variables.

For the primary outcome of HIV testing within 6 months, we reported the frequency (proportion) of participants who self-reported being tested for HIV within 6 months in each treatment arm, along with the corresponding risk ratio, 95% CI, and *P* value from the corresponding Pearson chi-square test. These same statistics were also reported for the secondary outcomes of intent to test (coded as "likely" if score was 4 or higher and "unlikely" if score was 3 or lower) and PrEP initiation at 6 months [55]. Since some participants were missing either one or more of these outcomes, we also conducted a sensitivity analysis using multiple imputation by chained equations [63] to impute the missing data and then assessed treatment effect using the imputed data. A full description of the procedure and results is provided in Multimedia Appendix 1. Similar analyses, stratified by sexual orientation, are provided in Multimedia Appendix 1.

For the HIV knowledge and intent scores, we fit linear mixed effects models with each score as the outcome and with treatment arm, time (coded as a 4-level categorical variable with baseline as the reference level and dummy variables for 1, 3, and 6 months), and the interaction between treatment arm and time as predictors. A participant-specific random intercept was also included to account for correlation between repeated observations from the same individual. We conducted a likelihood ratio test (LRT) using Kenward-Roger denominator degrees of freedom to test for a significant interaction between treatment arm and time. If the LRT *P* value was less than .05, we computed the model-based contrasts between the 2 treatment arms at each time point along with the corresponding 95% CIs and Wald test *P* values. If the LRT *P* value was greater than or equal to .05, we dropped the interaction terms and refitted the model with only the main effects of treatment arm and time and reported the model-based estimate for treatment effect and corresponding 95% CI and Wald test *P* value. Similar analyses, stratified by sexual orientation, are provided in Multimedia Appendix 1. In the exploratory analyses, we also conducted each analysis for the primary and secondary outcomes, stratified by sexual orientation (heterosexual vs non-heterosexual).

We computed mean and SD for the SUS, game and app satisfaction scores, and the MAKE scale measures of game-based learning. We also computed descriptive summaries for selected paradata measures. These results are provided in Multimedia Appendix 1.

A significance level of .05 was used throughout. All analyses were conducted using R (version 4.2.2) and the following packages were used: *lme4*, *lmerTest*, *emmeans*, and *mice* [63-66].

There were no changes to the trial protocol after enrollment began with respect to eligibility criteria, the interventions, outcomes, sample size, or analysis methods. The original randomization process was changed from a block size of 6 to a block size of 8; however, the treatment allocation ratio remained 1:1, allocation concealment was maintained, and the randomization sequence was generated prior to enrollment. Despite this change, the final treatment groups remained well balanced with respect to sample size and baseline characteristics, particularly on the stratification characteristics of age and sexual orientation.

Ethical Considerations

All study activities were reviewed and approved by the George Washington University Institutional Review Board (IRB # NCR191708) and the Children's National Hospital IRB. IRB approval included a waiver of parental permission and a waiver of written consent for participants younger than 18 years of age per 45 CFR 46.404. Privacy and confidentiality protections were put in place accordingly to safeguard the identity of participants, and all data were deidentified for analysis. No identification of individual participants was used in any images or supplementary materials. The informed consent forms were revised in March 2024 to include that there may be risks of discomfort from playing the game, as it discussed sensitive topics regarding sexual behaviors. Participants could receive up to US $30 for peer referrals and up to US $120 for participation in all study activities. The trial was registered prospectively, and the first participant was enrolled on November 14, 2023.

Harms

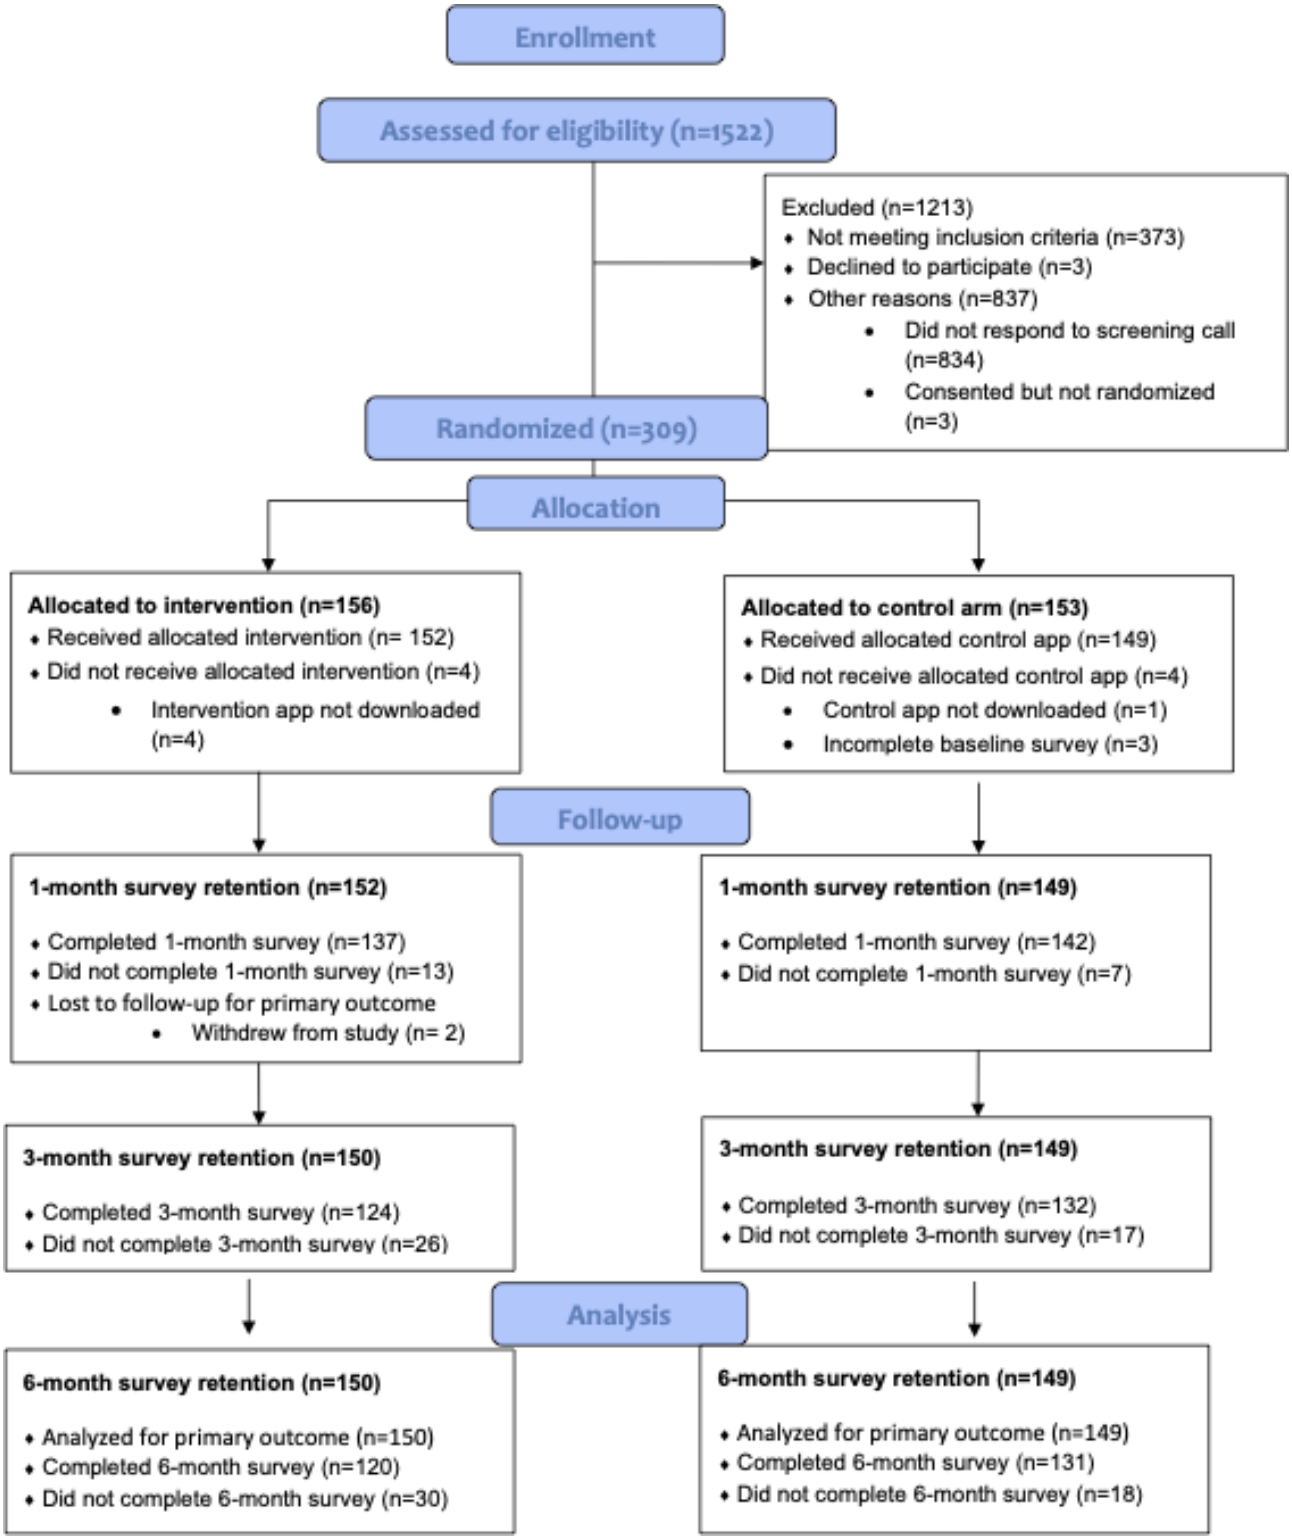
Harms and unintended effects to study participants were monitored by study staff. There were 2 participants who withdrew from the study. One participant reported being uncomfortable with the sexual content in the game, prompting

XSL•FO
RenderX

a change in the informed consent language. No other harms were reported by participants during the study period.

Sample Size

We conducted a power analysis to determine the appropriate sample size to be able to determine the efficacy of the intervention. We determined that a sample with approximately 300 participants (150 per arm) would achieve >80% power to detect a moderate effect corresponding to a difference of at least 13 percentage points (equivalent to a relative risk [RR] of 2.3 assuming a 10% prevalence of past 4 - 6 months HIV testing in the control group) in HIV testing between the intervention and control groups after 6 months using a 2-sided test at a 5% significance level and assuming a 16% attrition rate after 6 months.



Results

Participant Recruitment, Enrollment, and Retention

Over a 6-month period, we screened 1522 people for study eligibility, of whom 1213 (80%) were ineligible for reasons including not meeting inclusion criteria (n=373), not responding to the fraud check screening call (n=834), refusing to participate (n=3), or being consented but not randomized (n=3; Figure 3). Of the remaining 309 (20%) who were eligible and randomized, 156 (51%) participants were assigned to the intervention arm and 153 (50%) assigned to the control arm. A total of 299 participants successfully downloaded either the game or intervention app and completed baseline surveys. Participants were primarily recruited through social media (Instagram, Facebook, or Snapchat, 84%) followed by peer-referral (16%). Study retention at 1, 3, and 6 months in the intervention arm was 90% (137/152), 83% (124/150), and 80% (120/150), respectively. Study retention at 1, 3, and 6 months in the control arm was 95% (142/149), 89% (132/149), and 88% (131/149), respectively. Our final 6-month analytic end-point analysis included 150 intervention arm participants and 149 control arm participants who completed at least 1 study follow-up survey.

Figure 3. Study eligibility, enrollment, and retention.

Baseline Participant Demographics

Participants were a mean age of 20.7 (SD 1.84) years, with 8 (3%) participants being younger than 18 years of age (Table 1). Approximately 19% (56/299) were Hispanic, 20% (59/299) were non-Hispanic Asian, 19% (58/299) were non-Hispanic Black, and 34% (103/299) were non-Hispanic White. Women accounted for 49% (145/299), 41% (121/299) identified as men, 8% (23/299) identified as nonbinary, and 3% (4/299) identified as transgender. Participants were 46% (137/299) DC residents, 45% (135/299) had completed some college or technical school, and 58% (173/299) were employed. With respect to sexual orientation, 47% (141/299) reported being heterosexual and 47% (141/299) as gay, lesbian, or bisexual, with 6% (7/299) reporting "other" sexual orientation. Almost half (144/299, 48%) had previously tested for HIV, with 17% (52/299) reporting being tested within the prior 3 months.

[a]GED: General Education Degree.

[b]N/A: not applicable.

[c]The Napper self-perceived risk score was calculated based on responses to 8 items with possible scores ranging from 8 to 43, where 8 represents the lowest possible self-perceived risk and 43 the highest self-perceived risk.

[d]The HIV knowledge score was calculated based on true or false responses to 16 items with possible scores ranging from 0=all incorrect responses to 16=all correct responses.

[e]PrEP: pre-exposure prophylaxis.

[f]The PrEP knowledge score was calculated based on true, false, or do not know responses to 13 items with possible scores ranging from 0=all incorrect responses to 13=all correct responses.

[g]The PrEP intention score was calculated based on responses to 3 items each with a possible score of 1 - 4. Possible scores range from 3 to 12, with 3 representing the lowest level of PrEP intention and 12 representing the highest level.

At enrollment, 34% (101/299) reported being somewhat, very, or extremely likely to test for HIV in the next 6 months. The mean self-perceived risk score for HIV was 19.10 (SD 5.4) out of a possible 43, the mean HIV knowledge score was 9.25 (SD 3.01) out of a possible 16, and the mean PrEP knowledge score was 3.69 (SD 4.02) out of a possible 13. In total, 6% (18/299)

XSL•FO
RenderX

of participants had ever used PrEP, and the mean PrEP intention score was 6.32 (SD 2.02) out of a possible 12. Participants in the 2 treatment arms were similar based on baseline characteristics.

Participant Self-Reported Sexual and HIV Risk Behaviors

Participants reported a median of 3 (IQR 1 - 7) lifetime sexual partners, and 60% (178/299) had been sexually active within the last month, with most engaging in oral sex, followed by vaginal and anal sex (Table 2). A majority (256/299, 86%) reported engaging in either unprotected oral, vaginal, or anal sex. About one quarter (72/299, 24%) of participants did not know their sexual partner's HIV status, and 69% (206/299) reported that their recent sex partner was a primary partner. In total, 10% (30/299) of participants reported ever being diagnosed with an STI, with chlamydia being the most commonly diagnosed STI (19/30, 63%), followed by gonorrhea (5/30, 17%). The mean condom self-efficacy score was 6.45 (SD 2.69) out of a possible 20, which is the highest level of self-efficacy. Sexual and HIV risk behaviors were similar across arms.

[a]STI: sexually transmitted infection.

[b]Condom self-efficacy score was calculated based on responses to 4 items, with responses on a 5-point scale. The possible range of scores is 4=lowest self-efficacy to 20=highest self-efficacy.

Primary Efficacy and Secondary Outcome Analyses

In our analysis assessing the efficacy of the game intervention compared to the control app for our primary outcome of HIV testing, 26% (32/150) of game participants versus 38% (48/149) of control participants reported being tested for HIV within 6 months. Game participants were 32% less likely than control arm participants to be HIV tested at 6 months (RR 0.68, 95% CI 0.47 - 0.98; Table 3). With respect to intention to get tested in the next 6 months and intent to start PrEP, there were no statistically significant differences by study arm.

Table . Analysis of main and secondary outcomes[a] at 6 months.

	Control app, n (%)	Game intervention, n (%)	Game versus app, RR[b] (95% CI)	*P* value	Missing, n
HIV testing	48 (38)	32 (26)	0.68 (0.47-0.98)	.04[c]	51
Intent to test	81 (62)	74 (58)	0.94 (0.77-1.15)	.56	41
PrEP[d] initiation	14 (11)	11 (9)	0.80 (0.38-1.69)	.56	53

[a]All outcomes are dichotomous.

[b]RR: relative risk.

[c]Statistical significance.

[d]PrEP: pre-exposure prophylaxis.

When we examined selected secondary outcomes over time, we found that with respect to HIV knowledge, the treatment effect varied over time (LRT *P*<.001) such that there was a statistically significant difference in mean knowledge scores at 3 (*P*=.003) and 6 months (*P*=.02), with the game arm scoring nearly one point (0.99, 95% CI 0.33 - 1.65) higher than the control app arm at month 3 and 0.81 (95% CI 0.14 - 1.48) points higher at month 6. There were no statistically significant differences for other outcomes including PrEP knowledge, intent to test, condom self-efficacy, self-perceived risk, or PrEP intention (Table 4).

[a]Italics format indicates that *P* values <.05 are statistically significant.

[b]PrEP: pre-exposure prophylaxis.

Ancillary Analyses

We performed the Little missing completely at random (MCAR) test, restricting the data to numerical variables, and the 3 primary outcome variables coded as 0 - 1 binary variables. There were 15 missing data patterns, and the test statistic value was 270.0 with corresponding degrees of freedom of 220 and *P* value of .01, indicating adequate evidence against the MCAR assumption. We conducted sensitivity analyses of our primary and secondary outcomes accounting for missing data using multiple imputation, which is valid under the less restrictive missing at random assumption than MCAR, as well as stratified by sexual orientation (Tables S1-S4 in Multimedia Appendix 1). The estimated RR for the primary outcome of HIV testing at 6 months based on multiple imputation (0.68) was the same as that from the complete case analysis shown in Table 3; however, the corresponding *P* value is .05. Results for the intention to get tested in the next 6 months and intent to start PrEP were similar in the complete case and multiple imputation analyses.

Among participants identifying as heterosexual, the PrEP intention score increased on average 0.53 points (95% CI 0.05 - 1.00) in the game intervention arm compared to the control app arm across all study time points (*P*=.03; Table S3 in Multimedia Appendix 1). Additionally, at the 3-month time point, game participants identifying as heterosexual had a mean HIV knowledge score that was 1.52 points higher (95% CI 0.49 - 2.56) compared to the control arm (*P*<.01; Table S4 in Multimedia Appendix 1).

Game and Control App Usability Data

When assessing game intervention and control app usability data at 1 and 3 months, we found that at 1 month, participants in the game arm compared to the control had lower mean SUS scores (67.9, SD 14.22 vs 72.8, SD 12.26; *P*<.01), yet had statistically significantly higher MAKE and overall scores (all *P*<.01; Table S5 in Multimedia Appendix 1). At the 3-month follow-up, game arm participants had lower SUS scores versus control, but retained higher scores on all components of the MAKE measures (all *P*<.01). There were no statistically significant differences in overall game-app satisfaction at 1 month or 3 months when comparing across arms.

Game Intervention and Control App Paradata

The median number of times that a participant engaged with the game was 27 (IQR 7.4 - 64.0) minutes over the 3-month intervention period (Table S6 in Multimedia Appendix 1). When assessing game intervention progression through the various stages of the game, 47% (70/150) of participants progressed up to 25% of the way through the game; 16% (24/150) progressed through the entire game content. The median number of HIV learning content items seen was 10 (IQR 5 - 15) out of a possible 18 items. The median number of times that a participant opened a map to look for a provider was 2 (IQR 0 - 3). For participants in the control app arm, the median number of app openings was 4 (IQR 2 - 6) over the 3-month period; and the median number of URL clicks to access additional content was 0 (IQR 0 - 1).

Discussion

Interpretation

Using primarily online social media recruitment, we were able to recruit and retain a diverse population of adolescents and young adults at risk for HIV infection living in the Washington, DC area for a randomized controlled trial of an interactive educational gaming intervention compared to an educational control app. While we hypothesized that the game intervention

XSL•FO
RenderX

would be more effective in increasing HIV testing among adolescents and young adults after a 3-month exposure period, we found the gaming app was 32% less effective than the control condition in increasing HIV testing at the end of 6 months. Additionally, secondary data analyses also indicated that HIV testing intentions and intentions to start PrEP were not higher in the gaming group compared to the control group at 6 months. We did, however, observe a minimal yet statistically significantly higher HIV knowledge score among game intervention participants at 3 and 6 months, suggesting both short-term and sustained effects and that the interactive game intervention may have been better at delivering information on HIV to participants compared to the control. This effect persisted when stratifying by sexual orientation, with heterosexual participants having statistically significantly higher HIV knowledge scores at the 3-month time point and higher PrEP intention scores at all time points compared to the control arm. Finally, there were no statistically significant differences for secondary outcomes such as PrEP knowledge, intent to test for HIV, condom self-efficacy, and self-perceived risk.

Our findings are consistent with other HIV testing and prevention serious gaming app-based interventions focused on adolescents and young adults with respect to increases in HIV knowledge. For example, the MyPEEPS mobile randomized trial, which focused on reducing sexual risk among young men who have sex with men, found no differences in HIV testing or PrEP uptake, which is consistent with our results [67]. On the other hand, PlayTest!, a school-based randomized trial, found improvements in HIV testing attitudes and intentions, knowledge, and self-efficacy [68]. Several studies have reported preliminary improvements in sexual behavior knowledge and risk perception from pilot testing [37,69-71]; however, efficacy trial results are not available for these studies. As for our secondary outcomes, several other studies, including the Tumaini trial in Kenya, which was a community-level 2-arm randomized trial aimed at delaying the age of sexual debut and increasing condom use among persons aged 13 - 14 years [72], found significant effects on condom self-efficacy, as have other mobile gaming apps [69].

Possible explanations for the lack of efficacy of the intervention game to increase HIV testing may be related to the usability and acceptability of the gaming intervention and study design used. Although usability of the game was considered above average and higher MAKE scores were observed among the game intervention participants, we did not observe any statistically significant differences in satisfaction across the 2 study arms. The difference in usability scores across the 2 arms may be explained by the fact that the game was complex, had multiple steps, and was intentionally more interactive than the control app [73,74]. For example, intervention participants had to learn to play the game, whereas control arm participants only had to navigate a static informational app. Further, since control app satisfaction was also relatively high, the control app may not have represented a real-world placebo condition. However, it may also suggest that a lower level “intervention” such as our established control materials may be as effective as an interactive game. Other possibilities may be explained by the sample composition, where baseline participants already had a moderate level of HIV knowledge, and almost one-third reported already being likely to test for HIV in the next 6 months. The finding of higher PrEP intention among heterosexual-identifying participants is reassuring that the game content may have resulted in increased PrEP education and awareness among these participants who may not always be the focus of HIV prevention and PrEP messaging [8-11].

To increase the ability to measure the efficacy of the game, future iterations of the intervention might include a 3-arm trial with an observational group compared to the control app and the game intervention [75,76]. Alternatively, it was unclear if the duration of the game intervention may have been too short to demonstrate an effect; therefore, allowing participants continued access to the intervention components after the designated intervention period could determine if the intervention is delivered more effectively as a continuously available resource in a real-world setting versus being delivered over a specified and limited period of time. Finally, adding additional components to the game such as the ability to order home-based HIV and STI test kits [77,78] may have resulted in increased game use and possible efficacy results.

The game paradata also provided additional data to assist with interpretation of our findings. For example, it may be that the interactive game was not sufficiently engaging for our participants. Paradata found that game participants had relatively limited use at just under 30 minutes, and only 16% progressed through all of the game content with exposures to a median of 10 of 18 HIV educational items. Control app use was also limited, with a median of 4 openings and few to no clicks for supplemental information. Additional analyses by level of game use or content viewing may provide further information on the characteristics of participants who received various levels of exposure to the HIV content from the game and the potential dose-response effect on the primary and secondary outcomes [59,60].

Qualitative interviews were also conducted among a purposeful sample of game participants. These interviews are currently being analyzed and will provide valuable information to help elucidate game intervention components and features that were most effective and how the game can be improved upon to more effectively deliver HIV prevention and testing information to adolescents and young adults.

Despite the lack of efficacy of the intervention, we were successful in recruiting and retaining a diverse cohort of adolescents and young adults with respect to race, ethnicity, and sexual orientation. Importantly, 6-month retention ranged from 80% to 88%, and more than half of our sample self-identified as lesbian, gay, bisexual, or other sexual orientation, and 38% identified as non-Hispanic Black or Hispanic. Our retention and participant diversity mirror that of similar interventions, which have also recruited racially and ethnically diverse groups of adolescents and young adults and had high retention rates [67]. Given that racial, ethnic, and sexual minority groups account for the highest proportions of new HIV diagnoses younger than 25 years of age [1], it was essential that we were able to include and consistently engage these individuals in testing our HIV prevention intervention.

XSL•FO
RenderX

While we sought to recruit participants as young as 13 years of age in our study and tailored our social media advertisements to recruit younger participants, this proved more challenging, with only 8 participants younger than 18 years of age. At the time of study recruitment, several social media companies (eg, Meta) had restrictions placed that limited advertisements to persons younger than 18 years of age [79], and while we had over 1 million advertisement impressions from potential participants younger than 18 years of age, only 0.61% clicked on the advertisements. Moreover, of those 13-17 years of age who completed a screener (n=70), a total of 48 (69%) were ineligible for the study, as they had never been sexually active. Improved efforts to reach this younger age group are necessary and may include the delivery of school-based interventions, overall support for life skills development, educational videos, and clinic-based interventions that are accessible, relatable, and individually tailored to this younger age group [21,23,29,77,78,80,81]. While 6-month retention differed across the 2 study arms (80% game intervention vs 88% control arm), we do not think that this affected our results, as there were no baseline differences in randomization between the 2 groups, and study retention procedures were the same across the 2 study arms. This difference in retention may be partially explained by game fatigue, where participants tire of the existing game content and stop playing as much. Future iterations of the game could include periodically releasing new game content to increase participant engagement or inclusion of reward systems (eg, badges and prizes) to boost retention and increase access to HIV prevention educational material [82,83].

Limitations

Limitations of our study include that we were only able to include English-speaking participants who lived in the DC metropolitan region and that we did not recruit a large enough sample younger than 18 years of age to conduct further stratification by age, thereby limiting the representativeness and generalizability of our findings. Study recruitment at clinical sites was limited due to the COVID-19 pandemic and subsequent operational changes at the clinic level. Had recruitment included clinic-attending adolescents and young adults, it may have resulted in recruitment of more participants younger than 18 years of age. The game was created to appeal to both adolescents and young adults; however, given the limited number of participants younger than 18 years of age, we do not know if it would have been more effective with this younger age group since design choices made for adolescents may not necessarily have the same appeal to young adults. Future intervention testing should consider different versions of the game based on age and more purposeful sampling of younger age groups, as they tend to face more barriers to accessing HIV education and testing than those older than 18 years of age [17,46,84]. Additionally, testing the intervention in regions of the United States that have different policies, laws, and levels of access to HIV preventive care than the DC area would also increase the generalizability and potential reach of our intervention, particularly in areas where HIV education may not be occurring in schools or access to HIV testing is restricted in adolescents and young adults [85]. Despite these limitations, strengths include successful social media recruitment with limited numbers of fraudulent participants and high retention rates among an often-transient population.

In conclusion, to our knowledge, very few other life-simulation apps focused on HIV testing among both adolescents and young adults, regardless of sexual orientation, with integration of HIV testing and prevention features have been rigorously tested for efficacy in the United States to date. Prior studies that have looked at increasing HIV testing uptake and knowledge are feasibility and pilot studies [32], have focused solely on young men who have sex with men [86], have been conducted outside of the United States [72], or have focused on PrEP adherence rather than PrEP education [87]. Moreover, results from large, randomized trials are limited [37,39,68,70,82,87], allowing our study to add to this important and emerging body of research.

In this study, we sought to determine if an interactive life-simulation approach to delivering HIV testing and prevention information would be more effective than an informational control app. We found that the interactive game was not more efficacious, and our “active” control app may be as good at engaging young adults in HIV prevention activities. Given the limited number of participants ages 13 to 17 years, additional testing of the intervention is needed to determine its potential efficacy among this younger age group. Nevertheless, the game intervention was able to increase HIV knowledge and PrEP intention among heterosexual adolescents and young adults, indicating that it was able to effectively deliver information to increase their exposure to HIV prevention and interventions. Our novel and early findings of observed improvement in PrEP intention add to the limited body of literature on the role of interactive gaming interventions in HIV prevention and PrEP specifically, and among all adolescents and young adults and not just young men who have sex with men [31,87,88]. Digital interactive game-based technologies are regularly used by adolescents and young adults, and their ability to deliver feasible, acceptable, scalable, and affordable HIV interventions is yet to be fully realized [31,88,89]. Thus, additional research and innovative approaches are needed to scale technology-based interventions to increase engagement in HIV testing and knowledge and PrEP intention and knowledge for all adolescents and young adults at risk for HIV acquisition so that they can be applied and shown to be effective in real-world settings.

Acknowledgments

Abstract

Background: Subthreshold depression (StD) increases the risk of progression to major depressive disorder. Although exercise can reduce depressive symptoms, adherence remains challenging. Exergames on platforms such as Nintendo Switch may improve motivation and participation in physical activity; however, evidence for efficacy in StD is limited.

Objective: This study aims to evaluate the effects of a Nintendo Switch–based exergaming intervention on depressive symptoms, anxiety, and sleep quality, and to explore participant experiences among adults with StD.

Methods: This sequential explanatory mixed methods study comprised a randomized controlled trial followed by semistructured interviews. Eighty-four adults with StD were randomized using computer-generated permuted blocks with concealed allocation to an intervention group (IG; n=42), which received an 8-week Nintendo Switch–based exergame program (2 - 3 sessions/week, 50 - 60 minutes/session), or a control group (CG; n=42), which continued usual activities. Outcome assessors and data analysts were blinded. Depressive symptoms, anxiety, and sleep quality were assessed at baseline (T0), postintervention (T1, Week 8), one-month follow-up (T2, Week 12), and 2-month follow-up (T3, Week 16). Generalized estimating equations (GEE) were used to analyze longitudinal changes and time×group interactions under the intention-to-treat principle. Semistructured interviews were conducted with a purposive subsample of IG participants (n=17) at T1 and analyzed using thematic analysis.

Results: Eighty-four participants were randomized; 81 completed the postintervention assessment, with 3 out of 42 (7.1%) CG participants lost to follow-up at T1. Baseline characteristics were similar across groups (mean age 23.07, SD 1.45 years; 70/84, 83.3% female). Compared with CG, the IG showed significantly greater reductions in depressive symptoms at all time points (T1: β=−4.07, 95% CI −5.84 to −2.30; *P*<.001; T2: β=−4.29, 95% CI −6.14 to −2.43; *P*<.001; T3: β=−3.81, 95% CI −5.54 to −2.08; *P*<.001), along with significant improvements in sleep quality (T1: β=−2.98, 95% CI −4.55 to −1.40; *P*<.001; T2: β=−2.19, 95% CI −3.58 to −0.80; *P*=.002; T3: β=−2.45, 95% CI −3.81 to −1.09; *P*<.001). Anxiety also improved significantly at T1 (β=−2.60, 95% CI −4.70 to −0.50; *P*=.02) and T3 (β=−2.38, 95% CI −4.62 to −0.14; *P*=.04). Group×time interactions were significant for depressive symptoms (Wald χ^2_3=28.18; *P*=.001) and sleep quality (Wald χ^2_3=23.21; *P*<.001), confirming sustained intervention effects. Qualitative findings supported these results, highlighting immersive engagement, perceived psychophysiological benefits, and adherence facilitators. No adverse events were reported.

Conclusions: A Nintendo Switch–based exergaming intervention was associated with improvements in depressive symptoms, anxiety, and sleep quality in adults with StD. Using mixed methods design, this study provides evidence integrating effectiveness and participant experience, extending prior research focused on other populations or quantitative outcomes. These findings suggest that commercially available exergaming platforms may serve as accessible, engaging tools for early mental health support in real-world settings.

Introduction

Background and Rationale

Subthreshold depression (StD) is considered a precursor stage of major depressive disorder (MDD) and represents an important target for early intervention [1]. It is typically characterized by the presence of 2-4 depressive symptoms persisting for at least 2 weeks without meeting the full diagnostic criteria for MDD [2]. Epidemiological studies suggest that StD is highly prevalent in the general population, with estimated rates ranging from 7.3% to 17.2% among adults, and is associated with a significantly increased risk of developing MDD and other psychiatric disorders [3]. In addition, individuals with StD may experience impaired functioning and an elevated risk of suicidal ideation [4]. Therefore, early and effective interventions targeting StD are essential to prevent the progression to MDD and to reduce associated public health burdens.

Exercise therapy is a proven nonpharmacological intervention for reducing depressive symptoms, offering advantages such as low cost, few side effects, and rapid efficacy [5]. However, its repetitive and unengaging nature often limits motivation and long-term adherence. Given that depression is characterized by low mood and diminished interest in activities [6], interventions that incorporate behavioral activation and intrinsic motivation are particularly suitable.

In recent years, serious games, digital games designed for purposes beyond entertainment, such as education, rehabilitation, or health promotion, have increasingly been explored as innovative tools for behavioral and mental health interventions [7]. Within this broader category, exergames represent a specific type of serious game that combines physical activity with interactive gameplay and may help overcome some of the limitations of traditional exercise interventions [8]. During exergaming activities, participants are more likely to experience a state of flow, which has been associated with greater enjoyment and sustained engagement in physical activity [9,10].

Through game mechanics such as goal-oriented tasks, real-time feedback, and reward structures, exergames have emerged as a promising approach for enhancing enjoyment, intrinsic motivation, and adherence to physical activity programs while simultaneously delivering therapeutic benefits. Previous studies have shown that exergames not only facilitate light-to-moderate intensity exercise but also enhance users' self-efficacy and willingness to engage in physical activity [11], thereby improving adherence [12]. These features may be particularly relevant for individuals with StD, who often exhibit reduced behavioral activation and altered reward sensitivity [13].

Nintendo Switch, featuring somatosensory controls and immersive design, has shown high safety, feasibility, and user satisfaction across health contexts [14,15], and is increasingly applied in neurorehabilitation and mental health care. Studies have shown that Nintendo Switch–based exergames improve physical [16,17] and psychological outcomes across populations [18-21]. Furthermore, the qualitative studies have also shown their feasibility and acceptability among stroke survivors [22] and older adults [23], who reported positive experiences and social enjoyment.

Despite the growing body of research on exergaming interventions, most studies have primarily focused on older adults [18,19] or specific clinical populations [20,21]. Evidence specifically targeting adults with StD remains limited. Moreover, most existing studies have primarily focused on quantitative outcomes, while participants' subjective experiences and perceptions of exergame-based interventions remain underexplored. Understanding both the effectiveness and user experience of such interventions may provide important insights for optimizing digital mental health strategies.

Objectives

Therefore, this study, conducted based on a previously published protocol [24], was designed as a mixed methods exergaming effectiveness trial to evaluate a Nintendo Switch–based exergaming intervention using Ring Fit Adventure (RFA; Nintendo Co Ltd) as the intervention platform. The study aimed to: (1) evaluate the effectiveness of a Nintendo Switch–based exergaming intervention in improving depressive symptoms, anxiety symptoms, and sleep quality among adults with StD; and (2) explore participants' subjective experiences of the intervention, including engagement, perceived benefits, and acceptability.

Methods

Trial Design

This mixed methods sequential explanatory design comprised an assessor-blinded, parallel-group randomized controlled trial (RCT) and semistructured qualitative interviews to evaluate the effectiveness of Nintendo Switch–based exergaming in adults with StD. This RCT adhered to the CONSORT (Consolidated Standards of Reporting Trials) 2025 statement (Checklist 1) and the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) extension for electronic and mobile health interventions to enhance transparency and reproducibility of reporting (Checklist 2) [25,26]. The qualitative component followed the APA Journal Article Reporting Standards for Qualitative Research (JARS-Qual; Checklist 3) [27].

Involvement

No patient or public involvement was incorporated into the design, conduct, reporting, or dissemination of this research.

Changes to Trial Protocol

The protocol registered in the trial registry differed from the final study protocol in several aspects. First, the sample size was provisionally estimated as 50 participants in total (25 per group) based on previous studies at the time of trial registration. Prior to participant recruitment, a meta-analysis of available studies on exergame-based exercise training for depressive symptoms in adults was conducted to obtain a more precise estimate of the expected effect size [28]. Based on the pooled effect size (0.69), the required sample size was recalculated, resulting in a revised target of 38 participants per group. Second, in the trial registry, StD was defined by the Center for

XSL•FO
RenderX

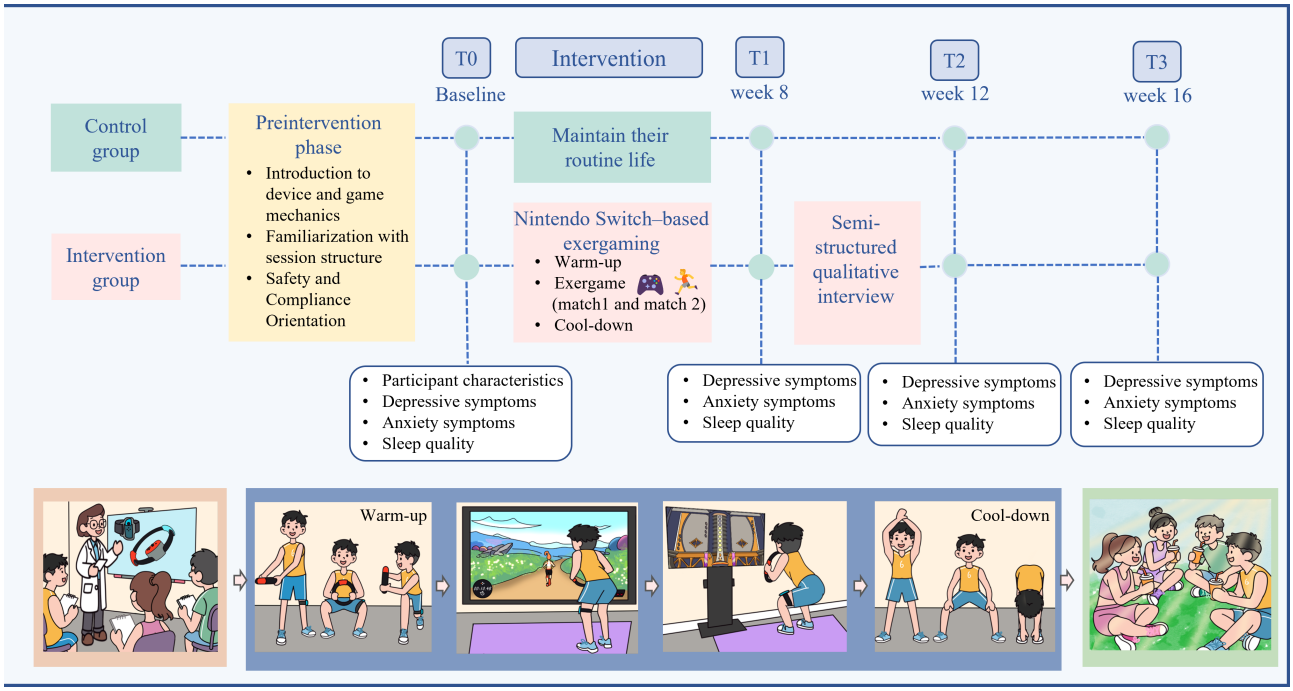
Epidemiologic Studies Depression Scale (CES-D) ≥16 and a 24-item Hamilton Depression Rating Scale (HAMD-24) score between 8 and 20. Prior to recruitment, this criterion was refined to align with contemporary diagnostic practice. In the final protocol, StD was defined as CES-D≥16 in individuals not meeting *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition)* diagnostic criteria for MDD. Third, the trial registry included several additional secondary outcomes (eg, subjective experience, flow experience, physical training, sports motivation, exercise intensity, and BMI). The present report focuses on the primary outcome (depressive symptoms) and 2 secondary outcomes (anxiety symptoms and sleep quality), while the remaining registered outcomes will be reported separately.

Quantitative Phase: RCT

Setting and Participants

Participants were recruited from 3 universities in Northeast China using a combination of strategies, including posters, flyers, social media outreach, and on-site information sessions from January to February 2023. Screening and evaluation were conducted via the WeChat (Tencent)-based Questionnaire Star platform and supplemented with face-to-face assessments. The sample size calculation is described in detail in the previously published study protocol [24], which determined a required sample size of 76 participants (38 per arm).

The participants were included in the study if they met the following criteria: (1) aged 18 years or older; (2) fulfillment of the diagnostic criteria for StD, defined as not meeting the *DSM-5* criteria for MDD but presenting with a CES-D score of 16 or higher [29]; (3) volunteered and agreed to participate in the study and signed informed consent; and (4) individuals who had not received treatment for depression in the past 6 months and did not plan to receive treatment outside the study during the trial period. Participants were excluded if they: (1) presented an intellectual disability and/or physical limitations (eg, severe mobility, visual, or hearing impairments); (2) had previously participated in the Nintendo Switch–based exergame within the past 6 months; (3) presented other types of mental health disorders; and (4) presented a suicide risk.



Intervention

The intervention was delivered by 5 trained facilitators, including 3 registered nurses with clinical experience and 2 faculty members with expertise in psychological nursing and sports medicine. To ensure fidelity, all facilitators completed 2 standardized training sessions covering the study protocol, system operation, safety monitoring, and communication strategies, with practical simulations to standardize delivery. Moreover, participants also received 2 60-minute structured preintervention training sessions from facilitators to introduce StD, Nintendo Switch, and safety education. During the intervention sessions, facilitators supervised the exercise process, guided participants through the intervention sessions, provided technical guidance on the use of the equipment, ensured participant safety, monitored adherence, and offered general encouragement to maintain participant engagement with the program.

The intervention program was developed based on existing literature on exergaming, the game category of Ring Fit Adventure (Nintendo), and the exercise prescription guidelines from the American College of Sports Medicine (ACSM), and further refined through group meetings and a pilot study. The total intervention period lasted 16 weeks, consisting of an 8-week intervention followed by an 8-week follow-up period. The intervention was conducted in a psychological and exercise laboratory with sessions held 2 - 3 times per week, each lasting 50 - 60 minutes. Each session included 3 stages: “Warm-up” (5.5 minutes), “Exergame” (40 - 50 minutes) and “Cool-down” (4.5 minutes). The exergaming stage primarily used the adventure mode of Ring Fit Adventure, which integrates aerobic exercise, resistance training, and balance activities through interactive gameplay. This mode incorporates narrative-based progression, in which participants advance through different in-game levels and environments while completing exercise challenges. Participants performed movements using the Ring-Con (Nintendo) and leg strap accessories, enabling movement-based exercises such as squats, running-in-place movements, and upper-body resistance actions that engaged upper-body, core, and lower-limb muscles. During each session, participants progressed through the adventure mode gameplay, which tracks performance across levels and gradually increases exercise intensity through the game’s leveling system and real-time performance feedback. The game provides immediate feedback on movement execution and task completion, allowing participants to adjust their movements and advance to more challenging stages as their performance improved. In addition, 1-2 mini-game challenges were selected each week to enhance motivation and maintain engagement. These mini-games could involve different movement domains, including upper-limb, lower-limb, and balance-related tasks. To further support participant adherence, the exergame content, including adventure mode gameplay and mini-games, was systematically varied across the intervention period, with different gameplay tasks incorporated each week according to the intervention schedule. This structured variation allowed participants to experience diverse exercise challenges while maintaining consistency with the overall training framework. Detailed descriptions of the weekly intervention content and session structure are provided in Figure 1 and Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. Overview of the Nintendo Switch–based exergaming intervention protocol and assessment schedule in a randomized controlled trial among college students with subthreshold depression.

One investigator supervised each session, encouraging participation and recording attendance. Absentees were promptly contacted and encouraged to rejoin. Researchers monitored participants' well-being and ensured safety. To enhance motivation, weekly results were announced ("Match 1" and "Match 2"), upcoming game content previewed, and small incentives were given.

Comparator

Participants in the CG continued with their usual daily activities and were not involved in any additional intervention or structured exercise program during the study period. They did not participate in supervised sessions and received no exercise-related guidance from the research team.

Measurements

This study used structured questionnaires to assess the general characteristics of the participants. The primary outcome was depressive symptoms, and the secondary outcomes included anxiety symptoms, sleep quality, and adherence.

Depressive Symptoms

Depressive symptoms were screened using the CES-D, developed by Radloff et al [30] and revised by Zhang et al [31]. Responses were rated on a 4-point Likert scale, ranging from "rarely or none of the time" to "most or all of the time." The total score ranges from 0 to 60, with higher scores indicating greater depression. The Cronbach α was 0.90 [31].

Depressive symptoms were assessed using the Patient Health Questionnaire-9 (PHQ-9) [32], which contains 9 items. Responses were rated on a 4-point Likert scale, from "not at all" to "nearly every day." The total score ranges from 0 to 27, with higher scores indicating greater severity. The scale has demonstrated good internal consistency (Cronbach α=0.899) in this study.

Anxiety Symptoms

Anxiety severity was assessed using the 7-item Generalized Anxiety Disorder Scale (GAD-7), rated on a 4-point Likert scale. The total score ranges from 0 to 21, with cut-off scores of 5, 10, and 15 indicating mild, moderate, and severe anxiety, respectively. In this study, Cronbach α=0.903.

Sleep Quality

Sleep quality was measured using the 19-item Pittsburgh Sleep Quality Index (PSQI) [33], which includes open-ended and 4-point Likert scale items. Higher scores indicate worse sleep quality. The PSQI demonstrated good reliability, with a Cronbach α of 0.845 [34] and a test-retest reliability of 0.994. In this study, Cronbach α=0.744.

Adherence and Adverse Events

The intervention was considered successful if participants completed at least 80% of the target practice time [15], calculated as the average of the minimum (800 minutes) and maximum (1440 minutes) durations over the 8-week period, yielding a total of 896 minutes. The facilitators supervised participants during the sessions to prevent injuries, overexertion, and excessive gaming behavior. Gameplay was limited to the scheduled intervention sessions, and facilitators monitored participants through direct observation for signs of fatigue or excessive engagement. Any adverse incidents were documented, including their impact and the actions taken to address them.

Randomization

Participants were randomly allocated to the IG or CG in a 1:1 ratio using computer-generated permuted block randomization. The random allocation sequence was generated by an independent research coordinator who was not involved in participant recruitment or intervention delivery. Allocation concealment was ensured using sequentially numbered, sealed,

XSL•FO
RenderX

opaque envelopes containing the group assignments. After participants completed the baseline assessment, the envelopes were opened in sequence to assign participants to the study groups.

Blinding

Due to the nature of the intervention, blinding of participants and intervention providers was not feasible. However, outcome assessors and data analysts were blinded to group allocation to minimize potential bias.

Data Collection

Data collection was conducted at 4 time points, including baseline (T0), postintervention (T1, Week 8), one-month follow-up (T2, Week 12), and 2-month follow-up (T3, Week 16), between June 2, 2023 and August 29, 2023. The outcome assessments were conducted by trained assessors, including one psychologist and one registered nurse with clinical experience, who were not involved in delivering the intervention. Before the study began, all assessors received standardized training on the assessment procedures to ensure consistency and reliability. All assessments were conducted using structured checklists in the same simulation environment to maintain procedural consistency. The data collection followed the survey data collection process model [35] (Multimedia Appendix 2). To promote participant retention and minimize loss to follow-up, several strategies were implemented, including supervised intervention sessions, regular reminders before scheduled assessments, flexible scheduling to accommodate participants' availability, and incentives for completing follow-up assessments.

Statistical Analysis

Quantitative data were entered into EpiData (The EpiData Association) and analyzed using SPSS (version 26.0; IBM). Analyses followed the intention-to-treat (ITT) principle. Missing data were assessed using Little's Missing Completely at Random (MCAR) test. Since the test indicated that the missing data were completely at random, missing values were imputed using the last observation carried forward method. Baseline differences between the 2 groups were assessed using independent 2-tailed *t* tests, Mann-Whitney *U* tests, chi-square tests, or Fisher exact tests, as appropriate. Changes in primary and secondary outcomes from T0 to T1, T2, and T3 were analyzed using generalized estimating equations (GEE) [36] with an exchangeable correlation structure. A *P* value ≤.05 was considered statistically significant.

and analyzed using SPSS (version 26.0; IBM). Analyses followed the ITT principle. Missing data were assessed using Little's MCAR test. Since the test indicated that the missing data were completely at random, missing values were imputed using the last observation carried forward method. Baseline differences between the 2 groups were assessed using independent *t* tests, Mann-Whitney *U* tests, chi-square tests, or Fisher exact tests, as appropriate. Changes in primary and secondary outcomes from T0 to T1, T2, and T3 were analyzed using GEE [36] with an exchangeable correlation structure. A *P* value ≤.05 was considered statistically significant.

Qualitative Phase: Semistructured Interviews

Research Design

A qualitative descriptive design using qualitative content analysis was adopted to explore participants' experiences of the Nintendo Switch–based exergaming intervention.

Researcher Description

To minimize potential bias, 2 trained researchers (KH and LS) conducted the interviews. The corresponding author (LC), who has extensive experience in qualitative research, facilitated the interviews, while the second author took detailed field notes. Both researchers (KH and LS) were trained to remain neutral and not influence participants' responses. The research team was balanced in gender (1 female, 1 male) to enhance participant comfort during the interviews. No prior relationship existed between the researchers and participants before the study.

Participant Recruitment and Selection

Purposeful sampling was used. An email invitation was sent to 42 adults with StD who had completed the 8-week intervention, encouraging them to share their experiences and reflections. Eligibility criteria for participation in the qualitative study were (1) completion of the 8-week Nintendo Switch–based exercise intervention and (2) provision of informed consent and voluntary agreement to participate. Seventeen participants (2 males and 15 females) from the intervention group (IG) volunteered for semistructured interviews.

Data Collection

Semistructured interviews were conducted in a quiet conference room to ensure privacy. Interviews lasted between 20 and 40 minutes. A semistructured interview guide (Multimedia Appendix 3) was used to ensure consistency across interviews while allowing flexibility for participants to elaborate on their experiences. With participants' consent, all sessions were audio-recorded and transcribed verbatim by a researcher. Participants were assured of anonymity and informed of their right to withdraw at any time. All interviews were transcribed verbatim within 24 hours of completion, and the transcripts were imported into NVivo (12.0; QSR International Pty Ltd), which was used for data management and coding. A second researcher verified all transcripts against the audio recordings to ensure accuracy.

Data Analysis

Qualitative data analysis was conducted concurrently with data collection in an iterative manner, allowing emerging insights to inform subsequent interviews and refine thematic exploration until thematic saturation was achieved, that is, no new categories or meaningful information emerged. Qualitative content analysis was used following established methodological guidelines [37,38]. Two researchers independently conducted 2 rounds of open coding, identifying meaningful units of text, and assigning initial codes. These codes were iteratively compared and refined, then grouped into subcategories and further abstracted into generic and main categories through constant comparison. Representative quotations were selected to illustrate and substantiate the identified themes, ensuring interpretations remained grounded in participants' narratives. Coding results

XSL•FO
RenderX

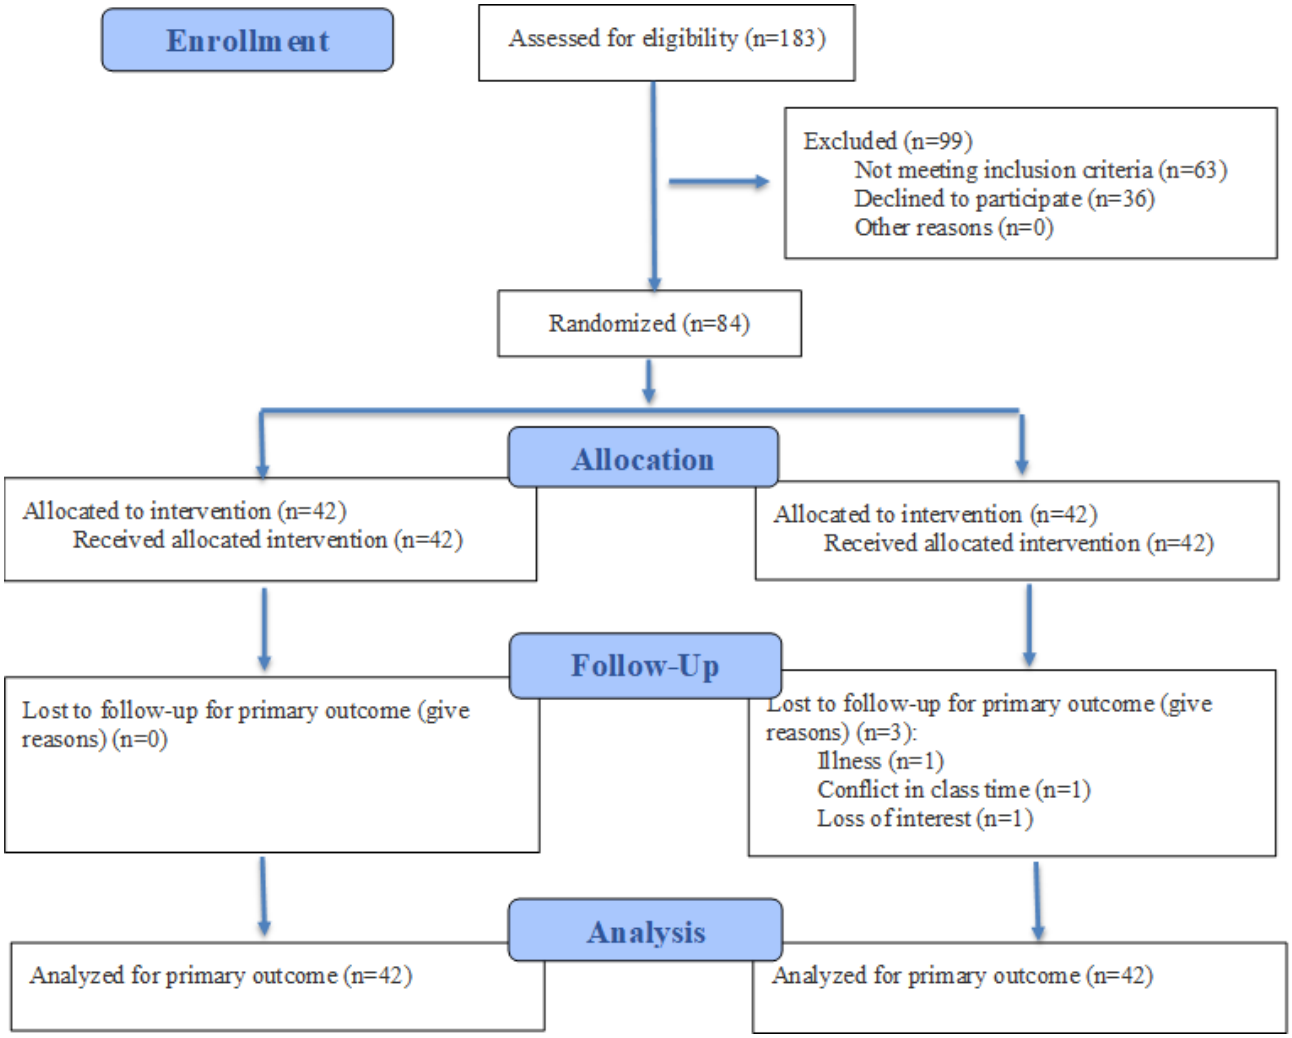
from the 2 researchers were compared throughout the analytic process. Disagreements were documented and resolved through discussion. When consensus could not be reached, a third senior researcher adjudicated the decision to enhance analytical rigor.

Methodological Integrity

Methodological integrity was ensured through attention to data adequacy, analytic consistency, and grounding of findings in the data. First, purposive sampling and continued data collection until thematic saturation supported the adequacy of the data. Second, analytic consistency was enhanced through independent coding by 2 researchers, iterative comparison of codes, and resolution of discrepancies through discussion, with adjudication by a third senior researcher when necessary. Third, findings were grounded in participants' narratives through the use of representative quotations. Finally, field notes, neutral interviewing, and iterative comparison throughout data collection and analysis were used to minimize potential researcher bias and enhance the credibility of the findings.

Ethical Considerations

Ethical approval was obtained from the Clinical Research Ethics Committee of the School of Nursing, Jilin University (Ref: 2022091401). The study protocol has been published previously [24], providing detailed information on the study design, target population, intervention procedures, and planned data analyses. All study procedures complied with the principles of the Declaration of Helsinki and relevant ethical guidelines for research involving human participants. Written informed consent was obtained from all participants prior to enrollment. To protect participant privacy, all data were deidentified immediately after collection and stored using anonymous identification codes. All analyses were conducted using these coded identifiers, and no personally identifiable information is included in this manuscript or any supplementary materials. Participants who completed the full study protocol, including assessments at T0, T1, T2, and T3, received small gifts after each assessment as appreciation for their participation. Participants who completed all assessments and intervention sessions received an additional gift package valued at approximately Renminbi (RMB) 200, equivalent to approximately US $30.



Results

Participant Flow and Recruitment

Figure 2 shows the recruitment and assessment process. Between January and February 2023, eligibility assessments were conducted on 183 potential participants. Of these, 99 individuals were excluded, including 63 who did not meet the inclusion criteria and 36 who declined to participate. A total of 84 eligible participants were randomly assigned in a 1:1 ratio to either the IG (n=42) or the control group (CG; n=42). During the follow-up period, 3/42 (7.1%) participants in the CG discontinued participation at T1 due to illness (n=1), scheduling conflicts with class time (n=1), and loss of interest (n=1). No participants in the IG were lost to follow-up. The overall attrition rate was 3/84 (3.6%). To examine the mechanism of missing data, Little's MCAR test was conducted for variables included in the outcome analyses (PHQ-9, GAD-7, and PSQI scores), which indicated that the missing data were completely at random (χ^2_6=3.606; *P*=.73). Therefore, missing values were handled using the last observation carried forward method under the ITT principle, and all randomized participants (n=84) were included in the final analysis.

RenderX

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) 2025 flow diagram of participant recruitment, allocation, follow-up, and analysis.

Intervention Delivery and Adherence

The intervention was delivered as planned throughout the 8-week intervention period. A total of 42 participants in the IG received the 8-week Nintendo Switch–based exergaming intervention under the supervision of trained facilitators in the psychological and exercise laboratory setting. All sessions were conducted according to the predefined intervention protocol. Facilitators supervised the exercise sessions, provided technical guidance on the use of the Ring-Con and leg-strap accessories, ensured participant safety, and offered encouragement to support engagement during gameplay. Session attendance and participation were recorded to monitor adherence. Overall, adherence of adults with StD was relatively good; most students (35/42, 83.3%) exceeded 896 minutes of participation time. No adverse event was reported.

Baseline Data

Table 1 summarizes the baseline characteristics of the participants. The mean age was 23.07 years (SD 1.45), and 83.3% (70/84) of the participants were female. There was no statistically significant difference between the 2 groups in demographic information and outcome variables (P>.05).

[b]CG: control group.

[c]For continuous variables, an independent *t* test was used when variables were compared between the 2 groups.

[d]For categorical variables, a chi-square test was used when variables were compared between the 2 groups.

[e] Calculated as weight in kilograms divided by height in meters squared.

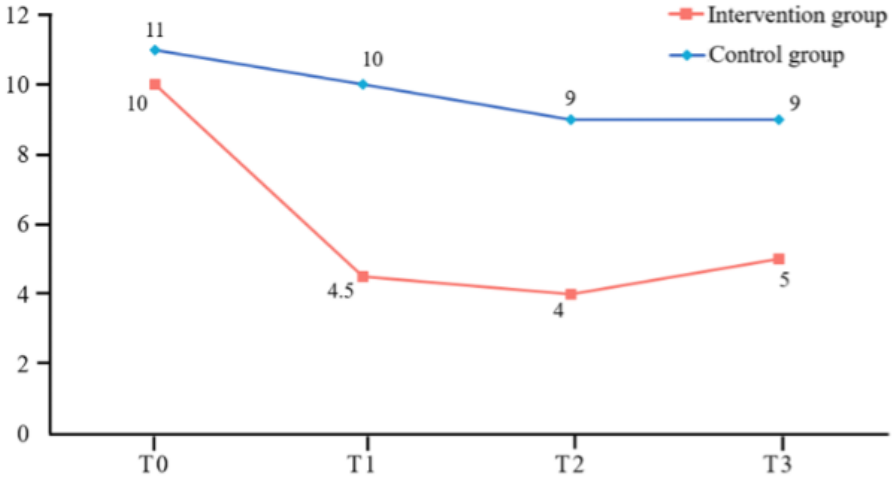
[f]CES-D: Center for Epidemiologic Studies Depression Scale.

[g] If the scale scores followed a normal distribution, an independent sample *t* test was used.

[h]PHQ-9: Patient Health Questionnaire-9.

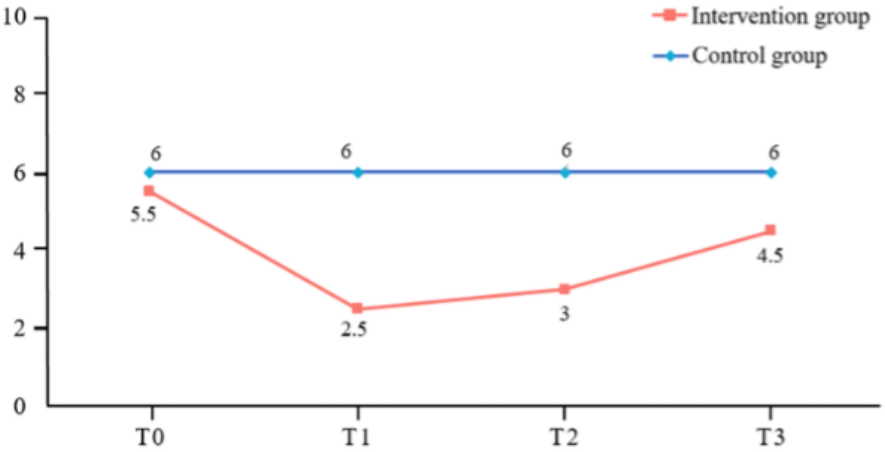
[i]If the scale scores did not follow a normal distribution, a nonparametric rank sum test was used for statistical analysis.

[j]GAD-7: Generalized Anxiety Disorder-7.



[k]PSQI: Pittsburgh Sleep Quality Index.

Effects on the Depressive Symptoms



As shown in Table 2, the statistically significant effects of the group×time interaction between the 2 groups were found in PHQ-9 scores (T1: β=−4.07, 95% CI −5.84 to −2.30; *P*<.001; T2: β=−4.29, 95% CI −6.14 to −2.43, *P*<.001; T3: β=−3.81, 95% CI −5.54 to −2.08; *P*<.001). The results of the pairwise contrast tests are shown in Table 3. The IG showed greater significant improvements in PHQ-9 scores at all T1 (mean difference [MD]=−5.48, 95% CI −6.72 to −4.23; *P*<.001), T2 (MD=−6.10, 95% CI −7.41 to −4.78; *P*<.001), and T3 (MD=−5.79, 95% CI −7.10 to −0.47; *P*<.001) compared with the CG. Figure 3A illustrates the temporal trends of depression outcomes, derived from the results of the GEE analyses.

Effects on the Sleep Quality and Anxiety Symptoms

As shown in Table 2, the group×time interaction had a statistically significant effect on PSQI scores at all follow-up points (T1: β=−2.98, 95% CI −4.55 to −1.40; *P*<.001; T2: β=−2.19, 95% CI −3.58 to −0.80; *P*=.002; T3: β=−2.45, 95% CI −3.81 to −1.09). Anxiety symptoms also improved significantly at T1 (β=−2.60, 95% CI −4.70 to −0.50; *P*=.02) and T3 (β=−2.38, 95% CI −4.62 to −0.14; *P*=.04). For sleep quality in Table 3, the IG showed greater significant improvements in PSQI scores at all T1 (MD=−1.67, 95% CI −2.66 to −0.67; *P*=.001), T2 (MD=−2.00, 95% CI −2.78 to −1.22; *P*<.001), and T3 (MD=−2.05, 95% CI −2.81 to −1.28; *P*<.001) compared with the CG. In terms of anxiety, there was a significant improvement in the IG compared with the CG also at T1 (MD=−3.19, 95% CI −4.54 to −1.84; *P*<.001), T2 (MD=−3.19, 95% CI −4.54 to −1.84; *P*<.001), and T3 (MD=−2.24, 95% CI −3.73 to −0.75; *P*=.003). Figure 3B-3C illustrates the temporal trends in sleep quality and anxiety outcomes.

Qualitative Findings

Seventeen adults with StD participated in the semistructured interviews, including 2 males and 15 females, aged 22-29 years (mean 23.18, SD 1.78). The average duration of the interviews was 26.7 minutes. Details are shown in Multimedia Appendix 4.

Three major themes emerged from the semistructured interviews content analysis. The corresponding codes and representative quotations are presented in Table 4. Figure 4 presents the thematic map that shows the relationships among the themes, categories, and codes identified in the qualitative analysis. To protect confidentiality and preserve anonymity, participant quotations are followed by their participant number (P_n).

Themes, categories, and codes	Examples of quotations
Immersive engagement in exergaming	
Progressive game design and personalization	
Narrative novelty	• "The adventure mode unfolds step-by-step with a sense of mystery." (P2)
Adaptively diverse	• "Everyone can customize the skin, hair color, and eyes to match my preferences." (P4) • "The adventure mode lets you choose paths and customize boosts—it's fun to explore." (P15)
Feedback-driven engagement	
Sensory feedback	• "The stress gage and progress bar helped me track performance and stay motivated." (P11) • "I really liked the sound cues, hearing the music after completing a move gave me a strong sense of satisfaction." (P13)
Exercise feedback	• "Guided movements help ensure accuracy and boost the effectiveness and professionalism of the workout." (P4)
Gamified incentive structures	
Level-up system	• "The level-based challenges, points, and mini-games gave me a real sense of enjoyment and competition." (P16)
Social bonding	• "During the workout, the on-screen character moved with me, which gave me a sense of companionship." (P1)
Psychophysiological benefits of exergaming	
Psychological well-being enhancement	
Mood regulation	• "Just want to sweat a bit to release negative emotions." (P8) • "My confidence grew as I completed small goals, I felt I could actually achieve something." (P9)
Exercise dose sensitivity	• "I feel better when the intensity matches my ability. if it's too high, I lose motivation and can't stick with it." (P9)
Physical fitness improvement	
Comprehensive physical enhancement	• "When climbing stairs or doing physical activities, my heart rate doesn't rise as quickly — my cardiac function has improved." (P17)
Body sculpting and toning	• "I noticed my body getting firmer, my waist slimmer, which made me feel accomplished and motivated to continue." (P12)
Quality of life improvement	
Improved sleep quality	• "I used to wake up around 1 or 2 AM, but recently I've been sleeping through the night." (P9)
Positive lifestyle transformation	• "Since I started training, I feel more energized and motivated. It's not just exercise, it's become a fun part of my weekly routine and helps me maintain a healthier lifestyle." (P14)
Facilitators and barriers to adherence	
Game-related factors	
Motivational mechanics and goal orientation	• "Knowing there were rewards really motivated me to participate and give my best." (P3) • "Defeating monsters and earning coins kept me focused and engaged." (P11)

Themes, categories, and codes	Examples of quotations
Narrative immersion and sensory engagement	• "The immersive storyline drew me in and kept me engaged." (P2) • "I was always eager to know what would happen next, that curiosity kept me coming back." (P13)
Individual-level factors	
Personal health and development needs	• "I gained weight over the holiday and wanted to lose some fat." (P4) • "I want to improve my skills and prove to my parents I can stick with it—they always say I give up too easily." (P16)
Emotional and recreational fulfillment	• "I came here to enrich my after-class life." (P5) • "If I score high and get a small prize, that would make me really happy." (P6)
Environmental factors	
Accessibility of resources	• "It's hard to exercise in the dorm—too noisy downstairs, too cold outside. Coming here is just right." (P5) • "Running outside means worrying about traffic, people, noise, and safety." (P8)
Time and cost considerations	• "The location and timing work well for me since my classes are nearby, I don't need to travel far." (P17) • "The staff's weekly schedule and reminders really helped me stick with it." (P4)

Figure 4. Thematic map displaying themes, categories, and codes.

Theme 1. Immersive Engagement in Exergaming

Progressive Game Design and Personalization

Participants noted that the narrative novelty and diverse and personalized game design fostered curiosity and a strong sense of achievement.

Feedback-Driven Engagement

Participants described that sensory feedback and real-time exercise feedback enhanced their movement accuracy and immersion, improving both training effectiveness and safety.

Gamified Incentive Structures

Gamified features like points, rankings, and gear upgrades enhanced goal orientation and sustained motivation. Interactive

XSL•FO
RenderX

elements such as peer competition and collaboration fostered social connectedness and satisfaction.

Theme 2. Psychophysiological Benefits of Exergaming

Psychological Well-Being Enhancement

Engaging in exergames was perceived to improve psychological well-being by relieving negative emotions, enhancing self-efficacy, and supporting mood regulation through appropriate exercise intensity.

Physical Fitness Improvement

Participants reported that exergames enhanced physical fitness by combining aerobic, strength, and flexibility training, improving endurance, muscle tone, and overall body control.

Quality of Life Improvement

Participants noted that exergames enhanced their quality of life by promoting energy, mood, metabolism, appetite, and sleep through an engaging blend of exercise and entertainment.

Theme 3. Facilitators and Barriers to Adherence

Game-Related Factors

Core game elements, including goals, challenges, rewards, narrative, social interaction, and audiovisual effects, enhanced immersion, enjoyment, and engagement, thereby fostering player motivation and adherence.

Individual-Level Factors

Participants identified health improvement, recreational enjoyment, self-challenge, skill development, and emotional fulfillment as key individual drivers of sustained engagement.

Environmental Factors

Participants indicated that accessibility of equipment and venues, along with time availability and financial cost, were key environmental factors influencing adherence to exergames.

Discussion

Principal Findings

This study evaluated the effectiveness of a Nintendo Switch–based exergaming program for adults with StD using a mixed methods design. The results showed that participants who engaged in the exergaming program experienced significant improvements in depressive symptoms and sleep quality, along with reductions in anxiety symptoms, compared with the CG. The qualitative findings further complemented the quantitative results by providing deeper insights into participants' experiences with the exergaming intervention. Participants described immersive engagement during gameplay, perceived psychophysiological benefits, and multiple facilitators and barriers influencing adherence (eg, game-related, individual-level, and environmental factors), which helped contextualize the observed improvements in depressive symptoms, anxiety symptoms, and sleep quality.

Interpretation

Our findings indicate that the 8-week Nintendo Switch–based exergaming intervention significantly improved depressive symptoms among adults with StD, with improvements maintained at both 4-week and 8-week follow-up assessments. Consistent with previous literature, regular physical activity has been widely recognized as an effective nonpharmacological strategy for improving depressive symptoms [39]. These benefits may be partly explained by biological mechanisms whereby exercise promotes neuroplasticity and neurogenesis through the regulation of neurotrophic factors and modulates the synthesis and release of key neurotransmitters involved in mood regulation [40]. In addition to these physiological mechanisms, exercise may also contribute to mood improvement through behavioral and psychological pathways, including behavioral activation, improved sleep, and enhanced psychological well-being [40]. However, traditional exercise programs often face challenges related to low motivation and poor long-term adherence, particularly among individuals experiencing depressive symptoms [41].

Exergames, as a specific type of serious game that integrates physical activity with interactive gameplay, may help address these challenges by enhancing engagement and motivation [8]. From the perspective of behavioral activation theory [42], individuals with StD often experience reduced activity levels and diminished exposure to rewarding experiences [43]. Exergames such as Ring Fit Adventure provide structured, goal-oriented tasks, real-time feedback, and reward systems that encourage participants to re-engage in meaningful and rewarding activities [44]. Through repeated participation, these mechanisms may help break cycles of avoidance and inactivity and promote behavioral activation [45]. In addition, several design features of exergames may further contribute to their psychological benefits [46]. As reflected in participants' postintervention interviews, game elements such as progressive game design and personalization, feedback-driven engagement, and gamified incentive structures may enhance users' self-efficacy and perceived competence. According to social cognitive theory, higher self-efficacy is an important determinant of sustained behavioral engagement [47]. At the same time, gamified reward structures and immersive gameplay may increase enjoyment and intrinsic motivation, thereby promoting sustained participation in physical activity [48]. This mechanism was further reflected in participants' feedback; for example, one participant noted that "the level-based challenges, points, and mini-games gave me a real sense of enjoyment and competition," highlighting how game-based elements can transform exercise into a more engaging and motivating experience.

The present findings differ from those reported by Wu et al [16], who reported less favorable mood-related outcomes following a 4-week Ring Fit Adventure intervention in university students. One possible explanation is intervention duration. Longer intervention periods may provide more time for participants to establish regular engagement and benefit from repeated behavioral reinforcement [49], thereby supporting more stable behavioral and emotional change, consistent with behavior change theory [50]. This interpretation is also consistent with our previous meta-analysis, which suggested that longer-duration exergame interventions were associated with greater improvements in depressive symptoms [28].

XSL•FO
RenderX

Another possible explanation relates to differences in sample characteristics. The present study included a higher proportion of female participants. Previous research has suggested that women may demonstrate higher adherence to structured health programs, which could influence intervention outcomes [51]. Therefore, the gender composition of the sample may have partly contributed to the more favorable results observed in the present study.

A slight rebound in depressive symptoms was observed at the T2 and T3 follow-up stage. One possible explanation is that the beneficial effects of the intervention gradually attenuated after the withdrawal of structured guidance and routine participation. In addition, the later follow-up period overlapped with examination periods for many students, which may have increased academic stress and negatively affected mental health [52].

Although the group×time result for GAD-7 was not statistically significant, pairwise comparisons revealed significantly greater anxiety reductions in the IG at all time points. This suggests that Nintendo Switch–based exergaming may still exert beneficial effects. The finding is broadly consistent with a prior study [53]. One possible explanation lies in the differential sensitivity of anxiety to behavioral activation. While both anxiety and depression involve disrupted emotional regulation, anxiety is often more reactive to acute stressors and environmental uncertainty [54]. Exergames may contribute to anxiety reduction by providing structured physical routines, immersive attentional distraction, and rhythmic motor engagement [55].

The study also suggested that exergaming intervention showed potential to improve sleep quality, although a previous study using a similar intervention did not report statistically significant effects [16]. These improvements may reflect both psychological and physiological pathways. Psychologically, reductions in depressive symptoms, anxiety, and stress may indirectly contribute to better sleep [56,57]. Physiologically, exergaming may support sleep through mechanisms related to thermoregulation, autonomic function, and overall physical activation [58,59]. In addition, qualitative findings suggested that participants experienced relaxation and enhanced well-being during the intervention, which may also have contributed to improved sleep.

The study demonstrated high adherence and no adverse events, indicating the intervention's safety and feasibility. This strong engagement was likely supported by both the design features of the exergame and the structured implementation context [46]. On the one hand, game elements such as interactive feedback, clear goals, progressive challenges, and an engaging narrative may have enhanced participants' motivation and enjoyment [44]. On the other hand, the intervention was delivered in a structured laboratory environment with scheduled sessions, facilitator supervision, and regular support from the research team, which likely further promoted adherence and sustained participation [60]. Accordingly, the observed effects may reflect the combined influence of both game design and human support.

Limitations and Future Directions

This study has several limitations. First, the sample consisted exclusively of university students, whose stress patterns, sleep routines, and lifestyle characteristics may differ from those of the broader adult population, particularly during examination periods, thus limiting the generalizability of the findings. Second, the intervention was delivered in a structured laboratory environment with scheduled sessions and facilitator supervision. Although this likely supported adherence and intervention fidelity, it differs from the typical home-based use of Ring Fit Adventure. Therefore, caution is needed when generalizing the findings to less controlled real-world settings. Third, the IG and CG differed in the degree of structure and contact with the research team. Participants in the IG received supervised sessions and regular support, whereas the CG continued usual activities without comparable contact. As such, some of the observed effects may have been influenced not only by the exergaming intervention itself but also by differences in attention and support. Fourth, because the intervention combined both game-based design features and facilitator support, it was not possible to fully disentangle the relative contributions of human scaffolding and game design to the observed outcomes. This distinction is important for understanding the scalability of the intervention in less supported settings. Fifth, the follow-up period was limited to 8 weeks. As such, the long-term sustainability of the observed improvements in depressive symptoms and sleep quality remains uncertain. Future studies with extended follow-up periods are warranted to determine whether these benefits persist over time. Sixth, due to the nature of the intervention, blinding of participants and intervention providers was not feasible. This may have introduced potential performance or expectancy biases, as participants aware of receiving the intervention might have reported greater improvements [61]. However, outcome assessors and data analysts were blinded to group allocation to minimize potential bias. Future studies could further strengthen methodological rigor by incorporating additional objective outcome measures.

Innovation and Contribution

This study makes several contributions to the exergame literature. First, it extends the evidence by focusing specifically on adults with StD, a population at elevated risk of developing MDD but underrepresented in exergaming research. In contrast to many previous studies that have primarily targeted older adults or specific clinical populations, the present study examined the potential of exergaming as an early preventive intervention for adults with StD. Second, this study was designed as a mixed methods exergame effectiveness trial, combining longitudinal outcome evaluation with qualitative inquiry. This approach not only assessed whether the intervention was beneficial but also provided insight into how participants experienced the program and which factors influenced engagement and adherence. Third, the findings contribute to the broader exergames for mental health field by showing how design features such as progressive challenges, feedback, and gamified incentives may support behavioral activation, self-efficacy, and sustained participation. Finally, from a practical perspective, the study suggests that commercially available exergaming platforms such as Nintendo Switch–based

XSL•FO
RenderX

exergaming intervention offer a feasible, engaging, and potentially scalable digital strategy for supporting mental health and sleep outcomes in adults with StD.

Conclusion

This study identified the positive effects of an 8-week Nintendo Switch–based exergaming intervention in improving depressive symptoms, anxiety, and sleep quality among adults with StD. Qualitative findings further revealed that immersive engagement, perceived psychophysiological benefits, and multifaceted adherence facilitators ranging from gameplay design to individual and environmental factors played a key role in sustaining participation and enhancing intervention effectiveness. Together, these findings suggest that gamified physical activity may represent a feasible and engaging approach for promoting mental well-being in adults with StD. By integrating interactive gameplay with exercise, commercially available exergaming platforms may offer a promising and accessible strategy for early mental health support in real-world settings.

Acknowledgments

The authors sincerely thank all participants for their time and commitment to this study.

Abstract

Background: Internet gaming disorder (IGD) is increasingly prevalent among adolescents. Although socially prescribed perfectionism (SPP) and resilience are both related to IGD, longitudinal evidence on their temporal relationships and underlying mechanisms remains limited.

Objective: This study aimed to examine the longitudinal associations among SPP, resilience, and IGD in Chinese adolescents; test the mediating role of resilience; and explore potential sex differences.

Methods: A 3-wave prospective longitudinal study was conducted among students from 4 middle schools in Zhejiang Province, China. Adolescents who had played online games in the past 12 months were recruited using convenience sampling. Data were collected at 6-month intervals: time 1 (T1; March 2024), time 2 (T2; September 2024), and time 3 (T3; March 2025). A total of 1332 Chinese adolescents (875/1332, 65.7% male; mean age 13.61, SD 0.70 years) participated in the baseline survey. SPP, resilience, and IGD were assessed using the Hewitt-Flett Multidimensional Perfectionism Scale-Short Form, the 10-item Connor-Davidson Resilience Scale, and the 9-item *Diagnostic and Statistical Manual of Mental Disorders* (Fifth Edition) IGD Checklist, respectively. Cross-lagged panel model (CLPM) and multigroup analyses across sex were conducted.

Results: All statistical tests were 2-tailed with α=.05. The CLPM demonstrated good fit to the data (χ^2_{38}=163.34; comparative fit index [CFI]=0.945; Tucker-Lewis index [TLI]=0.932; root mean square error of approximation [RMSEA]=0.054; standardized root mean square residual [SRMR]=0.047). Higher SPP predicted later IGD (T1→T2: β=0.10, 95% CI 0.04 to 0.16, *P*<.001; T2→T3: β=0.09, 95% CI 0.03 to 0.15, *P*=.004) and lower resilience (T1→T2: β=−0.09, 95% CI −0.16 to −0.02, *P*=.007; T2→T3: β=−0.12, 95% CI −0.18 to −0.06, *P*<.001). In contrast, SPP was not significantly predicted by prior IGD nor resilience. Higher resilience predicted lower subsequent IGD (T1→T2: β=−0.09, 95% CI −0.15 to −0.03, *P*=.001; T2→T3: β=−0.09, 95% CI −0.15 to −0.03, *P*=.001), whereas higher IGD predicted lower subsequent resilience (T1→T2: β=−0.19, 95% CI −0.27 to −0.11, *P*<.001; T2→T3: β=−0.09, 95% CI −0.15 to −0.03, *P*=.003). Bootstrapped mediation analysis showed a significant indirect effect of SPP at T1 on IGD at T3 via resilience at T2 (β=0.008, 95% CI 0.004 to 0.012, *P*=.005). However, multigroup analyses revealed no significant sex differences.

Conclusions: This study provides novel insights into the longitudinal associations among SPP, resilience, and IGD in adolescents. Unlike previous research based mainly on cross-sectional data, this 3-wave CLPM study clarifies the temporal relationships among these variables and shows that resilience mediates the association between SPP and subsequent IGD. These findings advance the field by identifying a temporal psychological pathway underlying adolescent IGD. They also have practical implications for early screening and for developing resilience-focused interventions for adolescents at risk of IGD.

KEYWORDS

socially prescribed perfectionism; internet gaming disorder; resilience; sex differences; adolescents

Introduction

Background

With the rapid expansion of digital entertainment, online gaming has become one of the most prevalent leisure activities among adolescents [1]. For a subset of individuals, however, excessive and poorly controlled gaming may develop into a maladaptive behavioral pattern with significant functional impairment [2]. Internet gaming disorder (IGD) refers to a persistent and recurrent pattern of gaming behavior marked by impaired control, prioritization of gaming over other activities, and

XSL•FO
RenderX

continuation of play despite negative consequences [3]. Recent epidemiological evidence indicates that IGD has become an increasingly salient public health concern among adolescents. A recent meta-analysis indicated that the pooled prevalence of IGD is about 10% among Chinese adolescents [4]. Empirical research further indicates that IGD is associated with a range of negative outcomes, including impaired academic performance, sleep disturbances, depression, and anxiety [5-7]. These findings highlight the importance of identifying the antecedents of IGD to inform early prevention and intervention efforts.

Socially Prescribed Perfectionism and IGD

Perfectionism is widely recognized as a multidimensional construct [8]. According to the Hewitt-Flett model, it comprises self-oriented perfectionism, which involves imposing exceptionally high standards on oneself; other-oriented perfectionism, which refers to placing unrealistic standards on others; and socially prescribed perfectionism (SPP), which reflects the belief that others expect one to be perfect and that acceptance depends on meeting these external standards [9-11]. Although all 3 dimensions may be relevant to adolescent development, this study focused specifically on SPP. Among these dimensions, SPP is most directly linked to external pressure, perceived social demands, and evaluative concerns, making it particularly salient during adolescence, a developmental period marked by heightened sensitivity to interpersonal evaluation and social approval [10]. In this study, SPP was conceptualized as a socially driven cognitive-personality vulnerability factor that reflects adolescents' perceived external expectations and evaluative pressure [12]. Prior research has consistently identified SPP as the most maladaptive dimension of perfectionism, showing robust associations with poorer psychological well-being, greater psychological distress, and behavioral maladjustment [13,14]. In addition, SPP among adolescents and young adults has increased substantially over time, highlighting its growing developmental significance [15].

The focus on SPP is also theoretically relevant for understanding adolescents' vulnerability to IGD. According to the Perfectionism Social Disconnection Model, individuals with high levels of SPP tend to perceive intense external demands and fear harsh evaluation from others [12]. To avoid criticism and preserve a flawless image, they may engage in self-concealment and emotional suppression [16], which can undermine authentic interpersonal relationships and contribute to persistent feelings of social disconnection [12]. These interpersonal and emotional difficulties may, in turn, increase adolescents' reliance on online environments as a means of coping [17]. From the perspective of compensatory internet use theory [18], adolescents may turn to online gaming to escape real-life stress, regulate negative emotions, and compensate for unmet social and psychological needs. For adolescents with high levels of SPP, online games may provide a relatively controllable context in which evaluation can be avoided or managed more easily while also offering temporary experiences of competence, achievement, and social connection [19]. Over time, this pattern of using gaming to cope with distress and interpersonal insecurity may increase vulnerability to problematic gaming behaviors and IGD [20]. Therefore, SPP may be understood as a socially driven vulnerability factor that contributes to the development of IGD in adolescents.

Empirical evidence supports the association between perfectionistic tendencies and problematic online behaviors among adolescents and university students. Studies have shown that maladaptive perfectionism is positively associated with IGD symptoms and higher levels of internet-related behavioral problems [21,22]. Research also indicates that individuals with stronger perfectionistic concerns rely more on online activities to regulate negative affect [23]. Additionally, a 12-month follow-up study involving 465 highly engaged Australian gamers found that higher baseline levels of perfectionistic gaming-related cognitions significantly predicted subsequent increases in problematic gaming behaviors [24]. Despite these observations, most studies examining perfectionism and IGD remain cross-sectional, limiting the ability to determine temporal direction or causal mechanisms. Besides, few studies have directly examined the association between SPP and IGD. Therefore, it is necessary to use longitudinal methods to clarify such association among adolescents.

Resilience as a Potential Mediator

Another notable gap in the literature is the insufficient research exploring the psychological mechanisms linking SPP to IGD. Although previous studies have identified SPP as a risk factor for various maladaptive behavioral outcomes, including problematic internet and gaming behaviors, the mediating pathway that explains this association remains underexamined. One potential mediator is resilience. Resilience is generally defined as a positive psychological trait that enables individuals to adapt successfully to stress, adversity, or failure through effective coping strategies and emotional regulation and may play a key role in this relationship [25,26]. Rather than representing a fixed personal attribute, resilience reflects a dynamic capacity to recover from setbacks, maintain psychological stability, and mobilize internal and external resources when confronted with perfectionism-related stress [27].

The model of compensatory internet use [18] provides a useful theoretical framework for understanding why resilience may mediate the association between SPP and IGD. It proposes that individuals may engage in online activities not only for enjoyment but also to compensate for offline stress, negative emotions, and unmet psychological needs [18,28]. In other words, problematic online behaviors may emerge when the internet is used as a coping tool to manage distress that individuals feel unable to handle effectively in real life [18]. From this perspective, resilience is highly relevant because it reflects the capacity to cope adaptively with stress and emotional challenges [29]. Adolescents with higher resilience are generally better able to regulate negative emotions, recover from setbacks, and rely on effective coping strategies [30], which may reduce the need to use online gaming as an escape or emotional outlet [31]. In contrast, adolescents with lower resilience may be less able to manage perfectionism-related stress in adaptive ways and therefore more likely to turn to online gaming as a compensatory strategy to avoid pressure, relieve distress, or

XSL•FO
RenderX

obtain temporary feelings of competence and control [20]. This process may be particularly relevant for adolescents with high levels of SPP and who tend to perceive elevated external expectations, fear negative evaluation, and experience greater emotional vulnerability in academic, social, and performance contexts [32]. Over time, repeated reliance on gaming for emotional relief may reinforce maladaptive coping patterns and increase the risk of IGD, especially given the immersive and performance-based features of online games, which provide immediate feedback, achievement, and social affirmation [20].

This interpretation is also consistent with the stress-vulnerability-protective factors model, which emphasizes that psychological outcomes are shaped by the interaction between stressors, vulnerability factors, and protective resources [33]. Within this framework, SPP may be understood as a stress-related vulnerability factor [12], whereas resilience may function as a protective resource that helps adolescents maintain psychological adjustment in the face of external pressure and evaluative stress [30]. Accordingly, adolescents with high levels of SPP may be at greater risk of IGD partly because perfectionism-related stress undermines resilience, thereby increasing reliance on maladaptive coping behaviors such as online gaming.

Existing empirical findings provide support for these theoretical accounts. Prior research has shown that higher levels of SPP are associated with lower resilience, as individuals who fear external evaluation or criticism tend to exhibit heightened stress sensitivity and reduced adaptive coping skills [34]. Resilience, in turn, has been found to buffer against addictive or compulsive technology use. Several studies have demonstrated that lower resilience predicts greater vulnerability to problematic gaming and internet behaviors among adolescents and young adults [31,35]. A large-scale study found that stress originating from adverse childhood experiences increased the risk of IGD by undermining resilience, supporting a stress-resilience pathway to IGD [36]. Complementary findings suggest that resilience and stress jointly influence IGD tendencies [37], highlighting the importance of coping resources in shaping susceptibility to gaming-related problems. Despite these advances, important gaps remain. Most existing studies have relied on cross-sectional designs, which capture only static associations and cannot establish temporal precedence among SPP, resilience, and IGD. In addition, few studies have integrated the compensatory internet use framework with longitudinal tests of resilience as a mediator between SPP and IGD.

Sex Differences

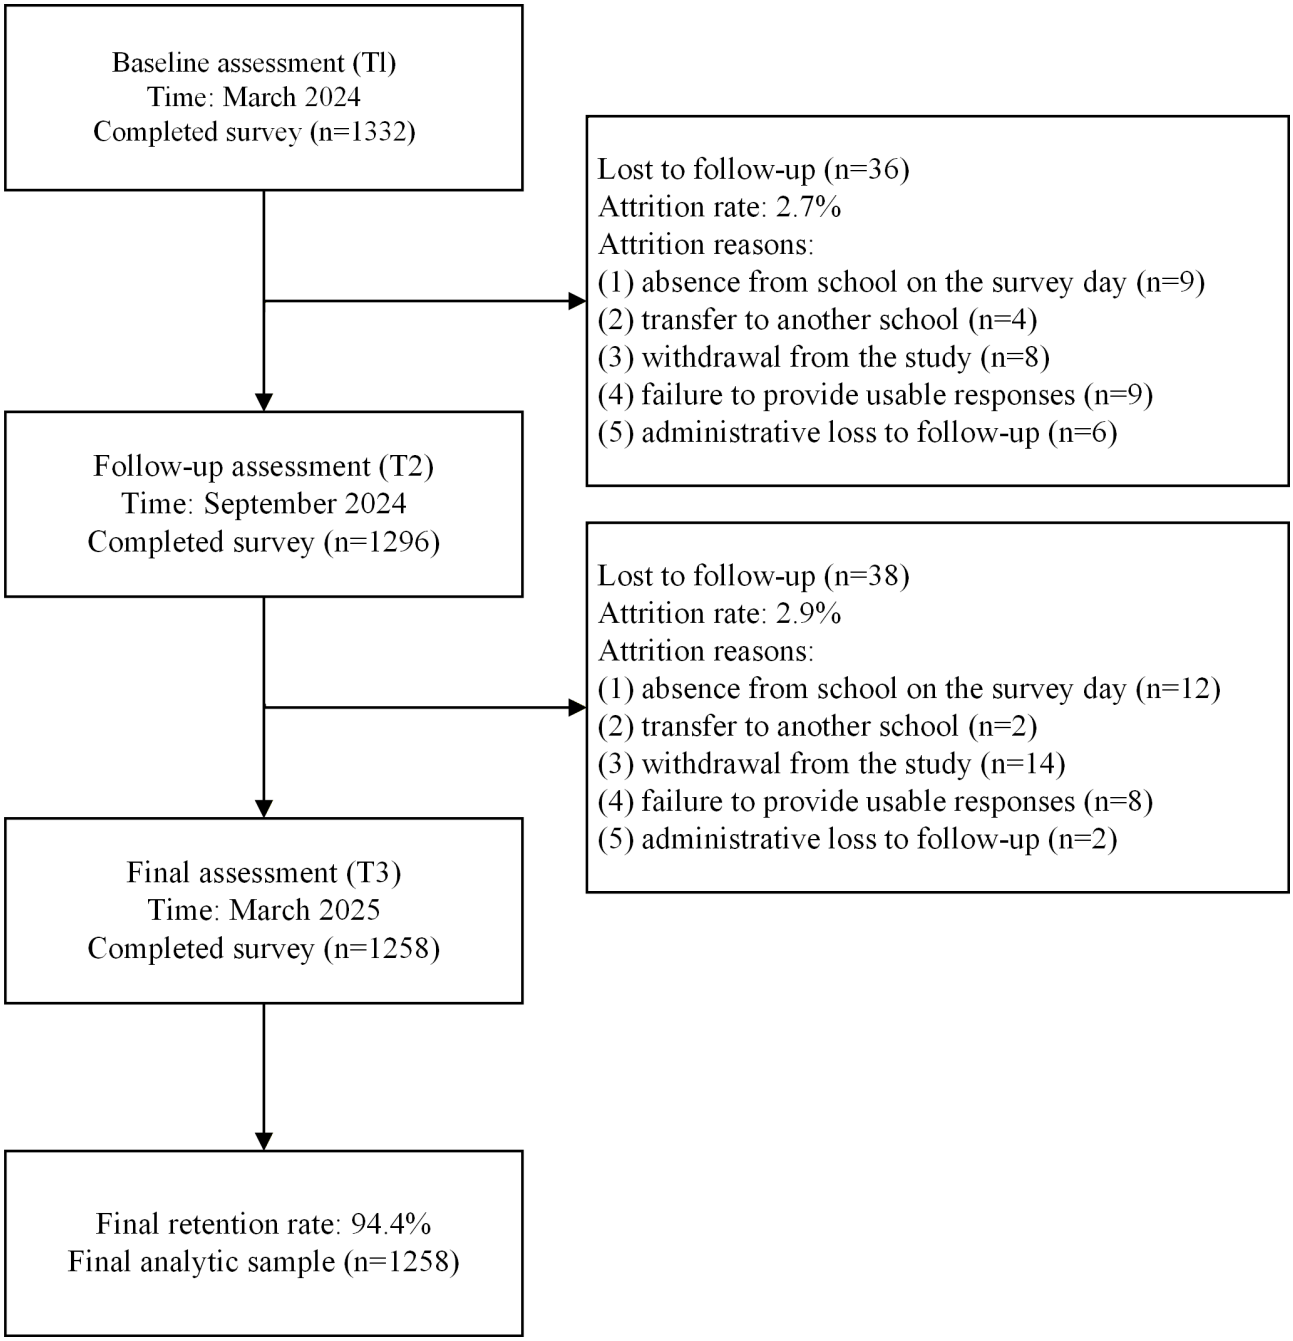
Researchers have highlighted that sex plays a significant role in shaping vulnerability to problematic gaming. Specifically, males tend to report higher levels of IGD than females [38], show greater preference for performance-oriented gaming activities, and exhibit stronger competitiveness in digital environments [39]. These sex differences may reflect distinct psychological needs that drive gaming engagement. Females are more likely to engage in digital activities for interpersonal connection and emotional satisfaction, whereas males tend to use gaming to pursue competition, achievement, and self-enhancement motives [40]. Moreover, researchers have suggested that the situational factors contributing to addictive gaming may vary by sex. For instance, SPP has been shown to predict problematic online behaviors through heightened concern with external evaluation, and this effect appears particularly salient among males [41]. Similarly, the protective effects of psychological resilience against problematic internet use or problematic gaming have been found to be stronger among females than males [41]. However, most of these studies have been cross-sectional, limiting our understanding of whether these sex-related mechanisms persist over time. Although sex differences in general problematic internet behaviors have been widely examined, very few studies have specifically investigated whether these differences extend to the longitudinal associations between SPP, resilience, and IGD. Given that IGD strongly emphasizes achievement-oriented rewards and performance feedback, it is important to examine whether similar sex-specific patterns exist in these pathways.

This Study

Given this background, this study used a cross-lagged panel model (CLPM) with a 3-wave longitudinal design to examine the longitudinal association between SPP and IGD and further test whether resilience mediates this relationship. It also explored potential sex differences in the associations among SPP, resilience, and IGD in adolescents. The following hypotheses were proposed: (H1) Higher levels of SPP positively predict subsequent IGD across adjacent waves; (H2) resilience mediates the longitudinal relationship between SPP and IGD; and (H3) the associations among SPP, resilience, and IGD differ by sex.

Methods

Study Design, Participants, and Setting



This study was designed as a 1-year prospective cohort study and conducted among students from 4 middle schools in Zhejiang Province, China. The recruitment setting was school-based, and participants were recruited from regular classroom populations in these 4 schools. The schools were selected based on accessibility and willingness to participate in the study. Data were collected at three 6-month intervals: time 1 (T1; March 2024), time 2 (T2; September 2024), and time 3 (T3; March 2025). The 6-month interval between waves was informed by prior adolescent longitudinal studies using similar follow-up periods [42-44] and was considered appropriate for capturing meaningful short-term changes in psychological and behavioral variables in a school-based design. Participants were recruited through convenience sampling, with all eligible students in the selected schools invited to participate during regular class hours through coordination with teachers and school administrators. Trained field researchers administered the surveys during regular class hours using self-report questionnaires. Prior to survey administration, both students and their parents (or legal guardians) were provided with comprehensive information about the study's aims, procedures, and confidentiality safeguards. Written informed consent was obtained from parents or guardians, while students were informed that submitting the completed questionnaire would be interpreted as assent. It was emphasized that participation was voluntary and that nonparticipation or withdrawal would

XSL•FO
RenderX

have no consequences on their academic standing or school records.

At baseline (T1), 1332 adolescents (875/1332, 65.7% males; mean age 13.61, SD 0.70 years) completed the survey. At T2, 1296 participants remained in the study, indicating that 36 participants were lost between T1 and T2. The reasons for attrition from T1 to T2 were as follows: absence from school on the survey day (n=9), transfer to another school (n=4), withdrawal from the study (n=8), failure to provide usable responses (n=9), and administrative loss to follow-up (n=6). By T3, 1258 participants had completed all 3 assessments, indicating that a further 38 participants were lost between T2 and T3. The reasons for attrition from T2 to T3 were as follows: absence from school on the survey day (n=12), transfer to another school (n=2), withdrawal from the study (n=14), failure to provide usable responses (n=8), and administrative loss to follow-up (n=2). Overall, 74 participants were lost across the 3 waves. The participant flowchart is presented in Figure 1. Participants who provided valid data at least once were retained in the analyses to maximize statistical power and preserve sample representativeness. Missing data patterns and the rationale for the handling of missingness are reported in the Results section.

Figure 1. The participant flowchart.

Ethical Considerations

This study was approved by the Ethics Committee of the Second Affiliated Hospital and Yuying Children's Hospital of Wenzhou Medical University (approval number: XMSQ-2024‐347). Before data collection, both students and their parents or legal guardians were provided with detailed information about the study aims, procedures, voluntary nature of participation, and confidentiality protections. Written informed consent was obtained from parents or legal guardians, and students were informed that submission of the completed questionnaire would be considered assent to participate. To protect privacy and confidentiality, student ID numbers were collected only for the purpose of matching responses across the 3 survey waves; these identifiers were stored securely and removed from the analytic dataset before analysis to ensure de-identification. Participation was voluntary, and participants could decline or withdraw without any academic consequences. No financial nor material compensation was provided for participation. In addition, no images in the manuscript nor supplementary materials contain identifiable information about individual participants.

Studied Variables and Measurements

Demographic Variables

Demographic variables included age, sex, parental educational attainment, self-reported household income level, academic performance, single-parent family status, and average gaming time per month.

Internet Gaming Disorder

IGD was measured using the 9-item *Diagnostic and Statistical Manual of Mental Disorders* (Fifth Edition; *DSM-5*) IGD Checklist [45], which assesses gaming-related symptoms occurring within the past 12 months using a binary (yes/no) response format. The instrument evaluates core diagnostic features, including excessive preoccupation with gaming, withdrawal symptoms, tolerance, impaired control, prioritization of gaming over other activities, continued gaming despite adverse consequences, misrepresentation of gaming involvement, use of gaming as an escape from negative moods, and functional impairment resulting from gaming behavior. The checklist has been validated in adolescent populations and has demonstrated adequate reliability and validity [46]. For analysis, the 9 items were summed to create an observed total score reflecting IGD symptom severity, with higher scores indicating greater severity. In this study, the Cronbach α of this scale was 0.70 at T1, 0.75 at T2, and 0.81 at T3.

Resilience

Resilience was measured using the 10-item short form of the Connor-Davidson Resilience Scale, which assesses individuals' capacity to adapt to stressors such as life changes, personal challenges, illness, pressure, failure, and emotional distress [47]. The Chinese version of the scale has demonstrated strong psychometric reliability and validity in prior research [48,49]. Items are rated on a 5-point Likert scale ranging from 0 ("not true at all") to 4 ("true nearly all of the time"), yielding total scores between 0 and 40, with higher scores indicating greater resilience. In this study, the Cronbach α of this scale was 0.82 at T1, 0.85 at T2, and 0.90 at T3.

Socially Prescribed Perfectionism

SPP was assessed using the corresponding 5-item subscale of the Hewitt-Flett Multidimensional Perfectionism Scale Short Form [50]. Participants rated each item on a 7-point Likert scale ranging from 1 ("strongly disagree") to 7 ("strongly agree"), with higher total scores indicating greater levels of SPP. The Chinese version of this subscale has demonstrated good reliability and validity in previous studies [51]. In this study, the Cronbach α of this scale was 0.83 at T1, 0.86 at T2, and 0.88 at T3.

Preliminary Data Analyses

Attrition analyses were performed using χ^2 tests for categorical variables and independent-samples *t* tests for continuous variables. Pearson correlation coefficients were calculated to examine the relationships among the main study variables. In the descriptive and correlational analyses conducted in SPSS (IBM Corp), listwise deletion was applied to address missing data. Given that the proportion of missing data was minimal (approximately 1%), this approach was considered suitable and unlikely to bias the results or substantially reduce the effective sample size.

Measurement Invariance

Longitudinal measurement invariance was examined for SPP, resilience, and IGD. An acceptable configural invariance model was determined based on standard model fit criteria, including a comparative fit index (CFI) ≥0.90 and root mean square error of approximation (RMSEA) and standardized root mean square residual (SRMR) values ≤0.08 [52]. Metric and scalar invariance were supported when changes in model fit indices remained within recommended thresholds (ΔCFI≤0.01; ΔRMSEA≤0.015), indicating stability of factor loadings and item intercepts across time points and sex groups. Because scalar invariance was supported, the constructs were considered comparable across waves and were retained for the subsequent longitudinal structural analyses.

CLPM and Mediation Analysis

In the longitudinal models, IGD was treated as an observed continuous summed score representing symptom severity rather than a categorical diagnostic variable. To investigate the longitudinal relationships among SPP, resilience, and IGD, an a priori CLPM was specified, which is well suited for testing directional and mediational effects in longitudinal datasets [52,53]. The model included autoregressive paths for SPP, resilience, and IGD across adjacent waves; cross-lagged paths among the 3 constructs across adjacent waves; and within-wave correlations among SPP, resilience, and IGD at each time point. Indirect effects were evaluated using bootstrapping procedures with 5000 resamples to generate 95% bias-corrected confidence intervals. Model adequacy was assessed using multiple goodness-of-fit indices, including $\chi^2(df)\leq 5$, CFI and Tucker-Lewis index (TLI)≥0.90, and RMSEA and SRMR≤0.08, consistent with established structural equation modeling guidelines [54].

XSL•FO
RenderX

Multigroup Analyses

Multigroup analyses were conducted to examine sex differences in the longitudinal associations among SPP, resilience, and IGD. A series of nested models, each constraining a specific pathway, were compared with an unconstrained model in which all parameters were freely estimated. Sex differences were evaluated by comparing the fit of the unconstrained and constrained models. Following commonly recommended criteria for measurement and structural invariance testing, ΔCFI and ΔRMSEA were used as the primary indicators of model differences, with ΔCFI>0.01 and ΔRMSEA>0.015 indicating meaningful deterioration in model fit and, therefore, significant sex differences in the examined associations.

Software, Estimation, and Missing Data Handling

Preliminary analyses were performed using SPSS version 26.0, and all longitudinal structural analyses were performed using Mplus 8.3. Before model estimation, the distributions of SPP, resilience, and IGD were examined across the 3 waves. Because no severe departures from normality were identified, maximum likelihood estimation was considered appropriate for the longitudinal analyses. For the longitudinal models estimated in Mplus, full information maximum likelihood (FIML) analysis was used to address missing data by retaining all available observations in model estimation [55]. No post hoc model respecification was undertaken for the primary longitudinal model. Statistical significance was set at a 2-tailed *P* value <.05.

Sensitivity Analysis

In addition, multiple imputation was performed as a sensitivity analysis to examine the robustness of the findings to the handling of missing data. This approach has been widely used in longitudinal studies [56-58]. The results obtained from the imputed datasets were highly similar to those from the primary FIML analyses, indicating that the main findings were robust.

Results

Missing Data

At T1, the sample included 1332 adolescents; missing data were observed for age (11/1332, 0.8%), sex (4/1332, 0.3%), father's educational level (11/1332, 0.8%), mother's educational level (8/1332, 0.6%), academic performance (11/1332, 0.8%), SPP (7/1332, 0.5%), resilience (10/1332, 0.8%), and IGD (14/1332, 1.1%). The following variables did not have any missing data: self-reported household income, single-parent family status, and gaming time per month. At T2, the sample included 1296 adolescents.

Missing data at T2 were as follows: age, 9/1296, 0.7%; sex, 6/1296, 0.5%; father's educational level, 12/1296, 0.9%; mother's educational level, 9/1296, 0.7%; self-reported household income, 15/1296, 1.2%; academic performance, 7/1296, 0.5%; single-parent family status, 14/1296, 1.1%; gaming time per month, 8/1296, 0.6%; SPP, 14/1296, 1.1%; resilience, 8/1296, 0.6%; and IGD, 9/1296, 0.7%.

At T3, the sample included 1258 adolescents. Missing data at T3 were as follows: age, 6/1258, 0.5%; sex, 4/1258, 0.3%; father's educational level, 7/1258, 0.6%; mother's educational level, 7/1258, 0.6%; self-reported household income, 10/1258, 0.8%; academic performance, 6/1258, 0.5%; single-parent family status, 11/1258, 0.9%; gaming time per month, 6/1258, 0.5%; SPP, 10/1258, 0.8%; resilience, 12/1258, 1%; and IGD, 9/1258, 0.7%. The Little test for missing completely at random was nonsignificant (χ^2_{18}=15.55, *P*=.62), indicating that the missing data pattern was consistent with the missing completely at random assumption. Therefore, FIML was considered appropriate and was used in the longitudinal analyses to retain all available data.

Distributions

Before fitting the CLPM, the distributions of the main study variables were examined across the 3 waves. The skewness and kurtosis values for SPP, resilience, and IGD indicated no severe departures from normality. Therefore, the use of maximum likelihood estimation in the subsequent longitudinal analyses was considered appropriate.

Attrition Analyses

As shown in Table 1, attrition analyses comparing participants who remained in the study with those lost to follow-up revealed no statistically significant differences in age, sex, parental educational level, self-reported household income, academic performance, single-parent family status, gaming time per month, SPP, resilience, and IGD at baseline (all *P*>.05). These findings suggest that attrition was unlikely to substantially influence the subsequent longitudinal analyses.

Correlation Analyses

As shown in Table 2, SPP was significantly and positively correlated with IGD across the 3 waves (r=0.24 to 0.35, all P<.001). Resilience was significantly and negatively correlated with SPP and IGD across 3 waves (r=–0.28 to –0.11, all P<.001).

Longitudinal Invariance Test

Table 3 presents the results of the longitudinal measurement invariance tests for SPP, resilience, and IGD. The configural invariance models demonstrated satisfactory model fit across all 3 constructs (CFI and TLI values >0.90; RMSEA and SRMR values <0.08), indicating that the underlying factor structures of SPP, resilience, and IGD remained stable across the 3 measurement occasions. Metric invariance was further supported, as evidenced by minimal changes in model fit indices (ΔCFI≤0.01, ΔRMSEA≤0.015, and ΔSRMR≤0.01), confirming the stability of factor loadings and ensuring the comparability of the relationships between each latent construct and its indicators over time. Furthermore, scalar invariance was achieved, with similarly negligible changes in fit indices across waves, demonstrating the invariance of item intercepts across time points. These findings suggest that the longitudinal variations observed in SPP, resilience, and IGD reflect genuine temporal or developmental changes rather than artifacts arising from measurement inconsistency.

CLPM Results

The CLPM demonstrated a good model fit to the data (χ^2_{38}=163.34; RMSEA=0.054; CFI=0.945; TLI=0.932; SRMR=0.047). The final interpreted model was the originally specified model, and no post hoc model respecification was undertaken. As illustrated in Figure 2, SPP at T1 significantly and positively predicted IGD at T2 (β=0.10, SE=0.03, 95% CI 0.04 to 0.16, *P*<.001), and SPP at T2 significantly and positively predicted IGD at T3 (β=0.09, SE=0.03, 95% CI 0.03 to 0.15, *P*=.004). In contrast, IGD did not significantly predict subsequent SPP across waves. With respect to resilience, SPP at T1 significantly and negatively predicted resilience at T2 (β=−0.09, SE=0.04, 95% CI –0.16 to –0.02, *P*=.007), and SPP at T2 significantly and negatively predicted resilience at T3 (β=−0.12, SE=0.03, 95% CI –0.18 to –0.06, *P*<.001). However, resilience did not significantly predict subsequent SPP. Resilience at T1 significantly and negatively predicted IGD at T2 (β=−0.09, SE=0.03, 95% CI –0.15 to –0.03, *P*=.001), and resilience at T2 significantly and negatively predicted IGD at T3 (β=−0.09, SE=0.03, 95% CI –0.15 to –0.03, *P*=.001). Meanwhile, IGD at T1 significantly and negatively predicted resilience at T2 (β=−0.19, SE=0.04, 95% CI –0.27 to –0.11, *P*<.001), and IGD at T2 significantly and negatively predicted resilience at T3 (β=−0.09, SE=0.03, 95% CI –0.15 to –0.03, *P*=.003).

Regarding longitudinal mediation, SPP at T1 significantly predicted resilience at T2, which in turn significantly predicted IGD at T3, indicating a significant indirect effect of SPP on IGD via resilience over time. Specifically, the indirect effect of SPP at T1 on IGD at T3 through resilience at T2 was significant (β=0.008, SE=0.002, 95% CI 0.004 to 0.012, *P*=.005).

No Significant Sex Differences

A multigroup comparison model was used to examine sex differences in the associations among SPP, resilience, and IGD. Initially, an unconstrained model was estimated, allowing all paths to vary freely between male and female groups. The model fit was χ^2_{30}=175.80, RMSEA=0.099, SRMR=0.039, CFI=0.957, and TLI=0.906. Subsequently, a constrained model was specified, in which the corresponding paths were set to be equal across both groups. The fit indices for the constrained model were χ^2_{36}=190.39, RMSEA=0.093, SRMR=0.039, CFI=0.955, and TLI=0.917.

Model comparisons revealed that constraining the paths to be equal across sex did not lead to a substantively worse model fit, as the changes in CFI (ΔCFI=0.002) and RMSEA (ΔRMSEA=0.006) were both below the commonly recommended cutoff values (ΔCFI<0.01; ΔRMSEA<0.015). These results indicate that the longitudinal associations among SPP, resilience, and IGD did not differ significantly between males and females.

Sensitivity Analysis

To examine whether the main findings were sensitive to the handling of missing data, multiple imputation was conducted as a robustness check. Missing data were imputed using multiple imputation with chained equations, generating 50 imputed datasets. Parameter estimates pooled across the imputed datasets were highly similar to those obtained from the primary FIML analyses. This close correspondence indicates that the main findings were robust to the method used to handle missing data and that attrition was unlikely to have materially affected the study conclusions. Detailed results of the imputation analyses are presented in Multimedia Appendix 1.

Discussion

Principal Findings

This study examined the longitudinal associations among SPP, resilience, and IGD across 3 waves in Chinese adolescents, with particular attention to the mediating role of resilience and potential sex differences. Consistent with the study hypotheses, higher levels of SPP predicted subsequent increases in IGD over time, and resilience served as a longitudinal mediator linking SPP to later IGD. Contrary to our third hypothesis, however, the structural associations among SPP, resilience, and IGD did not differ significantly by sex. Together, these findings suggest that SPP pressure may contribute to adolescents' problematic gaming both directly and indirectly through lower resilience.

The Association Between SPP and IGD

This study provides longitudinal evidence regarding the role of SPP in the development of IGD. Consistent with H1, higher SPP predicted higher subsequent IGD across both time intervals, suggesting that SPP may function as a relatively stable longitudinal risk factor for problematic gaming in adolescence. This pattern aligns with prior research showing that maladaptive perfectionistic tendencies are linked to an elevated risk of problematic internet-related behaviors and behavioral addictions among adolescents and young adults [59-61]. These findings suggest that externally imposed perfectionistic expectations may increase adolescents' vulnerability to IGD by fostering chronic evaluative stress and making self-worth more contingent

XSL•FO
RenderX

on external approval [60,61]. For adolescents with high levels of SPP, online gaming may become especially appealing because it provides a relatively controllable environment in which achievement, feedback, and social recognition can be obtained more immediately and, at least temporarily, with less fear of direct real-world evaluation [62,63]. In this way, gaming may serve not only as an escape from pressure but also as a compensatory context for restoring threatened competence and self-worth [64].

The predictive role of SPP in increasing IGD risk also highlights the importance of supportive offline environments [65,66]. Constructive academic and familial feedback may alleviate excessive self-criticism and reduce the tendency to seek external validation through online gaming platforms [65]. This implication is especially salient in the contemporary digital era, where online gaming is highly accessible and deeply integrated into adolescents' daily routines [67]. Accordingly, interventions aimed at modifying maladaptive perfectionistic beliefs and strengthening adaptive coping strategies represent promising avenues for prevention and early intervention in problematic gaming behaviors [68,69]. Notably, this study focused primarily on a socially driven cognitive-interpersonal vulnerability (ie, SPP); future research may incorporate additional contextual and interpersonal variables, such as peer norms, academic stress, and parenting styles, to further indicate the multifaceted pathways contributing to IGD [66,70].

The Mediating Role of Resilience

In support of H2, this study identified a significant mediating role of resilience in the longitudinal relationship between SPP and IGD. More importantly, this finding helps clarify how a socially driven perfectionistic vulnerability may be translated into problematic gaming over time [10,71]. The result is broadly consistent with the compensatory internet use framework [71,72], which proposes that maladaptive online behavior is more likely when individuals experience offline stress but lack sufficient psychological resources to cope adaptively with that stress [73]. Within this framework, resilience is not merely a general positive trait; rather, it functions as a regulatory resource that may determine whether perfectionism-related distress is managed through adaptive coping or displaced into compensatory gaming behavior [31]. Adolescents with high levels of SPP are likely to experience chronic evaluative stress, fear of negative judgment, and heightened dependence on external approval [10]. When resilience is weakened under such conditions, they may become less able to tolerate frustration, recover from perceived failure, and regulate negative affect in offline contexts [74]. Online gaming may then become especially attractive because it offers immediate feedback, structured goals, a temporary distraction, and a controllable sense of competence [75]. In this sense, our findings extend the theoretical framework by suggesting that the pathway from perfectionistic vulnerability to IGD may operate partly through erosion of a key psychological coping resource rather than through distress alone [30,72].

At the same time, our findings suggest that the role of resilience is not purely unidirectional. In addition to the hypothesized pathway from lower resilience to later IGD, IGD also negatively predicted subsequent resilience. This reverse path is theoretically meaningful because it indicates that problematic gaming may not only reflect preexisting coping difficulties but also further deplete adolescents' psychological resources over time [76,77]. Excessive gaming may displace restorative offline experiences, weaken real-world problem-solving, disrupt sleep and daily routines, and reduce opportunities for supportive social interaction, all of which may undermine the capacity to recover from stress adaptively [78,79]. Thus, the findings point to a potentially reciprocal process: Lower resilience may increase vulnerability to gaming as a compensatory strategy, whereas higher levels of IGD may, in turn, erode resilience, thereby contributing to a self-reinforcing cycle [76,77]. However, this reciprocal dynamic did not appear to extend back to SPP, as resilience did not significantly predict subsequent SPP. This asymmetry is theoretically informative. It suggests that, although resilience is malleable and closely tied to adolescents' ongoing coping capacity [80], SPP may represent a more stable socially driven cognitive-personality vulnerability rooted in internalized external expectations and evaluative concerns [10]. In other words, problematic gaming may weaken adolescents' coping resources, but such depletion may not be sufficient to alter their broader perfectionistic beliefs over the relatively short time frame of the study [10,76,81]. These findings refine the proposed model by suggesting that SPP may function primarily as an upstream vulnerability factor, whereas resilience and IGD may constitute a more dynamic downstream process characterized by partial reciprocity [70,76].

It is important to recognize that, although the magnitude of the longitudinal indirect effect was small, this pattern is consistent with prior methodological and developmental research indicating that prospective effects in multiwave psychological models are typically modest in size [82]. Longitudinal mediation analyses inherently involve residualization of prior levels and multiplication of coefficients, both of which tend to attenuate effect estimates even when the underlying theoretical process is reliable [83]. Moreover, the current 3-wave design, which incorporated temporal ordering and statistical control of prior levels of both the mediator and outcome variables, followed established recommendations for testing mediational mechanisms using structural equation modeling and enables stronger causal inference than cross-sectional approaches [84]. The relatively small indirect effect may also reflect the fact that SPP is a comparatively distal cognitive-personality vulnerability, whereas IGD is a downstream behavioral outcome likely shaped by multiple intervening mechanisms. In this context, it is theoretically plausible that only a limited portion of the association between SPP and IGD would be transmitted through any single mediator, including resilience. Importantly, developmental research has emphasized that even modest cross-lagged or indirect effects may accumulate over time and retain theoretical and practical significance, particularly in adolescent psychosocial processes characterized by substantial temporal stability [85]. Accordingly, the mediation effect found in this study should not be overstated, but neither should it be dismissed as trivial. Rather, it suggests that resilience represents one meaningful, but not exhaustive, pathway through which SPP may contribute to later IGD.

XSL•FO
RenderX

Notably, resilience is unlikely to be the sole mediating pathway linking SPP and IGD. Other psychological processes, such as emotion regulation difficulties and depressive symptoms, may also play important intermediary roles [86]. For example, individuals with high levels of SPP may experience heightened emotional distress or impaired self-regulation, which may prompt them to seek immediate feedback and perceived controllability through immersive gaming environments [2,37]. The compensatory internet use framework further suggests that personality-related vulnerabilities and psychosocial resources interact dynamically in shaping excessive gaming behaviors, underscoring the value of incorporating multiple mediating variables for a more comprehensive understanding [18]. Future research should therefore examine additional mediators, such as self-esteem, coping styles, and broader personality traits, using longitudinal designs to clarify how these factors jointly influence the developmental trajectory of problematic gaming behaviors [87].

No Significant Sex Differences in the Longitudinal Associations

Contrary to H3, the results revealed no significant sex differences in the longitudinal pathways linking SPP, resilience, and IGD. This finding suggests that the temporal associations among socially driven cognitive interpersonal vulnerability, psychological resources, and problematic gaming behaviors are largely comparable for male and female adolescents [88,89]. Importantly, although prior studies have reported sex differences in the prevalence or mean levels of IGD [88], such mean-level disparities do not necessarily indicate differences in structural or longitudinal relationships among psychological constructs. Consistent with this distinction, our results demonstrate that the cross-wave relationships among SPP, resilience, and IGD operate similarly across sex groups [90]. One plausible explanation is that the core psychological processes underlying externally imposed perfectionistic expectations and maladaptive coping, including heightened self-criticism, increased stress sensitivity, and reduced coping flexibility, may function in comparable ways for both male and female adolescents [89,91]. In addition, adolescents often encounter shared developmental challenges and environmental pressures, such as academic competition, social evaluation, and uncertainty about the future, which may contribute to relatively uniform patterns of psychological vulnerability and behavioral responses regardless of sex [92,93]. Accordingly, sex may be less influential in differentiating longitudinal psychological mechanisms than in shaping overall levels of gaming involvement or emotional symptoms [88,93]. Future research should therefore consider whether other individual or contextual factors, such as age, gaming motivation, or peer norms, explain greater variation in these longitudinal associations than sex alone.

Implications

This study has several important implications. First, it advances the theoretical understanding of socially driven cognitive interpersonal vulnerability and behavioral addiction by demonstrating the longitudinal role of SPP in predicting IGD. Although previous studies have reported associations between perfectionism and problematic internet or gaming behaviors [23], our findings provide temporal evidence that SPP prospectively predicts IGD over time. Second, this study contributes to theoretical development in IGD research by incorporating resilience frameworks into the examination of SPP and IGD. The results indicate that adolescents with elevated SPP may experience reduced psychological resilience, which subsequently increases their susceptibility to problematic gaming behaviors. This mediating pattern supports compensatory theoretical perspectives within the behavioral addiction literature. In addition, the findings extend prior work by showing that SPP not only directly predicts IGD but also indirectly influences IGD through resilience, highlighting the importance of psychological resources as a key intermediary mechanism in the developmental pathway of problematic gaming.

From a practical perspective, these findings suggest that interventions addressing socially driven cognitive interpersonal vulnerabilities and resilience enhancement may serve as effective strategies for preventing and reducing IGD among adolescents. Because elevated SPP can weaken resilience and increase gaming risk, intervention efforts should focus on reshaping maladaptive perfectionistic beliefs, promoting flexible self-evaluation, and reducing excessive self-criticism [23]. Counseling and cognitive behavioral programs that encourage self-compassion, realistic performance standards, and adaptive responses to external expectations may alleviate the psychological pressure that fuels excessive gaming behaviors [94,95]. Furthermore, the results emphasize the value of resilience-focused initiatives in mitigating IGD risk. Schools, families, and mental health professionals may consider implementing programs that strengthen emotional regulation, coping flexibility, and problem-solving skills among adolescents [96]. Providing offline opportunities for meaningful achievement and social engagement, including group activities, mentorship programs, and counseling services, can further reinforce psychological resources and reduce reliance on online gaming as a compensatory outlet [97]. Finally, the findings highlight the importance of promoting digital self-regulation and healthy gaming education. Educational initiatives that cultivate balanced gaming habits, effective time management, and awareness of compulsive gaming tendencies may help adolescents establish a more sustainable relationship with digital entertainment and decrease the likelihood of problematic gaming involvement [98,99].

Limitations

This study has several limitations. First, all variables were assessed using self-report measures, which may introduce social desirability and recall biases. Future research would benefit from incorporating multi-informant or behavioral assessments, such as parent or teacher reports and objective usage records. Second, although a 3-wave longitudinal design was used, this study relied on a traditional CLPM, which has important limitations. In particular, CLPM may confound stable between-person differences with within-person change processes over time [100]. Therefore, the observed cross-lagged associations should not be interpreted as definitive evidence of causal or developmental effects. Future research could use more advanced longitudinal models, such as random-intercept CLPMs, as well as experimental or intervention-based designs

XSL•FO
RenderX

to provide a clearer test of within-person processes and causal relations. Third, IGD was measured using a questionnaire rather than clinical diagnostic interviews, which may limit the clinical interpretability of the findings. Replication in clinical or high-risk populations would strengthen external validity and enhance clinical relevance. Fourth, this study focused only on SPP and did not include other dimensions of perfectionism. Future longitudinal studies should examine multiple perfectionism dimensions simultaneously to compare their unique roles in the development of IGD. Finally, participants were recruited through nonrandom sampling within a limited geographic region, which may introduce sampling bias and restrict generalizability. Future research should therefore use broader and more diverse samples across cultural and socioeconomic contexts to verify the robustness of the observed associations.

Conclusions

This study extends existing research by using a 3-wave longitudinal design to examine how SPP, resilience, and IGD are associated over time in adolescents. Unlike prior studies that have relied primarily on cross-sectional data, these findings highlight resilience as one temporal pathway through which SPP may be associated with later IGD. These results contribute to the literature by refining understanding of how socially driven perfectionistic vulnerability and psychological resources jointly shape adolescent problematic gaming. In practical terms, the findings suggest that adolescents exposed to high external evaluative pressure may benefit from early identification and prevention efforts that target both maladaptive perfectionistic beliefs and resilience-related coping capacities.

Abstract

Background: Asthma is a prevalent chronic respiratory condition among children worldwide. Inhalation therapy is the primary treatment method, but children often make errors in its use and exhibit poor adherence, which impacts treatment effectiveness. Therefore, interventions to improve inhalation techniques and enhance adherence are urgently needed.

Objective: This study aimed to develop and evaluate BreatheBuddy, developed by Haoyu Zhang, a training system incorporating gamified feedback designed to enhance inhalation skills and treatment adherence in children with asthma.

Methods: This study used a single-factor repeated-measures design and recruited 20 children aged 6 to 8 years (10 boys and 10 girls), all of whom had prior experience with inhalers. The experimental group used the BreatheBuddy system, which combines a physical inhaler with an interactive game-based software. The system provides real-time animated feedback based on data from inhalation, breath-holding, and exhalation to guide the rhythm and depth of inhalation. The control group used a conventional inhaler method without a gamified system. Inhalation accuracy, adherence, and satisfaction were assessed using the respiration sensor, the Player Experience of Need Satisfaction scale, the Game User Experience Satisfaction Scale (GUESS), and the System Usability Scale (SUS) scales. Statistical comparisons between the groups were conducted using paired *t* tests and Mann-Whitney *U* tests to analyze differences.

Results: The experimental group demonstrated significant improvements in inhalation accuracy, with longer breath-holding times and more stable breathing patterns compared to the control group ($P<.001$). The experimental group also exhibited significantly higher engagement and motivation, with Player Experience of Need Satisfaction (standardized score=93.83) and GUESS (median 87.92, IQR 86.54-88.46) scores markedly higher than those of the control group. Usability scores for the experimental group were also superior, with an SUS score of 88.96 ($P<.001$). Additionally, children in the experimental group showed reduced anxiety and improved focus during training.

Conclusions: BreatheBuddy effectively optimized children's inhalation skills, boosted treatment adherence, and relieved inhalation-related anxiety. Different from conventional non-gamified training or simple game-based distraction, this study integrated breathing behaviors into core game interaction. With dynamic respiratory rhythm feedback, the system unifies skill training, motivation promotion, and emotional regulation. Combined with standard inhaler operation and immersive gamified interaction, it presents a novel behavior-oriented design paradigm. This work provides empirical evidence for gamified intervention in pediatric respiratory treatment and offers a practical auxiliary tool for clinical daily training to strengthen children's self-management. Further research will focus on personalized adjustment and wider clinical application of the system.

KEYWORDS

gamification intervention; human-computer interaction; inhaler training; pediatric asthma; treatment adherence

Introduction

Asthma and chronic obstructive pulmonary disease are common chronic respiratory disorders. Among them, asthma has emerged as one of the most prevalent chronic diseases in children worldwide [1-4]. Inhalation therapy, primarily through inhalers, is the preferred treatment modality, as it delivers medication directly to the airways, enhances local drug concentration, and minimizes systemic side effects [5-7]. However, effective asthma control remains a clinical challenge. Studies indicate that approximately 55.1% of pediatric patients with asthma fail to achieve optimal therapeutic outcomes, largely due to poor treatment adherence and improper inhalation technique [8-11]. Surveys reveal that nearly 50% of patients cannot use inhalers correctly, and up to 80% make errors during operation, resulting in excessive oropharyngeal drug deposition, reduced pulmonary deposition [12,13], diminished treatment efficacy, and increased risk of acute exacerbations [14-16].

XSL•FO
RenderX

In pediatric patients, misuse of inhalers is particularly problematic due to physiological characteristics such as narrow airways, small tidal volumes, and high respiratory rates, as well as difficulties in coordination. Observational studies suggest that only 8% - 22% of children can use inhalers correctly [17-21]. Despite guideline recommendations for inhaler education at every clinical visit, about 25% of patients receive no instruction [22,23], and only 10% of children undergo inhalation technique assessment during consultations [24]. This educational gap limits improvements in treatment outcomes. Evidence shows that inhalation training significantly prolongs inspiratory duration and increases drug deposition [25]. Moreover, multidisciplinary reviews and clinical guidelines emphasize the importance of selecting age- and physiology-appropriate devices (eg, masks, spacers, or nebulizers) and reinforcing repeated training [26]. Nevertheless, limited cognitive development in children contributes to poor treatment adherence, with approximately 74.7% of pediatric patients exhibiting nonadherent behaviors—such as crying or refusing to wear masks—which significantly compromise therapeutic effectiveness [27]. Improving adherence in children has thus become a central focus of clinical care.

To enhance the treatment experience, numerous studies have explored various intervention strategies, such as distraction-based interventions, inhaler usage training, and the optimization of the clinical environment [28]. Moreover, educational interventions and inhaler training have been shown to significantly improve patient adherence [29]. Certain hospitals integrate colorful, cartoon-themed designs into the environment to alleviate children's anxiety [30]. Additionally, health care providers use games, videos, and relaxation techniques to divert children's attention and reduce their stress levels. In terms of equipment design, more compact and visually engaging nebulizers have been developed, including toy nebulizers and toy masks, which improve the airtight seal and help reduce anxiety [31]. Although these traditional approaches have seen some advancements, they still necessitate considerable resource investment, including the time required for implementing therapeutic games, additional training, institutional support, and the need for further financial resources and infrastructure modifications [32].

It is crucial to highlight that the use of most inhalation devices is based on three key steps: inhalation, breath-holding, and exhalation, which are essential for the effectiveness of inhalation therapy. Research has shown that the depth of inhalation, breath-holding duration, and exhalation rhythm directly influence the pulmonary deposition efficiency of medication [33,34]. Specifically, the duration of breath-holding is strongly correlated with the amount of medication deposited in the lungs. Proper breath-holding duration significantly enhances the deposition ratio in the lungs, thereby improving therapeutic outcomes. This is a critical aspect that should be emphasized in inhaler training for children [35].

In recent years, the use of gamification and digital serious games for the self-management of chronic diseases in children and adolescents has rapidly grown, becoming a major form of digital health intervention. These approaches effectively enhance health knowledge and self-management skills, particularly among children with chronic illnesses, demonstrating positive effects [36]. Systematic reviews show that digital interventions such as smart inhalers, mobile apps, and reminder messages positively impact asthma medication adherence and clinical outcomes [37]. Studies have found that augmented reality educational tools co-designed with children can significantly improve inhaler skills and increase engagement [38]. Training methods combining mobile games have also been shown to improve children's inhalation techniques and quality of life [39]. Additionally, smart inhalers equipped with audio and visual feedback systems have effectively improved medication adherence in children, and their real-time feedback enhances the interactivity and engagement of treatment [40]. Review papers indicate that electronic monitoring devices play a vital role in helping children use inhalers correctly, effectively improving inhalation techniques [41]. Innovative smart devices and gamification designs have also shown significant improvements in adherence and engagement [12]. Finally, computer interactive narratives and serious games have been found to increase children's adherence to inhaler use and improve therapeutic outcomes [42]. Although different types of inhalers (including dry powder inhalers, pressurized metered-dose inhalers, and combination devices) have different operational details, they all focus on regulating the breathing rhythm [43] (Multimedia Appendix 1). These studies collectively indicate that smart technologies and gamification designs are effective in enhancing self-management of chronic diseases in children, particularly in improving adherence and therapeutic outcomes. However, existing gamified devices have not sufficiently considered the inhaler itself as an input device. Although self-determination theory and flow theory provide psychological foundations for gamification [44], and frameworks such as Mechanics, Dynamics, and Aesthetics (MDA) offer practical guidance for system design [45], current applications fail to fully integrate children's physiological characteristics and the specific context of inhalation therapy, which limits their effectiveness. Additionally, many current gamified interventions rely on external devices such as tablets and smartphones, rather than integrating the inhaler itself into the interactive experience [46-48]. This may result in reduced interactivity and misalignment with the treatment process, ultimately limiting the devices' ability to improve children's breathing accuracy and medication adherence.

This study introduces BreatheBuddy, developed by Haoyu Zhang, a gamified feedback-based inhaler training system for children with asthma. The purpose of this study is to guide children in performing correct breathing exercises through real-time animations and gamified feedback, thereby enhancing their inhaler technique and treatment adherence. By integrating gamified intervention theory with human-computer interaction technology, the system aims to improve children's inhaler use behaviors and, ultimately, enhance treatment outcomes.

The main research questions (RQs) of this study are as follows:

- RQ1: How can an interactive inhaler training tool with a gamification system be designed for children?
- RQ2: Does the accuracy of children's inhalation/breath-holding/exhalation rhythm improve, thereby enhancing therapeutic outcomes?

XSL•FO
RenderX

- RQ3: Does children's treatment adherence improve?

Methods

System Design and Implementation

Before system design, the research team conducted surveys and semistructured interviews with children, parents, and health care professionals. This preliminary study aimed to identify the experiences, challenges, and needs of pediatric patients, caregivers, and experts in the process of using asthma inhalers. The findings served as direct empirical evidence for answering RQ1 ("How can an interactive inhaler training tool with a gamification system be designed for children?") and laid the foundation for the design of the BreatheBuddy system.

Multistakeholder Engagement

Sample and Participant Recruitment

To explore children's psychological states and coping strategies during inhaler use, questionnaires were administered to 20 preschool children (ages 5 - 8 years), 7 parents (ages 28 - 37 years), and 2 pediatric health care professionals (ages 29 - 31 years). Eligible children were required to have prior experience with nebulization and at least one use of an inhaler, while children with severe cognitive or language impairments were excluded. The parents were the primary caregivers of the aforementioned children, all of whom had accompanied their children during inhalation therapy. The health care professionals were 2 frontline pediatric nurses with teaching and guidance experience in inhaler use. All participants were recruited from local community health centers and kindergartens. Ethical guidelines were strictly followed, and all data were anonymized during collection and analysis.

Questionnaire Structure

The questionnaire was initially drafted by the research team and subsequently reviewed and revised by 2 health care professionals. The final version consisted of 3 sections: child-friendly questions (focusing on children's emotional experiences, common difficulties, and motivations during inhalation therapy), parent supplementary questions (designed to capture observations of children's behavioral responses while also exploring parental support strategies and attitudes), and health care professional questions (addressing inhaler operation errors, adherence barriers, and the potential clinical value of gamification). To ensure the validity of the data and maintain participant focus, a cognitive attention validation task was incorporated into the questionnaire. This task is intended to assess whether the participants are fully engaged and to exclude responses from participants who show signs of inattentiveness or inconsistent answers.

Interviews

Interviews were conducted either face-to-face or via online video conferencing, lasting 5 - 10 minutes each. Two researchers shared responsibilities: 1 facilitated and guided the interview, while the other documented and observed nonverbal behaviors. All interviews were recorded with participant consent, transcribed, anonymized, and subsequently used for qualitative analysis.

Children's Responses

Survey results showed that 50% of children reported disliking inhaler use, while 45% felt fearful, often exhibiting resistance or irritability. Many children commonly experience difficulties with inhaler operation, particularly in controlling inhalation timing and depth, frequently resorting to rapid nasal breathing, which results in poor synchronization with the device. Additionally, 90% reported that breath-holding was challenging, further contributing to resistance. Many children also displayed uncooperative behaviors during inhaler use; frightened children often cried, refused treatment, or sought parental help, with few attempts at self-regulation. Some children also perceived the training process as lacking sufficient engagement or playfulness.

Parents' Perspectives

Parents were particularly concerned about children's lack of adherence. About 42.86% of parents reported that their children often resisted or failed to cooperate, which they believed directly compromised treatment efficacy. Common parental coping strategies included enforced inhaler use (71.43%), use of electronic devices as distraction tools (57.14%), and continued use despite negative emotional states (28.57%). These findings suggest that many parents experienced significant stress and sometimes resorted to forceful measures to ensure inhaler use. Nevertheless, all parents reported using verbal encouragement to help children overcome resistance, indicating attempts to foster positive engagement despite the challenges. Around 57.14% of parents were also concerned about children's technical difficulties during inhaler use, such as maintaining proper breathing rhythm. These issues, intertwined with poor adherence, caused distress among parents and raised concerns about therapeutic effectiveness.

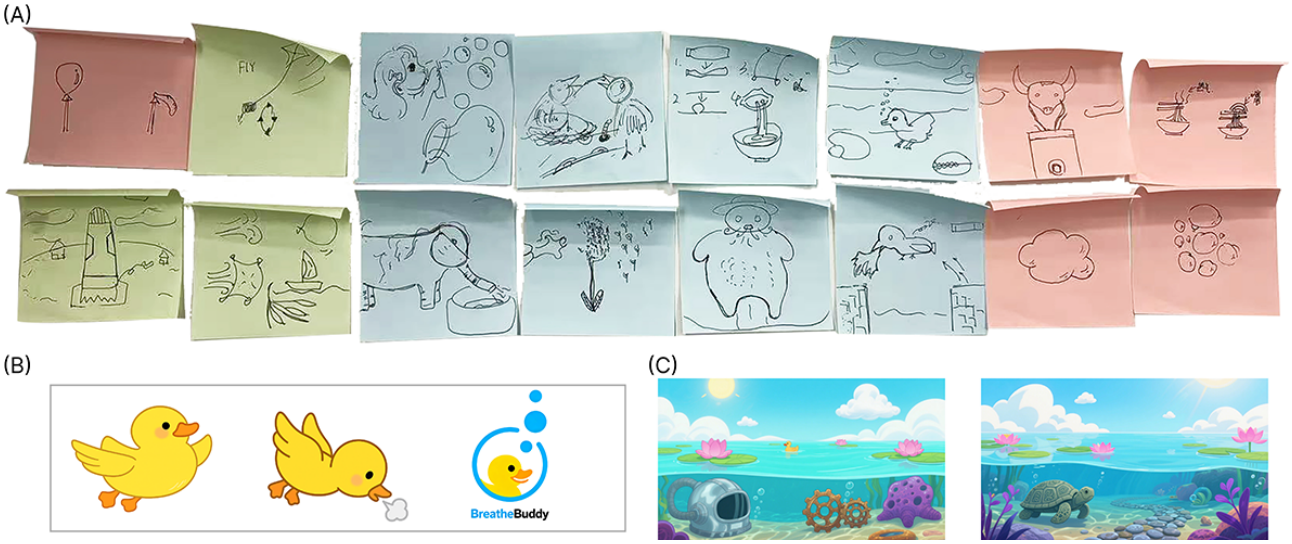
Finally, parents expressed both interest and concerns regarding future gamified inhaler systems. While many were worried about insufficient gaming effects (57.14%) and potential risk of addiction (57.14%), their most critical concern was whether gamification could compromise medication safety and efficacy. These results suggest that parents expect inhaler systems not only to provide enjoyable experiences but also to be designed with therapeutic effectiveness as the foremost priority.

Opinions of Health Care Professionals

Health care professionals highlighted that common errors made by children when using inhalers include inhaling too rapidly, insufficient breath-holding, and exhaling too early, all of which severely compromise drug deposition. They recommended incorporating stepwise rhythm guidance into the training tool to accommodate differences in lung function across age groups. In addition, concerns were raised that an excessive emphasis on gamification might produce counterproductive effects. Therefore, the degree of playfulness and interactivity should be carefully calibrated to reduce children's resistance and to avoid monotonous training experiences. Consideration should also be given to the compatibility of the system with clinical workflows.

System Design Concept and Interaction Mechanism

In the design of the system, we used the MDA game design framework to guide the development of the gamification elements. This framework improves the user experience by



XSL•FO
RenderX

refining the key aspects of gameplay—MDA—ensuring the game is both engaging and effective in supporting children's respiratory training. The software component was developed by the first author under the supervision of their doctoral advisor, using the TouchDesigner platform (developed by Haoyu Zhang). A real-time data feedback mechanism was integrated to enhance the interactivity and responsiveness of the game interface. For the hardware design, the first author was responsible for designing the inhaler, consulting with a structural design expert during the design phase to ensure the device's functionality and safety. Additionally, the doctoral advisor provided valuable guidance and oversight regarding the feasibility and real-world application of the hardware.

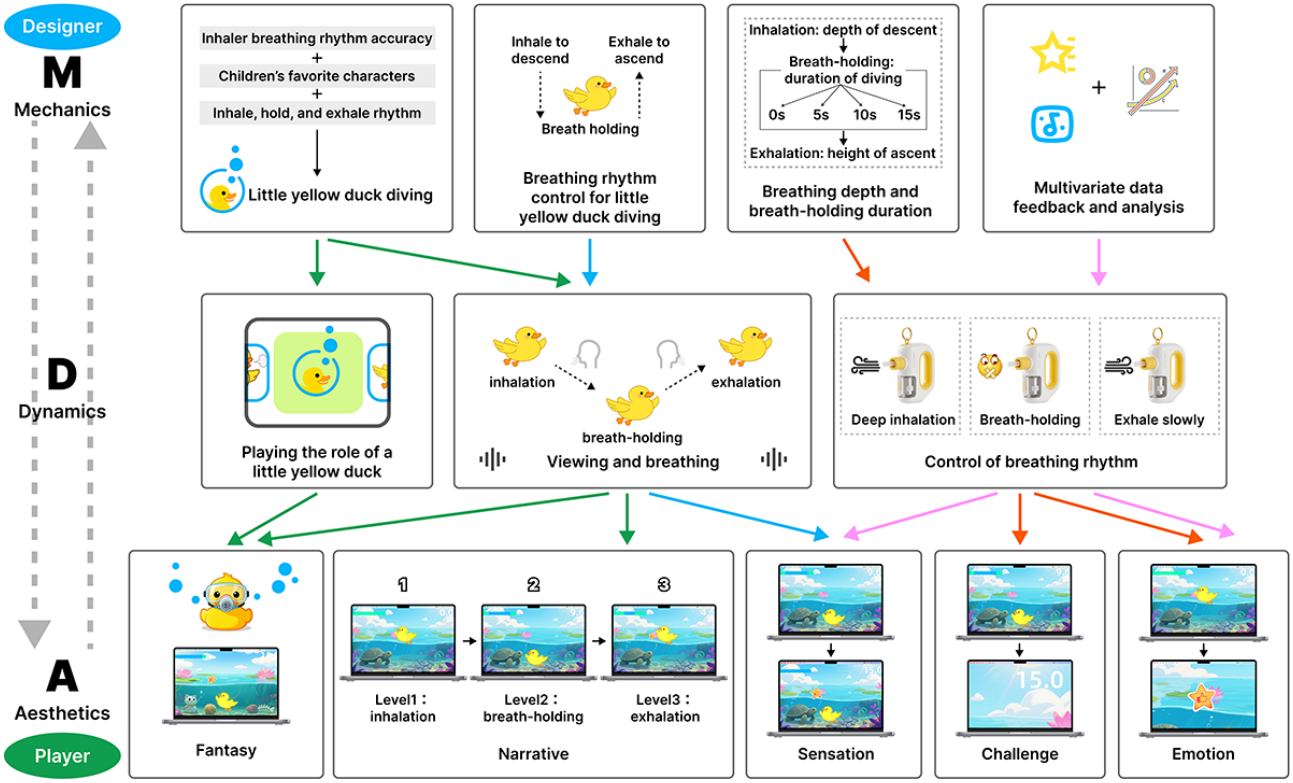
Conceptual Design

At the stage of concept development, the research team organized multiple workshop-style discussions at the User Experience and Interaction Design Laboratory of Hubei University of Technology, involving designers, child psychology researchers, and potential users. Through prototype demonstrations and scenario simulations, the team gradually established the narrative framework of "Little Yellow Duck Diving" for respiratory training. The discussions revealed that this narrative not only received positive feedback from both children and parents but was also perceived as effective in alleviating tension and anxiety during the training process. Figure 1A shows the design and selection of the training environment layout, aimed at enhancing the interactive experience; Figure 1B shows the selection and design of the yellow duck character, an engaging and appealing character; and Figure 1C shows the selection and design of the underwater-themed scene, incorporating diving elements to illustrate the various stages of breathing exercise.

Figure 1. (A) Workshop blueprint design proposals and selections, (B) selection and design of the Little Yellow Duck character, and (C) selection and design of the diving scene.

Selecting the Little Yellow Duck's diving adventure as the narrative backdrop was guided by the following design considerations: (1) the Little Yellow Duck is an innocent, cute, and highly approachable character that can effectively capture children's attention and evoke emotional resonance; (2) within the respiratory-training feedback mechanism, if a child's breath-hold duration is insufficient or their breathing rhythm deviates from the target pattern, the character will be unable to complete the diving action. Compared with terrestrial animals such as rabbits or cats, a diving scenario may trigger negative associations (eg, "drowning" or "suffocation"). As a natural adapter to aquatic environments, the Little Yellow Duck can plausibly surface even when a dive attempt is unsuccessful, which better aligns with its implied physiological affordances. This helps avoid introducing threatening contexts and supports a safe, friendly training experience; and (3) training for inhalation, breath-holding, and exhalation aligns naturally with the actions involved in diving: inhalation represents preparation before submerging, breath-holding simulates the underwater state, and exhalation corresponds to resurfacing. This close coupling between action and training further strengthens children's understanding and engagement. The following narrative logic establishes an intuitive mapping to respiratory-training actions: (1) inhalation phase: the child inhales deeply to charge the Little Yellow Duck with energy; (2) breath-holding phase: the Little Yellow Duck holds its breath and dives underwater, preparing to traverse beneath the surface; and (3) exhalation phase: as the child exhales, the Little Yellow Duck steadily resurfaces, completing the challenge.

Design of the Game Prototype



This study applied the MDA game design framework to guide the design and development process, aiming to improve the gameplay experience by optimizing three core elements. The mechanics define the fundamental rules and interactions, ensuring operational simplicity; the dynamics provide real-time feedback on children's breathing performance, dynamically adjusting difficulty to guide proper breathing; and the aesthetics enrich the affective experience through visual and auditory design, thereby enhancing engagement [45].

From the user perspective, the game is both entertaining and supportive of respiratory training; from the designer perspective, the MDA framework balances the core elements to ensure clear rules, timely feedback, and effective emotional guidance.

XSL•FO
RenderX

Mechanics are the primary concern for designers, while aesthetics are the first interaction for players. As shown in Figure 2, different arrow colors represent mechanisms that drive user dynamics, complemented by distinct aesthetic elements. The four mechanisms are duck diving background, breathing rhythm control, breath depth and duration, and multidimensional data feedback. These correspond to three dynamics: assuming the yellow duck role, watching and breathing, and controlling the breathing rhythm. Through these dynamics, users experience various aesthetic elements, including fantasy, narrative, sensation, challenge, and emotion.

Figure 2. BreatheBuddy system design based on the Mechanics, Dynamics, and Aesthetics (MDA) framework.

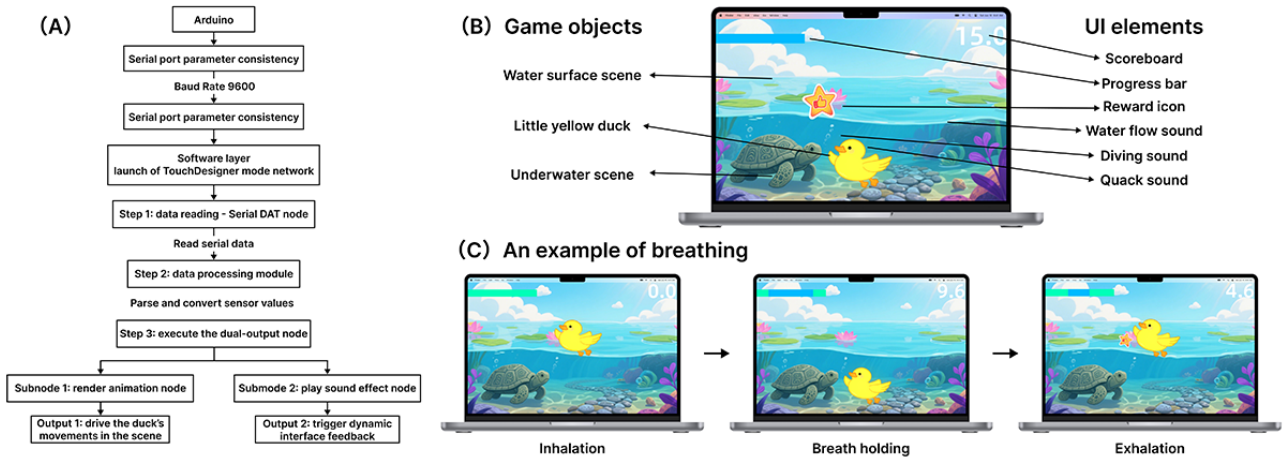
Mechanics

Breathing data guide the duck's movement—deeper inhalation increases dive depth, breath-holding keeps the duck submerged, and exhalation brings it back to the surface. Positive reinforcement encourages correct breathing, such as rewarding sustained breath-holding and successful dives.

Dynamics

Real-time sensor feedback synchronizes the duck's movements with the child's breathing rhythm, reinforcing correct behaviors.

Aesthetics



Cartoon visuals and lively music enhance interactivity and achievement, with sound effects (quacking and water flow) synchronized to breathing rhythms. The underwater environment, including corals, seaweed, and fish, increases immersion and reinforces breathing control.

Implementation of the Visual Interaction Layer

The visual interaction layer was constructed using the TouchDesigner platform. TouchDesigner is a real-time, node-based interactive visualization software that enables the creation of both 2D and 3D animations and audio. Its features of "real-time processing" and "visual programming" make it particularly well-suited for developing dynamic game feedback interfaces [49]. In this study, a node network was established in TouchDesigner, consisting of the Serial DAT node for reading serial data, data processing modules, and a rendering system for animations and sound effects. TouchDesigner natively supports Arduino (developed by Haoyu Zhang) data, allowing direct serial data acquisition through the Serial DAT node and enabling synchronization between hardware signals and visual animations [50]. The serial port baud rate was configured to match the Arduino program (9600 baud), and the table format was set to "one row per line." Under this configuration, each line of sensor values transmitted from the Arduino was received and parsed in real time by TouchDesigner to drive the duck's movements and interface feedback, as illustrated in Figure 3A.

XSL•FO
RenderX

Figure 3. Software implementation. (A) Implementation flow of the BreatheBuddy system's visual interaction layer; (B) using the breath-holding scenario as an example, labeling game objects and user interface elements; and (C) visual interaction screens corresponding to the 3 stages of breathing—inhalation, breath holding, and exhalation. UI: user interface.

In terms of visual presentation, the system uses interface elements such as a progress bar and a score panel to display children's breathing status and training progress in real time (Figure 3B). This provides intuitive feedback on training outcomes and enhances children's sense of accomplishment. When a child performs the breathing maneuver correctly, the system triggers a sequence of immediate positive feedback, including the duck's movement, a "successful dive" animation, and corresponding sound effects. This mechanism reinforces correct behaviors and helps sustain the training rhythm.

From the aesthetics dimension of the MDA framework, these audiovisual feedback cues cultivate an enjoyable interactive experience, thereby strengthening children's affective engagement and motivation to participate.

During software prototyping, multiple rounds of internal testing were conducted to verify animation smoothness and interaction accuracy under real-time breathing-data control. The system can dynamically tailor feedback content and visual effects according to children's breathing behaviors (Figure 3C), ensuring timely and clear feedback. In doing so, it supports training adherence while increasing the likelihood of sustained participation in breathing training.

Implementation of the Physical Interaction Layer

The hardware component primarily consists of an Arduino Uno microcontroller board and an airflow sensor. The Arduino Uno is based on the ATmega328P chip, offering 14 digital input and output pins (including 6 supporting pulse-width modulation output) and 6 analog inputs. It is also equipped with a USB interface and a power jack, facilitating convenient connection to computers and external power supplies [51]. The airflow sensor design is inspired by the water flow sensor, ingeniously adapting its working principle to measure airflow. Detailed parameters are provided in Table 1. Conventional airflow detection devices are typically expensive and possess specialized structural designs, limiting their wide application. By leveraging the principles of water flow sensors, airflow can be effectively detected, thereby providing technical support for interactions involving airflow or exhalation.

Table . Airflow sensor parameters.

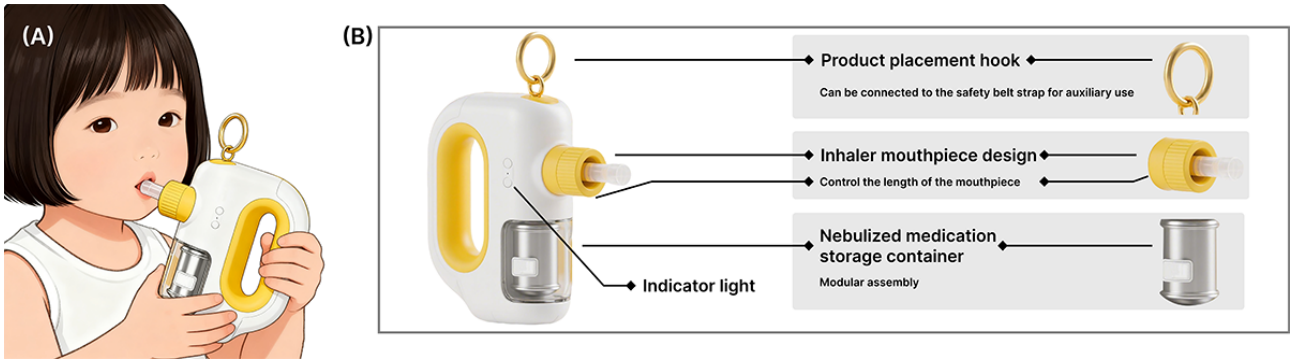
Parameters	Specifications
Module dimensions	Length 3 cm x width 2.1 cm
PCB[a] thickness	1.6 mm
Total module thickness	6 mm
Module weight	55 g (including breath sensor)
Supply voltage	DC[b] 3.3V/5V
Output signal	Serial port data output, raw pulse signal output, and TTL[c] level output

[a]PCB: printed circuit board.

[b]DC: direct current.

[c]TTL: transistor-transistor logic.

The sensor consists of a plastic valve body, a flow rotor assembly, and a Hall sensor. When airflow passes through the rotor, the rotational speed is proportional to the flow rate. The Hall sensor generates pulse signals, which are transmitted to the controller for computation, and the processed data are ultimately output via a serial port. In this system, the sensor is seamlessly integrated into the inhaler. Whenever the child inhales or exhales, the airflow passes through the airway, and the sensor continuously monitors the data in real time. The



XSL•FO
RenderX

Arduino controller processes this data to measure inhalation speed, breath-holding duration, and exhalation rhythm.

Appearance Design

The appearance design emphasizes child-friendliness and the minimization of a medical atmosphere. Both the inhaler shell and the sensor module adopt rounded shapes to ensure safety during use. The overall color scheme features bright yellow, complemented with cartoon duck elements, making the device resemble a toy rather than a medical instrument, thereby alleviating children's anxiety during use [31]. Furthermore, the sensor and inhaler body adopt a modular, detachable design, facilitating cleaning, maintenance, and replacement. All edges are rounded to avoid sharp corners, complying with child safety standards, as illustrated in Figure 4A and 4B. The main body of the inhaler measures approximately 12.6 cm (length) × 4.3 cm (width) × 15.2 cm (height).

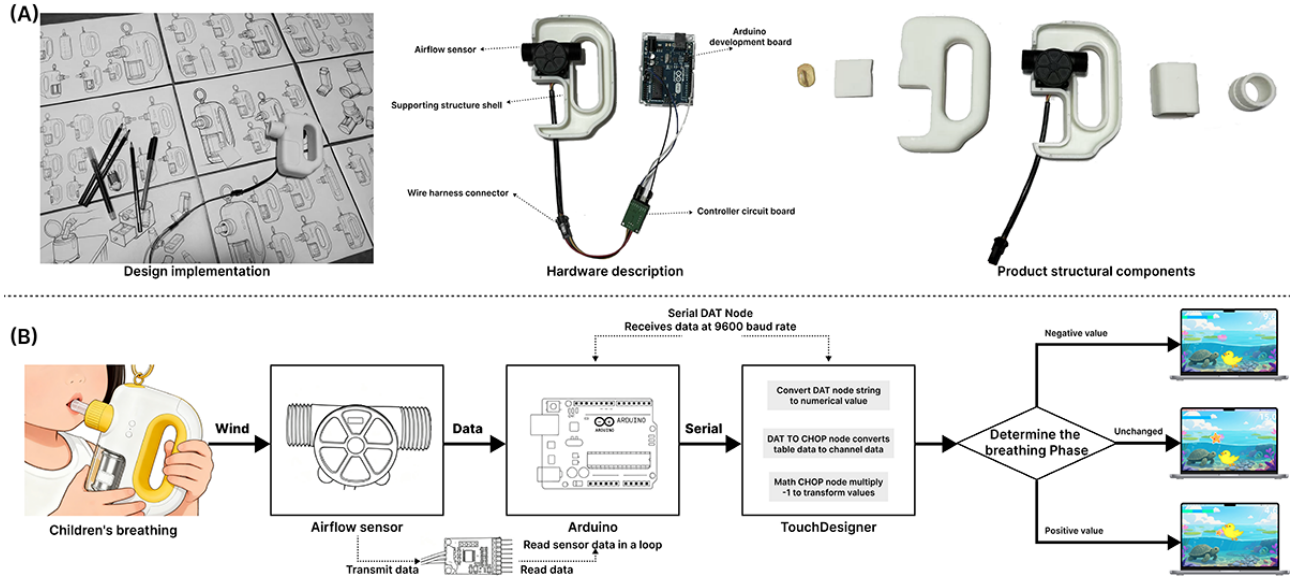


Figure 4. Inhaler design. (A) Rendering scene and (B) side view of the inhaler, illustrating the structure and function of its components.

Functional Implementation

The functional implementation encompasses both the deployment of the inhaler prototype and the flow of system data, as illustrated in Figure 5A and 5B. On the Arduino side, a program for serial communication and signal processing was developed to collect sensor data and transmit it to the software system. The program initializes the serial port using Serial.begin(9600) and then enters a loop to continuously read values from the airflow sensor. Within each loop iteration, the analog signal from the airflow sensor is read, and the sampled data, along with status information, is sent line by line via the USB serial interface using Serial.print(). In TouchDesigner, a Serial DAT node is configured at a baud rate of 9600 with a "one value per line" table format to receive this data. Through continuous sensor reading, the software layer captures children's respiratory information.

Figure 5. Functional configuration and implementation. (A) Inhaler device prototype: 3D printing, hardware specifications, and structural components, and (B) system functional data flow path.

In this system, airflow sensor output data are transmitted to TouchDesigner in string format by default. To facilitate subsequent mathematical operations and interaction design, the data are converted into numerical values.

To map inhalation values to negative numbers while maintaining exhalation as positive, mathematical operations are applied using a Channel Operator (CHOP). Since DAT stores tabular data, it is first transformed into CHOP format by creating a DAT to CHOP node (datTo1) from convert1 (Create → CHOP → DAT To). In the parameter panel of datTo1, the appropriate column is selected to convert the tabular data into channel data. Subsequently, a Math CHOP node (math1) is created (Create → CHOP → Math). In math1, the Operation is set to multiply with the value parameter as "−1," thereby inverting the original

XSL•FO
RenderX

positive values to negative during inhalation. This transformation ensures that inhalation is represented as negative, exhalation as positive, and breath-holding remains unchanged, which in turn drives the dynamic behavior of the virtual duck.

Research Hypothesis

To address RQ2 (Does the accuracy of children's inhalation, breath-holding, and exhalation rhythm improve, thereby enhancing therapeutic outcomes?) and RQ3 (Does children's treatment adherence improve?), this study was designed and implemented a quantitative controlled experiment, referencing the CONSORT (Consolidated Standards of Reporting Trials) reporting guidelines to ensure transparency and clarity in reporting (Checklists 1 and 2 [52]). The experiment compares the differences in respiratory behaviors, psychological experiences, and adherence between the BreatheBuddy system and the inhaler-only control group, to test the following research hypotheses:

- Hypothesis 1: compared with the control condition, children using BreatheBuddy will show significant improvements in inhalation rhythm accuracy, breath-hold duration, and exhalation control, indicating higher effectiveness-related indices of inhalation therapy.
- Hypothesis 2: compared with the control condition, BreatheBuddy will provide superior interactivity and enjoyment, thereby significantly increasing children's engagement and treatment adherence.
- Hypothesis 3: compared with the control condition, BreatheBuddy will better facilitate immersion and flow, reduce treatment-related anxiety, and improve attentional focus, thus alleviating discomfort during use.
- Hypothesis 4: compared with the control condition, BreatheBuddy will receive higher scores on user evaluation indicators, including usability, playability, and overall satisfaction.

Eligibility Criteria

Inclusion criteria were children aged 6-8 years with prior experience using inhaler-based therapy. Children in this age range typically have sufficient cognitive and expressive abilities to complete the experimental tasks [53], and prior inhaler experience helps minimize potential confounding effects due to unfamiliarity with device operation. Exclusion criteria covered two groups: (1) children with severe language or cognitive impairments who could not reliably follow the procedure or provide feedback; and (2) children who, within the past month, had respiratory infections, acute asthma exacerbations, or were unable to complete the tasks independently, as these factors could compromise the accuracy of respiratory-behavior measurements and overall data quality.

Patient and Public Involvement

A total of 20 children were recruited (10 boys and 10 girls), with a mean age of 6.9 (SD 0.79) years. All participants had prior experience with inhaler-based treatment. Sample size determination was guided by effect estimates from a pilot study. Given resource constraints and the practical challenges of recruiting pediatric participants, we adopted a small-sample controlled experimental design focused on children. Future studies may increase the sample size and conduct power analyses to improve statistical precision.

Sampling Procedures

Participants were recruited through local educational institutions and community organizations. Study information was disseminated via internal announcements. Parents or legal guardians voluntarily registered their children for participation after being fully informed about the study's purpose and procedures.

Trial Design

This study used a one-factor repeated-measures experimental design, with the independent variable being the type of intervention, which included 2 conditions assigned with a randomization ratio of 1:1 (ie, each participant received both intervention conditions, ensuring equal exposure to both conditions). This design aimed to minimize the confounding influence of individual differences on the experimental results, thereby enhancing statistical sensitivity and power.

Control Condition

Participants used an inhaler that matched the conventional clinical inhaler in hardware structure and operating logic for simulated training. No gamified or interactive feedback was provided; researchers offered operational guidance only when necessary. To improve children's acceptance, the inhaler's appearance was slightly "fun-optimized," without altering its core structure or operation.

Experimental Condition

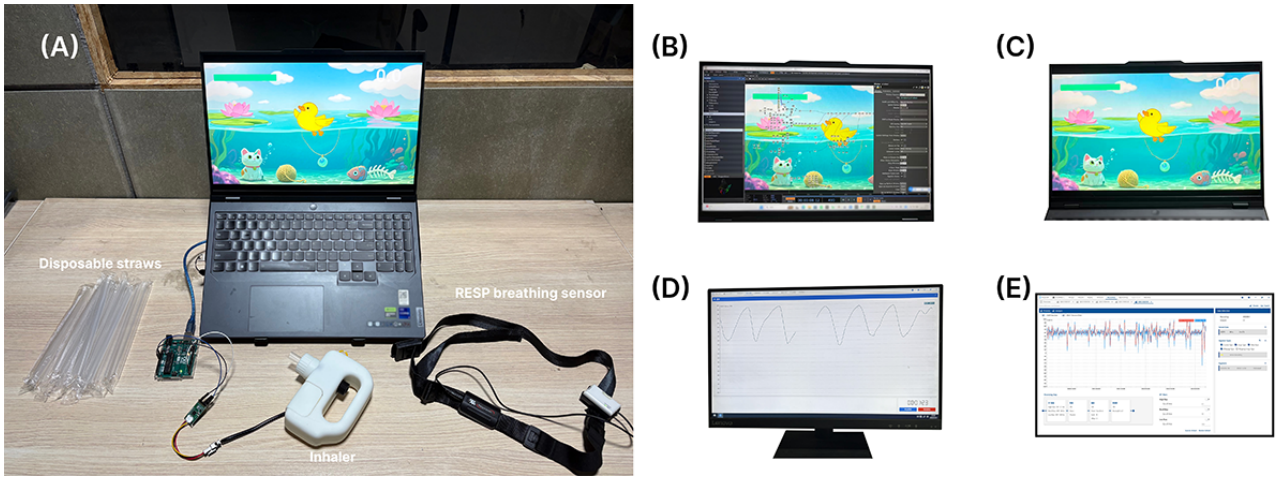
Participants used the same inhaler hardware as in the control condition, retaining all conventional structure and operating steps, but with an added gamified feedback mechanism (the BreatheBuddy training system). Children advanced the game by performing standardized inhalation actions, and the system provided real-time visual and interactive feedback to enhance engagement and adherence. All participants experienced both conditions in a randomized order to reduce the influence of individual differences, increase sensitivity to intervention effects, and improve statistical efficiency. No medication was administered; participants were informed that the tasks involved simulated training for inhaler use. Each intervention lasted 3 minutes. After each intervention, researchers assisted participants with questionnaires and conducted a brief interview.

Randomization

This study uses a sequential experimental design, where the order of intervention for each participant is determined by their sequence of arrival at the laboratory. Each participant completed all interventions for both the control group and experimental group in the assigned order. To avoid selection bias, the first 10 participants first underwent the experimental group intervention, followed by the control group intervention; whereas the latter 10 participants first underwent the control group intervention, followed by the experimental group intervention.

XSL•FO
RenderX

Blinding



Due to the significant differences in the interactive nature of the 2 intervention conditions (the experimental group includes gamified feedback, while the control group does not), blinding could not be applied to the participants or the experimental staff. However, blinding was implemented during the data collection and analysis phase. Researchers responsible for data entry and statistical analysis were unaware of the participants' intervention sequence and processed the data using anonymized codes to minimize measurement and analysis biases.

Instrumentation

Inhaler Device

The BreatheBuddy inhaler device was used. It integrates an airflow sensor to record respiratory data and transmits the data via Arduino to an interactive visual module. Disposable, eco-friendly straws were used as mouthpieces to prevent cross-contamination (Figure 6A).

Figure 6. Experimental setup and equipment. (A) Overall experimental materials: replaceable straws, BreatheBuddy system-specific inhaler equipped with airflow sensors, respiration (RESP) sensor for capturing respiratory signals; (B) interactive system configuration; (C) laptop computer loaded with experimental game software for presenting game content and facilitating interaction; (D) respiratory data acquisition device; and (E) RESP respiratory analysis module.

Data Acquisition Devices

A Lenovo Y9000P (2023) laptop displayed the experimental game content (Figure 6B and 6C). An iPhone was used to record semistructured interviews. A respiration sensor was used to collect real-time changes in respiratoryrhythm (Figure 6D and 6E).

Questionnaire Tools

Electronic questionnaires were created on Wenjuanxing and included the following standardized scales:

1. Player Experience of Need Satisfaction (PENS): the relatedness and belonging subscale was removed; autonomy, competence, immersion, and intuitive controls were retained (20 items), rated on a 7-point Likert scale.
2. Game User Experience Satisfaction Scale (GUESS): 7 dimensions (eg, creative freedom and enjoyment; 26 items), rated on a 7-point Likert scale.
3. System Usability Scale (SUS): 6 selected items, rated on a 5-point Likert scale.

Data Collection

The procedure consisted of four stages, lasting approximately 46 - 56 minutes in total:

1. Preparation (10 - 15 minutes): researchers explained the study purpose, procedures, and risks to participants and guardians, obtained written consent, helped participants adapt to the setting, prepared disposable straws, and installed them on the inhaler.
2. Task execution (16 minutes): participants completed training tasks under both conditions; each task lasted 3 minutes. A 10-minute recovery period was provided between the 2 interventions. Condition order was randomized to control for order effects.
3. Questionnaire and interview (15 - 20 minutes): after each intervention, researchers assisted participants in completing the electronic questionnaires and conducted semistructured interviews. Interviews focused on subjective experience and perceived mastery of breathing accuracy, while also collecting caregiver observations and expert feedback regarding clinical applicability.
4. Completion (5 minutes): researchers thanked participants and guardians and provided a small yellow duck–themed gift.

Quality of Measurements

Standardized data collection was implemented during questionnaire completion, during which researchers provided age-appropriate explanations and support to address limitations in children's literacy and expression, ensuring valid feedback data [54]. Scale quality assurance was ensured as PENS, GUESS, and SUS are well-established instruments in psychology and user-experience research with good reliability and validity, enabling robust assessment of children's intrinsic motivation, game experience, and system usability. Device calibration was conducted before the experiment, with all equipment rigorously calibrated and tested to ensure measurement accuracy and stable operation.

XSL•FO
RenderX

Data Diagnostics

Respiratory behavior data were denoised using Gaussian smoothing and downsampling to improve signal stability. Peaks and troughs were detected to determine the start and end of each breathing cycle. Each cycle was segmented into inhalation, exhalation, and breath-hold phases, and phase durations were computed. Breathing rate was calculated from the time differences between adjacent peaks, and breathing depth was estimated from peak amplitude differences. This study did not perform missing-data imputation or outlier removal.

Analytic Strategy

Quantitative analysis was conducted on respiratory behavior, and scale data were summarized using descriptive statistics. Paired-samples *t* tests were used to compare the 2 conditions; if normality assumptions were violated, the Mann-Whitney *U* test was used as a nonparametric alternative. Qualitative analysis was conducted as semistructured interviews were transcribed and analyzed using thematic analysis to extract key themes related to breathing accuracy, flow experience, and system usability, which were used to complement and help interpret the quantitative findings.

Qualitative Methods

Research Design Overview

The qualitative component of this study was embedded within a mixed method randomized crossover experimental design. Semistructured interviews were conducted to gain an in-depth understanding of children's subjective experiences under different intervention conditions, including their perceived mastery of breathing rhythm, emotional responses, sense of immersion, and evaluations of system usability.

Within the overall research framework, the qualitative inquiry served an explanatory function, complementing and interpreting the quantitative findings to enhance the comprehensiveness and interpretive depth of the study's conclusions.

Study Participants or Data Sources

Qualitative data were collected from all 20 child participants who completed the experimental tasks. Each participant took part in a semistructured interview after completing both intervention conditions. In addition, caregivers' observational feedback was documented during the interviews, and expert opinions regarding the system's clinical applicability were collected to supplement the children's self-reported data. All interviews were audio-recorded and transcribed verbatim after the experiment for subsequent analysis.

Participant Recruitment

The qualitative sample was identical to that of the quantitative experiment. All children who completed the full experimental procedure were invited to participate in the interviews, with no additional inclusion or exclusion criteria. Written informed consent was obtained from parents or legal guardians for the qualitative data collection procedures, and children provided verbal assent after receiving age-appropriate explanations from the researchers.

Data Collection

Semistructured interviews were conducted immediately after each intervention session, with each interview lasting approximately 10 - 15 minutes. Interviews were carried out in a quiet laboratory setting. The interview protocol focused on the following topics: perceived ease of system use, perceived ease of mastering breathing rhythm, levels of enjoyment or relaxation, willingness to continue using the system, and experiential differences between the 2 intervention conditions.

Interviews were conducted by researchers experienced in communicating with children. When necessary, a guardian was present to enhance the child's sense of comfort and security during expression. Data collection continued until thematic saturation was reached, defined as the point at which no new themes or concepts emerged in consecutive interviews.

Analysis

Following transcription, interview data were analyzed using thematic analysis. The analytic process involved familiarization with the data, initial open coding, clustering similar codes into candidate themes, reviewing and refining themes, defining and naming themes, and integrating themes into an interpretive narrative.

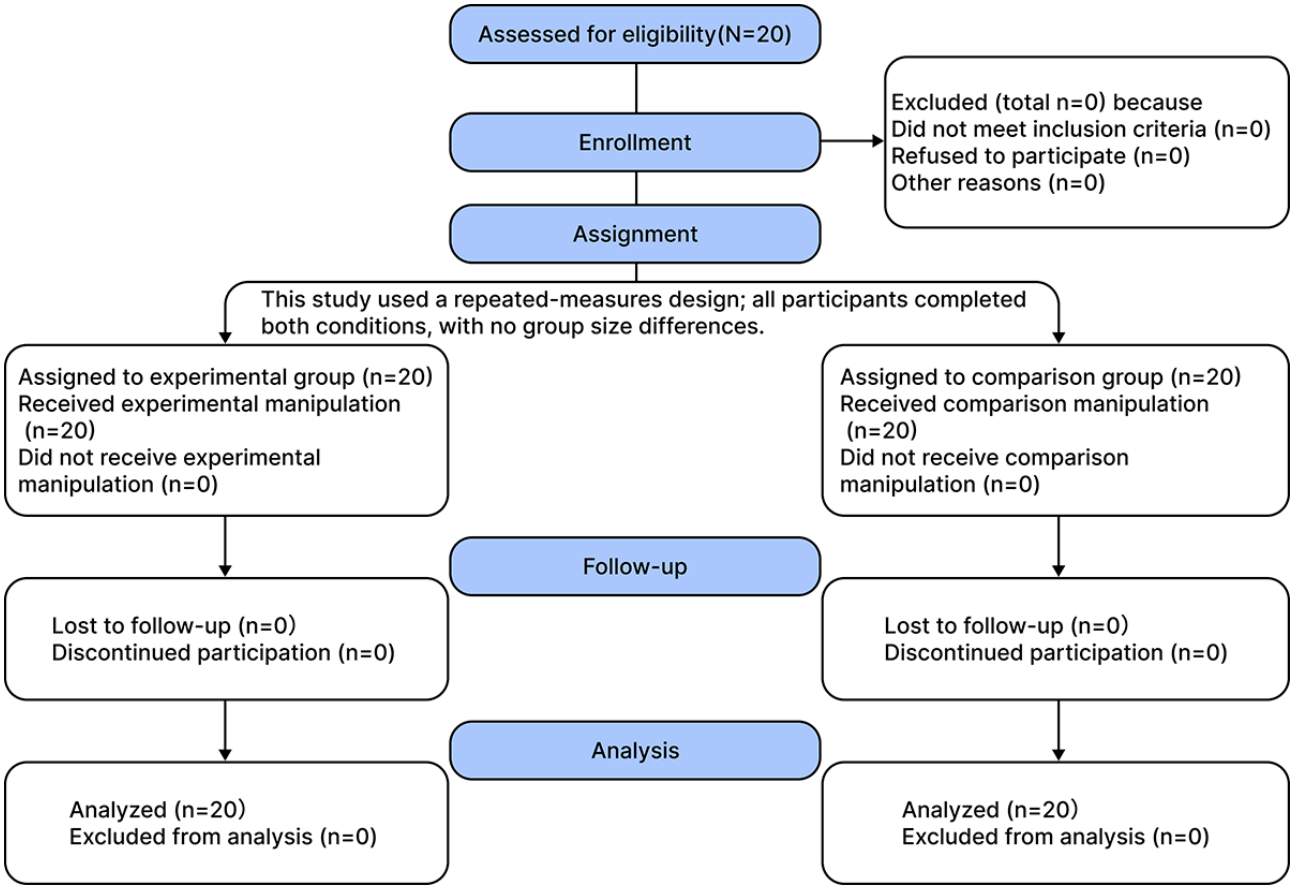
To enhance analytical rigor, 2 researchers independently coded the data and resolved discrepancies through discussion until consensus was achieved. The resulting codes and themes were used to complement the quantitative findings and to strengthen the explanatory depth of the mixed methods design.

Ethical Considerations

This study was reviewed and approved by the Ethics Committee of Hubei University of Technology (approval no HBUT20250043) and was conducted in accordance with established ethical guidelines for research involving human participants. Before the commencement of the study, written informed consent was obtained from the parents or legal guardians of all participating children. With parents present, researchers explained the experimental procedures to the children in an age-appropriate manner and obtained their verbal assent. Participation was entirely voluntary, and children were free to withdraw from the study at any time without any consequences. All participant data were anonymized and deidentified to prevent any linkage to personally identifiable information. Data were accessible only to the research team and were handled with strict confidentiality. All images included in this paper and its additional materials were carefully reviewed to ensure that no individual participant could be identified and that no personally identifiable information was disclosed. No monetary compensation was provided. Upon completion of the experiment, each child received a themed "Little Yellow Duck" card as a commemorative token. The experiment was conducted in the User Experience and Interaction Design Laboratory at Hubei University of Technology. The laboratory is equipped with a one-way mirror, allowing observation and supervision of procedural compliance and participant status to ensure the safety and integrity of the experimental process.

XSL•FO
RenderX

Results



Overview

To ensure comparability between the experimental and control groups on the same scale, we standardized the scores of the PENS, GUESS, and SUS to a range of 1 to 100 (standardized scores [SSs]). The Shapiro-Wilk test was performed to assess the normality of the data [55]. For data that did not follow a normal distribution, the Mann-Whitney *U* test was used to evaluate the differences between the 2 groups regarding breathing behavior and user experience [56]. For data that followed a normal distribution, paired *t* tests were conducted to compare the differences between the 2 groups.

This study involved 20 participants, a sample size chosen based on the design and effect size of previous similar studies. Although the sample size is relatively small, significant differences were observed between the experimental and control groups, which were consistently statistically significant across all indicators ($P<.05$). Furthermore, the 95% CIs for all results did not include 0, further confirming the reliability of the differences between the groups. These findings suggest that, despite the limited sample size, the results are statistically significant, supporting the effectiveness of the proposed system in improving inhaler accuracy and adherence.

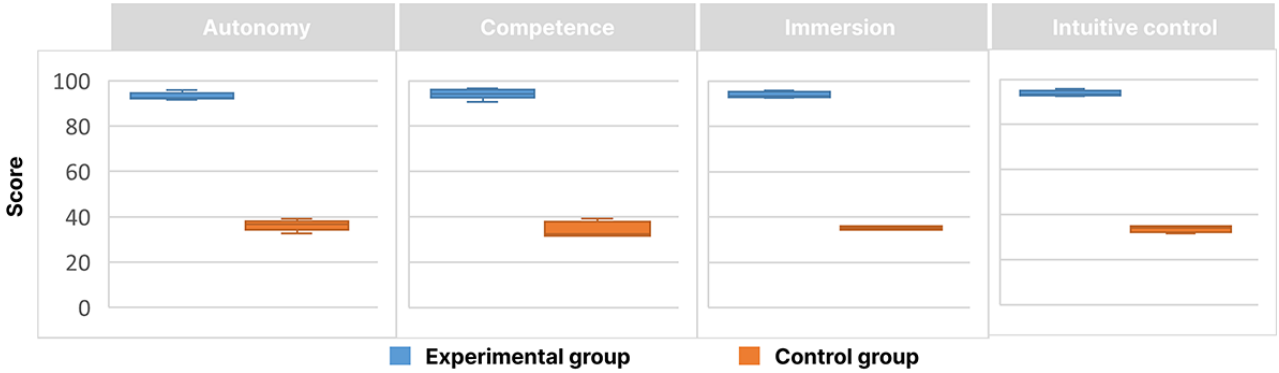
The progression of participants across each stage of the study is illustrated in the participant flowchart (Figure 7). All 20 participants completed both intervention conditions.

Figure 7. Participant flowchart for a repeated-measures controlled experiment comparing BreatheBuddy and standard inhaler training in children.

Accuracy of Respiratory Behavior

To facilitate comparison, we compared the longest breath-holding durations between the experimental group and the control group. The results showed that the data followed a normal distribution, with the experimental group's average longest breath-holding duration being 12.20 (SD 2.11 seconds; 95% CI 11.263-13.131 seconds), which was longer than the control group's 7.92 (SD 2.27 seconds; 95% CI 6.909-8.921 seconds), with a significant paired *t* test ($P<.001$). The control group, which used a traditional inhaler, demonstrated significantly shorter breath-holding durations. These findings suggest that after using the "BreatheBuddy" system, the experimental group was better able to maintain breath-holding time, showing both longer durations and more stable breathing rhythms.

Further time-domain analysis revealed that the data followed a normal distribution, with the experimental group's respiration data showing smaller variance and SD, which was statistically significant (paired *t* test; $P<.001$). This indicates that the experimental group exhibited more stable breathing rhythms. The smaller standard deviation and variance further support the advantages of the experimental group in terms of breath-holding duration and rhythm stability, demonstrating superior performance in breathing training. Additionally, the experimental group's average breathing frequency was 9.97 (SD 0.57 rpm; 95% CI 9.719-10.229 rpm), significantly lower than the control group's 10.47 (SD 0.82 rpm; 95% CI



XSL•FO
RenderX

10.110-10.837 rpm; paired *t* test; *P*=.03). The experimental group's minimum breathing frequency was 4.63 (SD 0.78 rpm; 95% CI 4.284-4.973 rpm), significantly lower than the control group's 6.02 (SD 1.15 rpm; 95% CI 5.508-6.525 rpm; paired *t* test; *P*<.001). These results indicate that the experimental group exhibited more stable and relaxed breathing patterns, further confirming its superiority in breath control and breath-holding stability.

User Motivation and Need Satisfaction

The PENS questionnaire data followed a normal distribution, and paired *t* tests were used to compare the scores between the 2 groups, revealing a significant difference (*P*<.001). After standardization, the experimental group (SS 93.833, 95% CI 92.819 - 94.847) scored significantly higher than the control group (SS 34.792, 95% CI 31.805 - 37.778). The results indicate that the experimental group participants scored significantly higher on the PENS questionnaire compared to the control group and outperformed the control group in the dimensions of autonomy, competence, immersion, and intuitive control, as shown in Figure 8.

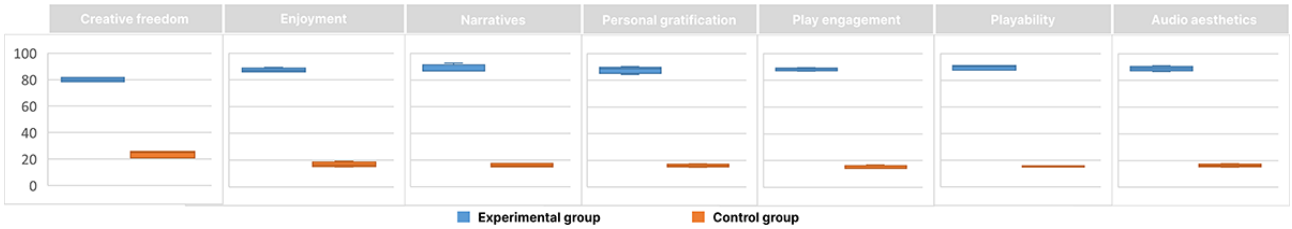


Figure 8. Evaluation and comparison of Player Experience of Need Satisfaction (PENS) for 2 groups across 4 dimensions.

User Experience Satisfaction

As the overall scores of the GUESS questionnaire did not follow a normal distribution, we used the Mann-Whitney *U* test to compare the median score differences between the experimental group (median 87.917, IQR 86.54-88.46) and the control group (median 15.833, IQR 15.38-19.23). The test results revealed a statistically significant difference between the 2 groups (*P*<.001). The results indicated that the experimental group scored significantly higher than the control group on the GUESS questionnaire and outperformed the control group across all 7 dimensions (refer to Figure 9).

Figure 9. Evaluation and comparison of Game User Experience Satisfaction Scale (GUESS) across 7 dimensions for 2 groups.

System Satisfaction

The SUS questionnaire results followed a normal distribution. An independent samples *t* test revealed a significant difference between the 2 groups (*P*<.001). The experimental group (SS 88.958, 95% CI 86.394-91.522) scored significantly higher than the control group (SS 20.833, 95% CI 18.844-22.823). These results indicate that participants in the experimental group reported substantially higher system satisfaction compared to those in the control group.

Interview Findings

During the analysis of interview data, the research team iteratively developed and refined a coding framework based on feedback from children, caregivers, and experts. Five core themes were ultimately identified: (1) intrinsic motivation and behavioral change, (2) flow experience and engagement, (3) game mechanics and playability, (4) feedback mechanisms and breathing accuracy, and (5) caregiver and expert perspectives. The detailed findings are presented in the following 5 subheadings.

Intrinsic Motivation and Behavioral Change

Most children reported that BreatheBuddy helped them understand the training goals, which became increasingly clear over time. Although the quantitative data did not reveal significant differences, this qualitative feedback remains noteworthy. Children found the system's instructions and tasks easy to follow, which facilitated mastery of the inhalation, breath-holding, and exhalation sequence. For example, one child stated, "I know what to do in each training session because the screen shows me." Another commented: "I like seeing the progress bar—I want to hold my breath longer so the little duck can dive deeper." Some children, however, felt that the tasks were insufficiently challenging. As one noted: "Some tasks are too easy and I finish them quickly—it doesn't feel difficult

XSL•FO
RenderX

enough." This suggests that adjusting task difficulty appropriately may enhance children's motivation.

Flow Experience and Engagement

The majority of children reported that they could maintain concentration during training, particularly when interacting with the "duck diving" animation and receiving real-time feedback, which enhanced their sense of immersion and control. One child remarked, "I like watching the duck dive; it feels like I'm diving too." Another explained: "When the system tells me I'm doing it right, I focus more." However, a few children noted that task repetition sometimes reduced their attention. One participant shared: "Doing it too many times gets boring—I want to level up." These findings suggest that balancing enjoyment with novelty is important to prevent monotony-induced disengagement.

Game Mechanics and Playability

The gamified design of the system, especially the "duck diving" interaction, was highly appealing to children. Most reported that the animations and auditory feedback enhanced both the enjoyment and attractiveness of the training. One child noted: "Every time I see the duck dive, I know I did it right." Another added: "I like watching the duck dive—it keeps me from getting distracted." The system's use of animation and diving tasks helped children sustain attention for extended periods, transforming breathing training from a monotonous activity into a playful and enjoyable experience.

Feedback Mechanisms and Breathing Accuracy

Most children believed the system's feedback mechanisms supported their gradual mastery of breathing accuracy, with the visual and auditory feedback in the "duck diving" task proving particularly effective. One child explained: "When I inhale, the duck dives under the water, and there's also a sound reward." Another said: "By watching what the duck does, I can adjust my breathing." This type of real-time feedback helped children correct errors and improve control over inhalation, breath-holding, and exhalation. Nevertheless, the depth of personalization in feedback requires further enhancement to better suit children at different skill levels. As one child suggested: "I hope the feedback could be more varied, based on my performance."

Caregiver and Expert Perspectives

Parents generally observed that their children showed high levels of interest and positive emotions while using the system and were able to complete the training as required. One parent shared: "My child was very engaged when using it—not anxious at all, and actually enjoyed the process." Another added: "I noticed he could follow the instructions more attentively, and his breathing became steadier than before." Experts highlighted the system's clinical potential for attracting children's attention, enhancing engagement, and improving breathing accuracy. One expert commented: "The gamified design is highly appealing to children and increases their willingness to cooperate with training." However, experts also recommended improvements, such as introducing a progressive difficulty system to accommodate varying ages and skill levels, thereby better supporting skill development.

Discussion

Principal Findings

This study focuses on the core research goal outlined in the introduction: to develop and assess an asthma inhaler training system, BreatheBuddy, which integrates gamified feedback to improve inhalation techniques and treatment adherence in children aged 6-8 years with asthma. The study also addresses 3 RQs (ie, RQ1-RQ3). Using a single-factor repeated-measures controlled experiment, the research systematically evaluates the practical effectiveness of this system in pediatric inhalation therapy. In line with the proposed research hypotheses 1-4, the main findings of this study are as follows: the BreatheBuddy system significantly improves inhalation rhythm accuracy, extends breath-holding duration, and stabilizes breathing patterns. It also enhances treatment adherence, engagement, and satisfaction while reducing anxiety related to the treatment process. Moreover, the system outperforms traditional inhaler training methods in terms of usability and playability. By embedding breathing behavior into the game interaction mechanism, BreatheBuddy achieves dynamic mapping of the breathing rhythm to real-time feedback, seamlessly integrating skill training, motivation enhancement, and emotional regulation. This addresses the key issues of RQ2 and RQ3 regarding improvements in inhalation accuracy and adherence. It also provides an empirically validated design paradigm for answering RQ1's question: "How can an interactive inhaler training tool with a gamification system be designed for children?"

Results Interpretation and Comparison With Literature

This study's primary findings focus on 3 key aspects: the standardization of respiratory behavior, the stimulation of intrinsic motivation, and the optimization of the gaming experience. These results not only align with existing research but also represent innovative breakthroughs in specific research contexts, further expanding the field of gamified health interventions and pediatric asthma treatment.

Regarding respiratory behavior accuracy and treatment effectiveness, this study demonstrates that BreatheBuddy effectively helps children develop a standardized and stable "inhalation-holding-exhalation" rhythm, particularly excelling in extending breath-holding duration and enhancing the stability of breathing patterns. Numerous studies have confirmed that breath-holding duration, inhalation depth, and respiratory rhythm stability are crucial factors influencing the efficiency of pulmonary drug deposition, directly determining the quality of treatment outcomes [57-59]. These findings are highly consistent with the results of this study, further confirming the potential of improving children's inhalation techniques through behavioral guidance. Unlike previous research that primarily relied on verbal guidance from health care professionals, passive demonstrations, or simple visual prompts for training [46-48], BreatheBuddy innovatively integrates respiratory behavior with visual and interactive gaming feedback. This allows children to immediately assess whether their actions meet treatment standards during the process, enabling them to correct their

XSL•FO
RenderX

actions without additional cognitive burden. This approach is in line with Zainal et al's [60] assertion that "immediate feedback is the core driver of health behavior change." However, this study goes beyond existing research by not only providing prompts for a single respiratory action but also integrating feedback mechanisms throughout the entire respiratory cycle, thus guiding inhalation, breath-holding, and exhalation. This comprehensive feedback system is a key factor in the significant success of this study in standardizing respiratory behavior. Moreover, traditional inhaler training often neglects the development of children's awareness of body rhythm and control over their movements, making it difficult to maintain training effectiveness [24,61]. In contrast, BreatheBuddy, through its design combining a physical inhaler with visual gaming feedback, provides children with clear rhythm cues and behavioral guidelines, significantly improving the consistency and stability of their breathing operations. This suggests that multimodal feedback may be more effective than single-modality interventions for helping children master complex therapeutic actions, offering a promising new approach for pediatric inhaler training.

In terms of intrinsic motivation and treatment adherence, this study found that BreatheBuddy effectively enhances children's intrinsic motivation and boosts their engagement in treatment. This aligns well with self-determination theory, which emphasizes that "autonomy, competence, and immediate feedback are the core elements of intrinsic motivation" [44,62]. Through features such as real-time animated feedback and progress visualization, the system enables children to clearly understand the link between their efforts and the results, helping them gradually develop a sense of control over their inhalation treatment, thus reducing resistance or negative emotions. Unlike some gamified health interventions that overly rely on external rewards, such as points or badges, to maintain participation [63], this study observed that BreatheBuddy fosters a shift from external rewards to intrinsic motivation. Children began to view "regulating their breathing to advance the game" as an inherently rewarding activity, rather than simply a burdensome treatment task. This finding supports Michaelsen and Esch's [64] conclusion that "short-term rewards can spark motivation, but long-term treatment adherence depends on cultivating intrinsic motivation." In contrast to traditional inhaler training, which lacks interactivity and contextual feedback, often leading to resistance and distraction in children [65], BreatheBuddy's gamified design effectively addresses these challenges, significantly increasing children's willingness to engage. This result is consistent with previous research on gamified interventions in pediatric health care [66] and contributes new empirical evidence in the specific context of inhaler training, offering fresh insights into improving adherence in pediatric chronic disease treatment.

This study demonstrates that BreatheBuddy outperforms traditional training methods in terms of immersion, playability, and overall user experience. These findings are consistent with the core principles of the MDA game design framework [45], which emphasizes the integration of entertainment and therapeutic effectiveness through optimization of the 3 key components: mechanics, dynamics, and aesthetics. Previous research has shown that immersive experiences can help users maintain focus during tasks, reduce discomfort sensitivity, and encourage sustained participation [67]. The results of this study further support this notion: BreatheBuddy, with its "Little Yellow Duck Diving" narrative, synchronized audiovisual feedback, and adaptive task difficulty, transforms the monotonous process of breathing exercises into an engaging game-like scenario with clear goals. This approach helps children maintain focus while reducing treatment-related anxiety. These results align with the findings of Lockwood et al [68], who concluded that "gamified interfaces can enhance emotional experiences and reduce anxiety in pediatric medical interventions." Furthermore, this study highlights that in medical training, a positive gaming experience not only provides emotional benefits but also helps standardize breathing behaviors by sustaining attention. However, some children reported in interviews that repeated tasks over time could diminish the sense of immersion, which reflects the well-documented issue of "diminishing novelty" in gamified interventions [69]. This feedback offers valuable insights for future system optimization.

Limitations

Although this study has validated the effectiveness of the BreatheBuddy system in enhancing children's inhalation skills, treatment adherence, and overall user experience, several limitations exist in the research design and implementation process that require further refinement in future studies. First, the sample size of this study is limited to 20 children, with a relatively narrow age range (6 - 8 years), all participants being recruited from local community health centers and kindergartens. This limited sample size reduces the representativeness of the study and may impact the generalizability of the results, making it difficult to extrapolate the findings to younger children (aged <6 years) or older children (aged >8 years). Furthermore, the study does not fully capture the experiences of children from different regions or socioeconomic backgrounds. Second, the study used a short-term intervention design without long-term follow-up, preventing the assessment of the system's sustained impact on children's inhalation techniques, treatment adherence, and overall effectiveness in daily use over time. The study also does not evaluate the system's impact on asthma clinical outcomes, such as the frequency of acute exacerbations or lung function improvements. Long-term adherence and clinical outcomes remain key objectives in pediatric asthma management [9]. Additionally, while the gamification mechanism effectively motivates children's engagement, it may inadvertently pose risks: certain children may become overly focused on achieving "excellent performance" in the game, such as holding their breath for excessive durations, thus compromising the comfort and safety of the breathing process. This is especially concerning for children with compromised lung function, as it could exacerbate respiratory strain. This potential risk was not specifically monitored in the current study and warrants further investigation in future research. Finally, while the gamification design was tailored to children's psychological traits, it did not sufficiently account for individual differences, such as variations in personality or cognitive abilities. This lack of personalized

XSL•FO
RenderX

adaptation may limit the system's effectiveness across diverse child populations.

Conclusion

This study empirically evaluated the effectiveness of the BreatheBuddy system in pediatric asthma inhalation therapy through a one-factor repeated-measures controlled experiment, successfully addressing the core RQs and achieving the research objectives. The primary innovation lies in the seamless integration of breathing rhythm with dynamic game interaction, facilitating the synergy of skill development, motivation enhancement, and emotional relief. This approach effectively addresses challenges related to improper inhalation techniques and poor adherence in children, offering an innovative behavior-guided paradigm for pediatric asthma inhalation training.

Academically, this study expands the scope of gamified health interventions in pediatric chronic disease management, providing new empirical evidence on the role of interactive design in promoting treatment adherence among children. Practically, the system is user-friendly, child-centered, and adaptable to both home and clinical environments, thereby improving long-term asthma treatment outcomes and self-management capabilities. The research findings also offer valuable insights for the treatment of other pediatric chronic conditions. Future efforts to expand the sample size, conduct long-term follow-ups, and optimize the system design will further enhance its clinical application value.

Acknowledgments

We extend our sincere gratitude to a faculty member from the Department of Structural Engineering for their helpful guidance on the structural validity of our work during the study. Additionally, we would like to acknowledge the participants who generously volunteered their time and effort, without whom this research would not have been possible. The authors declare the use of generative artificial intelligence (AI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to generative AI (GAI) tools under full human supervision: formulating research questions and hypotheses. The GAI tool used was ChatGPT-5. Responsibility for the final paper lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes. The declaration was submitted by the authors.

Funding

This research was funded by the Humanities and Social Science Fund of the Ministry of Education of China (grant no 24YJAZH070).

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

HZ contributed to writing the original draft, writing review and editing, conceptualization, data curation, formal analysis, investigation, methodology, project administration, resources, software, validation, and visualization. XL contributed to supervision and resources.

Conflicts of Interest

None declared.

Abstract

Background: Strabismus, commonly known as crossed eyes, is a condition characterized by the misalignment of the eyes, leading to impaired binocular vision and depth perception. Traditional management often involves occlusion therapy, which can be hindered by poor compliance. Video game therapy has emerged as a promising adjunct to traditional treatments, potentially improving compliance and directly stimulating visual and cognitive functions.

Objective: This study compares the effectiveness of traditional occlusion therapy with and without the addition of video game therapy in improving visual outcomes among children with strabismus.

Methods: This randomized, controlled clinical trial included 30 children aged 5 to 10 years diagnosed with various types of strabismus. Participants were randomly assigned to 2 groups: the control group (eye patching alone) and the treatment group (eye patching combined with video game therapy). The intervention lasted 3 months, with data collected at baseline and after the treatment. Primary outcomes included visual acuity, angle of deviation, and stereoacuity, while fixation stability was measured using the Tobii eye tracker. Data were analyzed using paired 2-tailed *t* tests, independent 2-tailed *t* tests, Mann-Whitney *U* tests, and multivariate analysis of variance, with a significance level set at $P<.05$.

Results: The treatment group showed significant improvements across all measured outcomes. Visual acuity improved significantly in both the amblyopic ($P<.001$) and fellow or nonamblyopic eyes ($P<.001$). The angle of deviation decreased ($P<.001$), and stereoacuity improved ($P<.001$). Fixation stability, as measured by the eye tracker, also showed significant improvement and was higher in the treatment group (mean 2.87, SD 0.56 seconds) compared with the control group (mean 1.88, SD 0.42 seconds; $P<.001$). The control group, which received only eye patching, also exhibited significant improvements, though to a lesser extent. Posttreatment visual acuity in the amblyopic eye was significantly better in the treatment group compared to the control group ($P<.001$), with similar results for the fellow or nonamblyopic eye ($P<.001$). Stereoacuity also showed superior improvement in the treatment group ($P=.01$). Fixation stability was significantly better in the treatment group ($P<.001$), and multivariate analysis of variance indicated a highly significant overall difference between the 2 groups across multiple outcomes ($P<.001$).

Conclusions: The combination of traditional eye patching with video game therapy significantly enhances treatment outcomes in children with strabismus, particularly in improving visual acuity, stereoacuity, and fixation stability. While both interventions effectively reduce the angle of deviation, video game therapy offers additional benefits by engaging in and improving the functional aspects of vision. These findings suggest that incorporating video game therapy into traditional treatment regimens could lead to more effective and engaging interventions for pediatric strabismus, potentially improving compliance and long-term outcomes. Future research should focus on understanding the underlying mechanisms and optimizing therapy for diverse patient populations.

Introduction

Background

Strabismus, commonly known as "a binocular ocular coordination disorder characterized by the misalignment of the eyes, where one or both eyes deviate from the intended point of fixation. This misalignment can interfere with binocular vision and depth perception but does not necessarily lead to vision loss unless complicated by additional conditions" [1]. It is a prevalent pediatric ocular disorder, affecting approximately 1.93% of children worldwide [2]. Early diagnosis and treatment are crucial to prevent the development of amblyopia, commonly referred to as lazy eye, a condition where prolonged misalignment leads to visual deprivation, and the brain begins to suppress the image from the misaligned eye [3,4].

Traditional management of strabismus typically involves the use of occlusion therapy, where an eye patch is placed over the stronger eye to encourage the weaker eye to work harder, thereby improving its visual function [5]. However, the success of occlusion therapy is often limited by poor compliance, especially among children who find the treatment uncomfortable or socially stigmatizing [6]. As a result, there has been growing interest in integrating more engaging, child-friendly interventions with traditional therapies. One such intervention is video game therapy, which holds the potential not only to enhance compliance but also to directly stimulate visual and cognitive functions through immersive, interactive gameplay [7].

This study aims to compare the effectiveness of traditional occlusion therapy with and without the addition of video game therapy in improving visual outcomes among children with strabismus. By using both therapeutic modalities, this research seeks to provide evidence for a more effective, engaging, and sustainable approach to treating strabismus.

Strabismus and Its Impact

Strabismus is a multifactorial condition characterized by the misalignment of the eyes, which prevents them from focusing on the same point simultaneously [8]. This misalignment can be constant or intermittent and may involve 1 or both eyes deviating inward (esotropia), outward (exotropia), upward (hypertropia), or downward (hypotropia) [9,10]. Amblyopia is defined as "a neurodevelopmental vision disorder characterized by a reduction of best-corrected visual acuity in one or both eyes, resulting from abnormal visual experience during the critical period of visual development. It arises due to disrupted binocular interaction (e.g., strabismus, anisometropia, or visual deprivation) and is not simply a suppression of visual input." Although strabismus and amblyopia can coexist, they are distinct conditions: strabismus reflects ocular misalignment, while amblyopia reflects impaired visual development [8].

The development of strabismus is influenced by a combination of genetic and environmental factors. Genetic predisposition plays a significant role, with studies indicating a higher prevalence among individuals with a family history of the condition [11]. Environmental factors, such as visual stress or neurological disorders, can also contribute to the onset of strabismus [12]. The condition poses significant challenges to the affected individuals, particularly children, as it can affect their social interactions, academic performance, and overall quality of life [13].

Traditional Treatments for Strabismus

The primary goals of strabismus treatment are to restore proper eye alignment, improve binocular vision, and prevent amblyopia. Traditional treatment modalities include corrective glasses, prism lenses, vision therapy, and, in some cases, surgical intervention [14]. Among these, occlusion therapy, or patching, remains a cornerstone of treatment, particularly for children with amblyopia [14]. Patching works by forcing the brain to use the weaker eye by occluding the stronger one, thus stimulating visual development in the affected eye [15].

Despite its effectiveness, occlusion therapy is often associated with challenges, particularly regarding compliance. Studies have shown that children frequently resist wearing eye patches due to discomfort or social embarrassment, leading to suboptimal outcomes [16]. Additionally, patching alone may not adequately address the underlying binocular dysfunction, highlighting the need for adjunctive therapies that can enhance the overall treatment effect [17].

The Emergence of Video Game Therapy

In recent years, video game therapy has emerged as a promising adjunct to traditional strabismus treatments. Video games designed for therapeutic purposes can be customized to engage specific visual and cognitive functions, such as eye-hand coordination, visual tracking, and depth perception [7]. These games are often interactive and visually stimulating, making them particularly appealing to children and potentially improving treatment adherence [7].

The effectiveness of video game therapy in improving visual outcomes has been demonstrated in several studies. For instance, Birch et al [18] conducted a study where children with amblyopia played a custom-designed video game during occlusion therapy, resulting in significant improvements in visual acuity and binocular function compared to traditional patching alone. Similarly, Vedamurthy et al [19] used a dichoptic video game to treat adult amblyopia, reporting improvements in visual acuity and contrast sensitivity. However, these studies did not incorporate eye tracking technology, leaving a gap in understanding the precise mechanisms through which video game therapy exerts its therapeutic effects.

The Role of Eye Tracking in Strabismus Treatment

Eye tracking technology has evolved significantly, offering precise and noninvasive methods to monitor and analyze eye movements. It involves measuring the position and movement of the eyes, often using advanced algorithms to track the gaze direction, saccades, and fixations. There are several prominent techniques used in eye tracking, including scleral search coil, infrared oculography, electrooculography, and video oculography [20]. Among these, video oculography, which uses video cameras to record eye movements and estimate gaze direction, is particularly common due to its noninvasive nature and ability to track eye movements accurately in real time [20].

XSL•FO
RenderX

Recent advancements, such as the integration of machine learning and Internet of Things, have further enhanced the capabilities of eye tracking systems, allowing for real-time data processing and the automation of gaze detection [20]. These technological improvements enable more sophisticated applications, including medical diagnosis and human-computer interaction [20]. By providing accurate gaze data, eye tracking facilitates a deeper understanding of visual attention and cognitive processes in various fields, from marketing to health care.

Eye tracking technology provides a noninvasive means of assessing visual function and ocular motility with high accuracy [21]. The Tobii eye tracker, in particular, allows for the detailed analysis of fixation stability, saccades, and smooth pursuit movements, which are critical in understanding how the eyes coordinate and maintain focus on a target [22]. This is particularly relevant for patients with strabismus, where poor fixation stability is common, leading to difficulties in maintaining binocular vision and increasing the risk of amblyopia [23].

In strabismus treatment, assessing fixation stability is crucial because it reflects the ability of the eyes to maintain a steady gaze on a single point [24]. By using eye trackers, clinicians can objectively measure improvements in eye stability following treatment, providing a clear metric for treatment success [25]. Moreover, the integration of eye tracking in therapy allows for real-time feedback during visual exercises, which can enhance the effectiveness of treatments like video game therapy by ensuring that the exercises target specific deficiencies in eye movement and coordination [25].

The Integration of Eye Tracking and Video Game Therapy

The combination of video game therapy with eye tracking technology represents a significant advancement in the treatment of strabismus. While video games alone have been shown to improve visual outcomes, integrating eye tracking provides a deeper understanding of how these improvements occur. Eye tracking allows for the monitoring of fixation stability and eye movement patterns during gameplay, offering real-time feedback that can be used to tailor the therapeutic experience to the specific needs of the patient [26].

Furthermore, eye tracking can help identify which aspects of the game are most effective in improving visual function, enabling the development of more targeted and efficient therapies. By capturing detailed eye movement data, researchers and clinicians can better understand the relationship between gameplay, eye movement control, and overall visual improvement.

This study aims to build on previous research by combining video game therapy with eye tracking to enhance the treatment of strabismus. By doing so, it seeks to provide a more comprehensive treatment approach that not only improves visual acuity and binocular vision but also enhances eye movement control, leading to more robust and sustained treatment outcomes.

Methods

Ethical Considerations

Ethics approval for the study was obtained from the institutional review board of Yarmouk University (reference IRB/2024/371), and informed consent was obtained from the parents or guardians of all participants. The study data were fully deidentified and anonymized prior to analysis, ensuring the privacy and confidentiality of all participants. The study was elective, and no monetary or material compensation was provided to participants for their involvement in the study.

Study Design

Demographic information, including age and sex, type and laterality of strabismus, and history of eye patching treatment, was collected using a structured patient-facing questionnaire completed by the child's parent or guardian. The questionnaire (Multimedia Appendix 1) was designed in the Arabic language and included closed-ended questions to ensure consistency of responses. Participation was voluntary, and all data were collected anonymously (Multimedia Appendix 2). All information collected was used for research purposes only and treated with strict confidentiality. The identity of the child or any personal data was not disclosed at any stage of the study.

This study is a randomized, controlled clinical trial designed to compare the effectiveness of 2 treatment modalities for strabismus in children: eye patching combined with video game therapy versus eye patching alone. The study was conducted over a period of 3 months and included children aged 5 to 10 years who were diagnosed with various types of strabismus, including esotropia, exotropia, and hypertropia. Data were collected at 2 time points: before the initiation of treatment (baseline) and after the completion of the 3-month treatment period. To assess the impact of the interventions, the Tobii eye tracker was used to measure fixation stability, providing precise and objective data on the consistency and duration of gaze fixation at both the baseline and final assessment.

Participants

The target population for this study was children aged 5 to 10 years diagnosed with strabismus. Participants were recruited from the outpatient ophthalmology clinic at Al-Basheer Hospital, Amman, Jordan, between January and August 2024. Inclusion criteria were as follows: age between 5 and 10 years, diagnosis of strabismus confirmed by an ophthalmologist, no prior history of surgical intervention for strabismus, and willingness to adhere to the treatment regimen and attend follow-up visits. Exclusion criteria included the presence of any neurological or systemic conditions that could affect vision, previous treatment with occlusion therapy for more than 3 months, and any contraindication to the use of eye patches or video game therapy.

Although participants with more than 3 months of previous occlusion therapy were excluded, 10 children had a history of short-term treatment prior to enrollment. These treatments included brief periods of patching and/or optical correction with glasses. Detailed data on the duration and adherence of these prior treatments were not consistently available.

XSL•FO
RenderX

A total of 30 participants were enrolled in the study, with 15 children randomly assigned to the control group (eye patching alone) and 15 to the treatment group (eye patching combined with video game therapy). Randomization was performed using a computer-generated random sequence.

Tobii Eye Tracker

The Tobii eye tracker (Tobii Pro X3-120) was securely mounted on a dedicated stand positioned directly in front of the participant, approximately 60 cm from the child's eyes, at eye level. This setup ensured consistent and accurate tracking of the participant's eye movements. Each child participates in the calibration process that is provided on the screen to ensure that the system accurately tracks their gaze across different areas of the screen. The eye tracker continuously monitors whether the child is looking at the screen or not by capturing real-time data on the duration and consistency of the gaze fixation. The eye tracker during sessions logs the track gaze position and detects fixations and timestamps to measure engagement, while excluding periods where gaze deviates from the screen for extended durations. The data collected by the eye tracker were automatically recorded and analyzed using the Tobii Pro Lab software, providing detailed insights into the child's fixation stability over time.

Intervention

The intervention group received a combination of eye patching and video game therapy. Participants in this group were instructed to wear an eye patch over the nonamblyopic eye for a total of 2 hours per day, during which they played a specifically designed video game aimed at improving visual acuity and binocular vision. The video game sessions lasted 30 minutes each day, 5 days a week, for a total of 3 months. The video game used in this study was developed to encourage visual tracking, eye-hand coordination, and depth perception, with levels of difficulty progressively increasing over time to match the child's improving visual capabilities.

The control group received standard occlusion therapy, in which the nonamblyopic eye was patched for 2 hours per day without any additional visual exercises or video game therapy. Parents of children in both groups were provided with detailed instructions on the proper use of the eye patch and were asked to maintain a daily log to record the duration of patching. As part of the routine clinical instructions, the attending ophthalmologist advised the children to engage in near-vision activities such as reading, writing, or drawing during the patching period as a form of passive visual therapy. However, adherence to these suggested activities could not be reliably confirmed, as children may not consistently perform them at home. In contrast, the video game–based therapy provided a structured and motivating experience that encouraged regular visual engagement and compliance with the therapy regimen.

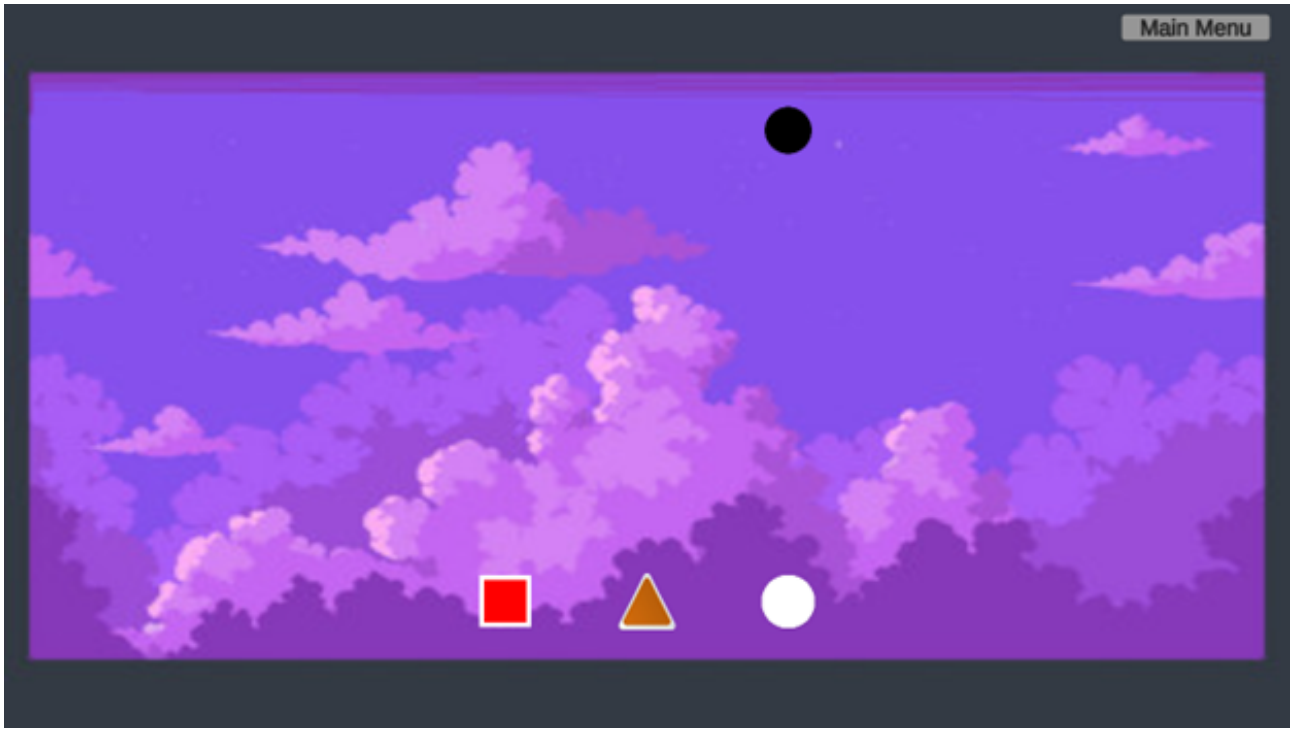
All participants who required refractive correction wore their prescribed glasses during both the ophthalmologic examinations and the video game therapy sessions to ensure optimal visual performance and standardization of testing conditions.

Clinical Evaluation

Ocular motility was assessed by a pediatric ophthalmologist through a standard 9-gaze examination. Motility was considered normal when full, symmetric ocular movements were observed in all gaze positions without limitation or overaction. It was classified as abnormal if any limitation, restriction, or overaction of extraocular muscles was noted in 1 or more directions of gaze.

Game Development

Game 1: Object Manipulation Based on Strabismus Type

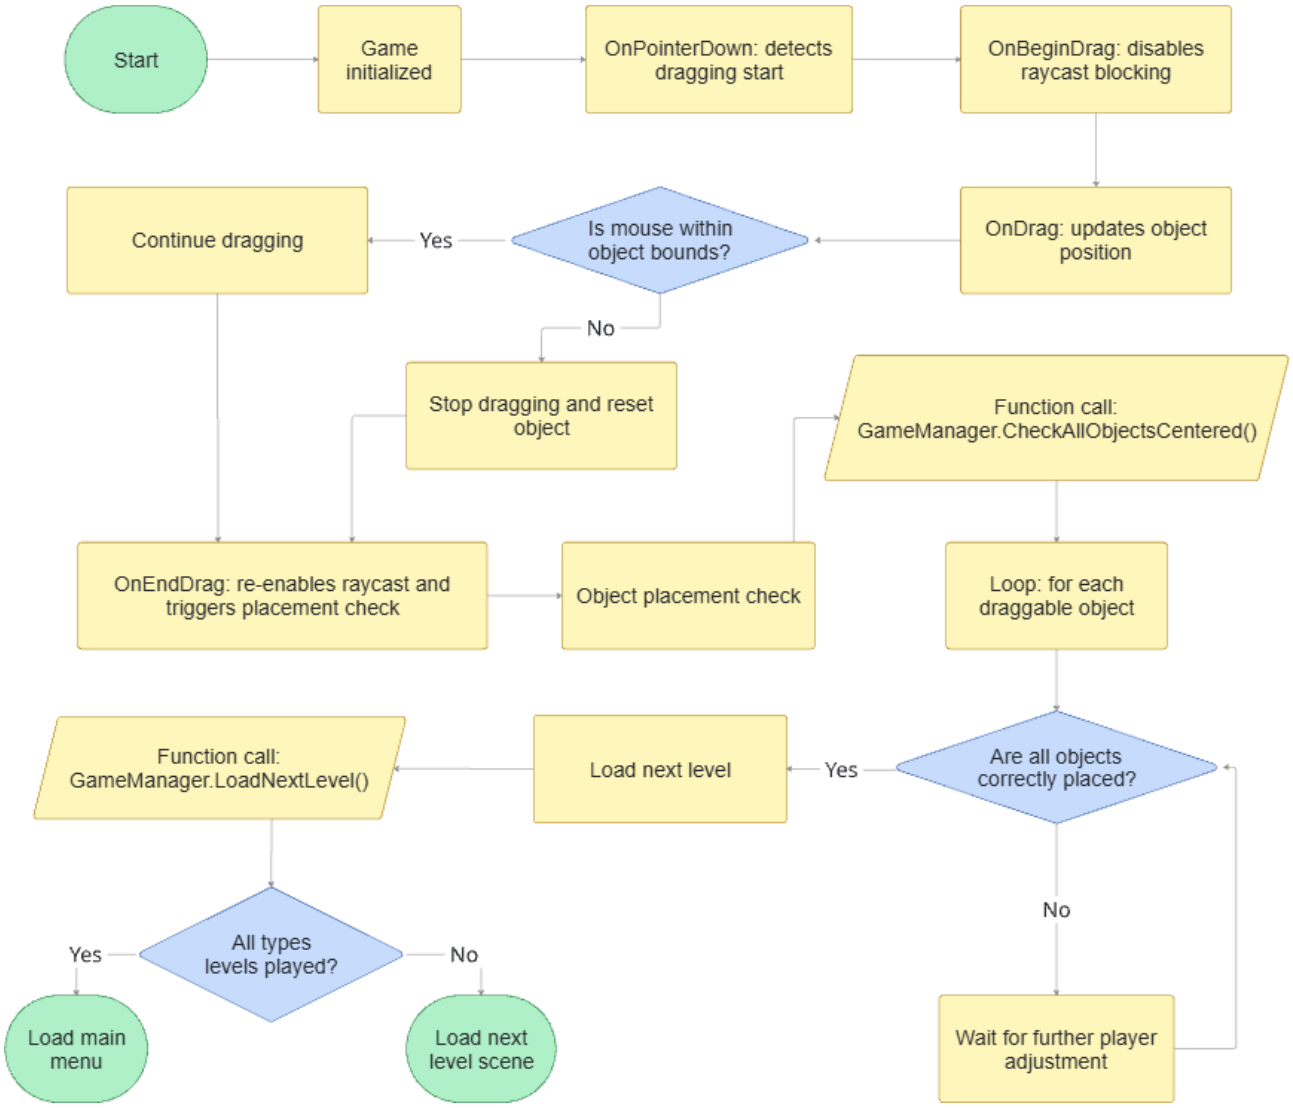


The first game developed for this study involves manipulating objects based on the specific type of strabismus diagnosed by the physician. Before the game begins, the physician selects the type of strabismus, esotropia, exotropia, hypertropia, or hypotropia, based on the child's condition, after which the Tobii eye tracker is activated to monitor eye movements during the gameplay as shown in Figure 1. In this game, the child is presented with a series of objects that they must hold and move to a target location. The game progresses through 3 levels, with each level increasing the number of objects to be manipulated, thereby enhancing the child's ability to control their eye movements and improve visual acuity and coordination. For esotropia, the objects initially appear on the outer edges of the screen and must be moved toward the center, mimicking the inward eye deviation. In the case of exotropia, the objects start in the center and are moved outward toward the edges, reflecting the outward eye deviation. For hypertropia, objects must be moved from a lower position to a higher target, representing the upward deviation of 1 eye, while for hypotropia, the objects are moved from a higher position to a lower target, simulating the downward eye deviation. The progression of the game, with increasing levels of difficulty, helps the children engage both eyes in tasks that challenge their binocular vision, hand-eye coordination, and depth perception. Figure 2 represents a visual of the game's background, with objects like squares, triangles, and circles. These objects serve as targets for the children to move and track according to their strabismus-related movement, reinforcing the connection between gameplay and visual improvement.

XSL•FO
RenderX

Figure 1. Object manipulation game's user interface: the interface allows the physician to select the type of strabismus, esotropia, exotropia, hypertropia, or hypotropia, based on the child's condition. Accordingly, the game's objects will appear and move in different ways related to their strabismus type.

Figure 2. Visual of the object manipulation game's background: this figure depicts the game's background environment with objects like squares, triangles, and circles. These objects serve as targets for the children to move and track according to their strabismus-related movement, reinforcing the connection between gameplay and visual improvement.



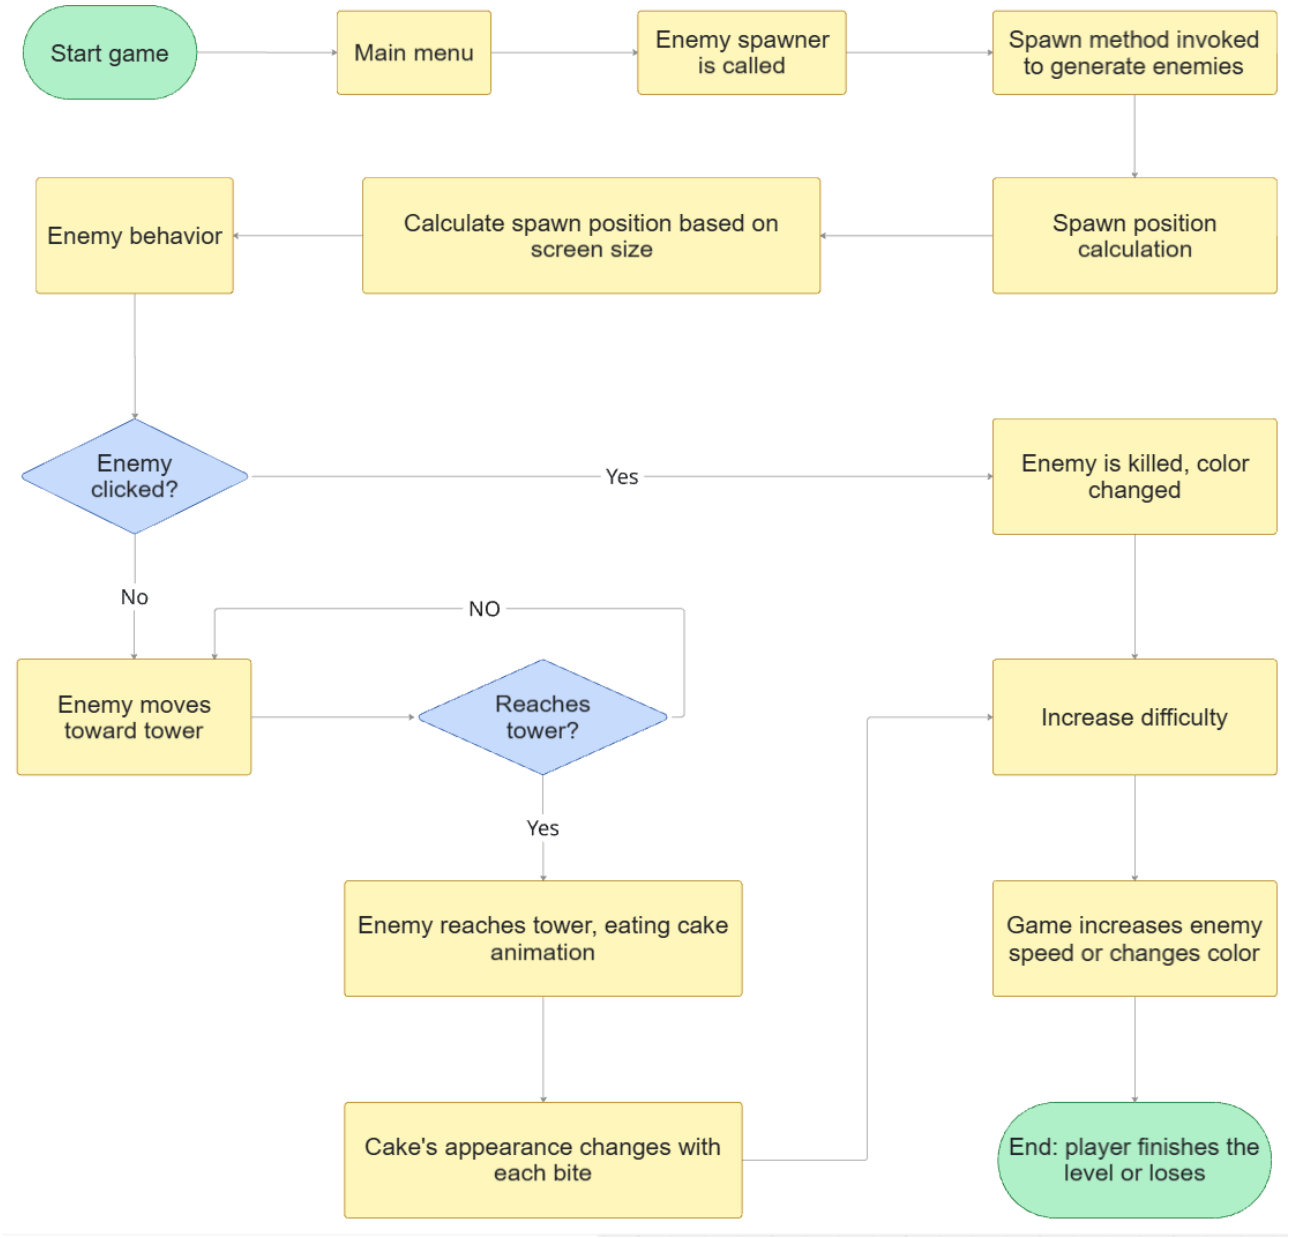
This game is a Unity-based interactive game developed in C# and features 3 levels for each of 4 types of eye movements: horizontal (exotropia and esotropia) and vertical (hypertropia and hypotropia). Dragging and dropping mechanics are implemented using Unity's event interfaces (IPointerDownHandler, IBeginDragHandler, IDragHandler, and IEndDragHandler), enabling precise control over object movement. The DragDrop script restricts object movement along predefined paths, either horizontally or vertically, based on the scene configuration. The GameManager script monitors the alignment of objects with their designated slots using vector calculations (RectTransform anchored positions) and automatically loads the next level when all objects are correctly placed. Scene transitions are handled dynamically by checking

XSL•FO
RenderX

scene names and indices to determine when to end the game and return to the main menu. This structured approach allows for controlled tracking of eye movements and data collection, providing valuable insights for medical research. The workflow is shown in Figure 3. The workflow begins with game initialization and proceeds through the drag-and-drop mechanics, including event handling for dragging, object position updates, and placement checks. Upon successful object alignment, the game advances to the next level or returns to the main menu once all levels are completed.

Figure 3. Object manipulation game's flowchart: the flowchart presents the game's step-by-step process, begins with game initialization and proceeds through drag-and-drop mechanics, including event handling for dragging, object position updates, and placement checks. Upon successful object alignment, the game advances to the next level or returns to the main menu once all levels are completed.

Game 2: Bug Tracking Based on Strabismus Type



As the first game in this Unity-based project, the experience begins with a transition to the main menu after the player selects "Start Game." From there, the player navigates to the "Select Level" option, where they choose the type of challenge, such as hypertropia. Upon selecting a challenge, the enemy spawner is activated, and its spawn method is invoked to generate enemies. The next step involves calculating the enemies' spawn positions relative to the player's screen size through the "Spawn Position Around Camera" function.

The core of enemy interaction revolves around player actions. If an enemy is clicked, it is killed, and its color changes to indicate its defeat. If the enemy is not clicked, it proceeds to move toward the tower. Upon reaching the tower, an "Eating Cake" animation is triggered, and the cake's appearance visibly changes as it is consumed.

Throughout the gameplay, difficulty is dynamically increased by periodically accelerating enemy speed or altering their color. The game concludes when the player either successfully completes the level or loses the challenge. This process is shown in Figure 4.

XSL•FO
RenderX

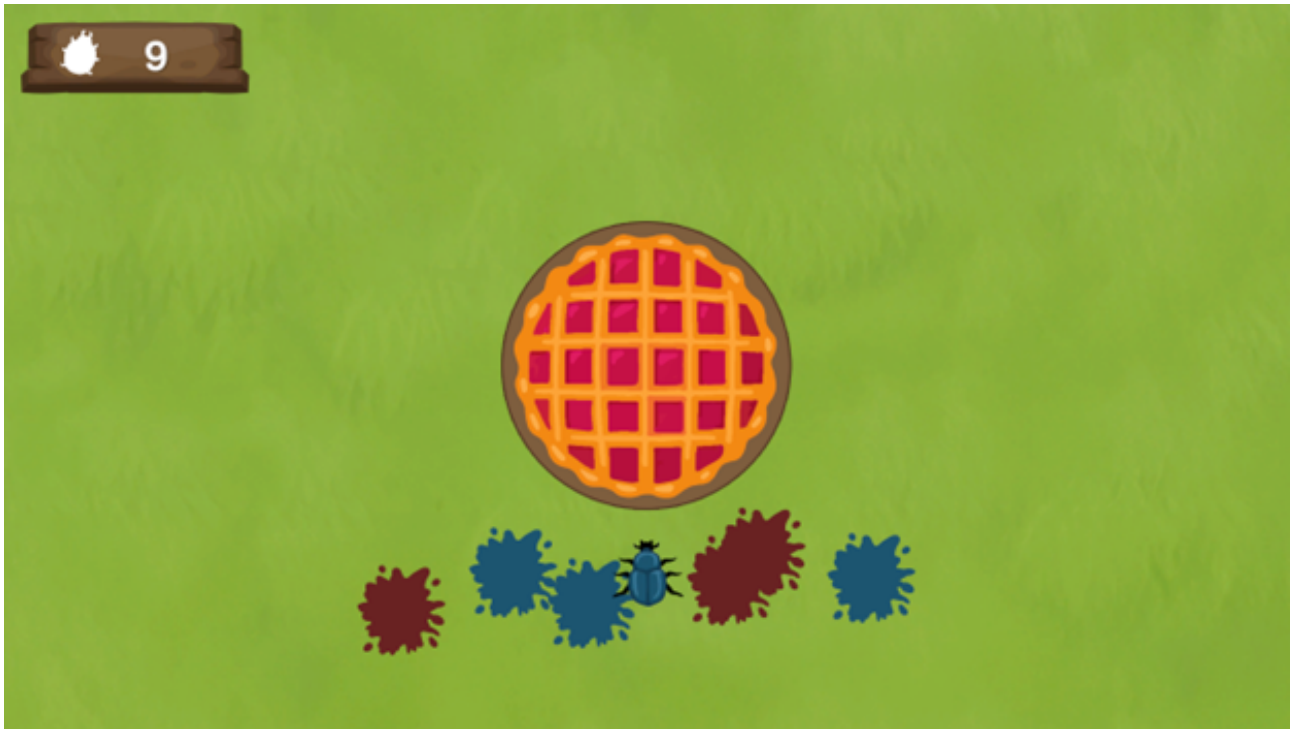


Figure 4. Bug tracking game's flowchart: the flowchart presents the game's step-by-step process, begins with a transition to the main menu, selecting the game's level to choose the type of challenge, activating the enemy spawner, and generating enemies with an aim of killing them to reach the tower and eating cake. The game ends when the player either successfully completes the level or loses the challenge.

The second game, shown in Figure 5, involves a bug that the child must track and move in a manner dependent on the type of strabismus they have. As in the first game, the physician selects the appropriate type of strabismus using the initial menu, and once selected, the Tobii eye tracker monitors how well the child can follow the bug's movement on the screen. The bug moves in specific directions based on the type of strabismus: for esotropia, the bug moves inward from the periphery of the screen toward the center, mimicking the inward deviation of the eye; for exotropia, the bug starts in the center and moves outward toward the edges, representing the outward deviation; for hypertropia, the bug moves upward, simulating the upward eye deviation; and for hypotropia, the bug moves downward, corresponding to the downward deviation of the eye. By engaging in this activity, the child strengthens their eye tracking ability and visual fixation, both of which are crucial for effective strabismus treatment.

XSL•FO
RenderX

Figure 5. Visual of the bug tracking game's background: this figure depicts the game's background environment with objects like bugs and enemies. The bug moves in a direction depending on the strabismus type to kill enemies and eat the cake object.

Outcomes and Measurements

The primary outcomes of the study were the improvement in visual acuity, reduction in the angle of deviation, and improvement in stereoacuity. Secondary outcomes included ocular motility and fixation stability as measured by an eye tracker.

Visual Acuity

Visual acuity was measured for both the amblyopic and fellow or nonamblyopic eyes using a standardized Snellen chart. The results were recorded in logarithm of the minimum angle of resolution (logMAR) units to provide a more precise quantification of visual improvement.

Angle of Deviation

The angle of deviation was measured in prism diopters using the alternate cover test with prism neutralization. Measurements were taken at both near (33 cm) and distance (6 m) fixation to assess the alignment of the eyes.

Stereoacuity

Stereoacuity was assessed using the Titmus fly test, which measures the finest level of binocular vision that can be detected by the patient. Results were recorded in seconds of arc.

Ocular Motility

Ocular motility was evaluated by an ophthalmologist using a standard 9-gaze test to determine the presence of any abnormal eye movements or restrictions in the range of motion.

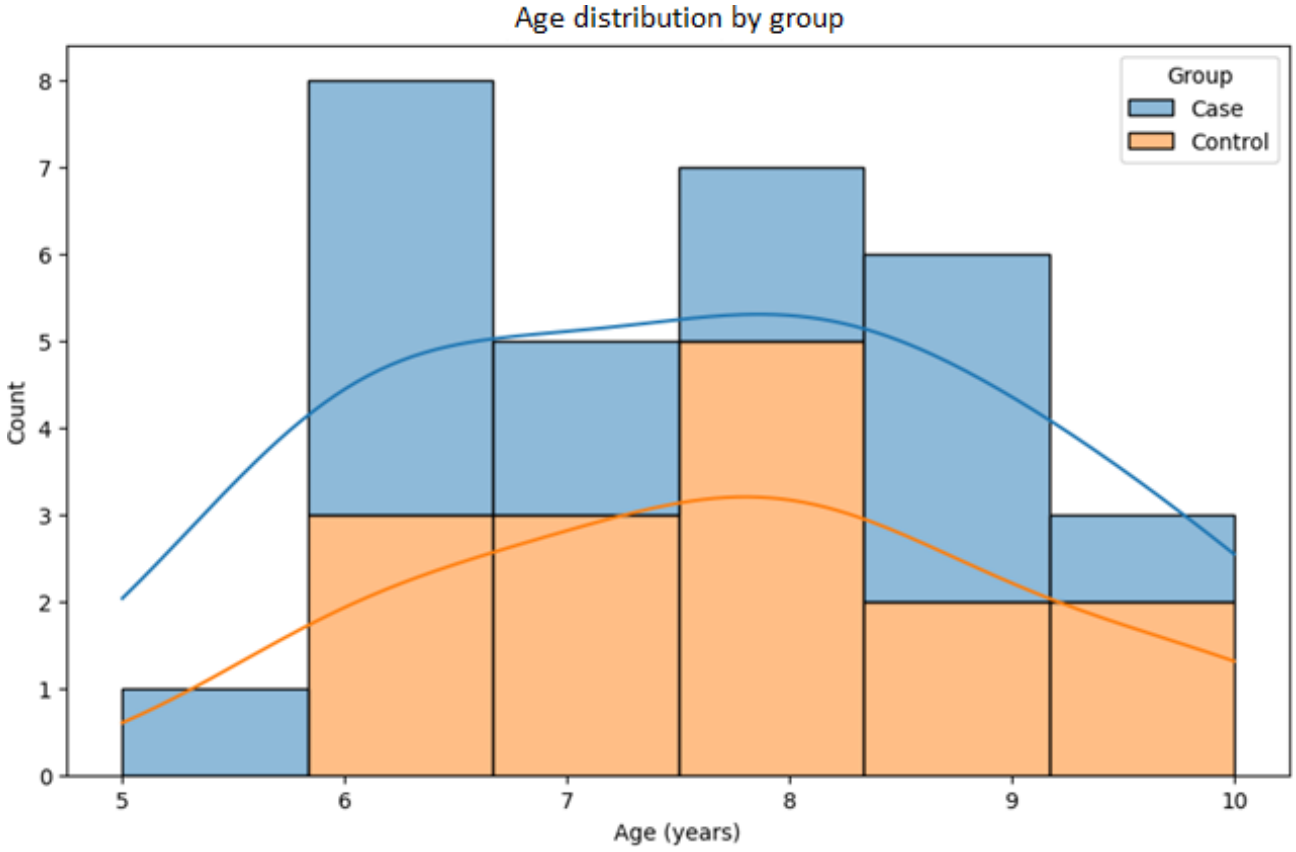
Fixation Stability

Fixation stability was measured using a Tobii eye tracker (Tobii Pro X3-120). The eye tracker was securely mounted on a dedicated stand positioned directly in front of the participant, approximately 60 cm from the child's eyes, at eye level. This setup ensured consistent and accurate tracking of the participant's eye movements. During the assessment, the child was asked to focus on a central target displayed on a computer screen for a period of 30 seconds. The eye tracker captured real-time data on the duration and consistency of the gaze fixation, with the results expressed in seconds. The data collected by the eye tracker were automatically recorded and analyzed using Tobii Pro Lab software, providing detailed insights into the child's fixation stability over time.

All outcomes were measured at baseline (day 0) and at the end of the treatment period (day 90). To ensure consistency, the same examiner conducted all assessments at each time point.

Statistical Analysis

Data were analyzed using the Python programming language on Google Colab. Descriptive statistics were used to summarize the baseline characteristics of the study population, including age, sex, duration of strabismus (which refers to the time since the condition was formally diagnosed), and family history. Continuous variables were expressed as mean and SD, and categorical variables were expressed as frequencies and percentages. The primary analysis compared the change in visual acuity, angle of deviation, stereoacuity, and fixation stability between the 2 groups from baseline to the 3-month follow-up. Paired 2-tailed *t* tests were used to assess within-group changes, and independent 2-tailed *t* tests were used to compare between-group differences. For nonnormally distributed data, the Wilcoxon signed rank test and the Mann-Whitney *U* test were applied. A multivariate analysis of variance was also conducted to assess the overall effect of the treatment across multiple dependent variables simultaneously. The significance level was set at $P<.05$.



XSL•FO
RenderX

Results

Baseline Characteristics

The study population consisted of 30 children aged 5 to 10 years (mean 7.6, SD 1.43 years) as shown in Figure 6. The mean duration of strabismus among participants was 29.23 (SD 16.62) months, with a range spanning from 2 to 57 months. Sex distribution was slightly skewed toward female participants, who represented 56.7% (17/30) of the cohort, while male participants accounted for 43.3% (13/30). Notably, none of the participants reported a family history of strabismus. Prior to the study, 33.3% (10/30) of the participants had received some form of treatment for strabismus, while the remaining 66.7% (20/30) had not.

Figure 6. Age distribution of participants in the study by group: this figure displays the age distribution across case and control groups, providing context for the demographic composition of the study.

Comparison of the Case and Control Groups

To ensure that the groups are comparable at the baseline, Table 1 summarizes the demographics and clinical characteristics.

Table . Baseline demographics and clinical characteristics of control and case groups.

Variable	Control group (n=15/30)	Case group (n=15/30)	*P* value[a]	Effect size (Cohen *d*)
Age (years), mean (SD)	6.07 (1.83)	5.47 (1.77)	.36	0.34 (small)
Sex, n (%)			.46	—[b]
Male	6 (20)	8 (26.6)		
Female	9 (30)	7 (23.3)		

[a]*P* values were calculated using an independent samples 2-tailed *t* test for continuous variables and a chi-square test for categorical variables.

[b]Not available.

As shown in Table 1, there is no significant difference between the 2 groups in the baseline characteristics (*P*>.35), which means both groups are well-balanced and supports the validity of treatment comparisons.

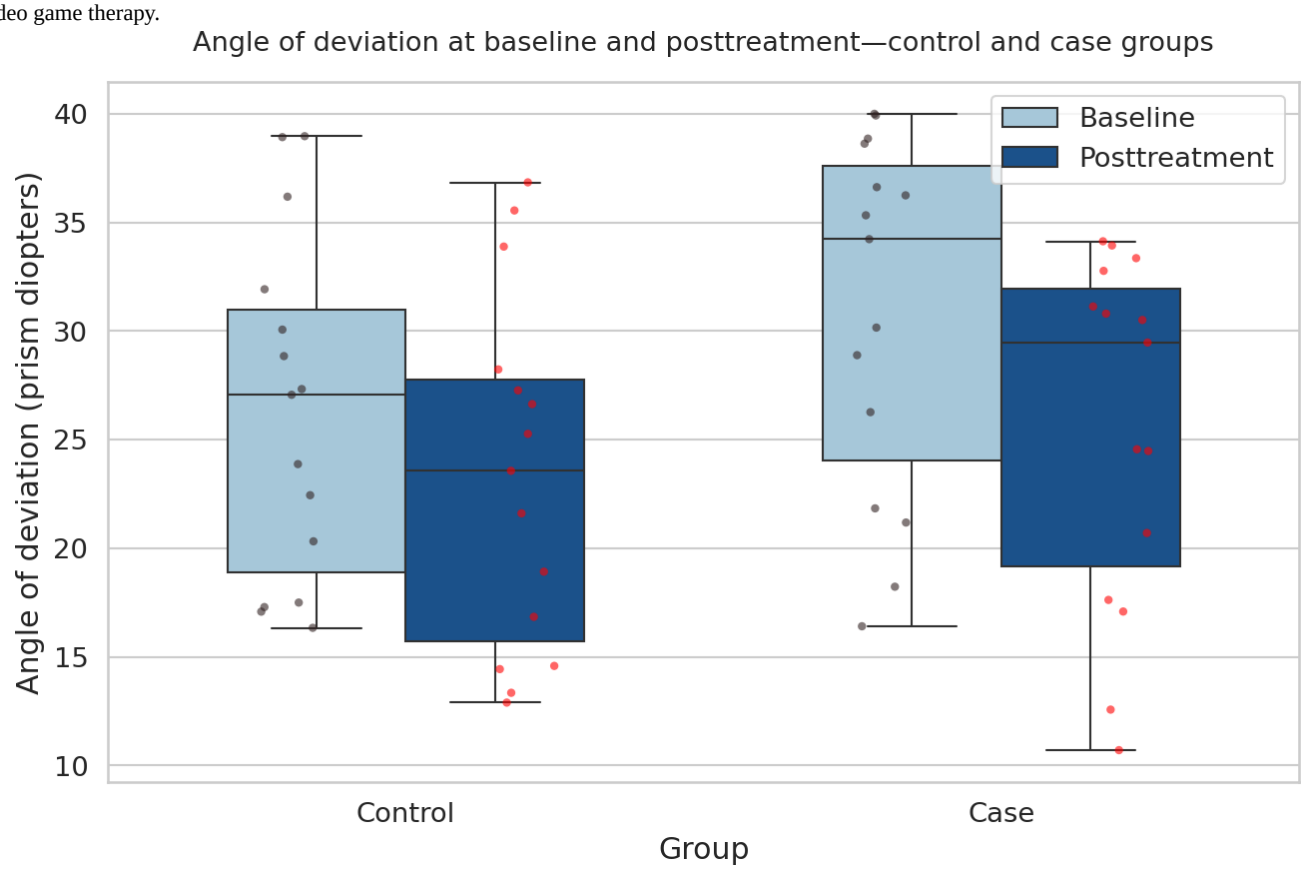
Visual and Motor Function at Baseline

At baseline, the mean visual acuity for the amblyopic eye was 0.59 (SD 0.18) logMAR, and for the fellow or nonamblyopic eye, it was 0.57 (SD 0.16) logMAR. The mean angle of deviation at baseline, measured in prism diopters, was 28.56° (SD 7.60°). Stereoacuity, reflecting binocular vision, had a mean

XSL•FO
RenderX

of 613.99 (SD 159.38) seconds of arc. Ocular motility was assessed and classified as either normal or abnormal, with 50% (15/30) of participants exhibiting abnormal motility. Baseline fixation stability, as measured by the eye tracker, averaged 1.06 (SD 0.29) seconds.

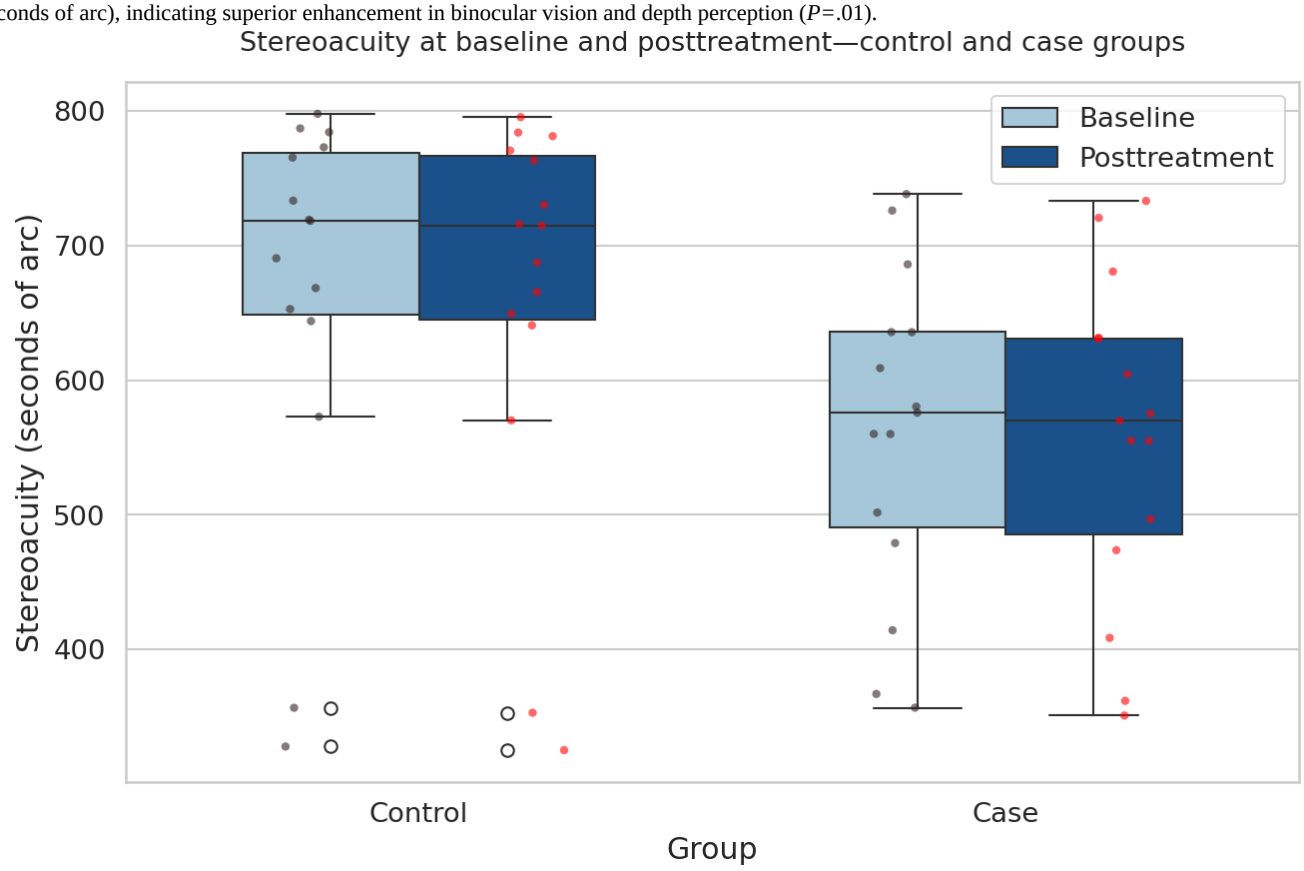
Posttreatment Outcomes



Significant improvements were observed across all outcomes within the treatment group following the intervention. The mean visual acuity improved markedly for both the amblyopic eye (P<.001) and the fellow nonamblyopic eye (P<.001). The angle of deviation, which indicates ocular alignment, significantly decreased (P<.001), suggesting enhanced alignment after the treatment. Stereoacuity also improved substantially, with the mean decreasing to 570.12 (SD 119.54) seconds of arc (P<.001), reflecting better binocular vision and depth perception. Fixation stability, as measured by the eye tracker, also showed significant improvement (mean 2.87, SD 0.56 seconds; P<.001), indicating enhanced control and consistency in eye movements.

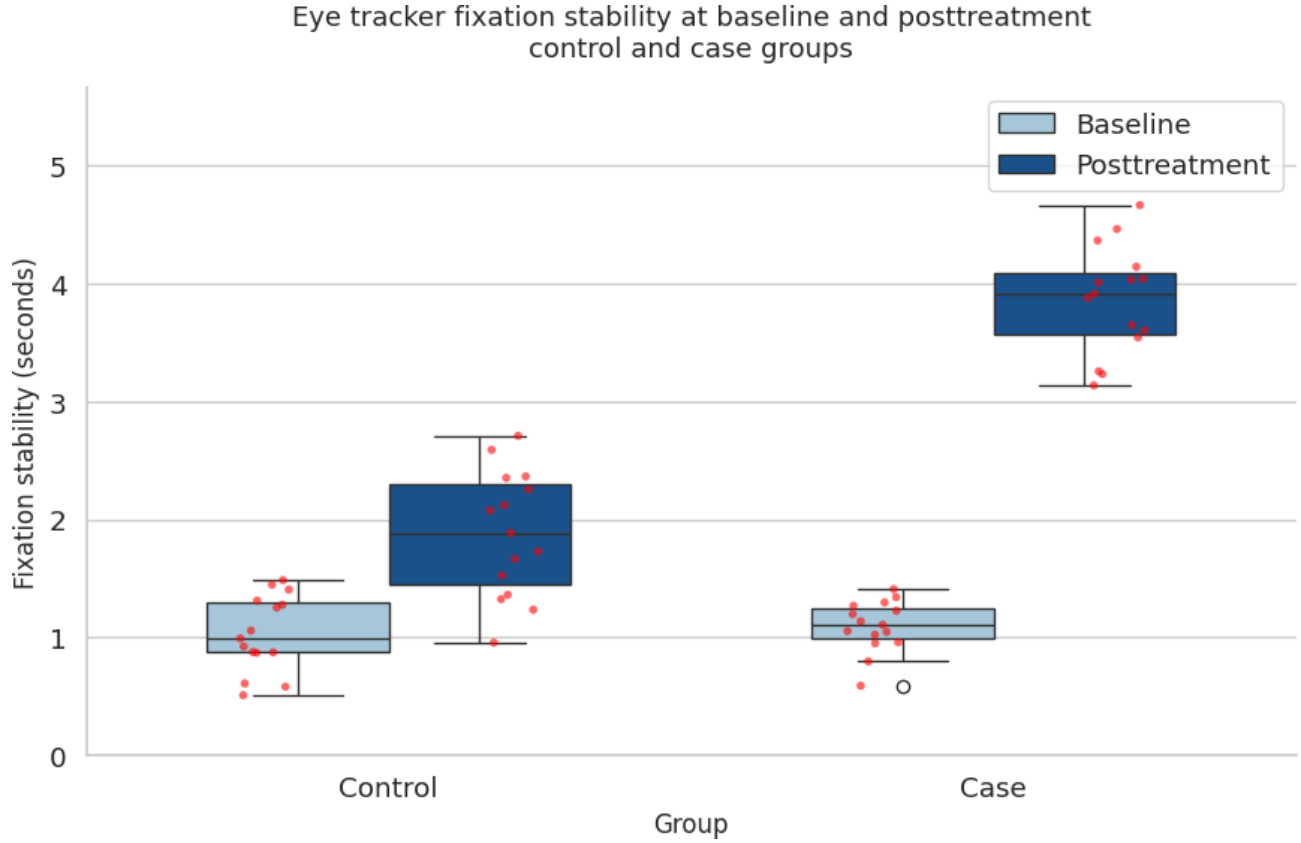
The control group, which received only eye patching, also exhibited significant improvements across all measured outcomes. Visual acuity improved in both the amblyopic eye (P<.001) and the fellow or nonamblyopic eye (P<.001). The angle of deviation decreased significantly (P<.001), and stereoacuity improved, with a mean posttreatment value of 698.74 (SD 145.89) seconds of arc (P<.001). Although these improvements were significant, the overall magnitude of change was generally less pronounced compared to the treatment group.

The comparison between the case and control groups across different metrics reveals notable differences in treatment outcomes. As shown in Figure 7, the angle of deviation (measured in prism diopters) exhibits a wider range in the control group compared to the case group, indicating more variability in the control group's treatment results. The case group, on the other hand, shows a more consistent range of deviation angles, suggesting a potentially more uniform response to the treatment that included video game therapy. In Figure 8, which compares stereoacuity (measured in seconds of arc), the control group again demonstrates a wider range of outcomes, with several outliers. This wider distribution suggests that the control group experienced more varied improvements in stereoacuity. In contrast, the case group shows a more concentrated distribution of stereoacuity scores, implying a more consistent improvement in their depth perception after treatment. Finally, Figure 9 highlights the differences in fixation stability (measured in seconds) between the groups. Both groups demonstrated posttreatment improvement. The control group shows a narrower range of fixation stability (from 1.03 to 1.88 seconds), indicating a more stable but less varied outcome. The case group, however, displays a wider range (from 1.06 to 2.87 seconds), with more outliers, suggesting that while some individuals in the case group achieved better fixation stability, there was also more variation in the treatment's effectiveness for this outcome. Overall, these figures suggest that while the control group experienced more variability across all metrics, the case group showed more consistent results, especially in terms of angle of deviation and stereoacuity, possibly due to the addition of video game therapy.



XSL•FO
RenderX

Figure 7. Box plot comparing the angle of deviation (measured in prism diopters) at baseline and after treatment between the control and case groups. The angle of deviation exhibits a wider range in the control group compared to the case group, indicating more variability in the control group's treatment results. The case group shows a more consistent range of deviation angles, suggesting a potentially more uniform response to the treatment that included video game therapy.



XSL•FO
RenderX

Figure 8. Stereoacuity at baseline and posttreatment for control and case groups. Boxplots display individual participant data (red dots). Lower values indicate better stereoacuity (measured in seconds of arc). Both groups demonstrated posttreatment improvement; however, the treatment (case) group showed a greater reduction in stereoacuity values (mean 570.12, SD 119.54 seconds of arc) compared with the control group (mean 698.74, SD 145.89 seconds of arc), indicating superior enhancement in binocular vision and depth perception (*P*=.01).

XSL•FO
RenderX

Figure 9. Eye-tracker fixation stability at baseline and posttreatment for control and case groups. Boxplots show individual participant data (red dots). Higher values represent greater fixation stability (measured in seconds). Both groups demonstrated posttreatment improvement; however, the case group exhibited a larger increase (baseline=1.06 seconds; posttreatment=2.87 seconds) than the control group (baseline=1.03 seconds; posttreatment=1.88 seconds), reflecting enhanced ocular motor control following the combined intervention.

Independent samples 2-tailed *t* tests and the Mann-Whitney *U* test were used to assess whether the treatment group showed superior outcomes compared to the control group, with the choice of test determined by the normality of the data. The analysis revealed that posttreatment visual acuity in the amblyopic eye was significantly better in the treatment group compared to the control group (P<.001). This pattern was consistent for the fellow or nonamblyopic eye, where the treatment group again outperformed the control group (P<.001), indicating that the treatment had a substantial positive impact on visual acuity in both eyes.

When evaluating the angle of deviation after the treatment, the comparison between the 2 groups did not yield a significant difference (P=.45), suggesting that both interventions were similarly effective in improving ocular alignment. However, a different outcome was observed for stereoacuity, where the treatment group showed significantly better improvement than the control group (P=.01). This finding indicates that the treatment group achieved superior binocular vision, as reflected in enhanced stereoacuity.

Fixation stability, as measured by the eye tracker, also showed significant improvement in the treatment group compared to the control group (P<.001). This result suggests that the combination of eye patching with video game therapy not only improved visual outcomes but also enhanced stability and control of eye movements, further supporting the efficacy of the treatment approach.

To assess the collective impact of the treatment on multiple dependent variables simultaneously, a multivariate analysis of variance was conducted. The results indicated a highly significant overall difference between the control and treatment groups when considering visual acuity (amblyopic and fellow or nonamblyopic eyes), angle of deviation, stereoacuity, and fixation stability together (P<.001). This finding highlights the superior efficacy of the treatment group across multiple dimensions of visual function.

In conclusion, the combination of eye patching with video game therapy was more effective than eye patching alone in improving visual acuity, stereoacuity, and fixation stability among children with strabismus. While both interventions were similarly effective in reducing the angle of deviation, the treatment group consistently outperformed the control group in other critical measures of visual function. These findings suggest that incorporating video game therapy into traditional eye patching regimens could enhance treatment outcomes for pediatric patients with strabismus.

Discussion

Principal Findings

The results of this study highlight the significant advantages of combining video game therapy with traditional eye patching in the treatment of children with strabismus. By comparing the outcomes of children who received eye patching alone to those who underwent a combined treatment regimen, this study

XSL•FO
RenderX

provides compelling evidence that video game therapy can substantially enhance the effectiveness of traditional treatments. The observed improvements in visual acuity, stereoacuity, and fixation stability in the treatment group suggest that the addition of video game therapy offers a multifaceted approach to addressing both the sensory and motor deficits associated with strabismus.

One of the most noteworthy findings of this study is the significant improvement in visual acuity in the treatment group compared to the control group. This result aligns with previous research that has demonstrated the potential of video games to stimulate visual pathways and enhance visual acuity, particularly in children with amblyopia [7,19]. However, our study extends this understanding by incorporating eye tracking technology, which provided a detailed analysis of fixation stability. The improvement in fixation stability observed in the treatment group suggests that video game therapy does not merely enhance visual acuity but also contribute to better control and coordination of eye movements. This dual improvement is likely due to the interactive nature of video games, which require sustained attention and precise eye movements, thereby providing a robust stimulus for the visual system.

Stereoacuity, which reflects the quality of binocular vision, also showed significant improvement in the treatment group, with posttreatment values markedly lower than those observed in the control group. This finding supports the hypothesis that video game therapy can play a crucial role in re-establishing binocular function in children with strabismus. The improvement in stereoacuity is particularly important, as it indicates that the treatment is effective not only in aligning the eyes but also in promoting the integration of visual information from both eyes [27]. This dual benefit contrasts with the traditional approach of patching, which focuses primarily on forcing the brain to use the weaker eye, often at the expense of binocular vision.

The use of eye tracking technology in this study provided a novel dimension to the assessment of treatment outcomes. While previous studies have focused primarily on sensory outcomes, such as visual acuity and stereoacuity [7,19], our study's use of eye tracking allowed for a detailed analysis of motor outcomes, particularly fixation stability. The significant improvement in fixation stability in the treatment group suggests that video game therapy can enhance both sensory and motor aspects of vision, leading to more comprehensive treatment outcomes. This finding is particularly relevant because poor fixation stability is a common issue in children with strabismus, and it is often associated with an increased risk of amblyopia and poor binocular function.

The comparative effectiveness of traditional patching versus the combined treatment regimen also offers valuable insights. While both treatment modalities were effective in reducing the angle of deviation and improving ocular alignment, the combined treatment was notably more effective in enhancing visual acuity, stereoacuity, and fixation stability. This suggests that while patching remains an essential component of strabismus treatment, video game therapy can significantly enhance its effectiveness by stimulating and improving the functional aspects of vision. The combination of these therapies, therefore, offers a more holistic approach to treating strabismus, addressing both the structural alignment of the eyes and the functional integration of visual information.

These findings have important implications for clinical practice. The integration of video game therapy into traditional patching regimens could improve patient outcomes, particularly in children who may be resistant to patching alone. The interactive and engaging nature of video games has the potential to improve compliance with therapy, which is a significant challenge in traditional treatments. Moreover, the use of eye tracking as part of the treatment protocol offers clinicians a valuable tool for monitoring progress and tailoring therapy to individual patient needs. The detailed eye movement data provided by the eye tracker can help identify specific deficits in ocular motility and fixation stability, allowing for more targeted interventions. This personalized approach to treatment could lead to better long-term outcomes and a lower risk of relapse.

Limitations and Future Directions

Despite the promising results, this study has several limitations. The sample size was relatively small, and the study duration was limited to 3 months, which may not fully capture the long-term effects of the interventions. Additionally, the study focused on a specific age group (5 - 10 years), and the findings may not be generalizable to older children or adults with strabismus. In addition, this study did not address the participants' insights into their experiences, both objective and subjective engagement, and satisfaction.

In addition, a subset of participants (n=10) had received prior short-term treatment in the form of occlusion therapy and/or optical correction before enrollment. Although this was consistent with the inclusion criteria that excluded longer treatment durations for more than 3 months, variations in previous management and the lack of detailed records regarding adherence may have influenced baseline visual acuity and binocular function. Future research with stratified analysis or exclusion of previously treated participants could help clarify the independent effects of video game–assisted therapy.

Future research should aim to include larger, more diverse populations and longer follow-up periods to assess the sustainability of the treatment outcomes and consider more homogeneous cohorts or stratified subgroup analyses to better isolate the effects of therapy across different clinical categories. Additionally, exploring the use of more advanced video game therapies, possibly incorporating virtual reality or augmented reality, could further enhance the therapeutic potential of this approach. Finally, investigating the neurophysiological mechanisms underlying the improvements observed with video game therapy could provide deeper insights into how these interventions influence visual processing in the brain.

This study focuses exclusively on the development and validation of an eye-tracking system rather than on the medical or disease-specific implications of its use. While the methodology may have future clinical applications, the absence of direct medical outcome analysis represents a limitation. Future work should incorporate multidisciplinary collaboration

XSL•FO
RenderX

with clinical experts to evaluate and expand the medical applicability of this technology.

The measurement of fixation stability was based on fixation duration (in seconds) rather than more established ophthalmological parameters such as bivariate contour ellipse area or fixation locus analysis. As such, this approach provides only a simplified assessment of fixation performance. Future studies should incorporate bivariate contour ellipse area and other position-based measures to better characterize fixation stability, particularly in patients with amblyopia where eccentric fixation is common.

Conclusions

The study demonstrates that combining traditional eye patching with video game therapy significantly enhances treatment outcomes in children with strabismus, particularly by improving visual acuity, reducing stereoacuity values, and increasing fixation stability. While both treatments effectively reduce the angle of deviation, video game therapy offers additional benefits by engaging and improving the functional aspects of vision. The integration of eye tracking technology provides valuable insights into the motor aspects of ocular function, allowing for a more comprehensive assessment and personalized treatment approach.

These findings suggest that incorporating video game therapy into traditional treatment regimens could lead to more effective and engaging interventions for pediatric strabismus, potentially improving compliance and long-term outcomes. Future research should continue to explore this promising approach, with a focus on understanding the underlying mechanisms and optimizing therapy for diverse patient populations.

Acknowledgments

The author would like to express sincere gratitude to the institutional review board team at Yarmouk University for their ethical oversight and support throughout the study. Appreciation is also extended to the physicians and technicians of the outpatient ophthalmology clinic for their valuable assistance in participant recruitment and data collection. The author gratefully acknowledges the contributions of all study participants for their time and cooperation. The author especially thanks the administrative staff for their support in coordinating clinical and research activities.

Funding

The authors declared no financial support was received for this work.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

The author was solely responsible for all aspects of this work, including conceptualization, methodology, software, validation, formal analysis, investigation, data curation, writing (original draft preparation, review, and editing), and visualization.

Conflicts of Interest

None declared.

Editorial Notice

This randomized study was only retrospectively registered, explained by authors as not being required by local regulations. The editor granted an exception from International Committee of Medical Journal Editors rules mandating prospective registration of randomized trials, because the author was able to provide a letter from their institutional review board (IRB) confirming that the IRB chair and a designated committee member had reviewed the manuscript and confirmed that the study objectives, design, methodology, and outcome measures described in the manuscript are identical to those that were approved by the IRB. However, due to the lack of prospective registration, readers are advised to assess with caution the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness.

Abstract

Background: Patient education is central to orthodontic care; however, most patients still learn about their malocclusion from conventional records, such as 2D image records. Immersive virtual reality (VR) allows patients to view and manipulate 3D dental models in a head-tracked environment, as part of the serious-games and extended reality family for health education. Evidence on patient-facing immersive VR in orthodontics remains limited, as most dental VR work has addressed student training rather than patient education.

Objective: This feasibility study aimed to evaluate acceptance, perceived educational value, self-rated experience, ease of use, and self-reported preference regarding an immersive VR consultation room among patients undergoing orthodontic treatment.

Methods: This cross-sectional, single-arm feasibility and acceptability study was conducted in a university orthodontic clinic between August and September 2024. Patients undergoing active orthodontic treatment completed a single, approximately 15-minute immersive VR educational experience using a Meta Quest 3 headset and a Unity3D-developed consultation room presenting a 3D rendering of each participant's own intraoral scan, followed by an investigator-developed postexperience questionnaire. The questionnaire combined a Likert scale and two 10-point numeric items with open-ended prompts. Closed-ended responses were summarized as counts, percentages, and 95% CIs, and numeric items were summarized as means with 95% CIs; open-ended comments were grouped into themes. No inferential testing was performed.

Results: Twenty-eight patients completed the study (mean age 21.6, SD 4.3, range 13 - 33 y; 18 males, 10 females; 5 minors). Sixteen (57%) patients had no prior VR experience, 22 (79%) were interested in using VR to learn about their teeth, and 24 (86%) agreed that VR could help patients understand their teeth and braces. The mean overall experience rating was 7.9 (SD 1.6; 95% CI 7.3 - 8.5) on a 10-point scale, and the mean ease-of-use rating was 6.6 (SD 2.6; 95% CI 5.7 - 7.6). Twenty (71%; 95% Wilson score CI 53 - 85) patients felt VR was a better learning modality than conventional 2D images; 19 (68%; 95% Wilson score CI 49 - 82) preferred VR with the current setup, and 25 (89%; 95% Wilson score CI 73 - 96) preferred VR under a hypothetically improved technology scenario. Positive comments emphasized interactivity, 3D visualization, and engagement; negative comments centered on controller difficulty, latency, and motion discomfort. Two (7%) patients reported mild, transient, motion-related discomfort; none discontinued.

Conclusions: Patients were generally receptive to an immersive VR consultation room. This work is novel in evaluating patient-facing immersive VR using each patient's own intraoral scan and in identifying actionable usability and motion-comfort barriers. Because the design was single arm and the comparison with conventional 2D image records was self-reported, the findings represent preliminary acceptability evidence, not learning effectiveness. If confirmed in more rigorous studies, immersive VR may serve as an adjunct to communication with patients undergoing orthodontic treatment, warranting controlled studies with an interactive flat-screen 3D comparator; validated usability, presence, and cybersickness instruments; and objective knowledge-gain measures.

Introduction

Background

Effective patient education is fundamental to orthodontic care because patients must understand their malocclusion, treatment goals, and expected outcomes to participate meaningfully in decision-making and long-term treatment adherence. Prior work in orthodontics has shown that patient satisfaction is shaped in large part by communication and by the extent to which patients feel involved in their care [1]. Digital tools that make treatment explanations clearer and more engaging may therefore improve the educational experience.

As orthodontics becomes increasingly digital, patients are also becoming more accustomed to technology-based visualization. Intraoral scanning and digital models, for example, have been shown to be acceptable to patients undergoing orthodontic treatment, and in some settings, preferred over conventional methods [2]. At the same time, the broader dental education literature suggests that virtual reality (VR) can improve engagement, confidence, and perceived educational value, although most published work has focused on student training rather than patient education [3-5]. Beyond dentistry, immersive VR has been found to be acceptable and feasible for education and engagement across diverse clinical populations, including users with limited prior VR experience [6,7]. Acceptability is nonetheless context- and population-specific, and evidence generated in other settings cannot be assumed to transfer to patients undergoing orthodontic treatment, who differ in typical age range, clinical context, and educational goals. Establishing acceptability in this population is therefore a necessary first step before larger controlled studies of educational effectiveness are warranted.

Prior Work

Immersive VR offers a different way for patients to interact with dental information by allowing them to view and manipulate 3D models in a head-tracked virtual environment using handheld controllers [8]. Unlike conventional 2D images or static physical demonstrations, immersive VR may provide a more interactive and spatially intuitive way to understand tooth position, occlusion, and treatment concepts [9,10]. Immersive experiences of this kind, which combine 3D visualization with goal-directed interaction and feedback, sit within the broader family of serious games and extended reality (XR) tools designed for health education and behavior change rather than entertainment. In the present study, these defining features (guided, goal-directed model manipulation with audiovisual feedback rather than free play) serve as the basis for situating the experience within the literature.

Evidence specifically addressing immersive VR as a patient-facing educational modality in dentistry remains limited. A pilot study in cleft care (N=20) suggested that VR-based education may improve caregiver understanding and treatment acceptance [11]. More recent patient-facing dental literature has also suggested potential benefits of VR for oral health instruction and for improving the patient experience in anxious dental populations, including a scoping review of VR for dental anxiety [12] and a randomized trial of VR-based toothbrushing instruction in adults (N=30) [13]. However, these applications remain distinct from patient education in orthodontics, and a recent scoping review in orthodontics identified patient engagement as a promising but still understudied use of XR technologies [14]. Recent orthodontic XR applications have largely targeted student and trainee education, such as VR for undergraduate orthodontic teaching [15] and web-based augmented-reality tools for orthodontic biomechanics [16], rather than communication with patients themselves. To our knowledge, patient-facing immersive VR that presents a patient's own intraoral scan for orthodontic education has not previously been evaluated for acceptability.

Study Objectives

Against this background, the aim of this feasibility study was to evaluate acceptance of an immersive VR consultation room among patients undergoing orthodontic treatment and to describe their perceptions of usability, educational value, and preference compared to conventional 2D image records. Findings are intended to inform iterative refinement of the system and the design of future controlled studies measuring objective knowledge gain.

Methods

Study Design and Setting

This was a cross-sectional, single-arm feasibility survey conducted in the orthodontic clinic at the Herman Ostrow School of Dentistry of the University of Southern California (USC) between August and September 2024. Current patients undergoing active orthodontic treatment were recruited during routine clinic visits and invited to complete a one-time immersive VR educational experience followed by a postexperience survey. The full questionnaire is available in Multimedia Appendix 1. This early-phase feasibility and acceptability evaluation is reported in accordance with the RATE-XR (Reporting for the early-phase clinical evaluation of applications using extended reality) reporting guideline for XR applications [17].

Inclusion and Exclusion Criteria

Inclusion criteria were (1) patients currently undergoing active orthodontic treatment in the USC orthodontic clinic, (2) recruited during a routine clinic visit within the study period, (3) able to understand spoken English instructions for the VR experience and the survey, and (4) able and willing to provide informed consent, or, for minors, assent, together with parental or guardian permission. Exclusion criteria were (1) inability to wear a head-mounted VR display, (2) a self-reported history of severe motion sickness or a vestibular disorder, and (3) any acute

XSL•FO
RenderX

medical condition precluding safe participation, as judged by the supervising clinician. No additional exclusion criteria were applied. Participation was voluntary, and declining the activity had no effect on routine clinical care.

Participant Characteristics

A total of 28 patients completed the study. The sample had a mean age of 21.6 (SD 4.3, range 13 - 33) years and included 18 male and 10 female participants. Five participants were minors (<18 y). All participants had previously reviewed their malocclusions using conventional 2D images of models of their teeth as part of routine orthodontic care. These conventional records were noninteractive and could not be manipulated in 3D by the patient.

Sampling Procedures

Participants were recruited using consecutive convenience sampling. Eligible patients undergoing orthodontic treatment attending routine visits at the USC Orthodontic Clinic during the study period (between August and September 2024) were approached in the order in which they presented and invited to participate until recruitment concluded; therefore, self-selection was possible. The numbers of patients approached and those who declined participation were not recorded prospectively; therefore, the percentage of those approached who participated is unknown. No advertising or external recruitment was used; participation was voluntary; and no compensation was provided. Institutional review board approval and consent procedures are described in the *Ethical Considerations* section.

Sample Size, Power, and Precision

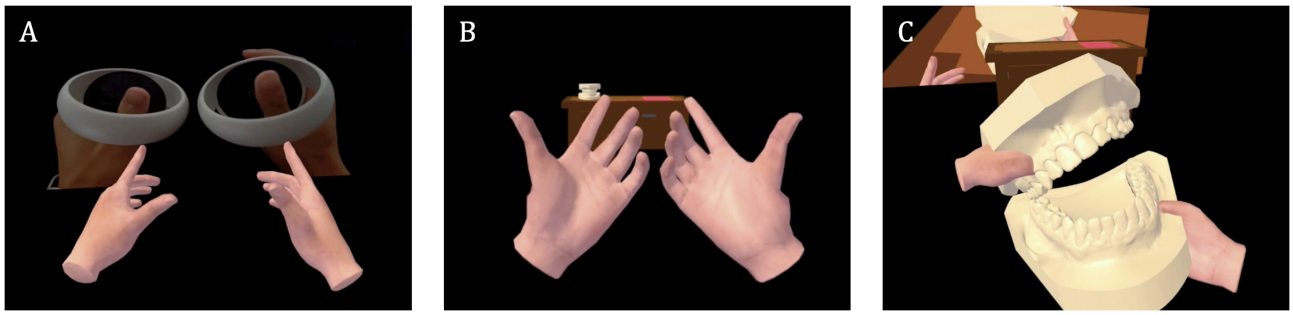
As an early feasibility and acceptability study, no formal sample-size calculation was performed and no hypothesis testing was planned. The achieved sample of 28 participants is consistent with the modest sample sizes of comparable feasibility and pilot studies, whose purpose is to assess acceptability and to inform effect-size and sample-size assumptions for a future controlled trial rather than to support inferential conclusions. CIs are reported throughout to convey the limited precision of estimates derived from this sample.

Immersive VR Intervention

The immersive VR intervention is reported in accordance with the RATE-XR reporting guideline for the early-phase clinical evaluation of XR applications. Participants used a Meta Quest 3 headset and handheld controllers (Meta Platforms) to navigate and interact with the virtual environment (Figure 1). Head tracking allowed users to change their viewpoint naturally by moving their heads, whereas the handheld controllers were used to point, select, grab, and manipulate virtual objects. The VR educational experience was developed in Unity3D (Unity Technologies) and presented in a virtual consultation room environment. The application was developed in-house by the study team; each participant's intraoral scan was exported from the intraoral scanner and imported into the Unity3D environment to generate a patient-specific 3D model.

XSL•FO
RenderX

Figure 1. Demonstration of the immersive virtual reality system used for patient education in orthodontics in a cross-sectional feasibility and acceptability study at the university orthodontic clinic between August and September 2024. A volunteer, shown here, used a Meta Quest 3 headset and handheld controllers to navigate and interact with the virtual educational environment; this individual is not a study participant, and written consent to publish the image was obtained.



The experience incorporated an embedded orientation sequence in which participants first familiarized themselves with the virtual environment and controls before proceeding to educational content based on a 3D rendering of their own intraoral scan, representing their individual malocclusion (Figure 2A). This familiarization sequence included looking around the virtual environment, learning basic hand and controller movements, interacting with virtual objects, and moving within the virtual space. Participants were then guided to a virtual desk, where a 3D model of their dentition appeared (Figure 2B). They were prompted to manipulate the model, including holding it, rotating it, and viewing it from different angles; repositioning it; and positioning it in and out of occlusion (Figure 2C). The experience incorporated voice narration, stepwise prompts, and immediate audiovisual feedback to guide participant interaction. The sequence was fixed and identical for all participants, with no alternative modules or system versions.

Each participant completed the experience in a single session of approximately 15 minutes, which was administered and supervised one-on-one by a trained study investigator. Participants stood throughout, and the experience required only minimal whole-body movement, consisting mainly of head turning and hand-and-controller gestures within a cleared area of approximately 1.5×1.5 m. To prevent falls or collisions, a headset guardian boundary was configured, the surrounding area was cleared of obstacles, and the investigator remained beside the participant throughout to monitor for discomfort or cybersickness and to provide steadying support or assistance if needed. Participants were informed that they could pause or stop at any time; no formal stopping threshold was prespecified beyond the investigator's judgment. Between participants, the headset and controllers were cleaned and disinfected as noncritical devices in accordance with standard dental infection-control protocols (consistent with American Dental Association and Centers for Disease Control and Prevention guidance), using an Environmental Protection Agency–registered hospital-grade disinfectant wipe. Setup required approximately 5 minutes per participant. Sessions were conducted in the clinic's standard consultation room and delivered during the participant's routine orthodontic visit rather than as a separate appointment. The VR application is an investigator-developed research prototype, is not publicly available, and has not been reviewed or cleared as a medical device by any regulatory body. It was used solely for research purposes.

Screenshots of the immersive virtual reality educational workflow used in a cross-sectional feasibility and acceptability study of patient education in orthodontics (Meta Quest 3 and Unity3D). (A) Orientation and familiarization with the virtual environment and controller-based hand movements. (B) Navigation within the virtual consultation room toward the instructional desk. (C) Manipulation of the virtual dental models for 3D viewing and assessment of occlusion.

Measures and Covariates

After completing the VR activity, participants completed an investigator-developed postexperience questionnaire. The questionnaire included (1) closed-ended items on prior VR experience, interest in using VR for patient education in orthodontics, perceived educational utility, comparison with conventional viewing of orthodontic records, current preference, and preference under an improved technology scenario, scored on Likert-type response options (eg, "very interested/interested/neutral/uninterested/very uninterested" and "strongly agree/agree/neutral/disagree/strongly disagree"); (2) two numeric items rated on a 1-to-10 scale for overall experience with the VR equipment and the test room and ease of using the VR system; and (3) open-ended items soliciting positive and negative aspects of the experience. Beyond age and sex, no additional demographic or clinical covariates were collected. The preference items (items 6, 9, and 10) asked participants whether they preferred the VR experience or conventional 2D records viewed on a computer screen, reflecting the on-screen record viewing used in routine orthodontic care in our university orthodontic clinic. No physical dental models were used in this study. The questionnaire was developed by the investigators for the purpose of this feasibility study and was not formally validated. No validated usability instrument (eg, System Usability Scale), presence questionnaire, standardized cybersickness questionnaire (eg, Simulator Sickness Questionnaire), or objective knowledge-gain assessment were administered, and no pre-experience baseline knowledge assessment was conducted.

Data Collection

Survey responses were collected through a web-based form completed on a study tablet in the clinic immediately after the VR experience. The form did not capture direct identifiers, and the analytic dataset contained no names or record numbers. However, because sessions were administered individually by a member of the study team, the investigator recorded each participant's age and sex alongside their responses in the export. Responses were therefore deidentified rather than anonymous, and age and sex could be associated with individual responses. The supervising investigator was present in the clinic area while participants completed the survey; this is acknowledged as a potential source of social-desirability bias in the *Limitations* section.

Conditions and Design

This was a single-group observational study. All participants received the same VR experience. There were no separate conditions or comparison groups, no randomization, and no masking. Because the study was not experimental, JARS (Journal Article Reporting Standards) reporting items that apply only to experiments are not applicable here, and reporting follows the JARS standards for nonexperimental designs.

Data Diagnostics

All survey items were required in the web-based form, so there were no missing data and no postcollection exclusion of participants. No statistical outliers were removed, no data transformations were applied, and no imputation was required. Because the analysis was descriptive, no distributional modeling assumptions were required.

Analytic Strategy

Nondata administrative summary rows generated by the survey platform were removed before analysis and no participant records were excluded. Closed-ended responses were summarized as counts and percentages with 95% Wilson score CIs. The 2 numeric items were summarized using means, SDs, medians, ranges, and 95% CIs based on the *t* distribution. Open-ended comments were reviewed and grouped into recurring descriptive themes by 2 investigators (YJK and GJ) by consensus; given the descriptive nature of the study, formal interrater reliability was not calculated. Because of the feasibility design and modest sample size, no inferential testing or formal subgroup analysis was performed. Analyses were conducted using descriptive statistical methods, and an exploratory descriptive cross-tabulation of reported interest against final preference was reported. No changes were made to the planned procedures, eligibility criteria, or analysis after the study commenced.

Ethical Considerations

This study was reviewed and approved by the USC Institutional Review Board under protocol APP-24 - 03274, which included the participation of minors. As a single-session, single-arm feasibility and acceptability survey rather than a clinical trial, the study was not prospectively registered. Adult participants (n=23) provided written informed consent prior to participation. Minor participants (n=5) provided written assent, and for each minor participant, a parent or legal guardian provided written

XSL•FO
RenderX

permission for that specific minor's participation, in accordance with the approved protocol. Participation was voluntary and had no effect on routine clinical care. No participant compensation was provided. Survey responses were deidentified at the point of export, and no identifiable participant information is presented in the analytic results. This paper's figures and materials do not include identifiable images of participants.

Results

Participant Characteristics and Prior VR Experience

Among 28 respondents, 16 (57%) reported that they had never used VR before, 7 (25%) had some prior experience, and 5 (18%) described themselves as very comfortable with VR. Despite limited prior exposure among many participants, 22 (79%) respondents reported being interested or very interested in using VR to learn about their teeth and how their teeth fit and work together. Four (14%) respondents were neutral, and 2 (7%) were uninterested or very uninterested. Closed-ended survey responses are summarized in Table 1 and participant flow through the cross-sectional feasibility and acceptability study at the university orthodontic clinic is displayed in Figure 3.

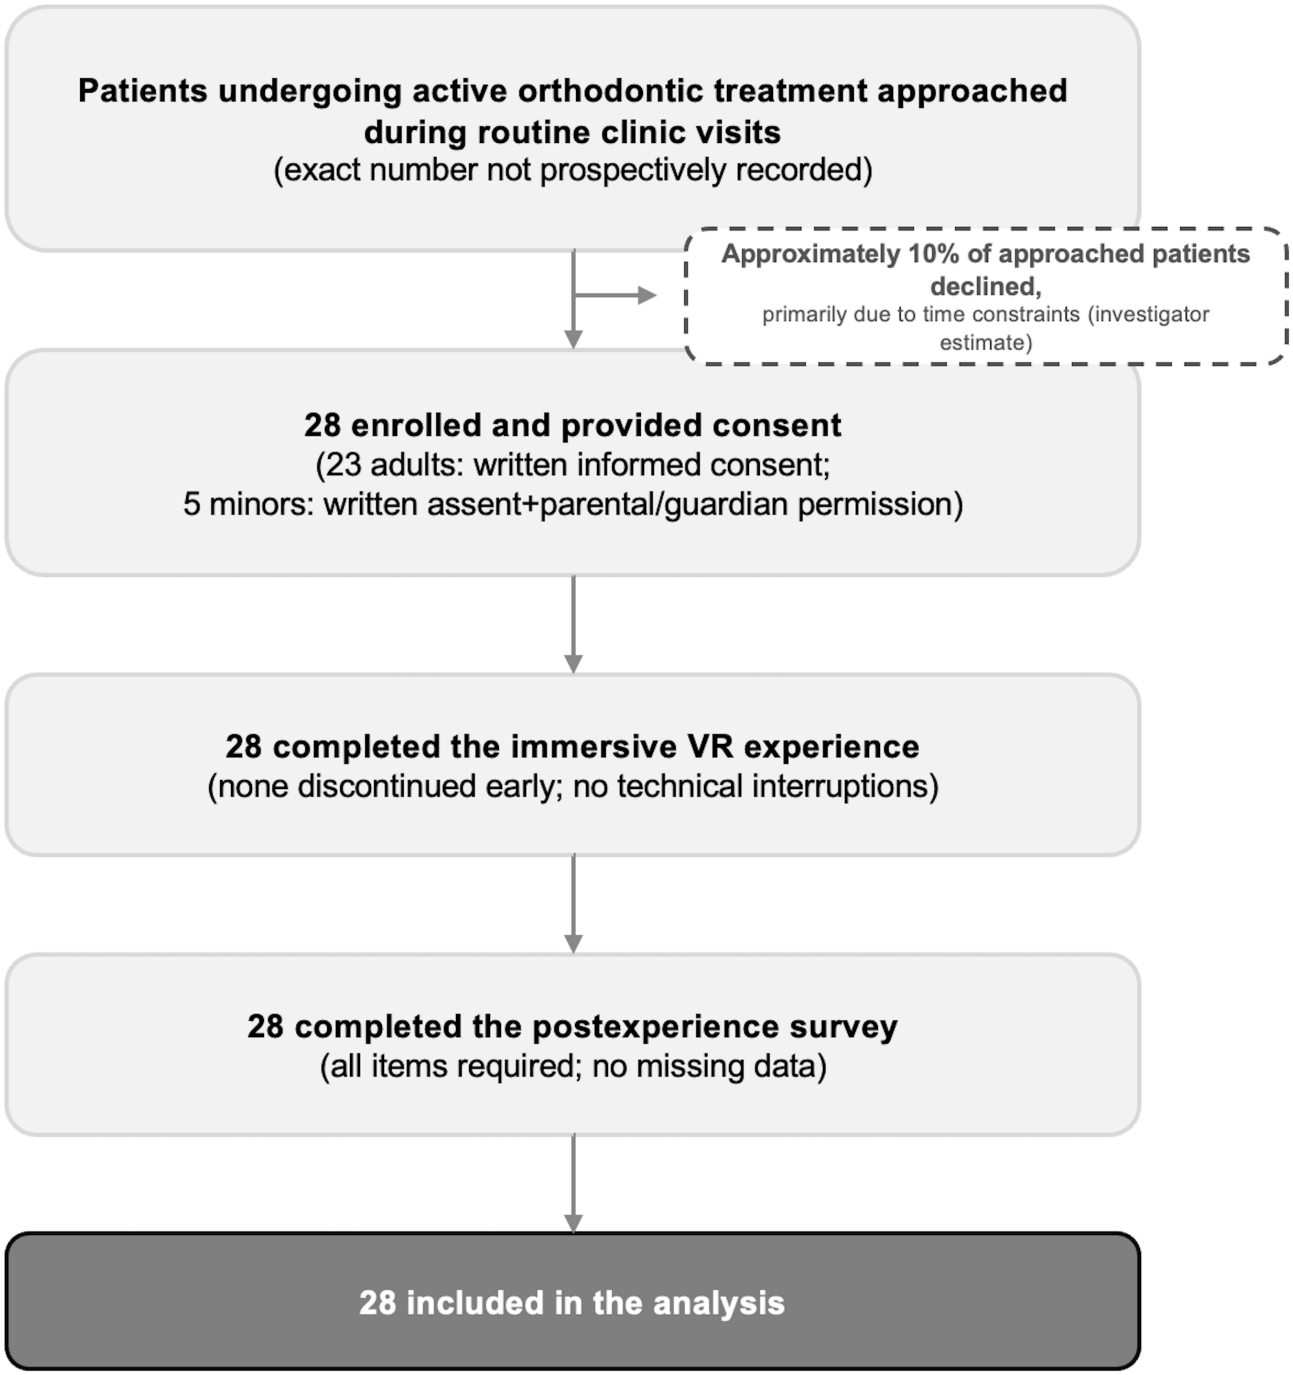

Table . Distribution of closed-ended survey responses among patients undergoing orthodontic treatment (N=28) in a cross-sectional feasibility and acceptability study of an immersive virtual reality (VR) consultation room at the university orthodontic clinic between August and September 2024.[a]

Item and response	Patients, n (%)	95% CI (Wilson score)
Prior VR experience		
Never used VR before	16 (57)	39 - 73
Some prior experience	7 (25)	12 - 44
Very comfortable with VR	5 (18)	8 - 36
Interest in using VR for learning		
Interested/very interested	22 (79)	60 - 90
Neutral	4 (14)	6 - 32
Uninterested/very uninterested	2 (7)	2 - 23
VR can help patients learn about teeth/braces		
Agree/strongly agree	24 (86)	69 - 94
Neutral	4 (14)	6 - 32
VR better than 2D image records		
Yes	20 (71)	53 - 85
No	8 (29)	15 - 47
Current preference		
VR	19 (68)	49 - 82
2D image records	9 (32)	18 - 51
Future preference if technology improves		
VR	25 (89)	73 - 96
2D image records	3 (11)	4 - 27

[a]Percentages may not sum to 100 because of rounding.

XSL•FO
RenderX

Figure 3. Participant flow through the cross-sectional feasibility and acceptability study at the university orthodontic clinic between August and September 2024. VR: virtual reality.

Perceived Educational Value and Preference

Out of 28 respondents, 24 (86%) agreed or strongly agreed that VR could help patients like themselves learn more about their teeth and what braces can do for them, whereas 4 (14%) respondents were neutral. When directly comparing VR with conventional 2D image records, 20 (71%) respondents felt that VR was a better way to learn, whereas 8 (29%) preferred conventional 2D image records.

With the current setup, 19 (68%) respondents preferred VR and 9 (32%) preferred conventional 2D image records. When asked whether they would prefer VR or conventional 2D image records if the technology were improved, 25 (89%) respondents selected VR and 3 (11%) selected conventional 2D image records. Because this latter item asked participants to imagine an unspecified improved system that was not actually tested, it is interpreted as a hypothetical-preference indicator rather than as an evaluation of an improved system.

Overall Experience and Ease of Use

The mean overall experience rating for the VR equipment and test room was 7.9 (SD 1.6) on a 10-point scale (median 8, IQR 4 - 10). The mean ease-of-use rating was 6.6 (SD 2.6; median 7, IQR 2 - 10), indicating generally favorable but somewhat more variable perceptions of usability than of overall experience. Numeric survey ratings are summarized in Table 2.

XSL•FO
RenderX

Table . Numeric survey ratings (1 - 10 scale) among patients undergoing orthodontic treatment (N=28) in a cross-sectional feasibility and acceptability study of an immersive virtual reality (VR) consultation room at the university orthodontic clinic between August and September 2024[a].

Item	Rating, mean (SD)	Rating, median (IQR)	Rating, 95% CI
Overall experience with VR equipment/test room	7.9 (1.6)	8 (4-10)	7.3 - 8.5
Ease of using the VR system	6.6 (2.6)	7 (2-10)	5.7 - 7.6

[a]For overall experience, 10 indicates the best experience; for ease of use, higher scores indicate greater ease.

Exploratory Descriptive Findings

An exploratory descriptive cross-tabulation of reported interest against preference for the current setup was examined, and both were measured in the same postexperience questionnaire. Among the 22 participants who reported being interested or very interested in using VR, 17 ultimately preferred VR and 5 preferred conventional 2D image records. Among the 6 participants who were neutral, uninterested, or very uninterested, 2 ultimately preferred VR and 4 preferred conventional 2D image records. This pattern is presented descriptively only; because interest and preference were both measured after the session, we cannot say that interest came first or predicted preference. Exploratory descriptive age-group patterns are summarized descriptively, among patients younger than 25 years, 77% (17/22) preferred VR and 23% (5/22) preferred conventional 2D image records. Among the 6 patients aged 25 years and older, 4 preferred conventional 2D image records and 2 preferred VR. Motion-related discomfort was reported only in participants aged 25 years and older. Because of the small subgroup sizes, these findings are presented descriptively only and should not be interpreted as evidence of an age effect.

Safety and Tolerability

Out of 28 participants, 2 (7%) reported mild, transient discomfort consistent with motion-related symptoms in their open-ended responses (described as feeling “a little dizzy” while the environment loaded, and “light motion sickness” when moving within the environment). Both episodes were self-limited; neither required intervention; and no participant discontinued the session early. No other adverse events or technical interruptions requiring session termination were reported.

Open-Ended Feedback

Open-ended comments were generally favorable. Common positive themes included the ability to visualize teeth and occlusion in 3 dimensions, direct interaction with the models, a sense of realism, and the novelty or fun of the experience. Participants frequently described the experience as interactive, cool, or engaging. Negative comments most often involved usability and hardware limitations. Several respondents noted that the controllers and navigation were difficult initially, whereas others mentioned lag, glitches, or insufficient responsiveness. A smaller number of participants described dizziness, motion sickness, or discomfort during the experience. Some participants also indicated that 2D image records still felt more intuitive in the current version of the system.

Discussion

Principal Findings

In this single-arm feasibility and acceptability study, immersive VR was well received as a patient-education modality in a university orthodontic clinic. Most respondents were interested in using VR to learn about their teeth, and a majority expressed a self-reported preference for VR over conventional 2D image records, even though most participants had no prior VR experience and the sample included both adolescents and adults. At the same time, ease-of-use ratings were relatively lower and more variable than overall experience ratings, and a minority of participants continued to prefer conventional 2D image records. These findings suggest that lack of prior familiarity with immersive technology may not prevent users from perceiving educational value, although prior experience may still influence aspects of immersion and usability [6,18,19]. Participants were generally able to engage with the experience and recognize its potential for learning, consistent with broader digital health and serious-games literature, showing positive perceptions of immersive technologies among end users [6,7,20]. Taken together, and interpreted in light of wide CIs, these findings provide preliminary evidence that immersive XR-based visualization is acceptable to patients undergoing orthodontic treatment and merits further, more rigorous evaluation.

Comparison With Prior Work

Patients consistently highlighted interactivity, 3D visualization, and enjoyment as strengths of the VR consultation room. These impressions may have been supported by light gamified design features, such as stepwise task progression and immediate audiovisual feedback, which have been associated with improved engagement in educational settings [20,21]. Together, these features may support orthodontic communication by allowing patients to manipulate and inspect 3D dental models, an approach associated with improved spatial understanding relative to 2D formats in educational contexts [22]. This interpretation is consistent with prior orthodontic and dental literature emphasizing the importance of communication, visualization, and patient involvement in shaping the treatment experience [1,2], as well as with the broader serious-games and XR-in-health literature describing immersion and interactivity as drivers of engagement [20].

Our findings extend existing orthodontic XR research from professional education to patient-facing communication. Although previous orthodontic applications have primarily involved student education [15,16], and a recent scoping review identified patient engagement as an understudied use of XR in orthodontics [14], the favorable responses observed here are

XSL•FO
RenderX

broadly consistent with patient-facing dental VR studies involving cleft care education, toothbrushing instruction, and dental anxiety [11-13]. They also align with reports that immersive VR is acceptable across clinical populations, including users with little prior VR experience [6,7,23]. The present study differs from these applications by allowing patients undergoing orthodontic treatment to view and manipulate their own intraoral scan to understand their individual malocclusion. At the same time, the usability and motion-comfort barriers we observed echo those reported for immersive VR more generally [24,25]. Overall, the findings provide preliminary evidence that patient-specific immersive visualization is acceptable in an orthodontic setting, while not establishing that it improves knowledge more effectively than conventional 2D image records.

Interpretation

The study identified usability as an important implementation barrier. Although the overall experience rating was favorable, ease-of-use ratings were lower and more variable, suggesting that participants generally liked the experience but did not always find the system easy to use. This interpretation was supported by open-ended comments, which frequently referenced navigation difficulty, glitches, and motion-related discomfort. These observations likely explain why a subset of participants still preferred conventional 2D image records in the present setup and why preference for VR was higher under a hypothetically improved technology scenario. Prior VR literature has similarly identified usability, latency, and cybersickness-related discomfort as important barriers to immersive VR uptake [24], and qualitative syntheses report that users often tolerate such discomfort when they find the experience valuable [25]. Motion-related discomfort was uncommon and mild in this sample, with no early discontinuations, which is reassuring for feasibility; however, both reports occurred in participants aged 25 years or older. Because this subgroup was very small and age was analyzed only descriptively, no age effect can be inferred, and these observations should not be equated with findings from older-adult VR populations. General motion-comfort strategies, such as seated experiences, attention to session duration, and comfort-oriented locomotion, may be worth considering in future iterations [26]. However, the present data do not support age-based recommendations. Future development should prioritize interface simplification, system responsiveness, latency reduction, and mitigation of motion discomfort and should incorporate validated usability and presence instruments, such as the System Usability Scale, and a standardized cybersickness measure, such as the Simulator Sickness Questionnaire.

The preference findings in particular should be read as an acceptability signal rather than evidence of superiority. Preference for VR may reflect its perceived value, the novelty of an unfamiliar technology for most participants, and the appeal of interactive 3D visualization, as much as the intervention itself; order and novelty effects of this kind are well documented in immersive VR and can inflate short-term preference [27,28]. In addition, because continuous narration, stepwise prompts, and audiovisual feedback were delivered alongside active model manipulation, the experience cannot determine whether narration supported learning or competed for attention, consistent with split-attention and redundancy effects described in multimedia-learning and cognitive-load research [29]. The design features underlying these cautions, and the comparators needed to address them, are considered in the *Limitations* section.

Limitations

This study should be interpreted as a feasibility and acceptability investigation, and several limitations should be considered. First, the sample size was modest (N=28), and the study was conducted in a single university orthodontic clinic, so generalizability is limited. The single-arm feasibility design and modest sample size precluded inferential testing or formal hypothesis evaluation; a retrospective power analysis was not performed because such analyses are not informative for already-completed studies. Instead, the present data are intended to inform sample size and effect size assumptions for a future controlled trial. Second, recruitment used consecutive convenience sampling with participation contingent on patient availability and willingness, introducing potential self-selection bias. Formal records of the number of patients approached and those who declined participation were not prospectively recorded. Third, VR was always experienced after participants' routine prior exposure to conventional 2D image records, creating a fixed order, and the experience was novel for most participants; both order and novelty effects can inflate short-term preference; therefore, a counterbalanced or crossover design would be needed in future work to compare preferences reliably. Fourth, the study did not include an interactive flat-screen 3D comparator, so it cannot determine whether immersion specifically, rather than 3D interactivity in general, drove the favorable ratings; a future arm using an interactive flat-screen 3D model, ideally using each patient's own scan, would isolate the contribution of immersion.

Fifth, the questionnaire was investigator-developed and was not formally validated; standardized usability, presence, and cybersickness instruments were not administered. No objective knowledge-gain measures were administered; therefore, the findings support acceptability, perceived educational value, self-rated experience, self-rated ease of use, and self-reported preference only, and not learning effectiveness or superiority. Sixth, no baseline knowledge was assessed before VR exposure, so perceived educational value cannot distinguish new learning from confirmation of prior understanding. Seventh, the forced-choice preference items did not allow participants to indicate equal preference, no preference, or uncertainty, which may have overstated the apparent strength of preferences. Eighth, the postexperience survey was completed with the supervising investigator present, introducing potential social-desirability bias. Ninth, although age and sex were recorded, the sample size was too small to support robust inferential subgroup analyses, and age-related findings should be interpreted as exploratory and descriptive. Finally, the comparison with conventional 2D image records was a self-reported preference rather than a controlled comparison. Therefore, future studies should incorporate pretest-posttest designs, validated patient-reported outcome measures, validated XR usability and cybersickness instruments, and direct

XSL•FO
RenderX

comparisons with established educational approaches and variations in narration load alongside interaction.

Conclusions

Patients undergoing orthodontic treatment in this cross-sectional feasibility and acceptability study were generally receptive to an immersive VR consultation room that presented each patient's own intraoral scan models for patient education in orthodontics. Most participants believed that VR could help patients better understand their teeth and orthodontic treatment, and many valued its interactivity, 3D visualization, and engaging format. This study is novel in evaluating patient-facing immersive VR specifically within orthodontics—an application that remains understudied relative to VR training for students and clinicians. However, usability issues, motion discomfort, and technical limitations remain important barriers to broader adoption. Because the design was single arm and the comparison with conventional 2D image records reflected self-reported preferences rather than a controlled comparison, the results should be regarded as preliminary and hypothesis-generating rather than evidence of educational effectiveness. If these acceptability signals are confirmed in more rigorous studies, immersive VR may have a practical role as an adjunct to orthodontic patient communication, supported by future controlled studies that incorporate validated usability, presence, and cybersickness instruments and objective measures of knowledge gain.

Acknowledgments

The authors thank the patients undergoing orthodontic treatment who participated in this study and the staff of the University of Southern California Orthodontic Clinic for their support with study recruitment. No generative AI tools were used in any part of the preparation of this paper.

Funding

The authors declared that no external financial support was received for this work. Internal support was provided by the University of Southern California Department of Orthodontics Research Fund. No funding or other support was received from the commercial products used in this research.

Data Availability

The datasets generated and analyzed during the current study are not publicly available because participant survey responses contain potentially identifying contextual information collected at a single clinical site. Deidentified summary data are available from the corresponding author upon reasonable request, subject to approval by the University of Southern California Institutional Review Board.

Abstract

Background: As survival rates for children, adolescents, and young adults with cancer improve, managing treatment-related side effects is increasingly important. Enhancing physical activity levels has been shown to be effective in reducing some of these effects. Digital interventions, such as mobile apps, offer engaging tools to promote physical activity in young populations.

XSL•FO
RenderX

Objective: This article introduces the "FORTEe Get Strong" app (Nurogames GmbH) and presents a formative evaluation of its acceptability among children, adolescents, and young adults with cancer.

Methods: The "FORTEe Get Strong" app was developed within the multicenter FORTEe trial. Grounded in behavior change theories, the app uses gamification to deliver a child-friendly platform promoting physical activity and health-related knowledge. An embedded mixed methods design, with qualitative insights contextualizing quantitative findings, was applied. User experience was assessed using a self-developed questionnaire combining Likert scale items (1 - 5: "not at all satisfied" to "very satisfied," 1 - 3 for participants aged <8 y) and open-ended questions. Quantitative data were analyzed descriptively and inferentially, including chi-square tests for differences in app usage by age, sex, and diagnosis, and Kruskal-Wallis tests to compare app feature ratings between age groups. Free text responses underwent qualitative content analysis.

Results: The app was published in May 2023; it integrates gamified features to teach health knowledge. Exercise videos address endurance, strength, flexibility, coordination, and gait. Feedback on user experience was provided by 53 patients aged 5 - 19 years (mean 11.4, SD 3.8 years, 95% CI 10.4 - 12.5; 27/53, 51% male). App use did not differ significantly by age groups (χ^2_3=5.1; *P*=.16; Cramer V=0.135), sex (χ^2_1=3.4; *P*=.06; ϕ=0.110), or diagnosis (*P*=.54; Cramer V=0.168). The app was generally well-received, with a mean Likert scale score of 4.14 (SD 1.04, 95% CI 3.84 - 4.43). For individual components, mean scores ranged from 3.52 (SD 1.44, 95% CI 3.09 - 3.95) for exercise content to 4.37 (SD 0.82, 95% CI 4.14 - 4.60) for design. Kruskal-Wallis tests revealed no significant differences among age groups. Qualitative analysis identified key categories regarding overall app evaluation, specific features, target group perception, usability, and suggestions for improvement. While participants highlighted the app's design and gamification, concerns arose regarding age-appropriateness, lack of supervision, and adaptability of exercises.

Conclusions: This study provides novel insights into user experience of children, adolescents, and young adults with cancer with a gamified exercise and health education app. Unlike previous studies focusing on survivorship, this evaluation offers a comprehensive understanding of how digital tools can support patients in maintaining physical activity during intensive treatment. Apps with interactive, gamified elements may complement clinical care by providing low-threshold access to exercise and health education. The findings advance the field by identifying key facilitators and barriers to engagement. Future research should assess adherence, behavioral outcomes, and effectiveness in larger samples to inform clinical implementation.

Trial Registration: ClinicalTrials.gov NCT05289739; https://clinicaltrials.gov/study/NCT05289739

KEYWORDS

childhood cancer; exercise; oncology; serious game; gamification; mHealth; mixed methods study; mobile phone

Introduction

Cancer is the leading cause of disease-related death among children, adolescents, and young adults. Approximately 14,000 new diagnoses were estimated in Europe in 2022 in children, adolescents, and young adults aged 0 to 19 years. Advances in treatment have significantly improved survival rates, leading to a survival rate of 81% in the mentioned age group [1]. However, this remarkable improvement in survival rates underscores the growing importance of addressing the short and long-term side effects [2,3]. Side effects can include fatigue, muscle weakness, reduced mobility, and long-term effects, such as cardiovascular diseases and metabolic disorders [2,3]. Exercise programs may offer an effective approach to addressing these issues [4]. Various studies demonstrate that exercise interventions can enhance physical aspects, such as muscle strength [5-7] and endurance capacity [5,7], as well as psychosocial outcomes, such as cancer-related fatigue [5,8] and quality of life [9,10]. Given the considerable side effects associated with the diagnosis and treatment of cancer, there is an urgent need for innovative, motivational, and age-appropriate interventions to support young patients in their physical activity and to counteract the observed side effects [11].

The increasing integration of digitalization and mobile technologies into everyday life has profoundly accelerated the use of digital tools in various domains of health promotion, including encouraging physical activity [12-15]. Among young populations, digital interventions, such as mobile apps, have become an effective and engaging tool to promote health-related behaviors [16,17]. A substantial number of these so-called mobile health (mHealth) apps designed for children, adolescents, and young adults target a variety of health outcomes, most notably physical activity [16,17].

To ensure the effectiveness of these digital interventions and to keep users motivated to engage in health-related behaviors, it is crucial to understand the mechanisms and design features that drive behavioral change, particularly in young populations. In this context, Baumann et al [16] highlight the efficacy of gamified approaches in promoting physical activity and reducing sedentary behavior in children, adolescents, and young adults, providing that these interventions are supported by individualization, a robust theoretical framework, and the integration of behavior change techniques. The role of social connections, including family, peers, and the wider community, is identified as a key factor influencing the success of mHealth strategies, demonstrating the need for interventions tailored to developmental stages and specific needs to reduce physical inactivity and sedentary behavior. Complementing this, Ghosh et al [18] investigate critical app design features that increase continued engagement and behavioral impact among

XSL•FO
RenderX

adolescents. These include user-friendly and aesthetically appealing interfaces, personalized goal-setting, comprehensive data tracking, and access to educational content, such as exercise recommendations and nutritional advice. Additionally, the integration of electronic health records has the potential to facilitate data sharing with health care providers, and gamification and social interaction components are known to enhance intrinsic motivation and lead to a sense of group belonging [18]. The findings emphasize the importance of theoretically grounded and thoughtfully designed mHealth interventions in achieving substantial and lasting health-related behavior improvements in young populations.

The Europe-wide, multicenter FORTEe trial (Get strong to fight childhood cancer – An exercise intervention for children and adolescents undergoing anti-cancer treatment) aims to implement exercise as a therapy and increase physical activity using digital approaches in children, adolescents, and young adults with cancer. As part of the trial, the "FORTEe Get Strong" app (Nurogames GmbH) was developed with the primary aim of engaging children, adolescents, and young adults with cancer in physical activity and secondarily to teach health-related behaviors. Details of the study design have been published previously [19].

Despite growing evidence on mHealth solutions for young populations, little is known about how children, adolescents, and young adults with cancer themselves perceive such apps and which refinements might be necessary to support long-term engagement. Addressing these gaps requires both quantitative assessments of user experience and qualitative insights into individual needs and expectations. Therefore, the objectives of this article are to (1) introduce the "FORTEe Get Strong" app and describe its design and development, and (2) present a formative mixed methods evaluation assessing the app's acceptability in a sample of children, adolescents, and young adults with cancer. The aim is to evaluate user experience ratings quantitatively and explore user perceptions qualitatively to contextualize the quantitative findings. Finally, both strands are integrated in a formative mixed methods evaluation, with the qualitative findings providing insight into, and helping to interpret, the quantitative data.

Methods

App Development

Overview

The "FORTEe Get Strong" app represents a component of the overall FORTEe exercise intervention, facilitating the transition from supervised, hospital-based training to self-directed exercise at home. The mobile app was developed by scientific and clinical experts of the FORTEe consortium and engineered by Nurogames GmbH. Nurogames GmbH is a software development company with expertise in creating games that, in addition to their entertainment value, contribute to the investigation of specific topics and the generation of scientific knowledge. To ensure the app resonated with its target group, patient representatives were actively involved in the design process. Feedback from patient interviews regarding their preferred theme and avatar design was essential in understanding patients' wishes and creating an appealing and relatable design. The app has been translated into 7 languages (Danish, English, French, German, Italian, Slovenian, and Spanish) for use on Android (Google LLC) and iOS (Apple Inc) devices. It is freely available for download from the App Store (Apple Inc) and Google Play Store (Google LLC), respectively.

Theoretical Framework

The development of the app is based on a combination of the social cognitive theory (SCT) [20] and self-determination theory (SDT) [21]. SCT explains the interaction between personal factors, environmental influences, and behaviors, emphasizing the importance of self-efficacy, an individual's belief in his or her ability to succeed. This belief influences goals, outcome expectations, and behavioral adoption, with environmental facilitators and barriers shaping these processes. The app's integration of evidence-based exercise and other health-related content (eg, on healthy diet) is intended to enhance self-efficacy in patients with cancer, enabling them to set meaningful goals, create actionable strategies, and develop skills to engage in regular physical activity [20,22,23]. SDT highlights the importance of fulfilling the psychological needs for autonomy, competence, and relatedness to enhance intrinsic motivation. When these needs are met, individuals experience greater autonomous motivation, leading to sustainable behavior change. For instance, gamification features (eg, a customizable avatar and interactive quizzes) may enhance relatedness and competence, while allowing patients to select and adapt activities to their preferences and individual needs may increase autonomy [21,23,24]. Behavior change techniques, like SCT and SDT, have previously been implemented as a guideline for an innovative mobile app designed for children, adolescents, and young adults with cancer in a study by Fuemmler et al [23]. While initial evidence for actual behavior change in that study was limited, the intervention demonstrated feasibility, positive user engagement, and overall favorable reception, supporting the use of theory–based strategies as a guiding framework for developing our app.

Data Protection

For data protection reasons, no personal data (eg, duration or frequency of app usage) is processed in relation to the use of the "FORTEe Get Strong" app due to its implementation in a clinical setting. The data attained in the app are stored exclusively on the local device. Upon uninstallation, the app is restored to its original factory settings. As such, it does not collect or process personal data, nor does it facilitate the transfer of health information, such as electronic health records.

App Design, Content, and Functionality

The app's gamification is characterized by a playful aesthetic, focusing on incentivizing physical activity as a health promotion strategy and directly providing access to individually tailored exercises. The purpose of the design of the app is to raise awareness of the importance of regular physical activity during cancer treatment and to promote intrinsic motivation for continued use of the mHealth app [18,25]. In accordance with the recommendations by Ghosh et al [18], the objective was to

XSL•FO
RenderX

provide simple and accessible guidelines for various exercises, thereby empowering young users to engage in independent physical activity and support self-efficacy. The exercises were developed by the Network Active-Onco-Kids and compiled in collaboration with exercise professionals from the FORTEe consortium, ensuring their adaptation to the needs of young patients with cancer. The compilation of all educational content, as well as the exercises themselves, was undertaken by a group of scientific researchers, as well as Network ActiveOncoKids and Youth Cancer Europe, and in line with preliminary German exercise guidelines in pediatric oncology [26], with the objective of providing content that is evidence-based, freely accessible, and easily comprehensible. To further support the gamification characteristics of the app, as recommended by Fuemmeler et al [23], Baumann et al [16], and Ghosh et al [18], various mini-games are integrated in the app. To enhance motivation and thereby support continued app use, patients are encouraged through a system of rewards to engage with the extensive knowledge content and to participate in the provided exercise sessions on a regular basis.

Evaluation of the App

Study Design and Rationale

As part of the FORTEe trial, the aim of this article is to conduct a formative evaluation of the mHealth "FORTEe Get Strong" app and gain insights into the experiences of children, adolescents, and young adults with cancer. This study represents a subproject and thus a secondary analysis within the overall FORTEe trial. This study adhered to the Mixed Methods Reporting in Rehabilitation and Health Sciences checklist (Checklist 1) [27].

A mixed methods approach was chosen in order to provide a comprehensive evaluation of the app, by combining quantitative and qualitative data. Quantitative data, such as user numbers and structured app ratings, capture levels of adoption and satisfaction and enable comparison across participant groups. Complementary qualitative analysis of open-ended responses adds depth by explaining why users rated the app as they did, highlighting specific usability issues and perceived benefits, and suggesting improvements. The embedded design, in which qualitative insights help explain and contextualize quantitative findings, allows both strands to complement each other, increasing the interpretability of user experiences and guiding targeted app refinements. Therefore, a self-developed questionnaire was administered between May 2023 and February 2025 with patients who participated in the randomized controlled FORTEe trial (prospectively registered on March 21, 2022). A self-developed tool was used as no existing validated instrument covered the specific app features that were intended to be assessed. Participants either responded in an interview format or answered the questions independently in written form. The interviews were not recorded. As the questionnaire or interview guidance was exploratory and context-specific, no formal psychometric validation was conducted. However, the items were reviewed and refined by pediatric oncologists (n=2) and exercise experts (n=4) on criteria including clarity of wording and developmental appropriateness. In order to minimize the influence of parents or study staff, participants were encouraged to respond independently. Parents or study staff were only permitted to provide clarification when necessary. Whenever feasible, participants were seated separately from their parents to support independent responding. The English version of the questionnaire is provided as Multimedia Appendix 1.

The integration of quantitative and qualitative data, expert review of the questionnaire or interview guidance items, and the standardized administration procedures used were intended to ensure methodological rigor and enhance the credibility and trustworthiness of the findings.

Participants and Recruitment

Participants were recruited within the multicenter FORTEe trial [19]. Patients were eligible if they had been diagnosed with cancer according to the International Classification of Childhood Cancer, Third edition, were between 4 and 21 years of age, and received chemotherapy and/or radiotherapy at one of the FORTEe trial sites. Participants for the app evaluation were purposively sampled from the FORTEe trial cohort, as they were the intended users of the "FORTEe Get Strong" app and could provide relevant insights into its acceptability and usability. The questionnaire has been performed at all participating recruitment centers of the FORTEe trial—University Medical Center of the Johannes Gutenberg-University Mainz, Childhood Cancer Center, Mainz (Germany); Fondazione Monza e Brianza per Il Bambino e La Sua Mamma, Monza (Italy); School of Sport, Nutrition and Allied Health Professions, Oxford Brookes University, Oxford (United Kingdom); Heidelberg University Hospital and National Center for Tumor Diseases, a partnership between DKFZ and University Medical Center Heidelberg, Germany, Department of Medical Oncology, Working Group Exercise Oncology, Heidelberg (Germany); Center de Lutte Contre le Cancer Léon Bérard, Lyon (France); Department of Pediatrics and Adolescent Medicine, Copenhagen University Hospital, Rigshospitalet, Copenhagen (Denmark); Universidad Europea de Madrid, Faculty of Medicine, Health and Sports, Department of Sport Sciences, Madrid (Spain); Research Institute of the Hospital 12 de Octubre ('imas12'), Madrid (Spain); University Hospital Essen, West German Cancer Center, Essen (Germany); Fondazione IRCCS Istituto Nazionale dei Tumori, Pediatric Oncology Unit, Milan (Italy); and University Medical Center Ljubljana, Ljubljana (Slovenia) in cooperation with Forma 3D Ltd, Ljubljana (Slovenia).

Ethical Considerations

The FORTEe study protocol and all related documents were approved by the Ethics Committee of the Medical Chamber of Rhineland-Palatinate (application 2021 - 15904 on August 4, 2021) as well as the local ethics committees of all FORTEe trial sites and reviewed by the local data protection officer. Written informed consent was obtained from all participants, or from their legal guardians in the case of minors. Where possible, documented assent was collected from children aged 6 years and older. All participant data were pseudonymized before analysis. Identifying information was accessible only to authorized study personnel, safeguarding privacy and confidentiality. Participants in this evaluation did not receive any financial or material compensation. All procedures adhered

XSL•FO
RenderX

to the principles outlined in the Declaration of Helsinki. Neither the paper nor the supplementary materials contain images of the study participants. Any individuals depicted are nonparticipant staff members, and it is not possible to identify individual study participants.

Method of Assessment

Overview

The questionnaire was designed to gather participants' perspectives regarding their use of technology. With regard to the "FORTEe Get Strong" app, it included questions about user satisfaction with the app as a whole, the design of the app, the FORTEe avatar, the range of exercises, the FORTEe quiz, the knowledge content included and the app's user-friendliness. The interviews were conducted by local exercise professionals with experience in pediatric oncology in their native language and translated into English language for further analysis. Their previous understanding of childhood cancer treatment and exercise interventions informed probing questions, while efforts were made to minimize bias by following standardized guidelines and allowing independent participant responses. To further support comprehension, interviewers followed standardized guidelines that allowed them to adapt the wording of items to the developmental level of the participants while preserving the original meaning.

Assessment of Quantitative Data

The quantitative component of the evaluation consisted of questions presented on a 5-point or 3-point Likert scale, depending on the age of the participant. The response options ranged from "not at all satisfied" to "very satisfied" and were illustrated by child-friendly emojis. The 3-point scale, developed for use of participants under the age of 8 years, included only the response options 1 ("not at all"), 3 ("somewhat"), and 5 ("very much"). The 5-point scale, which includes the additional options 2 ("hardly") and 4 ("quite a lot"), is used by participants aged 8 years and older. This age-differentiated scaling approach was chosen because it provides younger children with fewer, more distinguishable response categories [28-31].

Assessment of Qualitative Data

Furthermore, participants were invited to provide additional comments regarding their thoughts on the "FORTEe Get Strong" app in an open-ended format, allowing for qualitative analysis of their individual experiences and perceptions.

Study Size

This formative evaluation was embedded within the main FORTEe randomized controlled trial. No separate power calculation was performed for this app evaluation. The overall FORTEe trial included an a priori sample size calculation for the primary outcome (cancer-related fatigue), targeting 450 participants [19]. The sample for this evaluation comprises FORTEe participants who took part in the app evaluation during the data collection period.

Data Analysis

Overview

The ages of the participants were recorded as continuous variables and subsequently grouped into 4 predefined categories to enable group-based comparisons. According to Sawyer et al [32], chronological age boundaries are both arbitrary and context-dependent, varying according to cognitive, social, and cultural factors. For the FORTEe trial and therefore for the "FORTEe Get Strong" app, age groups were defined based on cognitive development, literacy, and school-related competencies, in order to ensure age-appropriate interaction and consent procedures. The age groups are (1) 4 - 5 years (preschoolers), (2) 6 - 11 years (school children), (3) 12 - 16 years (adolescents), and (4) 17 - 21 years (young adults) [19].

Analysis of Quantitative Data

For quantitative analyses, descriptive continuous variables are expressed as mean values with SDs and 95% CIs, while categorical variables are presented as the actual number of participants, accompanied by the corresponding percentage. For analysis and visualization, responses from the 3-point scale (used for participants younger than 8 y) and the 5-point scale (used for participants aged 8 y and older) were combined, with equivalent points being interpreted as the same level of satisfaction. A chi-square test was performed to investigate whether app usage differed across the defined age groups, sex, or diagnosis. If the assumption that the expected frequency in at least 20% of cells was less than 5 was violated, a Fisher-Freeman-Halton exact test was performed instead. A Kruskal-Wallis test was used to investigate possible differences in the evaluation of individual app features by age group. The significance level was set at 5%.

Analysis of Qualitative Data

Complementing the quantitative evaluation, qualitative content analysis, as outlined by Mayring [33], was used to facilitate a systematic examination of the free-text responses. A pragmatic interpretive approach guided the analysis, focusing on understanding participants' experiences and perceptions of the app in context. The objective was to categorize the responses and record the frequency of occurrence. A repeated review of all responses was conducted to identify key themes, and categories were formed inductively. The process of open coding was used to extract the recurring themes and group them into overarching categories. This was performed independently by 2 researchers (MK and LW), and discrepancies were resolved through discussion. The categories identified reflect the principal topics addressed in the free text responses. Categories were developed inductively, ensuring consistent interpretation across the dataset. A quantitative analysis was then conducted, counting the frequency with which each category appeared in the responses. This provides an initial approximation of the relative importance of the different topics.

Mixed Methods Integration

Finally, both data strands were integrated using an embedded mixed methods design, in which quantitative data provided an overview of adoption and satisfaction, and qualitative insights helped explain and contextualize the quantitative findings. This

XSL•FO
RenderX

approach allows the complementary strengths of both methods to reinforce the conclusions, while acknowledging their respective limitations. The integrated analysis enables a richer interpretation of the results and informs targeted app refinement and implementation strategies, illustrating the added value of using a mixed methods design.

The descriptive statistical analyses were conducted using IBM SPSS (version 27), while qualitative content analysis was carried out using Microsoft Excel (version 2016, 16.0.5474.1002). The graphs were created with R statistical software (RStudio; version 2024.09.1).

Results

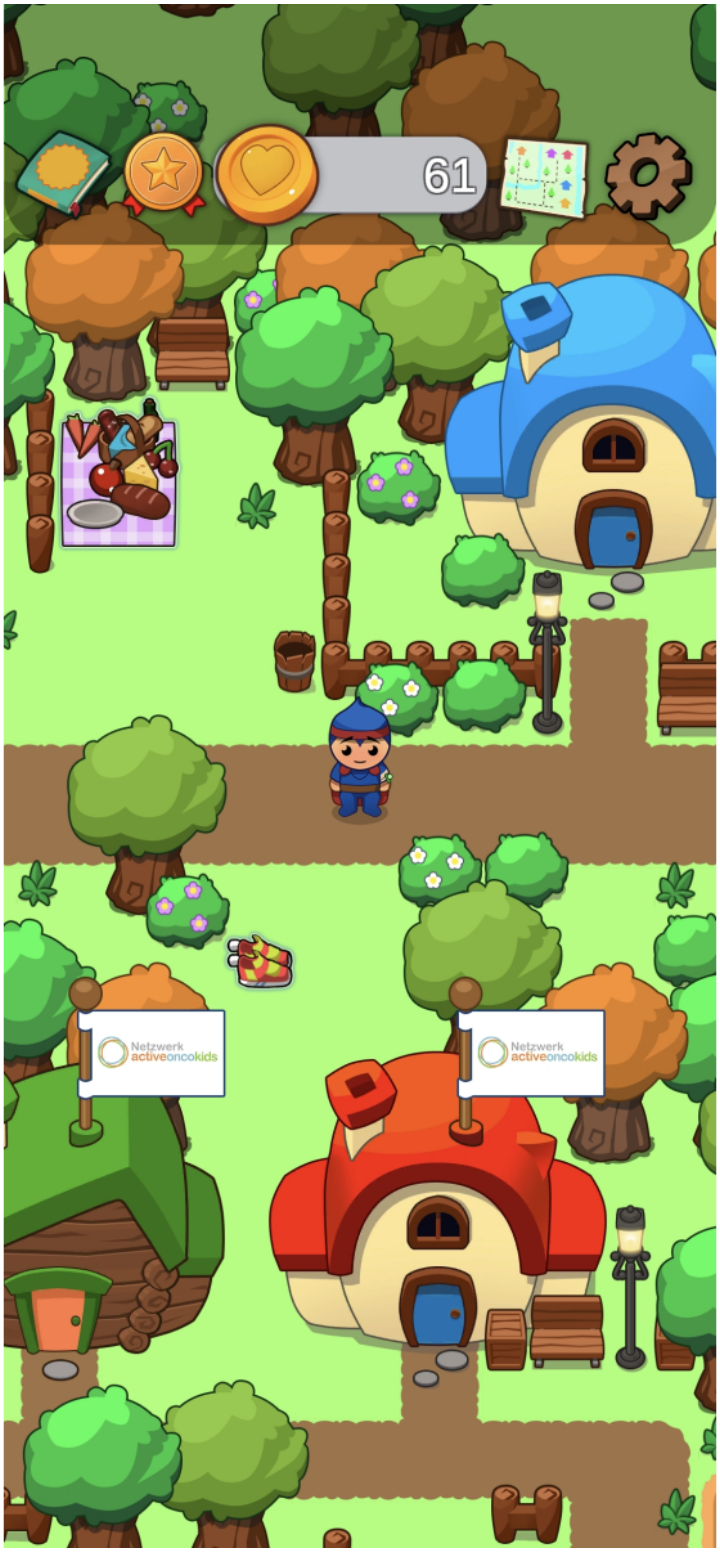
The App Development

Overview

The "FORTEe Get Strong" app (Figure 1) was published in May 2023 for use on Android (Google LLC) and iOS (Apple Inc) devices and is now freely available for download from the App Store (Apple Inc) and Google Play Store (Google LLC). Minor technical updates were made to the "FORTEe Get Strong" app during the evaluation period. These included correcting language inconsistencies, optimizing in-app texts, and resolving minor software bugs. The following versions were released, used, and evaluated by participants—version 1.0.1, version 1.1.1, and version 1.1.2. As all versions were functionally identical in terms of content and user interface, they were evaluated collectively.

XSL•FO
RenderX

Figure 1. The “FORTEe Get Strong” app.

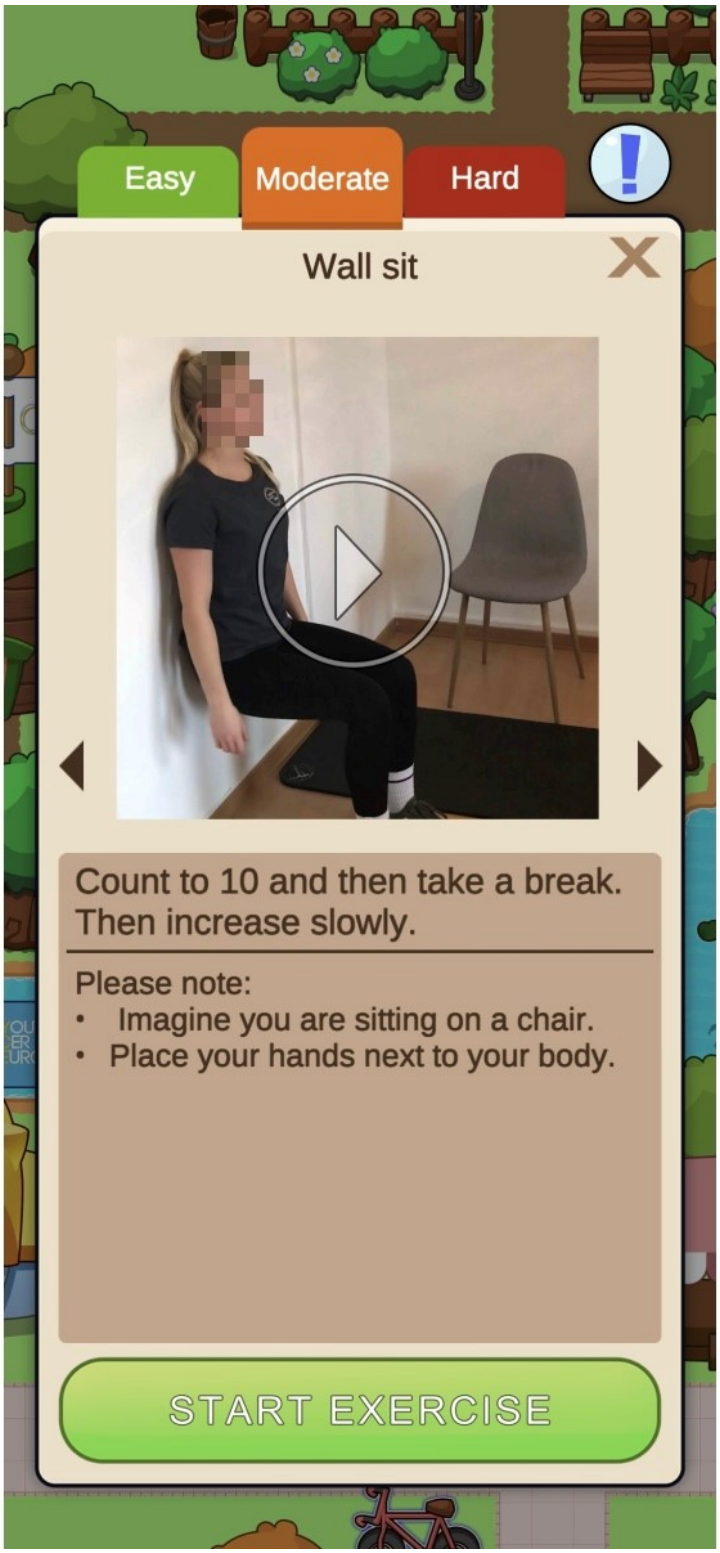


App Design, Content, and Functionality

The child-friendly app enables users to access a virtual environment, the FORTEe village (Figure 2). Within this virtual space, users can navigate their own avatar through a bright and colorful world containing educational content and entertaining facts focusing on physical activity and providing a range of exercises to improve different physical fitness components. The avatar includes features such as an infusion needle, bandage, alopecia, and a superhero cape, symbolizing the experiences of children and adolescents with cancer and fostering a sense of identification and empowerment when using the app.

XSL•FO
RenderX

Figure 2. The FORTEe avatar can move around the FORTEe village, interact with the characters in the village, and can explore various health content.



The interaction with child-friendly characters living in the FORTEe village enables users to explore relevant knowledge regarding physical activity during cancer treatment, as well as general information on a healthy lifestyle in a playful way. The educational content is tailored for children, adolescents, and young adults with cancer and provides guidance on topics such as safe exercise during intensive treatment, changes in muscle strength, fall prevention, and healthy nutrition and an active lifestyle. This information is reinforced through quizzes and mini-games. Additionally, by visiting the FORTEe house or the numerous market stalls located in the village center, users can gather insights into the background of the app—the randomized controlled FORTEe trial.

The FORTEe village consists of a series of exercise houses, each designed to target physical fitness components, including endurance, strength, flexibility, coordination, balance, and gait. The exercises are presented as exercise videos, accompanied by instructions on correct execution and number of repetitions,

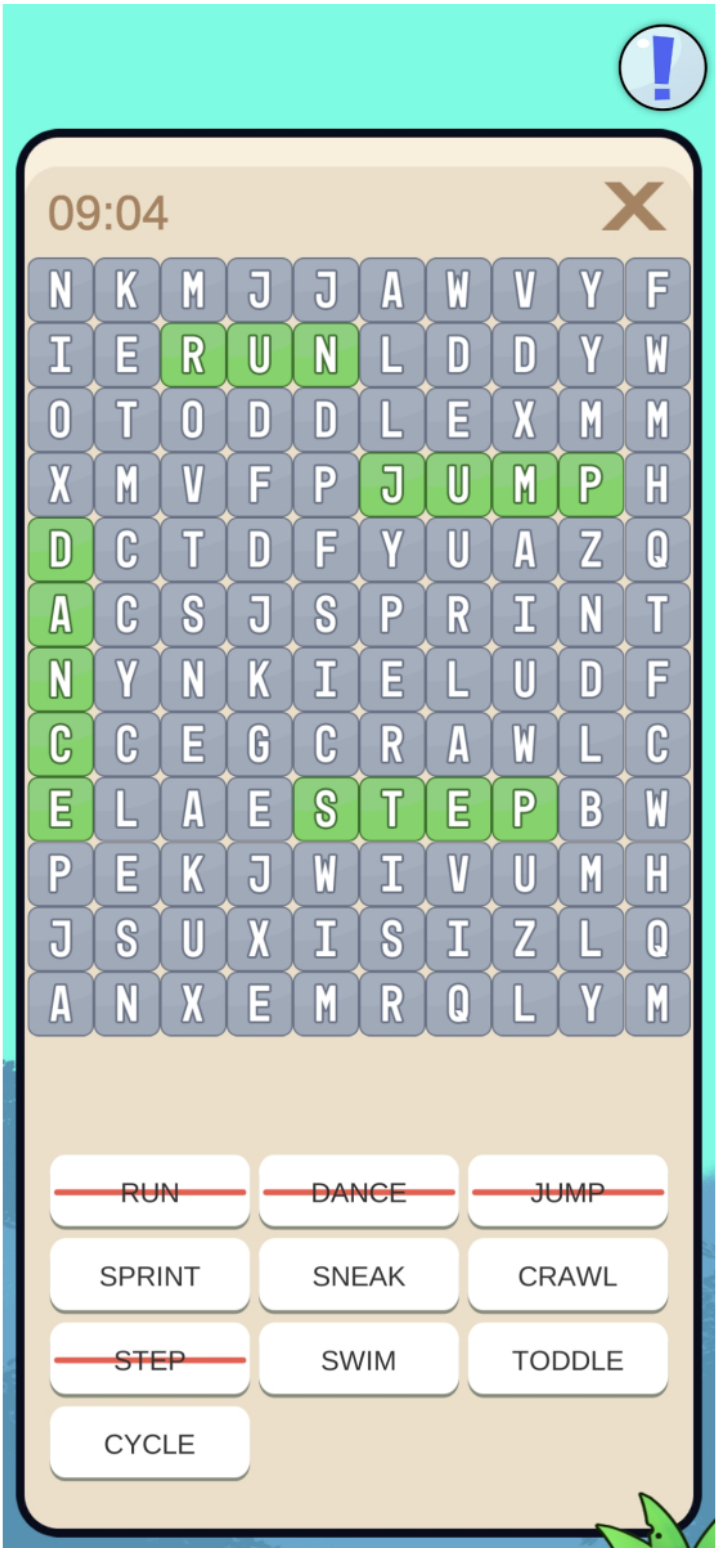
XSL•FO
RenderX

encouraging users to imitate and perform the demonstrated exercises themselves. The exercises are presented with a range of levels of difficulty, thus allowing for adaptation to the user's physical ability and current health status (Figure 3). Many exercises can be performed while sitting or lying down, enabling participation by patients with reduced mobility or an increased risk of falling.

Figure 3. The app offers different exercises for different functions, eg, strength exercises (such as "wall sitting" with video instructions) and different levels of difficulty.

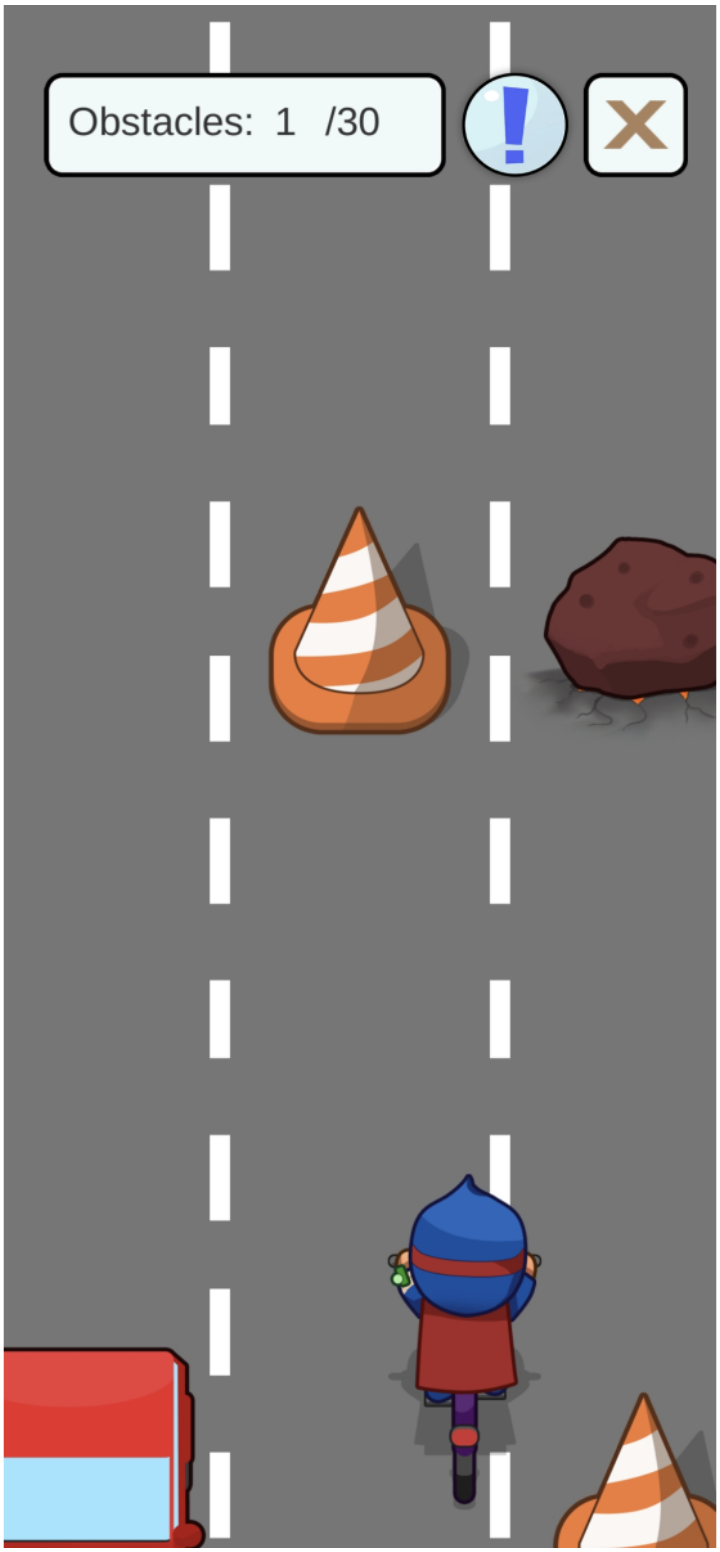
The app also provides various mini-games, including a FORTEe quiz (Figure 4), memory games, and others (Figures 5 and 6). Focusing primarily on physical activity, but also on a healthy diet, the mini-games are a fun way to introduce health-related topics and provide an insight into the FORTEe trial and the European partners involved in the study. By integrating the smartphone's gyroscope, some interactive exercises within the app require users to move or shake the device in specific

XSL•FO
RenderX



directions to complete simple in-game challenges. This feature transforms the smartphone into an active interface that requires physical motion, thereby playfully encouraging body movement. Finally, the app contains a “Parents” section that provides guidance on how to support their child in exercising safely during treatment. This section covers topics such as infection risk, postoperative activity, exercising with infusion stands, fall prevention, and information on peripheral neuropathy and bone metastases.

Figure 4. Dr Owls quiz is a fun way to learn about physical activity, exercise, and other health topics, as well as information about the FORTEe trial.

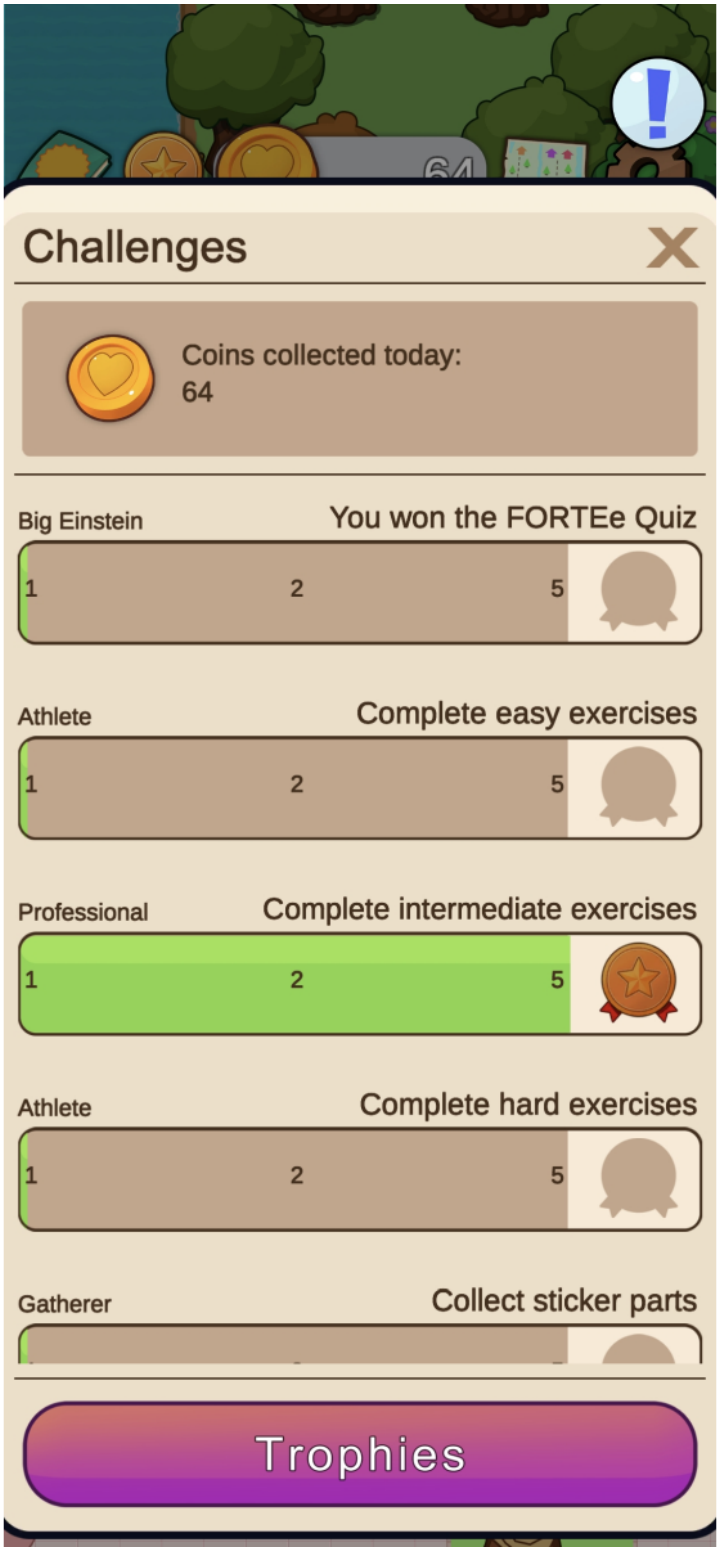


XSL•FO
RenderX

Figure 5. Other mini-games included in the app are a crossword puzzle, a memory game, and a nutrition puzzle.

XSL•FO
RenderX

Figure 6. Some mini-games also offer the option to use the gyroscope of the device to directly encourage movement. This allows users to engage in activities such as running, cycling, or surfing with their avatar, overcoming various obstacles, helping the avatar in picking apples from a tree, or guiding a frisbee through the air by moving, tilting, or shaking the phone.



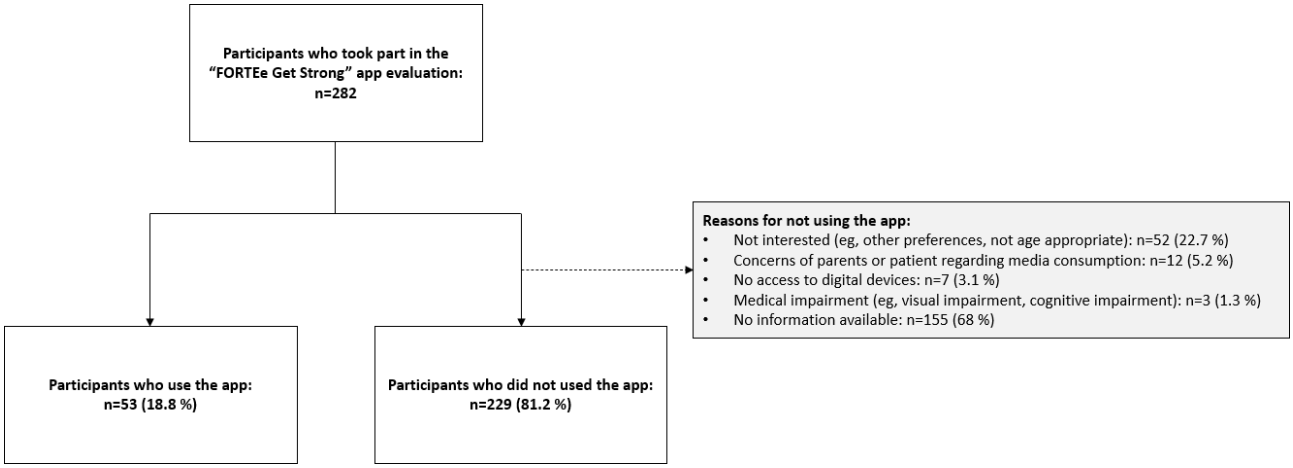
Patients are encouraged to use the app through a reward system. In addition to unlocking new content, patients will be rewarded with FORTEe coins, which can be used to personalize their avatar and customize their avatar's house. Various challenges also motivate exploration of the app and performance of exercise sessions. Completing challenges is rewarded with virtual medals and trophies that can be viewed in the trophy collection, to further enhance the extrinsic motivation of the users (Figure 7).

In the context of supervised exercise sessions at the FORTEe treatment centers, exercise professionals have the option of providing patients with a code as part of the rewarding system. These codes can be used in the app to unlock puzzle pieces, which, when assembled, yield engaging exercise-related images.

XSL•FO
RenderX

This feature aims to enhance patient engagement, thereby promoting active participation in the supervised sessions, while making the experience more appealing and gratifying.

Figure 7. Various FORTEe challenges with the intention to motivate users to interact with the app and engage with the rich health content and the reward system.



Evaluation of the App

Overview

A total of 282 participants took part in the evaluation regarding the “FORTEe Get Strong” app; thereof, 229 participants did not use the app. The reasons for not using the app are presented in Figure 8.

XSL•FO
RenderX

Figure 8. Participant flow in the evaluation of the "FORTEe Get Strong" app, showing user status and reasons for nonuse.

A total of 53 participants indicated having used the app and further provided detailed feedback. The number of responses varies between items because not all participants answered every question. Table 1 presents the characteristics of all participants who took part in the evaluation, as well as of those who used the app.

Group comparison analyses revealed no significant differences in app usage across age groups (χ^2_3=5.1; *P*=.16; Cramer V=0.135), sex (χ^2_1=3.4; *P*=.06; ϕ=0.110), or diagnosis (*P*=.54; Cramer V=0.168).

Patient Experience of the "FORTEe Get Strong" App

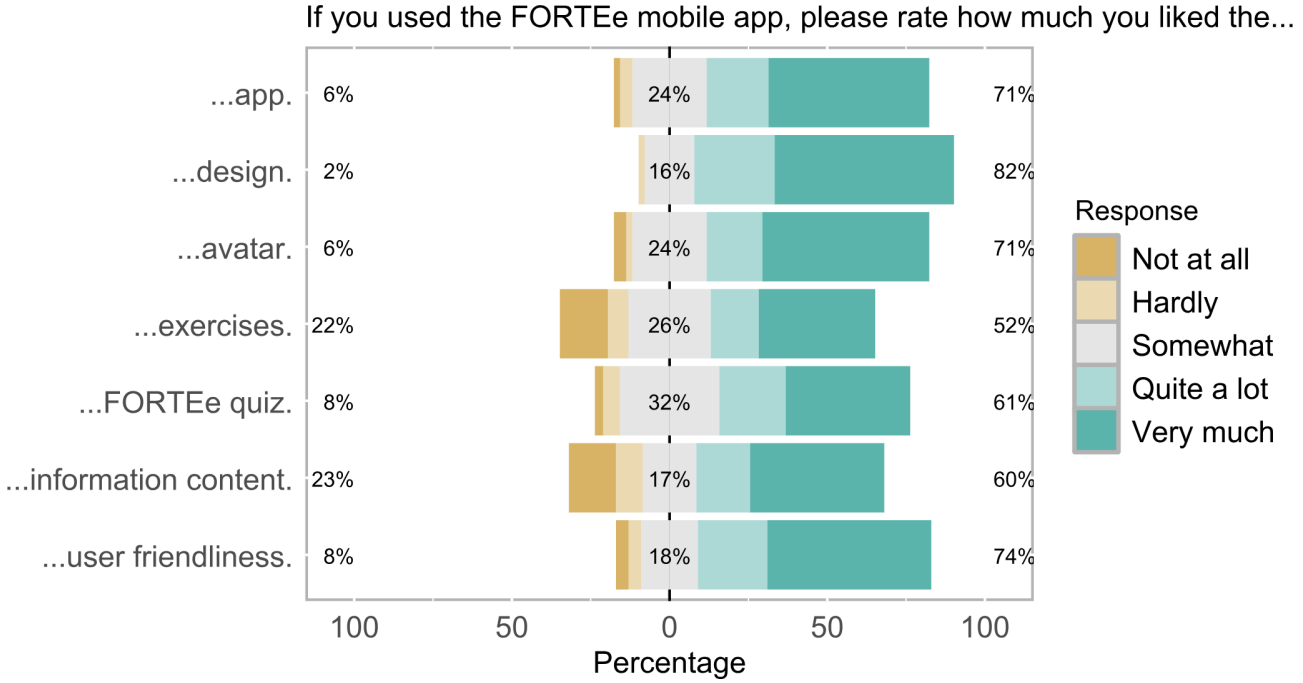
Results of the Quantitative App Evaluation

Overall, the "FORTEe Get Strong" app was well-received by the patients surveyed, receiving an average rating of 4.14 (SD 1.04) points out of 5 points. A clear majority of 71% (36/51) of participants gave the app an overall positive rating ("I liked the app quite a lot" or "I liked the app very much"), while only 6% (3/51) gave a negative rating ("I hardly liked the app" or "I liked the app not at all"). In particular, the design (mean 4.37, SD 0.82 points; 42/51, 82% positive ratings; 1/51, 2% negative ratings), the user-friendliness (mean 4.14, SD 1.11 points; 37/50, 74% positive ratings; 4/50, 8% negative ratings), and the avatar (mean 4.14, SD 1.10 points; 36/51, 71% positive ratings; 3/51, 6% negative ratings) were well-received. The quiz received an average rating of 3.89 (SD 1.07) points, with 61% (23/38) positive and 8% (3/38) negative feedback.

Opinions on the exercises and the informational content were more varied. Although more than half of the participants rated these features positively, nearly a quarter provided negative ratings. This represents a notably higher proportion of negative feedback than for the other app components. The average rating of the exercises was 3.52 (SD 1.44) points, with 52% (24/46) of participants rating the exercises positively and 22% (10/46) negatively. The informational content received an average rating of 3.64 (SD 1.48) points, with 60% (28/47) of participants giving positive ratings and 23% (11/47) giving negative ratings. Kruskal-Wallis tests revealed no significant differences in the evaluations of the various specific app features examined among age groups (Table 2).

The quantitative analysis demonstrated that the app was generally well-received, particularly in terms of its design, user-friendliness, and avatar. However, the ratings for exercises and informational content exhibited greater variability, with more than half of the participants providing positive ratings but nearly a quarter expressing negative feedback. Table 2 and Figure 9 present a summary of the quantitative rating of the app components.

Table . Results of the quantitative app evaluation, including comparisons across age groups[a,b].



If you used the FORTEe mobile app, please rate how much you liked the…	n	Mean (SD)	95% CI	H (*df*)	*P* value
…app.	51	4.14 (1.04)	3.84 - 4.43	1.66 (3)	.65
…design.	51	4.37 (0.82)	4.14 - 4.60	1.42 (3)	.70
…avatar.	51	4.14 (1.10)	3.83 - 4.45	1.42 (3)	.70
…exercises.	46	3.52 (1.44)	3.09 - 3.95	1.81 (3)	.61
…FORTEe quiz.	38	3.89 (1.09)	3.54 - 4.25	3.27 (3)	.35
…informational content.	47	3.64 (1.48)	3.20 - 4.07	2.56 (3)	.46
…user friendliness.	50	4.14 (1.11)	3.83 - 4.45	0.99 (3)	.81

[a]Values are presented as mean (SD) and 95% CIs.

[b]Group differences between age groups were analyzed using Kruskal-Wallis tests.

XSL•FO
RenderX

Figure 9. Results of the app evaluation. Participants rated various features of the "FORTEe Get Strong" app including the app in general, its design, the avatar, the exercises, the FORTEe quiz, the informational content as well as the user-friendliness rated on a scale from "Not at all" to "Very much." The percentages at the bottom show the distribution of ratings relative to the central reference point (0%), with negative values extending to the left and positive values extending to the right. The percentage of negative ratings ("I liked the app not at all" or "I hardly liked the app") is shown on the left (yellow), the percentage of neutral ratings ("I liked the app somewhat") is shown in the middle (gray), and the percentage of positive ratings ("I liked the app quite a lot" or "I liked the app very much") is shown on the right (green).

Results of the Qualitative App Evaluation

The qualitative analysis of the free text fields led to the identification of several central categories, such as (1) overall app evaluation, (2) evaluation of specific features (design, exercise content or app as a training tool, mini games, and informational content), (3) target group perception (age relevance), (4) app usability, and (5) suggestions for improvement, which summarize the experiences and opinions of the participants about the app. Thematic saturation was deemed achieved because responses repeatedly reflected the same set of themes, and no new categories emerged in the later stages of analysis. The main results are presented further in this study and in Table 3.

In total, 12 respondents provided additional positive feedback on the app in general, describing it as "very cool and fun" and said that the "app is nice during hospitalization," highlighting the opportunity to "use it offline." Moreover, 5 participants gave negative feedback, stating that the app had become uninteresting over time. With regard to the exercise content, patients (n=2) indicated that the exercises accessible via the app were beneficial. However, 5 patients stated that the range of exercises was less sophisticated than those offered in supervised settings and that they preferred to engage in exercise sessions with an exercise professional. In addition, 5 patients provided feedback on the design of the app, with 4 patients specifically mentioning the design of the avatar. However, 1 patient gave negative feedback on the design of the app. Furthermore, 2 patients provided comments on the mini-games, offering exclusively positive feedback. The feedback on the informational content of the app was mixed. One participant commented that the information about other centers was "nice to learn about," while 3 described the information as "too long" or stated that it was "more suitable for adults." Of the total, 7 patients provided feedback on the suitability of the app for their age group. The most common feedback from adolescents and young adults was that the app was perceived as more useful and engaging for younger children, or that the patients themselves felt that they were too old for the app. Moreover, 2 patients provided feedback indicating that the game control did not function as effectively as desired, and that "the app is not very intuitive to use." A total of 5 patients provided feedback on potential improvements to the app, giving both design-related suggestions and requests for additional features. Such suggestions included the addition of a chess game or a virtual fitness studio.

XSL•FO
RenderX

Table . Qualitative evaluation of the design and content of the "FORTEe Get Strong" app with main categories and subcategories to assess patient perspectives. Of the 53 patients included in the evaluation, 49 provided responses that could be assigned to the defined subcategories. Multiple responses per patient were possible, while some patients did not provide any feedback.

Main category and subcategory	Example quotes	Patients, n
Overall App evaluation		
General		
Positive	• "The app is very cool and fun." • "The app is nice during hospitalization." • "Especially during radios (no internet) I was able to use it offline"	12
Negative	• "It feels like it's not finished yet." • "The app got boring after a while."	5
Evaluation of specific features		
Design		
Positive	• "I liked the avatar." • "The avatar is cute."	4
Negative	• "I didn't like the design of the app."	1
Exercise content or app as a training tool		
Positive	• "I liked the exercises/workouts." • "The exercises are helpful."	2
Negative	• "The app's exercise offer is less sophisticated compared to other (supervised and supported) exercise offers." • "It is much more interesting to exercise with exercise professionals in real." • "The exercises are too easy."	5
Mini games		
Positive	• "I like the games, they are funny." • "The quizzes are nice."	2
Informational content		
Positive	• "It is nice to learn about other centers."	1
Negative	• "The information content of the app is more suitable for adults." • "The information about the other centers is too long."	3
Target group perception		
Age relevance	• "I am 20 years old and it is not funny for me. But nice idea for the youngest." • "Only a very small age group is suitable for the app." • "I like the games; they are funny, but more appropriate for younger children."	7
App usability	• "The avatar moves too slowly. The game control doesn't work well." • "The app is not very intuitive to use"	2
Suggestions for improvement	• "I would like the game design to be different, for example the first-person view of the player from the inside (more real)." • "You must add a chess game."	5

XSL•FO
RenderX

Mixed Methods Integration

The integration of quantitative and qualitative data provided a comprehensive understanding of users' experiences with the "FORTEe Get Strong" app. Quantitative findings indicated an overall positive evaluation. Qualitative findings from open-ended responses supported and expanded these results. Participants frequently described the app as "fun," "cool," and particularly useful during hospitalization, confirming the generally positive quantitative ratings. However, several users expressed different concerns, providing context for the variability observed in the quantitative ratings of some features. Taken together, the integration of quantitative and qualitative data revealed converging findings regarding the app's strong usability and appeal, while qualitative insights further clarified user preferences and contextualized the quantitative variability observed for certain app features.

Discussion

Summary

This mixed methods study aimed to (1) introduce and describe the development of the "FORTEe Get Strong" app, and (2) evaluate its usability, acceptability, and user experience among children, adolescents, and young adults with cancer participating in the multicenter FORTEe trial. The "FORTEe Get Strong" app was developed to promote physical activity and health awareness among children and adolescents with cancer, by including behavior change theory and gamification principles to foster motivation, engagement, and long-term participation in physical activity. By integrating quantitative patterns with qualitative explanations, the embedded mixed methods approach was used to provide a comprehensive understanding of user experience. The evaluation included data from 53 children, adolescents, and young adults with cancer who used the app within the FORTEe trial. The quantitative assessment revealed that the app was generally well-received, with high ratings for the app in general, the design, the user-friendliness, and the avatar. Ratings for exercise content and informational materials were more variable. Group comparison analyses revealed no significant differences in app usage according to age group, sex, or diagnosis. Similarly, there were no significant differences in evaluations of certain app functions among the 4 age groups. Qualitative content analysis of open-ended responses produced several themes, such as "overall app evaluation," "evaluation of specific features" (including "design," "exercise content or app as a training tool," "mini games," and "informational content"), and "target group perception" dealing with "age appropriateness," "app usability," and "suggestions for improvement." Participants described the app as "fun" and "cool," and found it particularly useful during hospitalization. However, feedback also highlighted limitations, including a perceived lack of supervision, limited adaptability of exercises, and concerns about age appropriateness. Overall, the findings of this mixed methods evaluation indicate that the app is usable, engaging, and well-received by children, adolescents, and young adults with cancer, while also highlighting clear directions for future refinement to enhance its motivational and educational value.

Synthesis With Existing Knowledge

The App Development: Theoretical Framework

From a theoretical point of view, the "FORTEe Get Strong" app integrates key elements of SCT [20], particularly observational learning and self-efficacy. Exercise videos demonstrating the correct performance of exercises allow users to learn by watching, while adjustable difficulty levels build confidence in their abilities. The app further applies SCT principles through reinforcement via gamified rewards, outcome expectations conveyed through educational content, and reciprocal determinism by providing an adaptive, feedback-driven environment that promotes autonomy, long-term engagement, and long-term behavior change [20]. However, a critical aspect of Bandura's framework [20], social modeling through peer or caregiver interaction [22], is lacking, primarily due to data protection restrictions. This hinders the app's ability to promote social reinforcement, a key element in facilitating behavioral change [20,22]. The app's alignment with SDT [21] is evident in its promotion of autonomy and competence. Users are given autonomy to choose their activities, customize their avatars, and set their own pace, giving them a sense of control and personal achievement. The structured and progressive nature of the exercise options, reinforced by clear instructions and a reward system, serves to enhance competence. However, the limited adaptability of the exercises in the app (only 3 difficulty levels) may restrict opportunities for individualized progression and thus only partially address the SDT need for competence [21,24]. Similarly, the lack of continuous supervision and real-time social interaction limits the extent to which the app can support the SDT need for relatedness [21,24]. While features that connect the supervised training as part of the FORTEe exercise intervention with digital rewards received in the app provide some connection, the lack of real-time social interaction with peers or caregivers limits the sense of connection and community, which is critical to developing long-term intrinsic motivation [21,24]. In comparison with the recommendations outlined by Ghosh et al [18] for mHealth apps targeting adolescents, the "FORTEe Get Strong" app effectively incorporates gamification, evidence-based educational content, and personalized exercise programs. However, it does not adequately address the need for social connectedness and individualized progression, which are highly valued by young people, caregivers, and health care providers. Moreover, the absence of ongoing supervision further limits opportunities for personalized feedback and adaptive guidance, both of which could strengthen users' sense of competence and relatedness. The app's limitations regarding opportunities for real-time interaction, personalized feedback, and peer engagement are primarily due to strict data protection regulations and the multicenter study design. This trade-off exemplifies the tension between maintaining high standards of data protection and implementing features that could potentially support behavioral change. While the app successfully upholds high data protection standards, these constraints, stemming from the requirements of a multicenter study and strict privacy regulations, made real-time supervision and more individualized adaptation infeasible. Future interventions could explore the integration of privacy-preserving methods for social modeling,

XSL•FO
RenderX

adaptive feedback, and individualized progression to better address all 3 SDT needs of autonomy, competence, and relatedness [21,24].

Evaluation of the App by Patient Representatives

Of the 282 participants who completed the survey, 53 reported using the "FORTEe Get Strong" app and provided detailed feedback. While the overall number of app users was relatively small, understanding the reasons for nonuse provides important context. A considerable number of patients indicated disinterest in the app as a digital tool, preferring supervised exercise sessions at the hospital or independent training at home. This highlights the challenge of addressing diverse user needs and preferences within a single digital health solution. Some participants also perceived the app as not age-appropriate. However, this perception was not entirely reflected in the usage data. Although 37% (104/282) of all respondents were school-aged children between 6 and 11 years old, nearly half of the app users (26/53, 49%) were in this age group. Descriptively, app usage appeared higher among younger participants; however, the chi-square test revealed no significant difference by age. Similarly, despite 60% (170/282) of all respondents being male, app users were evenly distributed between females and males, and no significant difference in app usage regarding sex was found. Compared with previous studies linking older age and female sex to higher engagement with mHealth apps among adolescents [34,35], our data revealed no significant effects of age or sex. Nevertheless, the perception of the app as being more suitable for younger children may have reduced uptake among older adolescents, despite the absence of statistically significant age effects. Some parents also expressed concerns about increased media consumption resulting in their children not using the app. Those concerns are understandable, as excessive media consumption in children and adolescents can be associated with negative effects on sleep, attention, and learning, as well as higher incidence of obesity and depression [36]. In order to overcome these challenges, app developers must find the right balance by designing tools that limit passive screen engagement and encourage active participation. Transparent communication with caregivers about the purpose of the app as a facilitator of healthier habits, rather than a replacement for physical activity, remains critical. By promoting trust and addressing parental concerns, the app can serve as a valuable resource to support the health and well-being of children, adolescents, and young adults with cancer.

Given the wide range of cancer entities, a small number of patients were unable to use the app due to medical reasons, such as vision impairments or cognitive deficits. Despite efforts to develop a tool tailored to the needs of children, adolescents, and young adults with cancer, addressing the diverse diagnoses and associated limitations remains challenging. Future adaptations, such as audio feedback or caregiver guidance, could enhance accessibility and inclusion for this subgroup of patients, ensuring broader usability and engagement. A considerable number of participants did not provide further information on their reasons for not using the app. Given that the FORTEe trial is a multicomponent intervention encompassing exercise sessions, fitness assessments, questionnaires, video training, and other digital tools, the app was offered as an optional component with voluntary participation. This may have led some participants to perceive the app as supplementary rather than essential, which could have contributed to its lower engagement and limited feedback from nonusers.

Although the number of users was relatively small, their feedback still provides valuable insights into the effectiveness and acceptance of the "FORTEe Get Strong" app among children, adolescents, and young adults with cancer. Designed specifically for this population, the app received overall positive feedback for its design, user-friendliness, and interactive features such as the avatar and quiz. These elements likely played an important role in making the app engaging and appealing to young patients—an essential factor when addressing the challenges of motivating children to participate in physical activity and engage in other health-related topics [16,18]. Suggestions for additional features, such as a chess game or a virtual fitness studio, further highlight the patients' preferences for more interactivity and variety. These findings provide valuable guidance for future app development, ensuring that the app becomes a more comprehensive and dynamic tool to support children, adolescents, and young adults with cancer.

However, certain areas of the app, particularly the exercise content and informational features, also received some less favorable ratings. This can be explained by the feedback from young users, who expressed a preference for supervised face-to-face training and the opportunity for more interaction. For example, several users noted that the exercises were less individually tailored compared with those provided during supervised training sessions, underlying the importance of supervision and personalization. Future versions of the app could address this gap by including a wider range of exercises with more adjustable difficulty levels to meet the diverse needs of users. Furthermore, the qualitative feedback about the app's suitability across different age groups indicated that the target age range was defined quite broadly, ranging from 4 to 21 years. While some patients appreciated the app, particularly during hospitalization, some adolescents and young adults found it less engaging and felt it was better suited for younger children. However, Kruskal-Wallis tests of the Likert-scale ratings of specific app features showed no significant differences across the 4 defined age groups, suggesting that age does not systematically affect app ratings in this sample. As a result, the development of future digital health technologies should be tailored to the different developmental stages of users to better address their individual needs. Furthermore, the involvement of users throughout the development process can further ensure that an app effectively addresses the interests and needs of its target audience. Therefore, patient representatives were consulted on as many aspects of the app as possible, including specific design aspects such as the main theme and avatar design to make the app appealing to the target group. However, even when user preferences are taken into account, not everyone's taste can be catered for, which may explain the feedback on age appropriateness.

Limitations

A notable limitation of this study is that the evaluation was based on a relatively small sample (n=53) using and providing

XSL•FO
RenderX

feedback on the app at the time of the assessment. As this evaluation was embedded within the larger FORTEe trial, the subgroup of app users was smaller than the trial's overall sample, and no dedicated power calculation was performed for the substudy. Consequently, the study may have limited power to detect small differences between groups. As previously discussed, the small sample size in this investigation may be partly due to the comprehensive nature of the FORTEe trial.

Previous studies have shown that children are less likely to engage with apps that have a strong educational component and tend to rate them lower than scientific experts [37], which could have resulted in limited app use. Additionally, due to data protection regulations, the app usage duration was not recorded, resulting in limited insights into the frequency and consistency of engagement, as well as the interpretation of usage patterns and the relationship between intensity of use and perceived effectiveness. Similarly, adherence to the prescribed use of the app could not be objectively monitored; however, this might be critical to the app's potential effectiveness. Therefore, future studies should consider incorporating self-reported adherence measures to better understand engagement behavior while maintaining compliance with data protection requirements.

Furthermore, although the app was conceptually grounded in SCT and SDT, the evaluation did not include explicit measures of theory-driven constructs, such as self-efficacy, outcome expectations, autonomy, and competence support. Consequently, it is unclear to what extent these mechanisms were activated. Future research should incorporate targeted assessments to empirically evaluate these theoretical processes.

Additionally, despite being designed for a broad age range (4 - 21 y), some adolescents and young adults found the child-friendly design less engaging. Future iterations may therefore benefit from offering more age-differentiated design options to better accommodate diverse preferences across developmental stages.

Although efforts were made to minimize potential social desirability bias by encouraging participants to complete the questionnaire independently and limiting parental or staff assistance to clarification only, some degree of influence, particularly among younger children, cannot be ruled out. In future studies, this bias could be reduced further by systematically recording the presence of parents during completion of the questionnaire (eg, through a binary question about parental presence) and by standardizing the setting in which responses are collected.

Furthermore, while conducting the interviews in the native language of both the exercise professional and the participants likely improved the clarity and depth, this subsequent translation into English for documentation may have introduced information loss or translation errors. Additionally, some questions may have been difficult for younger children to fully comprehend, even in their native language, leading to potential misinterpretations or incomplete answers. These factors could affect the reliability and accuracy of the collected data.

Conclusion

This study demonstrates that the "FORTEe Get Strong" smartphone app can support children, adolescents, and young adults with cancer in maintaining physical activity and health education. This study provides novel insights into user experience of children, adolescents, and young adults with cancer with a gamified exercise and health education app during intensive treatment, a phase that has largely been underrepresented in pediatric oncology mHealth research. Unlike previous digital interventions that focused primarily on survivorship, this mixed methods evaluation provides a more comprehensive understanding of how children, adolescents, and young adults interact with digital tools during intensive treatment. The findings contribute to the field by identifying key facilitators and barriers to engagement, including exercise variety, age-appropriateness, and the need for privacy-compliant peer interaction, thereby informing the design of future pediatric oncology mHealth interventions. From a clinical perspective, digital tools can help bridge care gaps when exercise professionals are unavailable by providing low-threshold access to exercise and health education, when in-person support from exercise professionals is limited, for example, during inpatient stays or periods of treatment-related isolation. These findings indicate that gamified digital interventions can facilitate continuity of exercise engagement, complementing traditional care across different settings. Overall, digital tools like the "FORTEe Get Strong" app have the potential to become an integral part of the comprehensive, multidisciplinary approach by empowering young patients with cancer to stay active, engaged, and supported throughout their recovery and beyond. Moreover, the insights gained from this study may be applicable to other pediatric patient populations with chronic conditions, suggesting broader relevance for the development of gamified digital interventions. Future studies should evaluate adherence, behavioral outcomes, and the app's effectiveness in improving physical activity in larger samples to obtain a broader perspective on the implementation and impact of the "FORTEe Get Strong" app in the clinical setting of children, adolescents, and young adults with cancer.

Abstract

Background: Augmented reality head-mounted displays could overcome the spatial dissociation between medical imaging and the surgical field, which may be particularly important in anatomically dense regions, such as the head and neck. Although many head-mounted displays offer markerless inside-out tracking at a fraction of the cost of navigation systems, their overlay accuracy with superimposition (SI) modality onto the surgical field remains limited. The virtual twin (VT), displaying holography adjacent to the surgical field, may offer a viable alternative. However, its performance is still unclear.

Objective: This study aimed to compare the accuracy and efficiency of the two visualization modalities, SI and VT, for anatomical localization in the head and neck region.

Methods: In a randomized crossover trial to compare two augmented reality visualization modalities (SI and VT), 38 participants used a HoloLens 2 to localize point, line-based, and volume-based anatomical structures on head phantoms. Their performance was evaluated with respect to accuracy, workload, time, and user experience.

Results: SI achieved significantly better point localization accuracy than VT both in absolute (mean 14.4, SD 4.2 mm vs mean 15.8, SD 5.5 mm; P=.003) and relative accuracy (mean 3.4, SD 2.2 mm vs mean 6.0, SD 5.0 mm; P<.001). In line-based structures, accuracy was comparable between SI (average surface distance [ASD], mean 23.4, SD 4.1 mm; Hausdorff distance [HD], mean 31.5, SD 7.8 mm) and VT (ASD=mean 23.0, SD 4.5 mm; P=.51; HD=mean 31.0, SD 7.5 mm; P=.57). However, SI showed significantly higher deviation than VT in volume-based structure (ASD=mean 37.1, SD 13.8 mm vs mean 34.1, SD 14.2 mm; P=.01; HD=mean 52.0, SD 16.8 mm vs mean 49.1, SD 15.8 mm; P=.03). Participants were faster with SI (P=.02), while workload NASA-TLX (National Aeronautics and Space Administration Task Load Index) scores did not demonstrate a significant difference (P=.79).

Conclusions: Given that SI did not clearly outperform VT under overlaid soft tissue and viewing challenges, VT remains a viable alternative in certain surgical scenarios where high accuracy is not required. Future research should focus on optimizing viewing angle guidance and the linkage between the anatomical target and the skin surface.

Introduction

The head and neck region contains a variety of complex anatomical structures, including numerous vital nerves, blood vessels, and organs [1]. Accurate localization of these anatomical structures is crucial in surgical practice to minimize deviation and improve outcomes [2]. Conventional medical imaging techniques, such as computed tomography (CT) and cone beam CT, as well as magnetic resonance imaging, are primarily used for diagnosis and preoperative planning [3,4]. Medical images require surgeons to mentally map medical images onto the patient's anatomy during the operation. This process demands a high level of cognitive effort, especially in the anatomically dense head and neck region, where misinterpretation could compromise the surgical accuracy and outcomes [5,6]. Surgical navigation systems (SNS) offer solutions by integrating image data into the surgical workflow. However, the limitations of the 3D display still leave the operator reliant on spatial imagination to understand complex anatomy. Furthermore, the broader adoption of SNS has been impeded by high expenses, the inherently sophisticated configurations like optical tracking cameras and reflective markers, and the possible additional radiation exposure to patients and staff [7,8]. As a result, there is still a lack of a cost-effective, intuitive, 3D interactive visualization approach that seamlessly displays the patient's medical images in the field.

Augmented reality (AR) could fill this gap by providing real-time holographic images directly within the surgical field mainly through head-mounted displays (HMDs) [7,9]. Moreover, many current AR HMDs can provide markerless inside-out tracking at a fraction of the cost of SNS and eliminate the need for additional markers [10,11]. Unlike SNS, which typically tracks the patient and instruments, this kind of HMD-based tracking focuses on aligning virtual content with the patient's anatomy to enable hologram overlay. However, the overlay or registration accuracy of many HMDs is still not as accurate as traditional SNSs with external optical tracking at the millimeter level [10]. This limitation becomes particularly critical for the superimposition (SI) visualization modality, where virtual anatomical structures need to be precisely placed on real anatomy, a process referred to as registration [12-14]. In addition, SI may introduce occlusion, as holograms can obstruct the surgeon's view of anatomy or instruments. These challenges raise concerns about the feasibility of SI as the optimal visualization modality for AR-assisted surgery, given the setup of currently available HMDs free of external tracking [15].

An alternative visualization modality is the virtual twin (VT), where the holographic representation is displayed adjacent to the physical anatomy instead of directly overlaid on the anatomy [15,16]. By avoiding overlay, VT reduces dependence on registration accuracy and eliminates occlusion.

However, the accuracy between two modalities under markerless HMD-based tracking remains unexplored. Yet, this could be important, since if SI with intrinsic markerless tracking does not show any advantage over VT, then VT would be the favored modality for certain surgical scenarios. Therefore, the aim of this crossover randomized controlled trial (RCT) was to compare the accuracy and efficiency of the two visualization modalities, SI and VT, for anatomical localization in the head and neck region. Localization accuracy was assessed on phantom heads for clinically relevant targets, including nerve exit points, the inferior alveolar nerve, and the salivary glands. Task duration and subjective workload were evaluated as secondary endpoints.

Methods

Overview

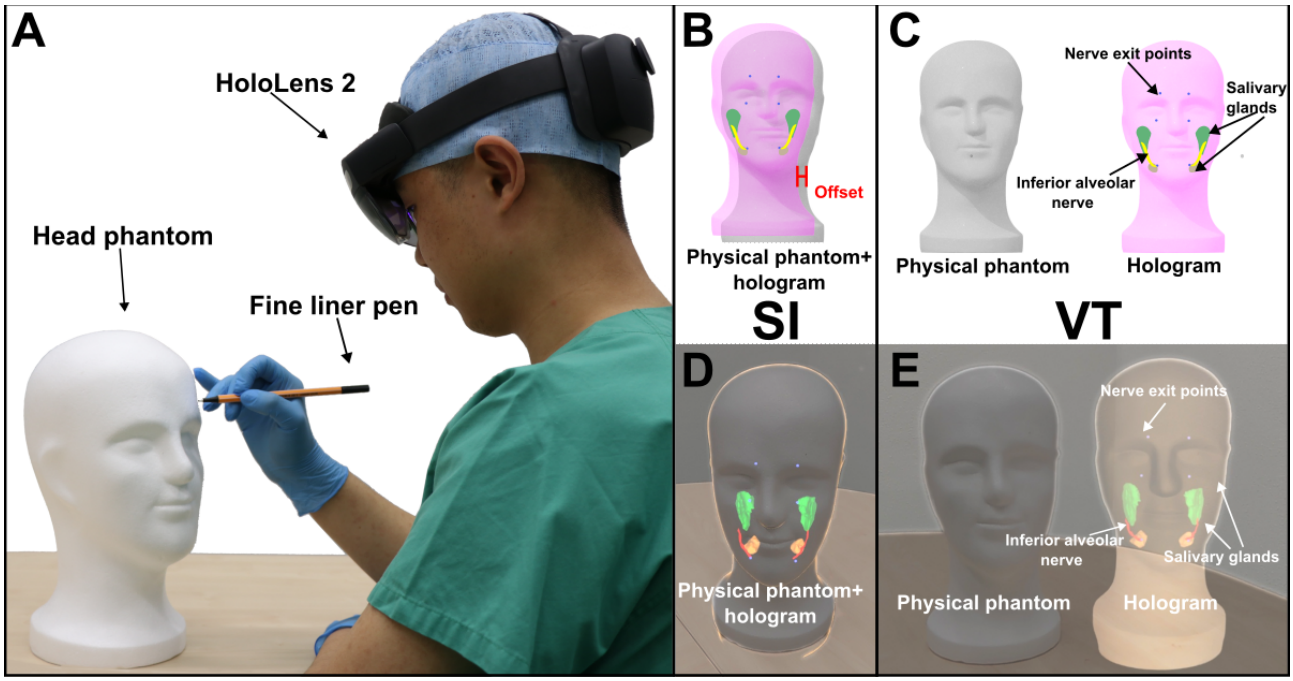
In total, 38 participants with different professional backgrounds (dental and medical students, resident and specialist surgeons in oral and maxillofacial, oral, and plastic surgery) were recruited and performed drawings on polystyrene foam head phantoms (Model SAM, Friseurbedarf D. M. Rudolph) in a crossover RCT with SI and VT visualization modalities. The participants were asked to draw the structures on the head phantoms, wearing HoloLens 2 (HL2; Microsoft Corp). The primary endpoint was the localization accuracy of the anatomical points (0D), which encompass nerve exit points at the supraorbital, infraorbital, and mental foramina. Secondary endpoints included the delineation accuracy of the inferior alveolar nerve pathways (2D) and salivary glands (parotid and submandibular; 3D), cognitive workload, and user experience.

System Description and Implementation

The AR visualization software for the HL2 was developed in-house to display anatomical 3D models in relation to the physical anatomy of patients or phantoms. Within the application, switching between the two different visualization modalities for the 3D models was possible. In addition to the HL2 software, a pipeline processed the medical image data. This pipeline converted volumetric CT scans into 3D models optimized for interventional planning and efficient rendering on the HL2.

Based on these requirements, the planning pipeline was built to segment the structures into meshes in 3D Slicer (version 5.2.2; The Slicer Community). The structures comprising the skull, salivary glands, and nerve exit points were manually segmented from a publicly available head and neck CT dataset [17], while the inferior alveolar nerves were segmented from a nonpublic dataset from the Medical University of Graz. A head phantom mesh was scanned by the Artec Leo 3D scanner (Artec 3D) as the skin surface. Finally, all segmented anatomical structures were nonlinearly registered to the scanned skin surface.

Our AR application was developed using Unity (version 2022.3.6f1; Unity Technologies). The registration between the head phantoms and the virtual head was implemented using the Vuforia software development kit (version 10.16.5, Parametric Technology Corporation). Vuforia Engine is a cross-platform AR solution that offers a variety of tracking features, which was frequently used in research for AR registration in surgical scenarios [18-20]. The model targets (object tracking) were applied, which possibly used edge-based techniques (not revealed by Vuforia) to recognize and track objects in real-time [21]. First, the scanned head model was uploaded to the model



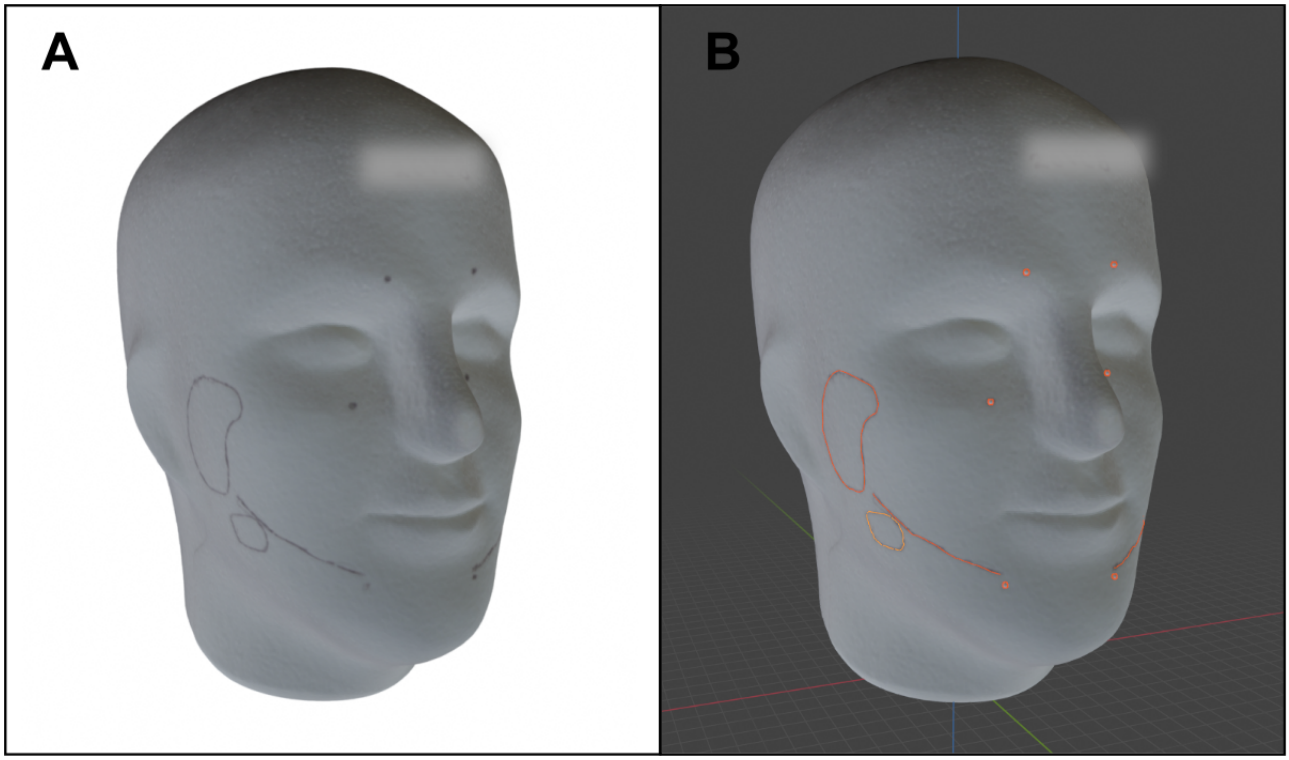
XSL•FO
RenderX

target generator tool and configured into a model target that could be integrated into Unity. After the software was deployed to the HL2, the Vuforia engine initiated tracking for target alignment. Once the participant is satisfied with the alignment, she or he could lock the tracking to anchor the virtual model in the environment. Similarly, in VT, Vuforia would track the phantom, and then the model would appear next to it; locking the tracking again would fix the model in place. The hand menu assisted users in controlling the visibility of various anatomical structures, including the skin and target structures. In addition, sliders were implemented to allow real-time adjustment of the transparency and brightness of these structures.

Trial

The participants were asked to fill out the initial questionnaire, which included demographic information (age, gender, educational stage or professional experience, professional field, and prior experience with AR and HL2). Randomization was generated by BHP using a randomized allocation rule to determine the starting modality (sequence) and the side of the face (right or left). The experiment assistant (KG) enrolled and assigned participants to the sequence of intervention. Registration was done once at the beginning of each modality by the experiment assistant, who could lock or unlock the tracking for registration as needed. Subsequently, they wore HL2, ran the eye calibration, and received a brief introduction to the device and the user interface with the 2 modalities. During this short session, they familiarized themselves with the device and its functions. The entire familiarization process was completed in less than 3 minutes, although precise timing was not recorded. Participants were then instructed to delineate target anatomical structures on the head phantom surface using Point 88 fine liner pens (Stabilo; Figure 1). This task was performed on the assigned half of the face using the first modality, with time recorded via a stopwatch. Upon completion, participants filled out the Likert questionnaire and NASA-TLX (National Aeronautics and Space Administration Task Load Index) for that method and an open-ended questionnaire. The same procedure was then repeated on the other side of the face using the second modality, followed by the corresponding questionnaires. Finally, an open-ended questionnaire for preference was answered.

Figure 1. Illustration of two augmented reality visualization modalities using HoloLens 2. (A) Participant drawing anatomical structures (nerve exit points, inferior alveolar nerves, and salivary glands) on the polystyrene head phantom with HoloLens 2. (B) Schematic illustration of SI showing physical and holographic alignment with potential rigid offset and occlusion. (C) Schematic illustration of virtual twin showing how holograms are displayed free of misalignment and occlusion problem. (D) SI modality in HoloLens 2, where holograms were overlaid directly into the physical head phantom. (E) Virtual twin modality in HoloLens 2, where the holograms were displayed spatially adjacent to the physical head phantom. SI: superimposition; VT: virtual twin.



Evaluation

After the trial, all the polystyrene head phantoms were scanned with the Artec Leo 3D scanner (Figure 2). To enable comparison, all head phantoms with the participant's delineations were registered to the virtual planned head in a pipeline by a Python (version 3.10; Python Software Foundation) script. The two-stage pipeline was initiated with a global random sample consensus alignment, followed by a local refinement with point-to-plane iterative closest point, achieving <0.4 mm root mean square error. Two independent investigators (YL and KG) evaluated the scanned heads using Blender (version 4.2; Blender Foundation). Both investigators were blinded to the applied visualization modality. To minimize a possible recall bias, KG, who served as the experiment assistant during data acquisition, underwent a washout period of 2 months before participating in the blinded evaluation. Nerve exit points were drawn by the stroke points and placed spheres. The nerve paths and salivary glands were drawn by the grease pencil tool along the curves on the head phantom surface, and the strokes were transformed into meshes in Blender (Figure 2).

XSL•FO
RenderX

Figure 2. (A) Scanned polystyrene head phantom with delineation. (B) In Blender, the scanned polystyrene head phantom is shown with inferior alveolar nerve and salivary glands annotations, and spheres marking the nerve exit points (orange).

Afterward, the points and curves were automatically compared using a Python script. The analysis for nerve exit points (0D) involved calculating Euclidean distance, which is the shortest distance in 3D space between the planned and drawn points, and we referred to this as absolute accuracy. Relative accuracy, defined as landmark-to-landmark localization accuracy, was compared by the Euclidean distance between the supraorbital-infraorbital and infraorbital-mental foramina on drawn versus planned landmarks. Since all anatomical targets were located on the underlying bone, yet localization was performed on the phantom's external surface, the concept of soft-tissue thickness was additionally introduced to capture the distance between the target structures and the skin. It was defined as the shortest distance from each anatomical point (0D) to the surface and as the mean of the vertex-to-surface distances for 2D nerve pathways and 3D salivary glands. Furthermore, the Hausdorff distance (HD) and the average surface distance (ASD) were used in order to assess the alignment and accuracy of the contours of the nerve paths (line, 2D) and salivary glands (volume, 3D). HD captures the maximum of the minimum distances between the two surfaces, providing insight into the worst-case alignment error, while the ASD quantifies the mean discrepancy, reflecting the overall degree of alignment.

The Likert questionnaire and NASA-TLX were quantitatively analyzed to assess usability and perceived workload. In addition, the feedback from open-ended questions was summarized by YL and reviewed by BHP.

Sample Size Calculation

The sample size calculation was conducted in R software (version 4.3.1; R Foundation for Statistical Computing). A minimum effect size of 5 mm was established as the threshold for an acceptable difference between the two modalities in absolute accuracy. A 5 mm difference in absolute accuracy causes a surface discrepancy exceeding 5 mm due to the geometric relationship, making it clinically relevant and detectable by oral and maxillofacial surgeons, corresponding to the widely accepted minimum margin in head and neck oncologic surgery [22,23]. Based on the results of a pretrial with 4 participants, the mean absolute accuracy was 10.1 (SD 4.8) mm (SI) and 12.1 (SD 5.0) mm (VT) across all nerve exit points. A normal distribution of the pretest values (Shapiro-Wilk test; P=.70) resulted in a required number of cases of 34 for the unpaired t test. An additional 4 participants were included to compensate for nonevaluable datasets and for dropout or withdrawal of consent.

Statistical Analysis

Statistical analysis was also performed in R. A linear mixed-effects model (LMM) was applied using the *lmerTest* package [24]. This LMM assessed the absolute accuracy at the point structures, modalities (SI vs VT), the sequence (starting method), the group (dental and medical students, and surgeons), subcutaneous soft tissue thickness, and side (left or right) as fixed effects and the participants as a random effect. When analyzing the ASD and HD for line and volume-based structures, the same LMM framework was applied. Subcutaneous soft tissue thickness was specifically included to account for anatomical variation across different locations. However, it was not considered in the analysis of relative accuracy for point structures, which instead relied more on spatial reference to other anatomical landmarks.

The normality of the data distribution was assessed using the Shapiro-Wilk test. Duration and each Likert question between methods were compared using the Mann-Whitney U test. The NASA-TLX scales were compared by unpaired two-tailed t

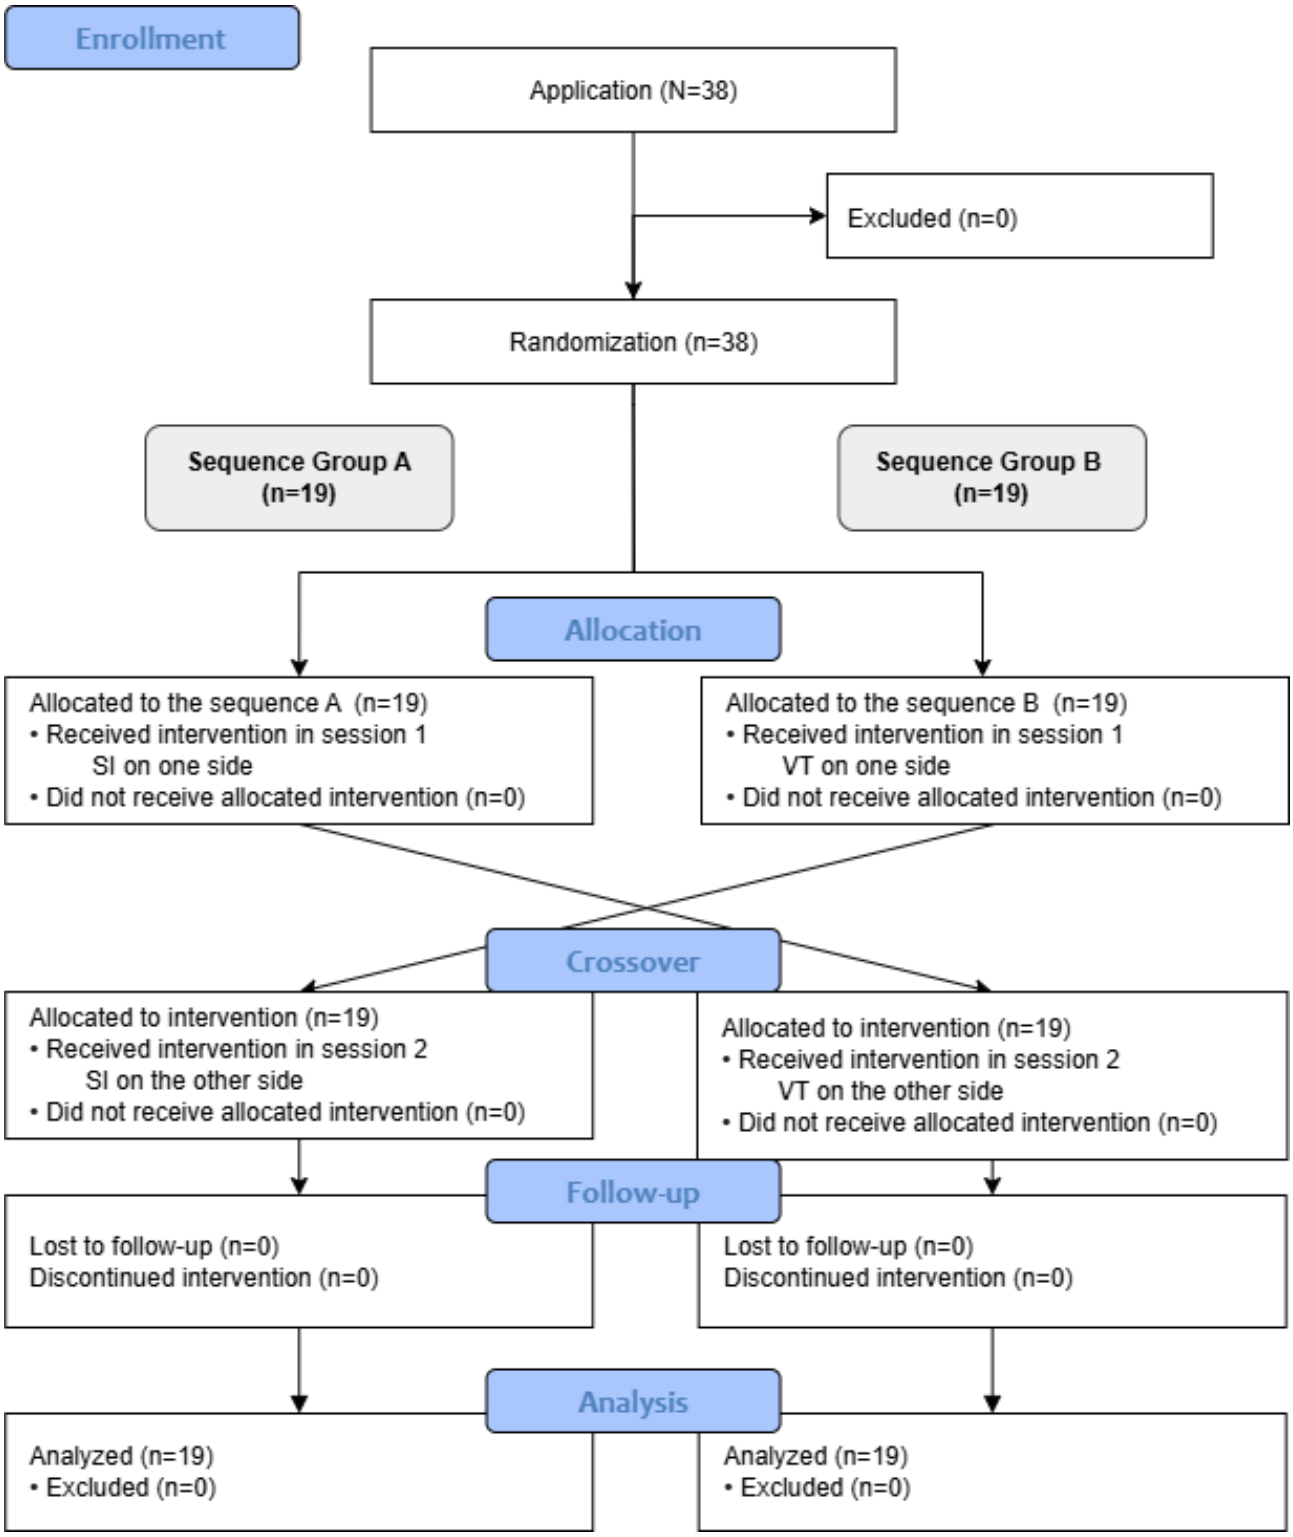
test. For all tests mentioned, a *P* value of <.05 was considered significant.

Ethical Considerations

This study was approved by the local ethics committee of the University Hospital RWTH (Rheinisch-Westfälische Technische Hochschule) Aachen (EK 24‐127; Chairman Prof Ralf Hausmann; April 3, 2024). The study was registered with a study protocol in advance in the German Clinical Trial Register (DRKS00032835) and followed the CONSORT (Consolidated Standards of Reporting Trials) 2010 guidelines (Checklist 1) and its extension designed and modified specifically for crossover studies, as illustrated by the flow diagram [25,26]. Informed consent was obtained from all participants involved in the study. To protect the privacy of the participants, all participants were anonymized, and no personally identifiable information was stored with the research data. It is to be noted that no financial compensation was provided to the participants involved in the present trial. Nevertheless, as a token of appreciation, two vouchers with a total value of €15 (US $17.5) were distributed through a raffle.



Results

Cohort

A total of 38 participants (16 females and 22 males) were successfully included in the study, comprising two groups, namely surgeons, and medical and dental students following the flow (Figure 3). Among the 18 surgeons, there were 12 residents and 6 specialists. This group included 9 oral and maxillofacial surgeons, 5 oral surgeons, and 4 plastic surgeons. In the student group, which consisted of 20 participants, 17 were dental students and 3 were medical students. The average age of participants was 26.8 (SD 5.1; range 20‐43). The average clinical experience of surgeons was 4.0 (SD 4.3) years, and the average clinical experience of medical and dental students was 4.2 (SD 0.9) years; mean 8.3 (SD 1.6) semesters (Table 1).

Localization Accuracy

In the 38 scanned head phantoms, all the required structures were successfully delineated, except for 1 pair of nerve exit points at infraorbital foramina and 1 pair at supraorbital foramina, which were missed by a single participant. The absolute accuracy of the nerve exit points (0D) was significantly higher in SI (mean 14.4, SD 4.2 mm) than VT (mean 15.8, SD 5.5 mm), with a mean difference of 1.4 (95% CI 0.5 - 2.3; LMM; *P*=.003) mm. The absolute accuracy was correlated with the soft tissue thickness. For each 1 mm soft tissue thickness, the accuracy decreased by 1.4 mm (*P*<.001), while no significant difference was found in sequence (*P*=.84) and group (*P*=.40) as fixed effects in the LMM. The average participant bias was 0.8 (SD 0.8) mm. The mean absolute error of the LMM residuals was 1.8 (SD 2.9) mm for SI and 2.5 (SD 3.5) mm for VT, respectively. The relative accuracy of the points was significantly higher for SI (mean 3.4, SD 2.2 mm) than VT (mean 6.0, SD 5.0 mm) by 2.6 (95% CI 1.3 - 3.8 mm; LMM; *P*<.001; Figure 4). In Figure 4, each violin plot (colored) includes a boxplot (white), with a red dot indicating the mean value. The black points represent the outliers. The dashed line marked the average subcutaneous soft tissue thickness over the nerve exit points.

The localization accuracy of the inferior alveolar nerve pathways (2D) assessed with ASD and HD was comparable between SI (ASD/HD=mean 23.4, SD 4.1 mm/mean 31.5, SD 7.8 mm) and VT (ASD/HD=mean 23.0, SD 4.5 mm/mean 31.0, SD 7.5 mm), with no significant difference (ASD/HD=mean difference 0.4 mm, 95% CI −1.0 to 2.0 mm; LMM; *P*=.51/mean difference 0.6 mm, 95% CI –1.6 to 2.9 mm; LMM; *P*=.57). Regarding the salivary glands (3D), the localization accuracy measured with ASD/HD (mean 34.1, SD 14.2 mm/mean 49.1, SD 15.8 mm) for VT was significantly more accurate than SI (ASD/HD=mean 37.1, SD 13.8 mm/mean 52.0, SD 16.8 mm) by ASD 3.0 (95% CI 0.7 - 5.4 mm; LMM; *P*=.01) mm and HD 2.9 (95% CI 0.2 - 5.8 mm; LMM; *P*=.03) mm (Figure 5). In Figure 5, each violin plot (colored) includes a boxplot (white), with a red dot indicating the mean value. The black points represent the outliers. The dashed line marked the average subcutaneous soft tissue thickness over the inferior alveolar nerves and salivary glands.

Workload and Time

The SI method (mean 61.3, SD 29.6 seconds) was significantly faster than the VT method (mean 77.4, SD 34.5 seconds) by 16.1 (95% CI 2.0 - 29.0; Mann-Whitney *U* test; *P*=.02) seconds. The NASA-TLX score for the SI method (mean 39.8, SD 17.3) and VT method (mean 40.8, SD 15.2) was comparable, with no significant difference (mean difference 1.0, 95% CI –4.2 to 6.2; *t* test; *P*=.79; Figure 6). In Figure 6, each violin plot (colored) includes a boxplot (white), with a red dot indicating the mean value. The black points represent the outliers.

Questionnaires

The Likert-type questions (scale 1-4; 1=strong disagreement; 4=strong agreement) showed no significant difference (Mann-Whitney *U* test) between the two modalities (Table 2). The participants perceived no clear advantage in accurate localization of target structures between SI and VT (mean 3.0, SD 0.9 vs mean 3.0, SD 0.6 points; *P*=.61; mean 2.9, SD 0.8 vs mean 2.8, SD 0.7 lines; *P*=.37; mean 2.7, SD 0.8 vs mean 2.7, SD 0.7 volume; *P*=.95). Participants also reported similar levels of confidence (mean 2.7, SD 0.7 vs mean 2.7, SD 0.6; *P*=.84), distraction (mean 2.2, SD 1.0 vs mean 1.8, SD 0.9; *P*=.05), provided assistance (mean 2.9, SD 0.8 vs mean 3.1, SD 0.6; *P*=.46), practicality (mean 2.4, SD 0.9 vs mean 2.8, SD 0.8; *P*=.09), perceived feasibility in interventions (mean 2.8, SD 1.1 vs mean 2.7, SD 0.9; *P*=.57), safety enhancement (mean 2.5, SD 0.9 vs mean 2.7, SD 0.9; *P*=.19), and overall satisfaction (mean 2.8, SD 0.9 vs mean 2.9, SD 0.8; *P*=.66). In addition, positive and negative detailed feedback was provided for both visualization modalities (Table 3). It is noteworthy that 19 participants expressed a preference for VT, 18 participants for SI, and 1 participant expressed equal preference for both.

Discussion

Principal Findings

We systematically evaluated the localization accuracy between two visualization modalities: SI with markerless inside-out tracking and VT for different types of anatomical structures in the head and neck region. The primary endpoint (absolute accuracy of 0D structure) revealed that SI was significantly more accurate than VT by 1.4 mm (P=.003). In terms of relative accuracy of 0D point structures, SI also outperformed VT by a margin of 2.6 mm (P<.001). VT showed comparable accuracy for 2D structures and notably superior accuracy (ASD, P=.01; HD, P=.03) for 3D structures, although it required an additional 16 seconds on average (P=.02). Likert questions revealed comparable results between two modalities. Feedback from open-ended questions (Table 3) highlighted SI for ease of understanding, intuitiveness, and time efficiency, yet noted persistent challenges with depth perception, visual occlusion, and virtual-real misalignment. Conversely, VT was perceived as simpler, clearer, and free of occlusion and misalignment issues, despite lacking direct positional cues on real head phantoms and requiring frequent attention shifts between physical and virtual models. Overall, user preferences were evenly split, reflecting comparable experiences despite each modality's distinct strengths and limitations.

Respective Strengths and Weaknesses

In contrast to VT without tracking, the accuracy of SI depends on the inside-out tracking of the HMD used and can be attributed to 3 main factors, namely the registration accuracy of the tracking (Vuforia), the spatial mapping performance (HL2), and the visual occlusion [27]. Previous studies illustrated Vuforia software development kit's registration in the HL2 highly depended on the richness of the shape and texture of the tracked target and ranged from less than 2 mm to more than 10 mm for translational error [19,28], which can propagate into an angular deviation of the task-specific cutting plane up to 14.7° [20]. Furthermore, Vuforia tracking is sensitive to environmental light intensity, distance to the target object, and the extent of the surface covered [29]. In addition, HL2 used visual inertial-simultaneous localization and mapping (VI-SLAM) to continuously map the environment and update its position and orientation within a global coordinate system, anchoring virtual content to real-world features [30,31]. However, VI-SLAM's accuracy can be affected by factors, such as pose prediction latency, user motion, environment, and sensor fusion, such as poor integration between the red, green, blue camera and inertial

XSL•FO
RenderX

measurement unit [30,31]. This VI-SLAM error accumulated along the way, reaching 5 mm per 628 mm traveled in the clinical environment [31,32]. Moreover, the jitter latency caused by such sensor fusion could further compromise user experience, increase cognitive load, and induce fatigue [30,33]. Last but not least, visual occlusion, where virtual objects can obstruct or distort the view of the physical counterpart, further compromises the accuracy of SI. Many participants reported difficulty in identifying the position of the pen, drawn line, and occluded virtual content, which was also observed in another study [34]. This occlusion problem could lead to severe damage during surgery by overlooking anatomical structures and events [35,36]. All these factors together may contribute to the overall accuracy achieved by SI.

On the other hand, VT showed comparable accuracy (inferior in 0D, comparable in 2D, and superior in 3D structures) to SI with markerless inside-out tracking of the HMD, but without the aforementioned problems of SI. This was largely due to VT's design, which bypassed the need for precise virtual-real overlay or accurate anchoring by displaying the virtual model next to the real head phantom. Nevertheless, VT as a visualization modality free of misalignment, unaffected by occlusion, and less sensitive to spatial mapping instability could substitute SI in macro localization tasks. Since VT lacked direct positional cues to guide localization, it likely depended on the surgeon's ability to estimate distance, where surgeons performed an average error of 1.4 (SD 1.2) mm in 5 mm and 2.0 (SD 1.9) mm in 1 cm estimation in a research [37]. The distances between the nerve exit points in our study were approximately 4 cm between supraorbital and infraorbital foramina and 7 cm between infraorbital and mental foramina. If we assume the estimation error was in a linear model, this corresponded to a mean error of 5.6-9.2 mm, which aligned with VT's average relative accuracy (mean 6.0, SD 5.0 mm), inferior to SI (mean 3.4, SD 2.2) mm). Therefore, one could argue that SI is only meaningful if its accuracy exceeds the limits of human distance estimation.

Comparison to Prior Work

In scenarios where precise localization is required, such as orbital fracture reconstruction or trajectory drilling, optical tracking remains the most accurate method to date [15]. Consequently, numerous studies have adopted optical tracking to optimize registration of SI. For instance, Tu et al [38] achieved entry point accuracy of mean 2.8 (SD 1.3) mm and angular accuracy of mean 3.0° (SD 1.2°), optimizing registration accuracy to mean 2.0 (SD 0.7) mm through optical tracking. Similarly, Iqbal et al [39] combined the HL2 built-in camera with an external optical tracking camera, further reducing translation and rotation errors to 2.1 mm and 1.5°, respectively. In contrast, VT with external optical tracking could also visualize both the virtual instrument and the target anatomy but adjacent to the patient in real-time. This framework achieved higher accuracy than the aforementioned SI systems and comparable accuracy to SNS, with translational deviations of mean 0.9 (SD 0.4) mm and mean 1.0 (SD 0.5) mm at entry and end points, respectively, and a rotational deviation of mean 1.1° (SD 0.6°) [15], within the clinically feasible range (~2 mm) [12]. The noticeable difference between VT by 0.9 (SD 0.4) mm and SI by 2.1 mm with a similar optical tracking framework likely resulted from the aforementioned factors, such as registration errors, VI-SLAM instability, jitter, and visual occlusion. This raises the question of whether SI with optical tracking should be considered the optimal AR visualization modality for surgical scenarios, particularly given that VT achieved similar accuracy under similar tracking conditions without encountering these limitations.

However, all these values assume that localization accuracy is measured in anatomically exposed structures, where perfect localization could theoretically reach 0 mm. However, this ignores a crucial aspect of real-world scenarios: anatomical structures are typically covered by tissue, which prevents direct access and inherently limits localization accuracy. In our study, this was particularly relevant due to the soft and bone tissue overlying the anatomical target structures (ie, nerve exit points, inferior alveolar nerves, and salivary glands). According to the literature, the average soft tissue thickness of the head, face, and neck is 9.4 (SD 6.2; range 2.4-28.1 mm) mm in women and 10.5 (SD 7.2; range 2.7-32.4) mm in men [40]. Thus, the measured localization accuracies observed with SI and VT for nerve exit points cannot be directly compared to classical navigation scenarios with fully exposed anatomical targets, as they are composed of 4 main influencing factors

$$\text{Localization Accuracy}_{ij} = \beta_1 \cdot \text{Overlaying Tissue Thickness}_i + \text{Anatomical Constraint} + \beta_2 \cdot \text{Modality}_{ij} + \text{Visualization Modality (SI vs. VT)} + u_j + \text{Subject Bias} + \varepsilon_{ij} + \text{Residual Error (AR Noise)}$$

First, the tissue thickness overlaid the target structure. This resulted in a decrease in localization accuracy of 1.4 mm per 1 mm of overlying tissue thickness (LMM, unstandardized coefficient β_1=1.4; P<.001). Then there is the influence of the VT modality, which added an additional error of 1.4 mm compared to SI (LMM, β_2=1.4; P=.003), and the average participant-specific bias, which was 0.8 mm (average magnitude of random intercept for individuals in the LMM). Finally, the residuals described the general pattern of localization error, with a mean absolute error of 1.8 (SD 2.9) mm for SI and 2.5 (SD 3.5) mm for VT.

For line- or volume-based structures, this correlation could not be reliably captured by the model. This was probably because localization accuracy depended not only on the viewing direction but also on dynamic changes in the perceived target margin along that direction. This contrasts with the single-point structure, which is invariably depicted as a point in all directions. As a result, the localization accuracy for line- and volume-based structures is biased by viewing direction and margin variability, in addition to the tissue thickness. As in Van Gestel et al [41], where a brain tumor was dynamically projected onto the skin along a vector from its center to the instrument tip, the participant's line of sight in our study played a comparable role to the instrument tip. As the viewing angle shifted, the visible margin of the gland changed in real time, introducing variability in the drawn curves and affecting both ASD and HD. Even for targets on the skin, like in wound area estimation using photography, variation in camera angle could introduce 10% error [42]. Although we could not directly quantify viewing

XSL•FO
RenderX

angles and changing margins, aligning the participant's gaze with the vector from the structure's centroid to its nearest skin projection may help minimize delineation errors related to such bias.

Clinical Implications

First, VT appears particularly advantageous for tasks requiring coarse localization and stable spatial orientation. VT provides a reliable anatomical context and could help mitigate cognitive errors, such as confusion of lateral sides or anatomical levels. These errors often arise in apparent symmetrical regions, especially in the absence of clear preoperative marking or adequate visual guidance. For example, in thoracolumbar spine surgery, reliance solely on intraoperative fluoroscopy may be insufficient to reliably distinguish vertebral levels, especially in the presence of anatomic variants, inadequate intraoperative imaging fields, and unreliable surface landmarks, with 50% - 67% of surgeons reporting such errors [43,44]. VT could orient the surgeon by allowing the user to align CT-based virtual models with the patient's posture, enabling clear visualization of the spine and reducing wrong-level or wrong-side misorientation. Second, in maxillofacial reconstruction, the VT technique offers significant value by displaying planned bone segments and prebent fixation plates alongside the operative field. This side-by-side visualization enables real-time comparison and intraoperative adjustment of plate bending, reducing the need for repeated fitting at the surgical site as standard techniques do [45], and thereby lowering the risk of infection. Compared with preoperative 3D printing, such a technique could also minimize fabrication time and offer greater flexibility for intraoperative adjustments. In the following free flap reconstruction procedures, VT offers robustness in environments prone to bleeding, swelling, or tissue deformation, where SI overlays can drift or become unreliable. By anchoring the virtual model generated from virtual surgical planning adjacent to the surgical site, VT provides a stable frame of reference with consistent skeletal landmarks, even when soft tissues shift [46]. Third, VT is well-suited to fractures and postoncologic defects of the orbit and midface requiring symmetry (eg, zygomatic arch, orbital floor, and medial wall) [47]. By rendering the contralateral mirrored anatomy, target orbital volume, planned implant contour, and craniofacial buttresses adjacent to the field, the surgeon could continuously compare the intraoperative reduction with the surgical plan.

While VT may help reduce orientation errors, SI demonstrates its strength in scenarios that demand high-precision localization. For example, in mandibular reconstruction surgery using the anterolateral femoral flap, accurate localization of the perforator vessels is crucial to flap viability and surgical success. One study found the SI with remote-controlled overlay (mean 3.5, SD 2.8 mm) achieved significant superior localization accuracy in anterolateral femoral perforator vessels than ultrasonic color Doppler (mean 9.6, SD 5.8 mm; P<.001) [48]. Our findings showed that SI had clear advantages in point-based localization tasks. This feature is particularly important in procedures such as sentinel lymph node biopsy, where accurately identifying nodes just a few millimeters beneath the surface is crucial for surgical success. Duan et al [49] reported that AR SI with motion compensation achieved sub-3 mm localization error in melanoma sentinel lymph node biopsy. Moreover, SI demonstrated significantly superior relative accuracy (P<.001). This is because, despite the offset, SI preserved the spatial relationships between landmarks. The scenario that benefits from this strength is when relative distances between anatomical points must be accurately estimated, especially when a landmark has already been explored and exposed. For example, in head and neck tumor surgeries, surgeons often use the tragal pointer as a surgical landmark to identify the facial nerve trunk and the maxillary artery during procedures, such as parotidectomy, mandibular osteotomy, and temporomandibular joint arthroplasty [50]. In addition, in skull base surgery, surgeons often rely on stable bony landmarks, such as the occipital condyle or mastoid process, to sequentially locate cranial nerve exit points, including the jugular foramen and hypoglossal canal [51].

SI with markerless inside-out tracking and VT could be combined across different stages of the tasks. First, VT provides general spatial awareness, such as adapting to specific patient positioning, orienting with comprehensive medical imaging, or selecting approximate entry points. Once a key anatomical landmark is exposed, SI could rapidly guide surgeons to adjacent structures by using relative spatial relationships, minimizing the need for repeated attention switching [52,53]. If SI causes visual obstruction, cognitive overload, or registration instability and inaccuracy, SI can be temporarily deactivated, allowing VT to take over as a stable spatial reference. This hybrid modality enables adaptive assistance, providing surgeons with tailored support at different procedure stages based on clinical needs.

Our findings showed that user preferences were almost evenly split between SI and VT, underscoring the limitations of relying on either visualization method in isolation. Rather than competing alternatives, SI and VT could be viewed as complementary tools that respond to different scenarios. While SI enables precise overlay of subcutaneous landmarks, VT provides more reliable orientation under deformation or registration drift. These complementary features suggest that future AR systems should integrate both approaches within a single workflow.

Limitations

This study has some limitations. First, the polystyrene foam head phantoms used in the experiment lacked realistic features, such as skin texture, natural color, and anatomical details, which are critical for accurate identification of anatomical landmarks in the real clinical scenarios. However, using these phantoms allowed for reproducible evaluation of the performance of two modalities. Second, the homogeneous and rigid phantom surface may have favored SI by registration. Unlike real surgical environments, phantoms lack deformable soft tissues, surgical draping, fluids, and light reflections, all of which can substantially increase registration and tracking errors for SI [54,55]. In contrast, VT does not require accurate overlay; thus, it was not hindered by those problems. These considerations suggest that the relative advantage of SI observed in phantom experiments may be attenuated in vivo, whereas VT could perform more robustly in real surgical settings. Third, in real clinical scenarios, the phantom's components, such as the

XSL•FO
RenderX

mandible, could not replicate the mobility of human anatomy. This mobility may pose a significant challenge to markerless inside-out registration and further accurate anatomical localization for SI. In contrast, mobile parts in VT may be a potential solution. To address these challenges, cadaver studies or studies with high-fidelity phantoms replicating the mobility of anatomical structures should be conducted to validate the clinical applicability and generalizability of the findings. Fourth, since the difference in absolute accuracy in the sample size calculation was less than 5 mm, the study may have been underpowered to detect the influence of some fixed effects. Subsequent studies should consider increasing the sample size to enhance statistical power and generalizability. Finally, current findings are constrained to the facial region, where underlying bone structures provide a stable spatial reference. It would be valuable to investigate the performance of two modalities in other regions of the body like the abdomen, where soft tissue may bring additional challenges.

Future Directions

In addition to further validation with cadaveric studies or high-fidelity phantoms, future work should also address technical factors that directly influence localization accuracy. In particular, subcutaneous soft tissue thickness, variations in viewing perspective, and the resulting margin variability were shown to pose consistent challenges for both AR modalities. To mitigate these effects, new visualization approaches need to be developed to reduce the effects of viewing perspective and account for the effects of the overlying tissue, regardless of the visualization modality. First, the user's viewing angle could be guided in AR. One possible strategy would be to create a virtual cylindrical tunnel of 2 circles between the target structure and the skin surface, orienting the user to view in a planned direction. Second, the AR visualization should establish a clear connection between the overlying tissue and the target structures, for example, for nerve exit points, a line connecting the points and their planned skin projection, clearly identifying the planned margin and mitigating the inaccuracy introduced by the overlying tissue.

While these approaches address specific visualization challenges, the next step lies in advancing toward a hybrid, context-aware AR system. With advances in registration accuracy, hardware performance, and integration of AI technologies, such a system could autonomously detect procedural phases, surgical context, and anatomical exposure. Based on this contextual understanding, it could dynamically switch between VT and SI modes, providing global spatial orientation and reference by VT and precise overlays for local structure localization by SI. This intelligent modality would reduce cognitive load and enable phase-specific surgical guidance.

Conclusion

This study systematically compared SI with markerless inside-out tracking and VT for surgical localization tasks in the head and neck region. SI demonstrated superior localization accuracy in 0D structures, whereas VT revealed robust spatial orientation, comparable accuracy in 2D, and superior accuracy in 3D structures. These complementary strengths suggested that VT represents a viable alternative for macro localization, while SI may be preferable for fine-grained, sequential landmark tasks. Rather than assuming SI to be universally applicable across all surgical contexts, our findings emphasize the need for context-adaptive AR strategies that can dynamically leverage the strengths of both modalities.

Acknowledgments

We sincerely thank all participating students and surgeons for their valuable contributions to this study. Open access funding provided by the Open Access Publishing Fund of RWTH (Rheinisch-Westfälische Technische Hochschule) Aachen University.

Abstract

Background: Childhood and adolescent malnutrition, encompassing undernutrition and overnutrition, poses significant global health challenges, necessitating comprehensive dietary assessment tools. Existing dietary assessment methods, such as 24-hour dietary recalls (24HR), often fail to capture eating behaviors and food preferences.

Objective: This study aims to compare a newly developed gamified dietary assessment tool (GDA) with a traditional 24HR and to explore its applicability in assessing dietary behavior tendencies among children and adolescents.

Methods: A 2-phase study was designed, including an exploratory and an application study. The exploratory study included 30 school-aged participants, comparing the GDA with the 3-day 24HR. Nutrient and food intakes were analyzed using Pearson or Spearman correlation coefficients and Bland-Altman plots. The application study, conducted among 1541 adolescents (11 - 18 y), assessed dietary intake and eating behavior tendencies. Differences in dietary intake across age, gender, socioeconomic status, and weight status were analyzed using the Kruskal-Wallis rank sum test. Multiple linear regression models were used to examine the associations of dietary intakes with emotional eating and with dining environment tendencies, respectively.

Results: In the exploratory study (n=30), the GDA demonstrated moderate agreement with 24HR for energy (r=0.46, P=.01) and carbohydrates (r=0.50, P=.005). Bland-Altman plots indicated good agreement for energy and carbohydrate intake between methods (mean differences around 0). For fat intake, although the mean difference was close to 0, the correlation was not statistically significant. In contrast, the GDA substantially overestimated protein intake (mean difference around 25 g). In the application study (n=1541), higher emotional eating scores were associated with higher snack consumption (β=0.438, 95% CI 0.035-0.840), and with lower protein (β=−0.159, 95% CI −0.267 to −0.052), fruit (β=−0.464, 95% CI −0.854 to −0.073), and nut consumption (β=−0.183, 95% CI −0.304 to −0.062). Participants who chose solitary screen eating consumed significantly more carbohydrates than those who selected “eat with peers” (β=4.2, 95% CI 1.2-7.1).

Conclusions: This study demonstrates that the GDA effectively captures both dietary intake and contextual eating behaviors in young populations, providing data distinct from traditional methods, such as 24HR. As a complementary assessment approach, it offers valuable insights into food preferences and eating patterns through its interactive design.

dietary assessment; gamification; dietary intake; food preference; eating behavior tendencies

Introduction

Children and adolescents have been facing a growing burden of malnutrition worldwide [1]. It is estimated that more than 390 million children and adolescents around the world are overweight, of whom 41% are obese [2]. At the same time, in low- and middle-income countries, approximately 16% of adolescents experience stunting and thinness [3], while micronutrient deficiencies have increasingly become a major threat to their development [4]. Malnutrition during childhood and adolescence can lead to substantial long-term health consequences in adulthood. Children in the highest BMI quartile could have more than twice the rate of death from endogenous causes compared to those in the lowest quartile [5], and obesity in adolescence also predicts a higher risk of type 2 diabetes [6] and cardiovascular disease [7] in adulthood. Also, early undernutrition has long-lasting effects on energy expenditure, lipid metabolism, insulin resistance, and mental health, which

XSL•FO
RenderX

may even be passed to the next generation [8]. Addressing these issues requires a better understanding of dietary patterns and the factors that influence food choices among children and adolescents. Traditional and emerging dietary assessment methods are both utilized to evaluate nutritional intake. Traditional methods, including retrospective methods (eg, 24-hour dietary recalls [24HR]) and prospective methods (eg, weighed food records), have long been used in research and clinical practice to capture individuals' food consumption [9]. Meanwhile, emerging technologies, including mobile apps [10], wearable devices [11], and virtual reality [12,13], are increasingly used to assist in dietary surveys. For retrospective methods, the main challenge is their reliance on self-reporting, which can be prone to bias, especially in younger populations. Young children have limited ability to recall, estimate, and cooperate in dietary investigations [14], and their diets and eating habits tend to be more variable compared to those of adults [15]. Prospective methods are often challenging to implement due to high labor costs and also rely on respondents' self-reports. Their food choices may be influenced by their tendency to report socially desirable food consumption [16], while novel methods, such as mobile apps, often underestimate the intake of energy or specific nutrients [10,17]. Additionally, all these methods were unable to capture the broader contextual dietary factors, such as eating environment and food preferences, that influence dietary behaviors in adolescents. Particularly, children's diets are typically shaped by their families or school environment [18], which may obscure their food preferences, including adverse tendencies toward unhealthy eating habits. It is reported that children would select different foods when they were away from their parents compared to when they were watched [19]. When food is freely available and parents are absent, they always tend to choose more restricted foods, often considered unhealthy, over unrestricted options, which may contribute more to their health and development [20].

To address these limitations, a combination of gamification and dietary assessment could be a potential solution. Gamification, defined as the use of game design elements in nongame contexts [21], is an emerging interactive digital strategy that has gained widespread application and research across various fields [22,23]. In the domains of health, gamification primarily targets children for chronic disease management [24], physical activity [25], mental health [26], and nutrition education [27,28]. To the best of our knowledge, there is a lack of studies applying gamification in dietary surveys and assessments, especially for children and adolescents.

Therefore, we developed a new gamified dietary assessment tool (GDA) that engages children and adolescents in a simulated autonomous eating scenario, aiming to capture their authentic food preferences and eating behavior tendencies. An exploratory comparison study was conducted to compare the GDA with 24HR, followed by an application study to explore how the GDA captures dietary behavior tendencies beyond the scope of traditional assessment methods. Through the integration of gamification, we seek to determine whether this innovative method can provide a more comprehensive understanding of young individuals' nutrition status and true dietary tendencies.

Methods

Study Design and Population

The study comprised 2 parts. The first is an exploratory study, aiming to compare the hypothetical food choices assessed by the GDA with the actual dietary intake estimated through a traditional 24HR. The second part is an application study, using the GDA to simulate the eating process of children and adolescents to assess their dietary intake and tendencies of eating behaviors.

The exploratory study was a cross-sectional study assessing the agreement of the interviewer-led 3-day 24HR and the GDA. The research took place at an elementary school in Changzhou, Jiangsu province, China. A total of 30 school-aged children were recruited voluntarily. The exclusion criteria for participants were (1) patients with metabolic diseases or other conditions requiring a special diet and (2) patients with eating disorders or other disorders that significantly impact eating behaviors.

The application study was conducted among school-aged children and adolescents at a middle school in Lanzhou, Gansu province, China. Cluster sampling was used to select 40 classes, which contained 2241 students. The inclusion and exclusion criteria were the same as the exploratory study. To ensure data quality, we further excluded (1) the ones with abnormal energy intake (energy intake exceeding 4000 kcal or below 500 kcal), (2) participants who did not complete the Emotional Eating Scale, and (3) those who failed the attention check questions.

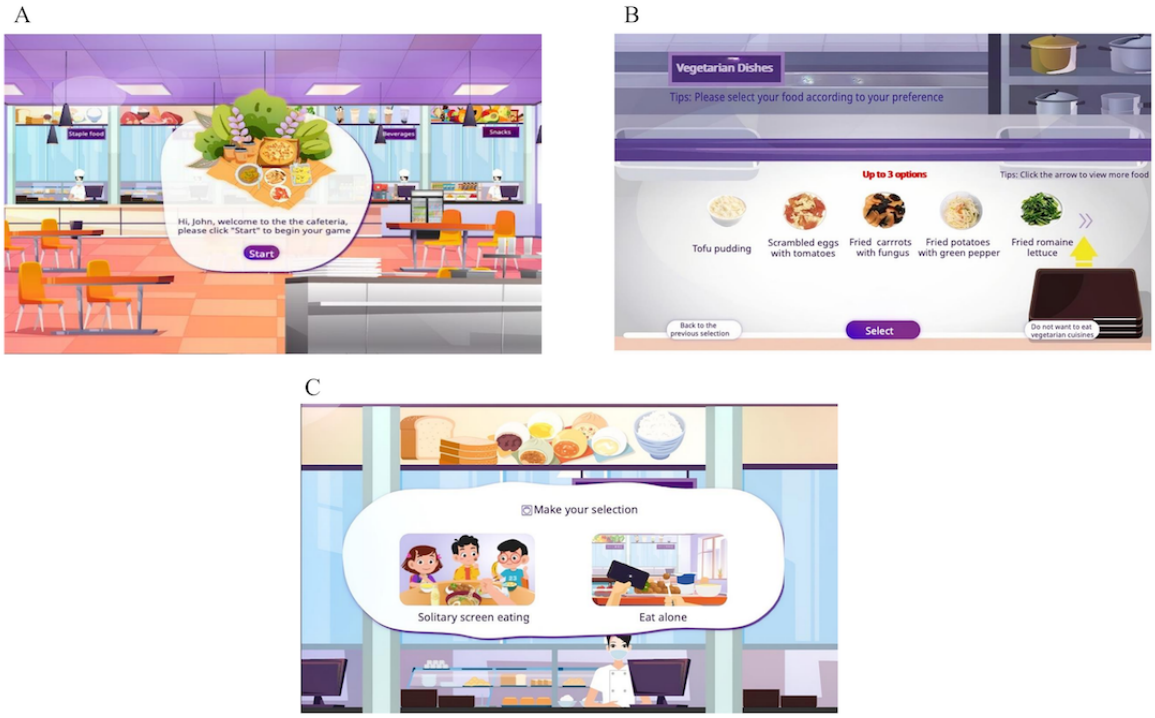
Ethical Considerations

The study was approved by the ethics committee of Institutional Review Board of Tsinghua University (Project No: 20220102). All participants and their parents were required to give consent before participating in the study, through which they were informed about the procedures and other related information of the study. No compensation was provided to participants. All human participant data have been anonymized or deidentified to protect participants' privacy, with no personal identifiers retained in records or analyses.

Data Collection

Data collection for 24HR and GDA in the exploratory study took place in May 2023. The first 24HR interview was conducted on day 1 by trained researchers, followed by the self-administered GDA survey on the same day. The remaining 2 24HR interviews were conducted on days 2 and 3, respectively.

In the application study, basic information was collected by trained researchers using a standard protocol. BMI-for-age *z* score (BMI *z* score) was then calculated according to the growth reference standards for children and adolescents aged 5 to 19 years provided by the World Health Organization [29]. The severity of emotional eating behaviors was assessed by emotional eating scores (EESs) based on the Emotional Eating Scale [30]. This scale is based on 1 dimension of the Intuitive Eating Scale-2, specifically the "Eating for Physical Rather than Emotional Reasons" dimension, which includes 8 items, 4 of which are reverse-scored. As no version specifically validated



XSL•FO
RenderX

for Chinese children and adolescents is currently available, a widely applied general version of the EES was adopted. Participants were instructed, “For each item, please check the answer that best characterizes your eating attitudes or behaviors.” The item-response scale was a 5-point scale, where 1 indicates strongly disagree, 2 indicates disagree, 3 indicates neutral, 4 indicates agree, and 5 indicates strongly agree. Reverse-scored items were rated inversely, with 1 indicating strongly agree to 5 indicating strongly disagree. EES ranged from 5 to 40, with higher scores indicating a greater likelihood of engaging in emotional eating behaviors as a way to cope with negative emotions. The EES was self-administered by participants via the digital platform under the supervision and guidance of trained investigators. Dietary intake data and dietary behavior data were collected with the GDA.

Gamified Dietary Assessment Tool

The dietary assessment tool was designed with gamification principles to improve user engagement and accuracy. Core gamification elements included (1) a drag-and-drop interaction mechanic for food selection, (2) a dynamic progress bar and encouraging prompts for real-time feedback, and (3) a visually engaging interface with animations and child-friendly graphics to reduce cognitive burden and enhance immersion. These features aimed to transform traditional dietary recall into a more intuitive and motivating experience for children and adolescents. The GDA consisted of 3 primary modules (Figure 1A-C): the guided tutorial module, the food selection module, and the dining scenario selection module. In the guided tutorial module, the GDA offered prompts to instruct participants on how to complete the survey. Participants then proceeded to the second module to choose foods for breakfast, lunch, and dinner in sequence under a virtual buffet situation. Children were asked to make their independent decisions on what types of dishes or beverages and what quantities they wished to consume by dragging and dropping food portions from the buffet table. There was a total of 66 dishes or beverages, which consisted of 81 food items belonging to 10 main food groups, including cereals, tubers, vegetables, fruits, livestock and poultry, aquatic products, eggs, dairy products, legumes, nuts, as well as 2 groups of processed food (including snacks and beverages). Specifically, alcoholic beverages were included in the GDA food list to reflect real-life dietary exposure and to allow the identification of potentially harmful alcohol intake tendencies, although alcohol intake data were not analyzed in this study. Dishes were designed by nutritional experts according to the dietary culture of China and their nutritional contents. The details of dish and beverage selection are shown in Multimedia Appendix 1. After completing the food selection, participants were supposed to select the dining scenarios, with 2 options available: “solitary screen eating” and “eat with peers.” Participants who chose “eat with peers” were presented with an animation featuring several children engaging in cheerful conversation while eating. In contrast, those who selected “solitary screen eating” were presented with an animation depicting a child eating while watching cartoons on a mobile phone. The main outputs of the GDA encompassed eating behavior tendencies, estimated food intake, and nutrient intake based on the selected food items in the GDA.

Figure 1. Three primary modules designed in the gamified dietary assessment tool (GDA): (A) module of guided tutorial, (B) module of food selection, and (C) module of dining scenario selection.

Food, Energy, and Nutrient Intake Assessment

In an exploratory study, the quantitative measurement of food intake by 24HR was assisted by Photographic Atlas of Food Portions for Accurate Quantification of Dietary Intakes in China [31] and standard utensil models, which allowed participants to estimate portion sizes by comparing their intake against

XSL•FO
RenderX

standardized images and models. Thereafter, energy and nutrient intake were calculated according to the China Food Composition Tables, Sixth Standard Edition [32]. The 3-day average intakes of energy and nutrients were used in statistical analysis.

For the GDA, all mixed dishes were decomposed into their constituent ingredients. Energy and nutrient intakes in both exploratory and application studies were calculated by summing the nutrient values of each component based on China Food Composition Tables, Sixth Standard Edition [32].

Data Analysis

The Shapiro-Wilk test for normality indicated that the energy intake and the nutrient intake in the exploratory study were not normally distributed. Consequently, descriptive statistics for energy and nutrient intake were reported as medians with interquartile ranges. The logarithmic transformation of the variables was performed, as dietary data on energy, nutrient, and food intake typically exhibit a right-skewed distribution that can be effectively normalized by this transformation, and Pearson correlation analysis was used to examine the association between the 2 dietary assessment methods regarding these intake measures. If the log-transformed data still did not follow a normal distribution, Spearman rank correlation analysis was then used to assess the correlation between the 2 methods. Additionally, Bland-Altman plots were constructed to visually assess the agreement between the 24HR and the GDA. This method involves plotting the mean value of the 2 measurements on the x-axis and the difference between them on the y-axis, with the mean difference and 95% limits of agreement displayed to evaluate the consistency between the 2 methods.

In the application study, descriptive statistics for energy intake, nutrient intake, food intake, and macronutrient energy ratio were also presented as medians with interquartile ranges. A comparison of demographic characteristics was also conducted between the included population and those who failed the attention check question using the Wilcoxon test and Fisher exact test. The distribution of macronutrient energy ratios was described and compared with the Dietary Reference Intakes for China [33]. The Kruskal-Wallis rank sum test was used to compare the energy intake, nutrient intake, food intake, and macronutrient energy ratio among participants with different sociodemographic characteristics, while Fisher exact test was used to compare the distributions of macronutrient energy ratio across different categorical groups due to small numbers in certain distribution groups. We used multiple linear regression models to examine the association between EES and nutritional outcomes. Age, sex, and socioeconomic status were included as covariates. Energy intake was divided by 10 due to the large values of energy intake. Stratified analysis was further conducted according to BMI *z* scores. BMI *z* scores less than –2 were defined as “thin,” scores −2 or higher and 1 or less as “normal,” and scores greater than 1 as “overweight and obese” [34]. The ß-values and 95% CI for each model were calculated to assess the effects of emotional eating behavior tendencies on nutritional outcomes. Three models were applied: model 1 made no adjustments; model 2 adjusted for age, sex, and socioeconomic status; and model 3 further adjusted for energy intake. Additionally, dynamic scatter plots were generated using the “gganimate” package in R, illustrating the association between EES and macronutrient intake across different BMI *z* score groups to visualize how emotional eating affects energy and macronutrient intake across weight statuses. Multiple linear regression models were also used to evaluate the association between dining environment tendencies and nutritional outcomes.

Statistical analysis was conducted using the R software (version 4.3.0; Posit PBC), with all tests being 2-sided and a significance level set at .05.

Results

Exploratory Study

A total of 30 school-aged children were recruited, including 9 (30%) male participants and 21 (70%) female participants. Participants ranged in age from 9 to 11 years, with an average age of 10.7 years (SD 0.55). Nutrient data from the GDA and 24HR were not normally distributed. Consequently, a logarithmic transformation was applied to the energy and nutrient intake values. Pearson correlation analysis of the transformed data showed significant positive correlations between the 2 methods for energy intake, carbohydrates, cholesterol, and a few micronutrients (vitamin A and vitamin C). No significant correlations were observed for the other nutrients, as presented in Table 1.

XSL•FO

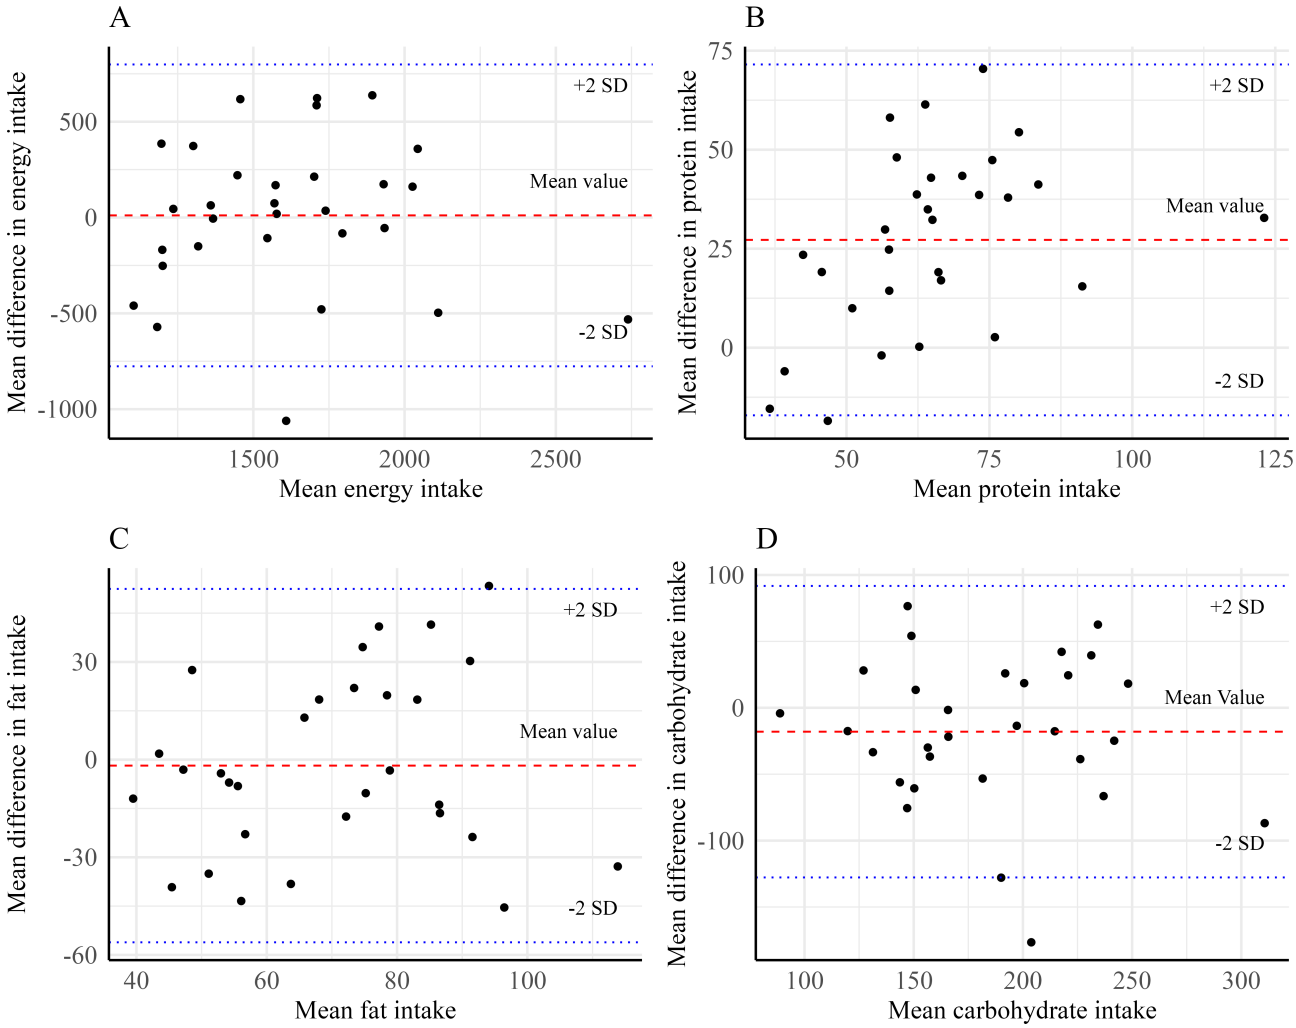
Nuts (g)[a]	0.0 (0.0-30.0)	0.0 (0.0-0.0)	−0.26	.17

[a]The intake of vitamin D and nuts showed minimal variability in 24-hour dietary recalls, which limits the interpretability of correlation coefficients for these variables.



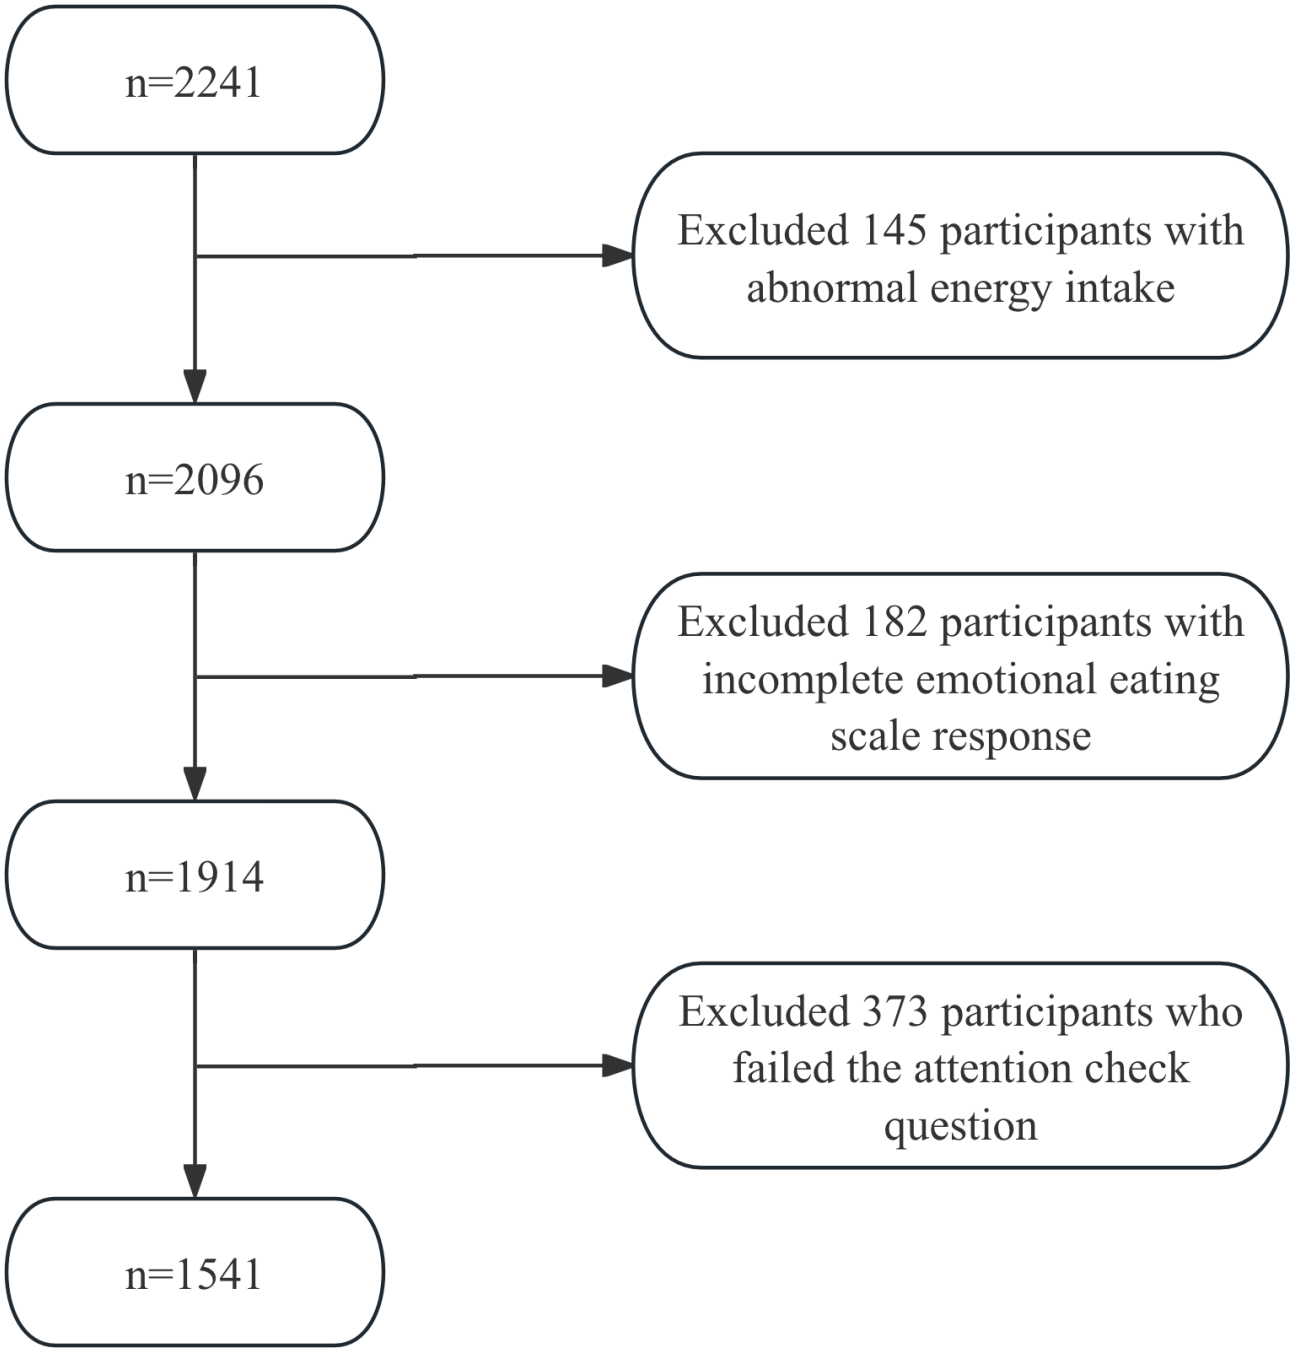
Food intake data were nonnormally distributed, requiring logarithmic transformation, but the transformed data still remained nonnormally distributed. Thus, Spearman rank correlation analysis was conducted. Significant positive correlations were observed between 24HR and the GDA for the intake of cereals, fruits, and dairy products, while no significant correlations were found for other food categories (Table 1).

The Bland-Altman plot showed that the mean differences in energy (Figure 2A), fat (Figure 2C), and carbohydrate (Figure 2D) intake between the 24HR and the GDA were centered around zero, with all observations evenly distributed within the

XSL•FO
RenderX

95% CI on both sides of the mean difference, which indicated good agreement between the 2 methods. However, the mean difference for protein intake (Figure 2B) was approximately 25 g, suggesting that the GDA may indicate a higher protein intake compared with 24HR.

Figure 2. Bland-Altman plots comparing the intake of energy and macronutrients in 24-hour dietary recall (24HR).



Application Study

In the application study, a total of 2241 participants were initially recruited, resulting in 1541 valid samples (Figure 3), comprising 949 (61.6%) male participants and 592 (38.4%) female participants with an age range of 11 to 18 years and a mean age of 15.2 (SD 1.6) years. Participants excluded due to failed attention checks were significantly younger than those included in the final sample (P<.001).

XSL•FO
RenderX

Figure 3. Flowchart of the application study.

The median GDA-estimated energy, protein, fat, and carbohydrate intakes were 1877.3 (IQR 1410.0-2221.8) kcal, 96.4 (IQR 69.5-113.9) g, 74.0 (IQR 52.5-96.8) g, and 202.0 (IQR 156.3-238.7) g, respectively. Participants aged 11 to 14 years showed a significantly greater tendency to intake more carbohydrate compared to those aged 15 to 18 years (P<.001). Male participants demonstrated a higher tendency to intake more energy (P=.003), carbohydrate (P=.04), protein (P=.01), and fat (P=.01) than female participants. However, no significant differences were observed in GDA-estimated energy and macronutrient intake across different weight status levels or socioeconomic status levels. The median GDA-estimated intake of various food groups among the participants was 210.1 (IQR 159.7-270.0) g for cereals, 58.5 (IQR 0-58.5) g for tubers, 201.0 (IQR 126.7-279.3) g for vegetables, 30.6 (IQR 0-61.2) g for fruits, 250.5 (IQR 156.2-340.0) g for livestock and poultry, 170.0 (IQR 90.0-250.0) g for aquatic products, 39.0 (IQR 12.9-67.1) g for eggs, 45.7 (IQR 11.1-148.1) g for dairy products, 0 (IQR 0-58.4) g for legumes, and 0 (IQR 0-0) g for nuts, 240.0 (IQR 120.0-360.0) mL for beverages, and 78.0 (IQR 48.0-106.8) g for snacks. Significant differences were found in GDA-estimated intake of cereals (P=.02), fruits (P=.003), and legumes (P=.02) across age groups. Sex differences were also observed, with male participants tending to consume significantly more cereals (P<.001), vegetables (P<.001), livestock and poultry (P=.02), and legumes (P=.009) than female participants, while female participants had a higher GDA-estimated intake of fruits (P<.001) and dairy products (P<.001) than male participants. No significant differences were observed in other food groups across different weight status

XSL•FO
RenderX

levels or socioeconomic status levels (Multimedia Appendix 2).

The median ratios of GDA-estimated protein energy contribution, fat energy contribution, and carbohydrate energy contribution were 20.4% (IQR 18.4%-22.1%), 35.8% (IQR 31.4%-41.1%), and 44.0% (IQR 39.7%-49.0%), respectively. The 11- to 14-year group had a higher carbohydrate energy ratio (P<.001) and a lower fat energy ratio (P<.001) compared with the 15- to 18-year group. Sex difference was also observed, with female participants having a higher carbohydrate energy ratio (P=.002). A total of 42.9% (n=661) of the participants had a protein energy ratio within the acceptable macronutrient distribution range (AMDR) (10% - 20%). 17.9% (n=276) of the participants had a fat energy ratio within the AMDR (20% - 30%). 20.1% (n=310) of the participants had a carbohydrate energy ratio within the AMDR (50% - 65%). Only the distribution of carbohydrate energy intake ratios (P=.02) showed significant differences across gender (Multimedia Appendix 3).

Furthermore, we explored the association between emotional eating behavior and nutritional outcomes among participants using the GDA. The median (IQR) EES was 22.3 (19-25). After adjusting for age, sex, and socioeconomic status, multiple linear regression analysis showed that higher EESs were significantly associated with a greater tendency to select more carbohydrates, while no significant associations were found for protein or fat selections. After further adjusting for energy intake tendencies, higher EESs were associated with a lower protein intake tendency, with no significant associations observed for fat or carbohydrate intake tendencies (Table 2).

Table . The association between gamified dietary assessment tool (GDA)–estimated intakes of energy, macronutrients, food groups, and emotional eating scores.

Variables	β (95% CI)

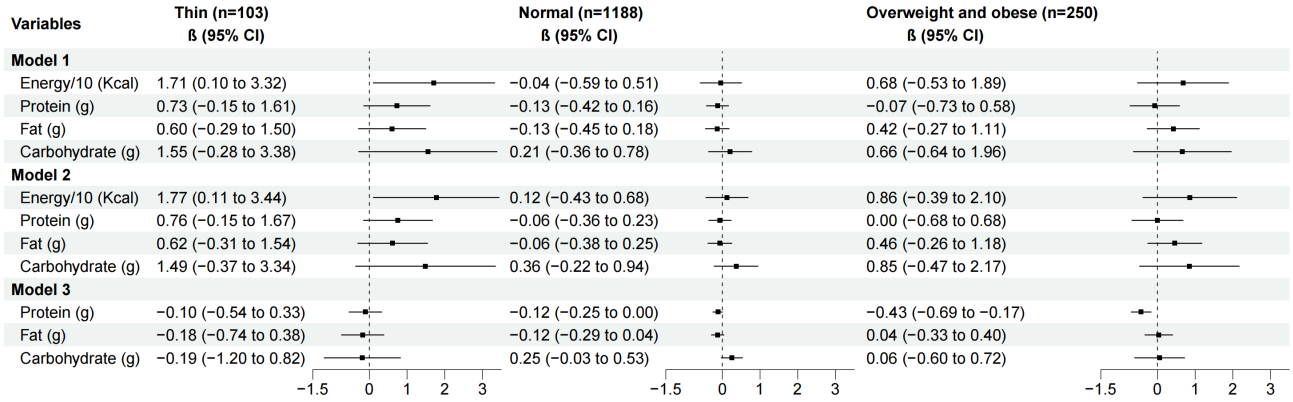
[a]Model 1 made no adjustment for any covariates. Model 2 was adjusted for age, sex, and socioeconomic status. Model 3 was adjusted for energy intake, age, sex, and socioeconomic status.



[b]Not available.

Emotional eating behavior also influenced the selections of several food groups. After adjusting for age, sex, and socioeconomic status, higher EESs remained positively associated with a greater tendency to select beverages and snacks, while the selection of fruits and nuts was significantly fewer. After further adjustment for total energy intake, higher EESs were still associated with higher snack selection and fewer selections of fruits and nuts, with no significant associations observed for other food groups (Table 2).

Stratified analysis indicated that higher EESs remained associated with a greater energy intake tendency among the thin population, even after adjusting for age, sex, and socioeconomic status. In the overweight and obese population, a higher EES was associated with a lower tendency to select protein-rich foods, but only after adjusting for age, sex, and total energy intake tendency. In the normal weight population, no significant associations were found between EES and the intake tendencies for energy, protein, carbohydrates, or fat (Figure 4).

XSL•FO
RenderX

Figure 4. Associations between the emotional eating scale (EES) and intakes of energy and macronutrients stratified by BMI-for-age *z* score (BMI *z* score).

Additionally, dynamic scatter plots were used to provide a clear visual representation of how the association between EES and the energy intake tendency levels varied across different BMI *z* scores. However, there is no significant association observed between EES and the intake tendencies of energy, protein, carbohydrates, or fat across different BMI *z* score categories (Multimedia Appendix 4).

We also applied the GDA to investigate the association between dining environment tendencies and nutritional outcomes. In total, 525 (34.1%) participants selected “eat with peers”, while 1016 (65.9%) participants selected “solitary screen eating”, and no significant difference in scenario selection was observed across age, sex, and socioeconomic status. The results presented in Table 3 indicated that participants who wished to eat alone while watching cartoons tended to select 6.9 g more carbohydrates, on average, than those who wished to eat with peers. Even after adjusting for age, sex, and socioeconomic status, those who wished to eat alone while watching cartoons still tended to select 7.7 g more carbohydrates than those who wished to eat with peers. Further adjusting for total energy intake, the difference remained significant, with those who wished to eat alone while watching cartoons tending to select 4.2 g more carbohydrates.

Table . Effects of dining environment tendencies on intakes of energy, macronutrients, and food groups.

Variables	β (95% CI)		
	Model 1[a]	Model 2	Model 3
Energy (kcal)	4.0 (−1.8 to 9.8)	3.9 (−1.9 to 9.6)	—[b]
Protein (g)	2.3 (−0.7 to 5.4)	2.1 (−1.0 to 5.2)	0.3 (−1.0 to 1.5)

Nuts (g)	−1.0 (−2.5 to 0.4)	−1.1 (−2.5 to 0.4)	−1.2 (−2.7 to 0.2)
Beverages (mL)	15.4 (−0.1 to 30.8)	17.7 (2.3 to 33.2)	13.9 (−0.5 to 28.3)
Snacks (g)	2.4 (−2.7 to 7.5)	3.3 (−1.8 to 8.4)	2.2 (−2.6 to 7.0)

[a]Participants who selected “eating with peers” were used as reference. Model 1 made no adjustment for any covariates. Model 2 was adjusted for age, sex, and socioeconomic status. Model 3 was adjusted for energy intake, age, sex, and socioeconomic status.

[b]Not available.

Regarding main food groups, participants who wished to eat alone while watching cartoons tended to select 4.3 g more eggs, on average, compared to those who wished to eat with peers, a statistically significant difference. After controlling for age,

XSL•FO
RenderX

sex, and socioeconomic status, the difference remained significant, and the former group tended to consume 10.2 g more cereals, 4.8 g more tubers, 3.8 g more eggs, and 17.7 mL more beverages than the latter (Table 3). However, after further adjusting for energy intake, a willingness to eat alone while watching cartoons did not influence the selection of any food group.

Discussion

This study suggests that the GDA may be a promising approach for simulating dietary choices and assessing eating behavior tendencies, providing insights into developing novel dietary survey methods.

GDA Could Reflect Some Aspects of Dietary Intakes

In exploratory analysis, we observed moderate associations between the GDA and 24HR for energy, carbohydrate, cholesterol, and certain vitamins, indicating that adolescents' hypothetical food selections in the GDA may reflect some aspects of their actual intake. However, no significant correlations were found for other nutrients, such as protein, fat, and several micronutrients, suggesting that the GDA may capture only specific dimensions of dietary behavior and not serve as a comprehensive measure of actual intake. This discrepancy may be attributed to the limited food options in the GDA, which cannot fully capture the variety of real-world foods. Despite efforts to include representative foods from different regions of China, a gap remains between the actual food choices of children and adolescents and those offered in the GDA. Similarly, a study using virtual reality technology to simulate dietary choices also found differences between the foods selected in the real world and those chosen in the virtual environment [12].

Additionally, the exploratory study found that the GDA significantly overestimated protein intake, possibly reflecting children's preferences for protein-rich foods. This finding aligns with the results of the application study, which showed that livestock and poultry meat intake exceeded 200 g, significantly higher than the recommended value in the Dietary Reference Intakes for China [33]. The high proportion of high protein energy ratio distribution may also result from the overestimation. Over the past decades, rapid economic development has significantly increased meat consumption in China [35], and people have become more aware of the importance of protein for the growth and development of children and adolescents, which may have led to a preference for meat among them. Another explanation could be the biased visual presentation or portion sizes of protein-rich foods in the GDA. It may have made these items more appealing, potentially encouraging the selection over other food groups. Excessive meat consumption can increase the risk of obesity [36]; therefore, the meat intake preferences identified in children and adolescents through the GDA should be addressed promptly. Dietary patterns during childhood and adolescence are highly malleable [37], making it crucial to correct unhealthy food preferences at this stage to promote lifelong health. Several other nutrients also showed substantial discrepancies between the GDA and the 24HR, although these differences are significant. Notably, sodium was markedly underestimated in the GDA, likely because the simulated environment includes fewer high sodium processed foods. For vitamin D, the GDA data showed a median (IQR) intake of 3.3 (2.4-4.3) µg, whereas 24HR's median (IQR) intake was 0 (0-0) since there were only 2 nonzero values. These differences further indicate that the GDA captures preference-driven hypothetical selections rather than actual nutrient intake, underlying the conceptual distinction between the 2 assessment methods.

Role of the GDA in Uncovering Food Preferences and Eating Behavior Tendencies

In the application analysis, we found the absence of significant differences in GDA-estimated energy selection across weight status groups. This may reflect both developmental and methodological factors. During adolescence, weight status does not necessarily correspond to energy requirements because of large variability in growth and maturation. Besides, the GDA captures hypothetical, preference-based food selection rather than physiological energy needs, allowing adolescents across weight groups to select some high-calorie foods in a virtual setting. Additionally, the limited range of food options in the GDA may further attenuate between-group differences. The primary aim of developing the GDA is to capture dietary behaviors and food preferences among children and adolescents. These aspects are often overlooked and challenging to obtain through traditional dietary surveys. In our application study, we found that the GDA can identify adverse eating behaviors. Individuals with high EESs tended to consume more carbohydrates and less protein, suggesting that they coped with their emotions by selecting high-carbohydrate foods. Regarding food groups, participants with higher EESs showed a greater tendency to choose more beverages and snacks and fewer fruits and nuts, despite median selections for some groups being zero. Previous studies have shown that emotional eating behavior in adolescents was positively associated with higher consumption of high-energy–dense foods, such as cake, ice cream, and beverages [38]. The mean frequency of high-energy–dense food intake was roughly 3 to 4 times higher than that of fruits and vegetables [39]. However, traditional dietary surveys collect data on school- or family-provided meals, potentially masking children's tendencies for emotional eating. The GDA may help reveal more authentic dietary behavior tendencies, such as emotional eating, by allowing children and adolescents to make food choices without the external constraints typically present in real-life settings—such as parental supervision or school meal policies. In this autonomy-simulated environment, their intrinsic preferences and decision-making patterns—such as a tendency to select high-calorie or high-fat foods—can be more clearly observed. This enables the following targeted psychological counseling and nutrition education, which not only enhances the mental health of children and adolescents but also promotes healthy eating patterns. More interestingly, a positive association between EESs and higher energy selection tendency was observed only in the thin subgroup. This finding suggests that the GDA may be particularly sensitive to identifying latent emotional eating tendencies before they translate into weight gain. Emotional eating behaviors may occur earlier than changes in BMI, especially among thin

XSL•FO
RenderX

adolescents. However, this result was preliminary and based on a relatively small sample size of thin groups, which should thereby be interpreted with caution.

In this study, we also identified that the dining environment can impact the nutritional outcomes of children and adolescents [40]. In this study, children and adolescents who selected the solitary screen eating scenario tended to choose more carbohydrates than those in the social eating scenario. Screen time during meals may be the critical influencing factor. A number of studies in Europe [41] and the United States [42] have demonstrated that screen exposure during meals, such as watching television, is significantly associated with obesity in children and adolescents. Therefore, the observed association could be attributable to the simulated screen time, which is known as an adverse eating behavior. Although the observed 7 g difference in daily carbohydrate intake may not be clinically significant in isolation, it may reflect meaningful behavioral tendencies—such as watching screens while eating food—that could cumulatively influence dietary patterns and health outcomes over time, particularly during adolescence. Our finding aligns with previous studies [43], as screen time, such as TV viewing, has been associated with increased consumption of sugar-rich foods, leading to higher carbohydrate intake [44].

Further Development

In the future, to fully realize the potential of the GDA in dietary assessment, ongoing improvements and upgrades to the GDA are needed. First, to better simulate children's eating processes and assess dietary intake, the GDA should incorporate a wider variety of foods and regularly update precise nutritional data for each item. Second, the mealtime environment can significantly influence the nutritional and behavioral outcomes of children and adolescents [45,46]. The GDA should therefore enrich meal setting options, such as meal duration and dining location, to maximize its effectiveness in addressing adverse eating behavior tendencies in advance. Finally, gamification has already been successfully applied in developing certain nutrition education games [27,47]. The GDA could also incorporate a food and nutrition education module, making the nutrition education process more engaging and accessible while offering users personalized, practical dietary improvement suggestions.

Strengths and Limitations

The study used a dual-phase approach, integrating both an exploratory study and an application study. This design not only explored the application of gamification in dietary assessment but also provided insights into the dietary behavior tendencies and food preferences of children and adolescents in a simulated context. However, we acknowledged some limitations. First, this study was conducted solely among populations in 2 Chinese cities, limiting the representativeness of the findings. Future research should involve a larger, multicenter population sample to enhance the generalizability of the results. Second, the exploratory study did not compare the GDA with the weighed record method, which was regarded as the gold standard for dietary assessment but was challenging to implement. The applicability of the findings may also be limited as EES was not specifically validated for our study population of Chinese children and adolescents. Third, this exploratory study included a small sample size (n=30), which may limit the generalizability of the findings. However, the primary aim was to preliminarily assess the consistency between the GDA and 24HR rather than to provide definitive validation or precise estimates. The thin subgroup (n=103) in stratified analysis was also small. This limited sample size reduced the statistical power of the regression models and resulted in wide confidence intervals, suggesting that the observed associations in this subgroup should be interpreted cautiously. Fourth, as participants in the application study were middle school students in an older age range, further research is needed to determine the applicability of the GDA for younger children. Another limitation is that the 24HR did not include weekend days, which might have introduced bias, as dietary patterns can vary between weekdays and weekends. This was due to the on-site data collection schedule during school days. Besides, this study did not investigate user acceptability, which may vary across ages and cultural backgrounds in response to the GDA. In addition, the high rate of exclusion due to failed attention checks (373 out of 2241) suggested potential selection bias since participants who failed attention checks were significantly younger. Besides, in the GDA, the solitary eating scenario involves screen exposure. Therefore, the independent effects of eating alone and screen exposure could not be disentangled. Finally, there are some methodology limitations. As the GDA is designed to capture preference-based dietary behavior tendencies rather than actual intake, several food groups exhibited zero-inflated distributions with median values of zero. These patterns reflect selective hypothetical choices rather than true absence of consumption and may limit the suitability of standard linear regression. There are conceptual and methodological mismatches between the GDA and 24HR. While 24HR aims to quantify 3-day averaged actual nutrient and energy intake, which smooths out daily variations, the GDA is designed to capture 1-time hidden dietary behavior tendencies in a simulated environment. This difference reflects the distinct purposes of the tools and should be considered when interpreting their comparison. Moreover, the gamified nature of the virtual buffet may have encouraged curiosity-driven selections that do not fully reflect habitual dietary behavior, potentially introducing bias unrelated to dietary behavior.

Conclusions

This study compared the new gamified dietary assessment tool with the interview-led 24HR among children and adolescents for intakes of food groups, nutrients, and energy. While the GDA cannot fully reflect actual food and nutrient intake, it is primarily designed to capture dietary intake tendencies, particularly adverse eating behaviors that may not be easily detected by traditional dietary assessment methods. Despite some discrepancies with 24HR data, the GDA provides valuable insights into patterns of food selection and eating habits tendencies among children and adolescents, which could be hidden in traditional dietary survey methods. The GDA can thus serve as a complementary tool to traditional dietary assessment instruments in the field of dietary survey methods, thereby enhancing the comprehensiveness and accuracy of dietary survey outcomes.

Abstract

Background: Internet gaming disorder (IGD) and school refusal are increasingly prevalent during adolescence, yet limited research has examined how they influence each other over time. Moreover, it is unclear whether the association differs by sex.

Objective: This study aimed to investigate the within-person longitudinal associations between school refusal and IGD and potential sex differences in these associations among Chinese adolescent gamers.

Methods: A 3-wave prospective cohort longitudinal study was conducted among students from 4 middle schools in Zhejiang Province, China. Adolescents who had played online games in the past 12 months were involved. Participants were recruited using convenience sampling. Data were collected at 6-month intervals: time 1 (T1, March 2024), time 2 (T2, September 2024), and time 3 (T3, March 2025). A total of 918 Chinese adolescents (n=609, 66.3% male; mean 13.55, SD 0.75) participated in the 3-wave survey. IGD and school refusal were assessed using the 9-item DSM-5 (*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*) IGD checklist and the School Refusal Assessment Scale-Revised. A random intercept cross-lagged panel model and multigroup analyses were conducted.

Results: All statistical tests were 2-tailed with α=.05. The random intercept cross-lagged panel model demonstrated good fit to the data (χ^2_5=16.02; comparative fit index 0.970; root mean square error of approximation 0.035). Cross-lagged effects indicated a reciprocal association between school refusal and IGD. School refusal predicted later IGD (T1→T2: β=.06, 95% CI .02-.08; *P*=.02 and T2→T3: β=.06, 95% CI .02-.08; *P*=.02), and IGD predicted subsequent school refusal (T1→T2: β=.12, 95% CI .09-.15; *P*<.001 and T2→T3: β=.13, 95% CI .08-.16; *P*<.001). Multigroup analyses revealed significant sex differences. Wald tests showed sex-specific effects: among females, school refusal predicted later IGD (T1→T2: β=.10, 95% CI .05-.15; *P*=.006 and T2→T3: β=.11, 95% CI .04-.17; *P*=.004), whereas these paths were nonsignificant for males. IGD predicted later school refusal in both sexes, but the effect was stronger for males (T1→T2: β=.15, 95% CI .12-.18; *P*<.001 and T2→T3: β=.15, 95% CI .12-.18; *P*<.001) than females (T1→T2: β=.07, 95% CI .03-.10; *P*=.02 and T2→T3: β=.07, 95% CI .03-.10; *P*=.02).

Conclusions: This study provides novel insights into the reciprocal within-person associations between school refusal and IGD among adolescents. By accounting for stable between-person differences, the model clarifies how within-person fluctuations in one behavior relate to subsequent changes in the other. Sex-specific patterns were observed: school refusal predicted subsequent IGD among females, whereas IGD predicted later school refusal more strongly among males. These findings highlight the dynamic interplay between school disengagement and problematic gaming and underscore the importance of sex-sensitive intervention strategies.

KEYWORDS

adolescent gamers; internet gaming disorder; school refusal; reciprocal association; sex differences

Introduction

Internet gaming disorder (IGD) refers to persistent and maladaptive engagement in online gaming that leads to significant functional impairment and is increasingly recognized as a pressing public health concern [1]. IGD is characterized by impaired control over gaming, prioritization of gaming over other responsibilities, and sustained engagement despite negative

XSL•FO
RenderX

consequences [2]. Prevalence estimates highlight its public health relevance during adolescence, with meta-analyses reporting pooled rates ranging from 6.7% to 8.8% [3,4], and studies across different regions document similar elevated levels [5]. In China, a recent meta-analysis reported an IGD prevalence of approximately 10% [6]. IGD has been associated with numerous psychological and social difficulties, including depressive symptoms, loneliness, aggressive behaviors, and strained family relationships [7-10]. These patterns highlight that IGD encompasses broader developmental risks beyond excessive gaming alone. Given its multifaceted impact, understanding the processes that may reinforce or exacerbate IGD is essential. One understudied yet potentially important factor is school refusal, which may interact dynamically with IGD and form reciprocal influences over time, particularly during adolescence.

School refusal refers to difficulties in attending or remaining in school, including tardiness, skipping classes, morning misbehaviors designed to avoid school, and attending school with significant distress or reluctance [11,12]. School refusal is often accompanied by marked negative emotions such as anxiety, fear, and emotional distress [13]. According to the Functional Behavioral Model [14], school refusal is maintained by 4 key reinforcement-based functions: avoidance of negative affectivity (ANA), escape from aversive situations (EAS), attention-seeking (AS), and PTR. Existing evidence suggests that school refusal is highly prevalent, with estimates ranging from 28% to 35% among children and adolescents in Western and global samples [15] and from 22.5% to 30% in various regions of China [16]. Importantly, adolescents who exhibit school refusal are more likely than their peers to develop subsequent behavioral and adjustment difficulties [17,18].

School refusal is closely related to IGD among adolescents. However, the directionality between these 2 behaviors remains unclear. Given these uncertainties, it is necessary to consider how school refusal and IGD might relate to each other in both directions. First, school refusal may increase IGD. According to escape-avoidance theory, individuals tend to withdraw from environments that elicit stress or negative affect [19]. Adolescents who experience academic pressure, social-evaluative concerns, or negative emotional states at school often show higher levels of school refusal [20]. Online gaming, which offers immersion, controllability, and immediate relief from distress, may thus become an attractive alternative to aversive school experiences, thereby school refusal and increased gaming engagement within a shared pattern of avoidance-oriented coping [21]. In other words, when school elicits persistent distress, gaming may function as an emotionally soothing and controllable environment, reinforcing avoidance tendencies and increasing adolescents' susceptibility to IGD.

Second, IGD may similarly increase school refusal. According to self-determination theory [22], individuals have 3 basic psychological needs: autonomy, competence, and belonging. Gaming environments frequently satisfy these needs through structured challenges, opportunities for volitional action, and social interaction [23,24]. When these experiences are perceived as more rewarding than those available in school, adolescents may experience lower motivation or diminished engagement in academic settings [25]. Sustained involvement in gaming may further weaken school-related motivation by displacing academic goals, reducing tolerance for effortful learning, and amplifying the contrast between gratifying digital environments and demanding school contexts. Under such conditions, stronger gaming involvement may be accompanied by increased tendencies toward school disengagement or avoidance. Together, these theoretical perspectives suggest that school refusal and IGD may mutually reinforce each other over time.

Empirical findings may provide support for this potential bidirectional association between school refusal and IGD. Consistent with theoretical expectations, studies across different cultural contexts show that adolescents who struggle with school engagement are more likely to rely on gaming or digital media. For example, digital game addiction was positively associated with school refusal among adolescents in Turkey [21], and excessive internet engagement was strongly related to both truancy and medically certified absences in a large Finnish national sample of more than 86,000 students [26]. Research also indicates that problematic internet use is a salient external correlate of school refusal; a latent class study among Chinese adolescents found that youth with school refusal behaviors frequently use gaming or online activities to escape academic and social pressures [27]. Additional evidence from Japan further shows that problematic internet use is highly prevalent among adolescents clinically identified with school refusal [28]. Conversely, research on school-related protective factors shows that stronger school identification predicts lower IGD risk [29]. This finding indirectly suggests that weakened school connectedness, which is often observed among youth with school refusal, may heighten vulnerability to gaming-related problems.

Reviews and meta-analytic work also highlight consistent associations between problematic internet use and school-related outcomes. A recent review synthesizing 10 studies concluded that problematic internet use represents a risk factor for school refusal [13], although no meta-analysis to date has examined school refusal and IGD specifically. Longitudinal findings further illustrate that digital behaviors are relevant to school functioning: problematic social media use and problematic smartphone use have been associated with declines in academic performance [30,31], problematic social network site use has predicted subsequent school absenteeism [32], and problematic gaming has been prospectively linked to increased truancy [33]. Despite these findings, no longitudinal studies have directly examined the potential bidirectional association between school refusal and IGD. This gap highlights the need for research that clarifies how school refusal and IGD may co-develop over time.

Emerging evidence suggests that the association between school refusal and IGD across developmental pathways may differ by sex. Epidemiological studies consistently show that male adolescents exhibit a higher prevalence of IGD than females [34,35]. Furthermore, male participants with IGD tend to be more sensitive to gaming-related rewards, whereas female participants show stronger affective dysregulation and mood-related symptoms [36]. These sex-specific patterns in gaming motivation and emotional processes may contribute to differential pathways linking school-related distress and

XSL•FO
RenderX

problematic gaming behavior. At the same time, sex differences have also been documented in school attendance problems. For instance, female students generally report higher levels of school nonattendance compared with male students [37]. Evidence from a latent profile analysis further indicates that although most school refusal profiles show no significant sex differences, females are overrepresented in the mixed school refusal behavior profile, albeit with a small effect size [38]. This suggests that while sex disparities in school refusal are small, females may be more likely to exhibit complex or multifaceted forms of school refusal.

Although no study has explicitly tested whether sex moderates the association between school refusal and IGD, the existing evidence provides a plausible basis for sex-specific pathways. School-related distress may have a stronger impact on IGD among females due to heightened emotional vulnerability [39], whereas IGD may more strongly contribute to school-related difficulties among males, given their higher reward sensitivity and greater IGD prevalence [40]. However, it remains unclear whether these potential sex-specific patterns develop over time. This study, therefore, examines sex differences in the longitudinal association between school refusal and IGD, with the aim of informing sex-sensitive prevention strategies and advancing understanding of underlying developmental processes.

To advance the understanding of how school refusal and IGD develop over time, the present study used a 3-wave longitudinal design among Chinese adolescent gamers. A random intercept cross-lagged panel model (RI-CLPM) was applied to disentangle stable between-person differences from within-person fluctuations. Focusing on the within-person level, this study aimed to clarify the reciprocal relationship between school refusal and IGD. Based on previous empirical findings and theoretical perspectives, three hypotheses were proposed: (H1) Increases in school refusal would predict higher IGD at the next time point. (H2) Higher IGD would predict increases in school refusal over time. (H3) The reciprocal within-person association between school refusal and IGD would differ between male and female adolescent gamers. Findings are expected to provide deeper evidence on how short-term changes in school refusal and IGD develop and to inform sex-sensitive prevention strategies.

Methods

Study Design, Participants, and Setting

This study was designed as a 1-year prospective cohort study and conducted among students from 4 middle schools in Zhejiang Province, China. Data were collected at three 6-month intervals: time 1 (T1, March 2024), time 2 (T2, September 2024), and time 3 (T3, March 2025). The target population comprised adolescents who had played online games in the past 12 months. The participating schools were selected using convenience sampling. In collaboration with school administrators, all eligible students in the selected classes were invited to participate. Trained field workers administered the survey during regular classroom sessions. Prior to completing the questionnaire, the field workers briefed the students on the objectives and procedures of the study, assured them of the anonymity and confidentiality of their responses, and emphasized the voluntary nature of participation. Parents or legal guardians were informed about the study in advance.

To enable linkage of repeated responses across the 3 assessment waves, students provided their school identification numbers, which were subsequently encoded for matching purposes. These identifiers were permanently removed from the analytical dataset after linkage to ensure participant anonymity.

At baseline (T1), 983 adolescents who met the inclusion criteria completed the survey. By the final wave (T3), 918 participants remained in the cohort (n=609, 66.3% male; mean 13.55, SD 0.75). Among the 918 participants who completed all 3 waves, baseline demographic variables had the following missing values: sex (2/918, 0.2%), father's educational level (8/918, 0.9%), mother's educational level (5/918, 0.5%), self-reported academic performance (9/918, 1.0%), and single-parent family status (3/918, 0.3%). There were no missing data for perceived family financial situation or gaming time per month. A test for missing completely at random indicated that the missingness was completely random.

Ethical Considerations

Prior to each wave of data collection, detailed information regarding the aims, procedures, potential risks, and confidentiality protections of the study was provided to both students and their parents or legal guardians. Written informed consent was obtained from parents or legal guardians, and written assent was obtained from the students. Participation was entirely voluntary, and it was clearly communicated that students had the right to decline or withdraw from the study at any time without any academic or administrative consequences. All questionnaires were self-administered and completed anonymously. An information sheet outlining participants' rights and data protection measures was distributed before survey administration. No incentive was provided to the students. No identifiable images of participants were collected or used in this study. The study protocol and consent procedures were reviewed and approved by the Institutional Ethics Committee of the Second Affiliated Hospital & Yuying Children's Hospital of Wenzhou Medical University (approval 2024-K-239‐02).

Studied Variables and Measurements

Background Factors

Background factors were collected, including age, sex, parental educational level, self-reported academic performance, perceived family financial situations, single-parent family status, and gaming time per month.

IGD

IGD was assessed using the 9-item *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*) IGD checklist [1]. The checklist captures the presence of IGD symptoms over the past 12 months (yes/no response). The 9 criteria include preoccupation with gaming, withdrawal, tolerance, loss of control, giving priority to gaming over other activities, persistence despite negative consequences, deception regarding gaming time, escapism, and functional impairment

XSL•FO
RenderX

due to gaming. It has been validated among adolescents and demonstrated satisfactory psychometric properties [41]. In this study, the Cronbach α of IGD was 0.78 at T1, 0.84 at T2, and 0.81 at T3.

School Refusal

The School Refusal Assessment Scale-Revised (SRAS-R) was used to assess school refusal [11]. It is a 24-item scale comprising 4 dimensions: ANA, EAS, AS, and PTR. Sample items include the following: "How often do you have bad feelings about going to school because you are afraid of something related to school (eg, tests, school bus, teacher, fire alarm)?," "How often do you stay away from school because it is hard to speak with the other kids at school?," "How often do you feel you would rather be with your parents than go to school?," and "When you are not in school during the week (Monday to Friday), how often do you leave the house and do something fun?." The items are rated on a 7-point Likert scales (1=never to 7=always). It has been validated among adolescents and demonstrated satisfactory psychometric properties [42]. In this study, the Cronbach α of school refusal was 0.88 at T1, 0.90 at T2, and 0.94 at T3.

Data Analysis

Attrition analyses were conducted to compare participants who completed all 3 waves with those who discontinued participation at follow-up. Independent-sample *t* tests were used to examine sex differences in the 4 school refusal dimensions and IGD, and Pearson correlations were performed among the key study variables. These preliminary analyses were performed in IBM SPSS Statistics (version 28.0) using listwise deletion, as they were primarily descriptive and exploratory in nature and aimed to summarize observed data based on complete cases.

To evaluate the temporal stability of the measurement models, longitudinal measurement invariance tests were conducted for both school refusal and IGD. Criteria for acceptable fit followed established recommendations [43], including comparative fit index (CFI) and Tucker-Lewis Index (TLI) values ≥0.90 and root mean square error of approximation (RMSEA) and standardized root mean square residual (SRMR) values ≤0.08. Metric and scalar invariance were assessed by examining changes in model fit across nested models, with ΔCFI≤0.01 and ΔRMSEA≤0.015 indicating invariance. Results supported longitudinally consistent factor structures, confirming both metric and scalar invariance across waves.

The reciprocal associations between school refusal and IGD were examined using RI-CLPM. In these models, school refusal was specified as a latent construct indicated by the 4 functional dimensions of the SRAS-R: ANA, EAS, AS, and PTR. The 4 subscale scores were used as observed indicators of a higher-order latent school refusal factor at each wave, consistent with the functional behavioral model [14] of school refusal and allowing the shared variance across dimensions to be captured at the construct level. IGD was operationalized as a continuous symptom count score by summing the 9 DSM-5 IGD checklist items, which is a commonly adopted approach in IGD research [44-46]. Prior to model estimation, observed variables were grand-mean centered so that intercepts reflected overall mean levels across the 3 assessment waves. Model specification began with an unconstrained RI-CLPM in which all autoregressive and cross-lagged paths were freely estimated across time. To obtain a more parsimonious and stable model, cross-lagged paths were then constrained to be equal across adjacent time intervals. In a subsequent step, both autoregressive and cross-lagged paths were constrained to be time-invariant, and model fit was compared across nested models to identify the optimal specification. After identifying the optimal model, covariates were incorporated as predictors of the between-person random intercepts, including age, sex, self-reported academic performance, perceived family financial status, and single-parent family status. Gaming time per month was included as a time-varying covariate at the within-person level, such that gaming time at each wave predicted the within-person deviations of school refusal and IGD at the corresponding time point, thereby controlling for concurrent fluctuations in gaming behavior.

The multigroup RI-CLPM approach was adopted to test potential sex differences in the longitudinal association between school refusal and IGD. An unconstrained model allowing all structural paths to vary across groups was compared with a model in which the cross-lagged effects were constrained to equality. A significant χ^2 difference indicated the presence of sex-specific effects.

All structural equation models, including the RI-CLPM and multigroup models, were estimated using Mplus version 8.3 (Muthén & Muthén). Full information maximum likelihood estimation was used to handle missing data in these models, given its advantages in longitudinal structural equation modeling for producing unbiased parameter estimates and maximizing data utilization under the missing at random assumption [47]. Statistical significance was set at 2-tailed $P<.05$ for all analyses. This study was reported in accordance with the American Psychological Association Reporting Standards for Studies Using Structural Equation Modeling [48].

Results

Attrition Analyses

As shown in Table 1, the 2 groups did not differ significantly with respect to sex, father's and mother's educational level, self-reported academic performance, perceived family financial status, single-parent status, gaming time per month, age, ANA, EAS, AS, PTR, and IGD.

Sex Differences in Main Variables

Male participants showed significantly lower mean scores (SD) than female participants across the 4 dimensions of school refusal across the 3 waves, except EAS at T1. In contrast, male participants showed significantly higher mean scores (SDs) than female participants in IGD across the 3 waves (Table 2).

Table . Sex differences in school refusal dimensions and internet gaming disorder (IGD) across 3 waves among Chinese adolescent gamers[a].

Measurement Invariance Tests

Table 3 presents the results of longitudinal measurement invariance testing for school refusal and IGD. The configural invariance models again demonstrated acceptable fit, with CFI and TLI exceeding 0.90 and RMSEA and SRMR below 0.08, indicating that the basic factor structures of both constructs were stable across the 3 waves. Metric invariance was supported, as changes in fit indices (ΔCFI ≤0.01; ΔRMSEA ≤0.015) fell within recommended thresholds, suggesting that the factor loadings remained consistent over time. Scalar invariance was also established, with minimal declines in model fit (ΔCFI ≤0.01; ΔRMSEA ≤0.015), indicating equivalence of item intercepts across measurement occasions.

[a]CFI: comparative fit index.

[b]TLI: Tucker-Lewis Index.

[c]RMSEA: root mean square error of approximation.

[d]SRMR: standardized root mean square residual.

[e]SR: school refusal.

[f]Not available.

Measurement invariance across sex was examined for school refusal and IGD. The configural invariance models showed acceptable fit, with CFI values above 0.90 and RMSEA and SRMR values below 0.08, indicating similar factor structures for males and females. Constraining factor loadings across groups resulted in minimal changes in model fit (ΔCFI ≤0.01; ΔRMSEA ≤0.015), supporting metric invariance. Scalar invariance was further supported (ΔCFI ≤0.01; ΔRMSEA ≤0.015), suggesting that item intercepts were comparable across sex. These results indicate that observed sex differences reflect substantive variation rather than measurement bias. Corresponding results are presented in Table S1 in Multimedia Appendix 1.

Correlations

As shown in Table 4, the 4 dimensions (ANA, EAS, AS, and PTR) of school refusal were positively intercorrelated across the 3 waves, with *r* ranging from 0.22 to 0.69 (all *P*<.001). Each dimension of school refusal was also significantly and positively associated with IGD at all waves, with *r* ranging from 0.21 to 0.40 (all *P*<.001).

RI-CLPM

The fit indices of the final selected model are presented in Table S2 in Multimedia Appendix 1, demonstrating a good model fit to the data ($\chi^2_5=16.02$; CFI=0.970; TLI=0.953; RMSEA=0.035; SRMR=0.029). The detailed results of model estimation are shown in Figure 1.

XSL•FO
RenderX

Figure 1. Random intercept (RI) cross-lagged panel model illustrating the longitudinal reciprocal associations between school refusal (SR) and internet gaming disorder (IGD) across 3 waves in a sample of Chinese adolescent gamers. School refusal was modeled as a latent construct indicated by 4 functional dimensions. The model separates stable between-person differences from within-person fluctuations over time. Standardized path coefficients are shown. β indicates standardized path coefficients. *P<.05, **P<.01, ***P<.001.

Within-person autoregressive paths were significant for both school refusal (T1 → T2: β=.40, 95% CI .29-.51; P<.001 and T2 → T3: β=.42, 95% CI .30-.54; P<.001) and IGD (T1 → T2: β=.37, 95% CI .16-.58; P<.001 and T2 → T3: β=.26, 95% CI .14-.38; P=.003), suggesting temporal stability.

Regarding cross-lagged effects, school refusal significantly predicted later IGD (T1 → T2: β=.06, 95% CI .02-.08; P=.02 and T2 → T3: β=.06, 95% CI .02-.08; P=.02). A reciprocal relationship was also observed, as IGD significantly and positively predicted school refusal (T1 → T2: β=.12, 95% CI .09-.15; P<.001 and T2 → T3: β=.13, 95% CI .08-.16; P<.001).

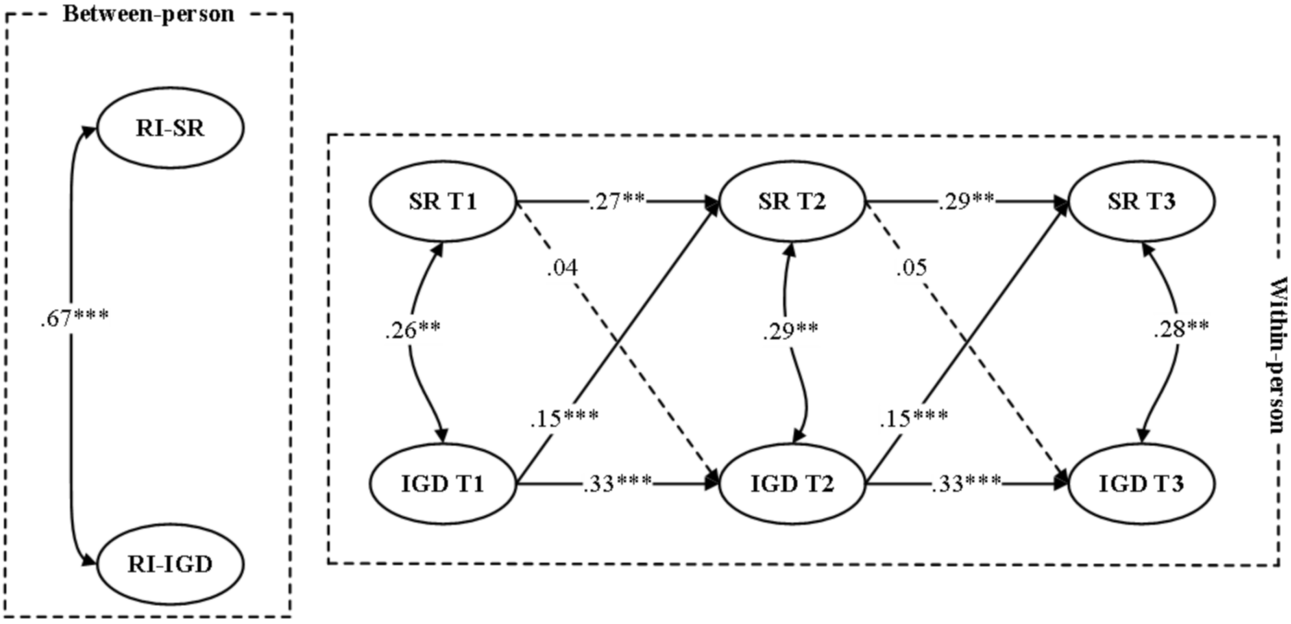
Within-person residual correlations among school refusal and IGD were positive and significant across all time points, with r ranging from .26 to .32. At the between-person level, the latent trait factors of school refusal and IGD were positively correlated (r=.76), indicating that adolescents who reported higher average levels of school refusal across time also tended to report more severe IGD.

Multigroup RI-CLPM

In the first step, an unconstrained model was estimated in which all autoregressive and cross-lagged paths were freely estimated across males and females. The model demonstrated good fit to the data (χ^2_{10}=17.86, CFI=0.994, TLI=0.982, RMSEA=0.045, SRMR=0.034). In the second step, a constrained model was tested in which all cross-lagged paths were constrained to be equal across groups. This model showed a less optimal fit (χ^2_{14}=48.84, CFI=0.973, TLI=0.943, RMSEA=0.056, SRMR=0.061). A chi-square difference test indicated that the constrained model fit significantly worse than the unconstrained model ($\Delta\chi^2_4$=30.98, P<.001), suggesting that the within-person association between school refusal and IGD differed significantly by sex. Figures 2 and 3 present the standardized results.

XSL•FO
RenderX

Figure 2. Random intercept (RI) cross-lagged panel model depicting longitudinal associations between school refusal (SR) and internet gaming disorder (IGD) among male adolescent gamers across 3 measurement waves. The model estimates within-person cross-lagged effects while accounting for stable between-person differences. Standardized path coefficients are presented. ***P*<.01, ****P*<.001.



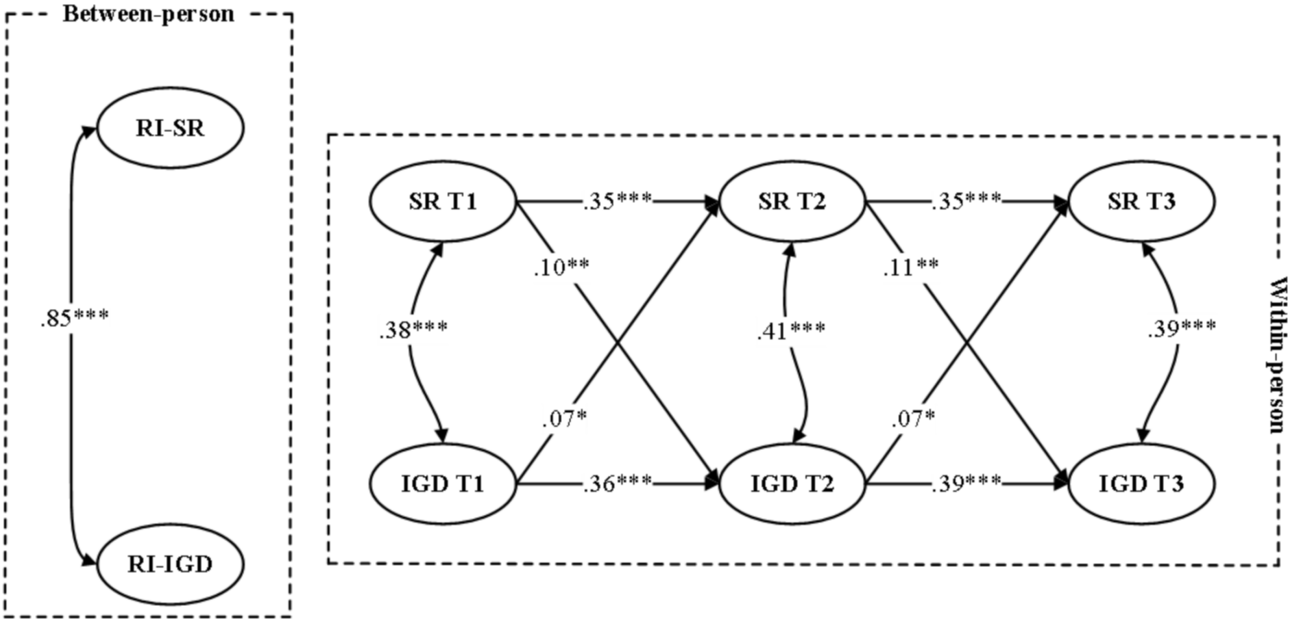


Figure 3. Random intercept (RI) cross-lagged panel model depicting longitudinal associations between school refusal (SR) and internet gaming disorder (IGD) among female adolescent gamers across 3 measurement waves. The model separates within-person temporal effects from between-person stability. Standardized path coefficients are presented. **P*<.05, ***P*<.01, ****P*<.001.

Specifically, sex differences were observed in the pathway from school refusal predicting subsequent IGD. A Wald test of parameter constraints indicated a significant difference between males and females (Wald $\chi^2(1)=10.74$, *P*=.001). Among females, school refusal significantly predicted later IGD at both time intervals (T1 → T2: β=.10, 95% CI .05-.15; *P*=.006 and T2 → T3: β=.11, 95% CI .04-.17; *P*=.004). In contrast, for males, the corresponding cross-lagged paths were not statistically significant. Sex differences were also found in the reverse pathway from IGD predicting school refusal, with a Wald test indicating a significant difference across sexes (Wald test estimate=8.96, *P*=.003). For males, the paths from IGD to later school refusal were significant (T1 → T2: β=.15, 95% CI .12-.18; *P*<.001 and T2 → T3: β=.15, 95% CI .12-.18; *P*<.001). Among females, IGD significantly predicted school refusal (T1 → T2: β=.07, 95% CI .03-.10; *P*=.02 and T2 → T3: β=.07, 95% CI .03-.10; *P*=.02), but the effects were weaker.

Discussion

Principal Findings

The present study used RI-CLPM to investigate the longitudinal association between school refusal and IGD among Chinese adolescent gamers. By isolating within-person fluctuations from stable between-person differences, this study offers the novel longitudinal evidence that these 2 behaviors co-develop over

XSL•FO
RenderX

time in this population. Across 3 waves, school refusal was consistently associated with IGD at the subsequent wave, while IGD was likewise associated with subsequent increases in school refusal. Although the cross-lagged effects were modest in magnitude, their consistency across waves suggests a reliable within-person association. Multigroup RI-CLPM analyses indicated that females showed a significant path from school refusal to later IGD, whereas this path was not significant for males. In the opposite direction, IGD predicted later school refusal for both sexes, but the effects were stronger for males than for females. These findings suggest that school refusal and IGD are associated over time, with the direction and strength of these associations differing by sex.

Using RI-CLPM, the present study revealed significant within-person associations between school refusal and IGD across 3 waves. By separating stable between-person differences, the model captures how fluctuations relative to one's typical level are associated across time. The results showed that when adolescents reported higher-than-usual levels of school refusal, they also tended to report higher-than-usual levels of IGD at the subsequent wave. Likewise, when adolescents experienced temporary increases in IGD, they tended to show higher levels of school refusal at the next measurement point. Recent methodological work by Orth et al [49] suggests that cross-lagged effects of approximately 0.03, 0.07, and 0.12 can be interpreted as small, medium, and large, respectively, in longitudinal panel models. Within this framework, the association from school refusal to later IGD (β=.06) represents a small-to-medium effect, whereas the association from IGD to later school refusal (β .12 - .13) reaches the medium-to-large range. Considering that RI-CLPM typically yields conservative estimates, these coefficients suggest that the associations are meaningful at the within-person level rather than trivial.

The within-person association from school refusal to later IGD is consistent with the logic of the escape-avoidance framework and supports H1. Among adolescent gamers, school refusal often reflects attempts to disengage from distressing or overwhelming school-related contexts, such as academic pressure, teacher criticism, peer rejection, or bullying [50]. Avoiding school temporarily removes adolescents from environments that evoke anxiety, shame, or fear of failure and simultaneously creates large blocks of unstructured time with minimal external demands [13]. Online gaming becomes an appealing outlet in such circumstances because it offers immediate feedback, clear goals, rapid progress, and a sense of efficacy that contrasts with the uncertainty and evaluative nature of school settings [51]. When adolescents experience a within-person surge in school refusal, the psychological discomfort underlying avoidance, combined with increased discretionary time, may heighten the likelihood of turning to online games as a form of emotional relief and distraction [52]. Although the effect size for this pathway is small to medium, its repeated appearance across waves suggests a stable association. The finding emerging under the conservative RI-CLPM model further indicates that increases in school-related avoidance tend to be followed by increases in problematic gaming.

The reverse association, that is, from IGD to later school refusal, was stronger in magnitude and aligns with a self-determination perspective on adolescent gaming motivations, supporting H2. Online games often provide highly rewarding compensatory experiences, giving adolescents feelings of competence, relatedness, and autonomy that may be less accessible in the school environment [53]. As IGD intensifies, adolescents may increasingly structure their daily routines, emotional needs, and social relationships around virtual spaces [54]. Activities such as coordinating with guilds or teams, maintaining rankings, or progressing within a game's achievement system may become central to their identity and self-worth [55]. Under such circumstances, attending school can feel not merely unappealing but actively disruptive. School attendance interrupts gaming activities, reduces contact with gaming peers, and may expose adolescents to criticism about their gaming habits from adults [56]. Consequently, when adolescents exhibit within-person increases in IGD symptoms, school avoidance may function as a strategy to protect the psychological rewards and social belonging embedded in the gaming environment. The medium-to-large effect size suggests that increases in IGD are subsequently followed by higher school refusal.

These reciprocal associations suggest that increases in school refusal and IGD tend to occur together, creating a pattern that may become more stable over time if not addressed. Although each wave-to-wave association is modest in size, the fact that these associations appear consistently across multiple waves suggests that their effects may accumulate. During adolescence, even relatively small but persistent shifts in everyday behavior can, over the course of a school year, influence students' engagement with school, relationships with peers, and general well-being [57]. Rather than viewing school refusal and IGD as separate concerns, the present findings indicate that they often co-occur and may reflect a broader process through which adolescents manage stress and seek more controllable or rewarding environments. This close connection between the 2 behaviors highlights the value of approaches that consider both behaviors together rather than treating them as unrelated issues.

The *t* test results showed a familiar pattern often reported in previous studies. Across the 3 waves, males had lower mean scores on most dimensions of school refusal (except EAS at T1), whereas they consistently scored higher than females on IGD [34,37]. These mean-level differences suggest that females may be more likely to respond to school-related stress with emotional withdrawal, while males tend to spend more time in gaming. However, mean differences alone cannot tell us whether the 2 behaviors are associated in the same way for males and females over time. For this reason, a multigroup RI-CLPM was performed to examine whether the longitudinal association differed by sex.

The multigroup RI-CLPM results revealed clear sex-specific patterns in the longitudinal associations between school refusal and IGD, as confirmed by Wald tests comparing constrained and unconstrained models. Overall, the findings suggest a more reciprocal pattern among females, whereas for males, the dominant direction runs from IGD to subsequent school refusal, supporting H3. For females, school refusal significantly predicted later IGD at both intervals, whereas this longitudinal

XSL•FO
RenderX

path was not significant for males. This indicates that school-related avoidance may play a more central role in the development of problematic gaming among females. In line with the escape-avoidance perspective, females may be more inclined to use gaming as a way of managing school-related distress, such as anxiety about performance, worry about teacher evaluation, or tension in peer relationships [58]. When school experiences become emotionally overwhelming, online games may offer a relatively safe and controllable context, making this coping function more common for females [59]. Importantly, this pattern remained after accounting for stable differences between individuals. This suggests that for females, short-term increases in school-related avoidance are followed by increases in IGD rather than merely reflecting general vulnerability.

In contrast, short-term increases in school refusal among males were not associated with subsequent within-person changes in IGD, despite males reporting higher levels of IGD on average. This pattern suggests that for males, school refusal and gaming are not associated in the same "avoid school then turn to games" sequence that appears for females. Instead, the reverse direction was more evident: for males, IGD significantly predicted later school refusal at both intervals, whereas for females, the same paths were significant but weaker. This pattern implies that among males, periods of higher IGD are more strongly tied to later problems with school participation. One possible interpretation is that males may be more likely to organize their daily routines around gaming. They may stay up late to play, give priority to in-game commitments such as matches or team activities, and gradually reduce the time and energy available for schoolwork and attendance [60]. Over time, these shifts in time use and focus may make school feel less relevant or more burdensome, increasing the likelihood of school refusal when gaming becomes difficult to balance with academic demands [61]. For females, IGD was also associated with later school refusal, but the weaker effect suggests that problematic gaming is less central as a driver of school avoidance than it is for males.

The findings have several implications. First, the reciprocal within-person association between school refusal and IGD suggests that these behaviors should not be treated as independent problems. When adolescents show shifts in either school-related avoidance or gaming involvement, these changes may influence the other domain, which indicates that interventions may be more effective when targeting both areas simultaneously. Second, the sex-specific results further highlight the need for more individualized approaches. For females, providing support to help them manage academic stress, improve classroom experiences, and feel more connected at school may reduce the likelihood of turning to gaming as a coping strategy [62]. For males, paying attention to patterns such as sleep disruption, late-night play, and reduced time for schoolwork may help prevent later school disengagement [63]. More broadly, the study shows that RI-CLPM can help identify how short-term changes in adolescents' school and gaming experiences relate to each other over time.

Conclusion

The present study used RI-CLPM to examine how school refusal and IGD develop over time among Chinese adolescent gamers. By separating within-person changes from stable between-person differences, the findings provide evidence of a reinforcing within-person association. The multigroup RI-CLPM further showed that this bidirectional pattern was evident among females, who showed significant paths in both directions. In contrast, males showed a different pattern: IGD predicted later school refusal, but school refusal did not predict later IGD. Given the observational design and the modest effect sizes, these findings should be interpreted cautiously and as indicative of developmental tendencies rather than deterministic processes. These findings provide a clear longitudinal pattern of mutual reinforcement and highlight the importance of considering school disengagement and problematic gaming together rather than as separate issues. The results also show that these processes develop differently for males and females. This suggests important implications for tailored prevention and intervention efforts, as sex-specific differences should be taken into account.

Abstract

Background: Slowness in voluntary movements is a hallmark of Parkinson disease (PD); yet, objective measurement outside clinical settings is limited. Serious games represent a promising alternative to extract motor performance metrics during interactions. However, evidence on the effectiveness of these games in discriminating motor performance between individuals with and those without PD is still scarce.

Objective: This study aimed to objectively assess slowness using the RehaBEElitation serious game, based on in-game estimated measurements.

Methods: The study included 15 individuals with mild to moderate PD (Hoehn and Yahr I-III), assessed in both ON and OFF medication states, and 15 age- and gender-matched healthy controls (10 men and 5 women; mean 66.27, SD 9.13 years; range 45-82 years). All participants played each phase of the game on the easiest level. Slowness was evaluated by detecting the voluntary movement of the gyroscope signals using the singular spectrum analysis method. The response time (RT) and angular velocity (AV) of the participants while playing RehaBEElitation were estimated. Group-level comparisons were performed to investigate the presence of slowness patterns across conditions. The Kruskal-Wallis test and Wilcoxon signed rank test with Bonferroni correction were used to confirm the differences between groups, and the effect size was estimated using eta square (η^2). Spearman correlation analyses were conducted to examine associations between the RT and AV and the Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) motor items.

Results: Groups were age-homogeneous (P>.05). Participants with PD had significantly higher scores on MDS-UPDRS Part III in the OFF state compared to the ON state of medication (mean difference 2.86, 95% CI 2-12; P<.05). RT was generally shorter and AV higher in controls than in participants with PD. In the PD group, RT decreased and AV increased from OFF to ON states, reflecting an improvement in motor performance. Significant differences in RT were observed between groups in all phases of the game, with effect sizes ranging from small to moderate (η^2=0.0239 - 0.0650). AV differed markedly between groups in phase 4, with a large effect size (η^2=0.404). Correlation analyses revealed weak positive associations between RT and MDS-UPDRS items, while AV showed strong negative correlations with each motor item and the summary score for bradykinesia.

Conclusions: This study proposes a new method to assess slowness in PD by using inertial sensor data to extract objective motor measures (RT and AV) during a serious game, allowing continuous and quantitative evaluation beyond traditional clinical scales and tests. The findings demonstrate that RT and AV extracted from gameplay can detect slowness-related motor differences, supporting the RehaBEElitation serious game as an alternative and objective digital biomarker, with potential applications in both clinical and home-based monitoring of symptom progression.

Introduction

Serious game–based interventions have attracted considerable attention from the medical community. These technologies are defined as digital games developed with a primary purpose beyond entertainment, typically aimed at supporting education, training, or promoting behavioral change. In addition to providing rewarding experiences, these technologies can encourage interaction and enjoyable gameplay [1]. People with a variety of illnesses, including Parkinson disease (PD), can benefit from exercise training, symptom monitoring, and health improvement through serious games' engaging gaming dynamics [2]. The loss of dopaminergic neurons in the mesencephalon's substantia nigra is a hallmark of PD [3]. The lack of dopamine hinders the ability to execute and control movements, causing a number of identifiable motor symptoms, including bradykinesia, tremor, and rigidity [4].

The primary motor deficit seen in people with PD is bradykinesia, which is the incapacity to prepare, start, and carry out motions [5]. More specifically, bradykinesia can be understood as a failure of the basal ganglia to reinforce the cortical mechanisms that prepare and execute commands to move [6]. In this context, slowness in performing voluntary movements, prolonged reaction time (defined as the time between the stimulus presentation and the start of the movement), prolonged movement time (defined as the time between the start and finish of the movement), and, ultimately, prolonged response time (RT), which is the sum of reaction time and movement time, are the main characteristics of bradykinesia [7]. RT represents the capacity of an individual to identify pertinent information sources, interpret that information, and apply it to produce a suitable movement response [8]. Since PD impairs both reaction and movement time [7], RT could be an accurate indicator of slowness severity.

The most popular and well-accepted technique for the clinical evaluation of bradykinesia is the Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) [9]. The capacity of the patient to make quick, repeated, and alternating movements—like tapping fingers, opening and closing hands, and pronating and supinating the forearms—is the base for the clinical assessment of this symptom. To determine the severity of the condition, the clinician grades these movements from 0=normal to 4=severe [10]. However, this kind of evaluation is subjective and inaccurate due to a number of factors, including the evaluator's expertise level, patient compliance, and individual bias [11]. Furthermore, the clinical evaluation is unable to precisely characterize the severity of a symptom in a patient [12].

Inertial sensors can address the limitations of qualitative visual scales by providing objective motion measurements [12]. Recent studies confirm that inertial measurement units (IMUs) accurately quantify bradykinesia in PD in standardized tasks and remote monitoring. In upper limbs, studies such as Bremm et al [13] confirm that the extraction of metrics of speed, amplitude, and rhythm in tasks such as finger tapping, pronation-supination, and opening or closing the hand showed consistent correlations with clinical scales (such as the MDS-UPDRS). In terms of mobility and overall function, Hong et al [14] used IMUs to capture walking speed, cadence, and stride length, as well as sit-to-stand performance, suggesting that wearable sensors provide a comprehensive and objective approach to assessing a wide range of motor symptoms in PD.

Recent studies in the field of continuous monitoring have highlighted the potential of wearable devices and smartphones to remotely detect patterns of slow movement and reduced range of motion throughout the day. The results demonstrated the feasibility of more accurate and personalized monitoring, reducing the need for frequent in-person visits and supporting therapeutic decisions [15].

Despite covering different tasks and contexts, and demonstrating that the use of devices with IMUs is a promising alternative that can identify and quantify slowness, no study has been conducted to evaluate this symptom with data collected from people with PD during interaction with serious games. In other words, IMU-based strategies are already valid and sensitive for assessing bradykinesia, but they have not yet been applied in gamified protocols, highlighting a methodological gap and a clear opportunity for innovation. Objective evaluation supplements the clinical evaluation [16].

This shortcoming motivated us to develop a serious game, so-called RehaBEElitation (Institute of Industrial Property—INPI registration: BR512021001975-0), which features 4 phases, to assess bradykinesia objectively and collaboratively [17]. The system uses a custom wearable glove interface with conductive threads and inertial sensors. According to the evaluation of the game's usability, RehaBEElitation is a serious game with an easy-to-understand narrative that meets adequately with the players' mental models, which aligns with the players' expectations of movement-control correspondence (eg, hand extension and flexion to move the bee up and down, adduction and abduction to move it left and right, and a pinch gesture to collect nectar—represented in the game as a droplet). This facilitated the interaction of individuals with the serious game and helped the system as a whole gain widespread acceptance [17,18].

This study extends a previous work [19] by evaluating bradykinesia across all 4 game phases (rather than just 2) using a time-based variable and introducing an improved human-machine interface (HMI) device. Additionally, because the signals captured by the HMI device consist of both the voluntary movement the person makes to play the game and the involuntary movement caused by the disease (ie, tremor), it is necessary to separate the involuntary movement from the detected signals since it could affect the slowness estimation. Another distinction in this work is the detailed explanation of the signal processing strategy used to exclude tremors from the collected data and, additionally, the inclusion of a correlation analysis between slowness-related variables and the clinical scale.

A key advantage of the RehaBEElitation serious game is the recording of real-time motion time series during interaction, enabling more in-depth and accurate analysis of the collected data. A recent literature review conducted by our group [20] revealed that previous studies evaluated PD symptoms or

XSL•FO
RenderX

monitored health conditions related to the disease using serious games combined with physical instruments, such as the Box and Blocks Test [21], the Purdue Pegboard Test [22], the Nine Hole Peg Test [23], the Time Up and Go test [24], the Maximum Step Length test [25], or the Trail Making Test [26]. None of these studies used data concerning the neuromuscular response of people with PD for the assessments. In the study, Sánchez-Herrera-Baeza et al [22], for example, players performed a test that assesses manual dexterity (the Box and Blocks Test) before and after interactions with the serious game developed, and the authors evaluated manual dexterity by comparing the results of the test performed at these different moments.

Similarly, Jäggi et al [27] conducted a pilot study with hospitalized patients with typical and atypical forms of PD using cognitive and motor exergames. Several cognitive tests (eg, Go/No-Go test, Reaction Time test, and Trail Making Test) and motor tests (eg, Preferred Gait Speed, Maximum Gait Speed, and Time Up and Go) were performed before and after playing the game to assess the motor and cognitive characteristics of the participants. Bégel et al [28] tested the effect of fine motor skills training, administered through serious games played on tablets, on the walking abilities of people with PD. Participants underwent motor performance tests before and after training with 2 games. The authors assessed the participants' gait and mobility using the Battery for the Assessment of Auditory Sensorimotor and Timing Abilities and the Beat Alignment Test, respectively. Finally, Ganzeboom et al [29] applied a serious game aimed at speech training in patients with PD-associated dysarthria. Each participant recorded 24 speech utterances before and after playing the game. The participants' speech was then evaluated for intelligibility by untrained listeners, comparing it with corresponding utterances made by a healthy speaker.

In contrast, the system developed in this study captures inertial sensor data that reflect neuromuscular activity to control the game avatar, enabling the objective quantification of motor symptoms, such as bradykinesia, through the extraction and analysis of variables that characterize the symptom. This distinctive capability constitutes a key differentiator of the present research. Accordingly, the purpose of this study was to objectively assess slowness in people with PD through their interaction with the RehaBEElitation serious game, using neuromuscular data to provide a precise and engaging way to quantify motor symptoms. Importantly, our intention is not to replace the clinical evaluation provided by the MDS-UPDRS, but rather to complement it by adding a fine-grained, performance-based measure obtained directly from the participants' motor behavior during the game.

Methods

This is an observational and cross-sectional study focused on the objective assessment of slowness, one of the main characteristics of PD. The experimental design involves collecting data from healthy individuals and individuals with PD in 2 different conditions: before taking medication that controls the motor symptoms of the disease (OFF state) and after administering this medication (ON state).

Ethical Considerations

This research was approved by the Ethics Committee for Human Research at the Federal University of Uberlandia (UFU; protocol: 43229921.8.0000.5152). All participants provided written informed consent prior to enrollment in the study. The informed consent included authorization for the use of anonymized data for research and publication purposes. The experimental protocol was conducted in accordance with national and international ethical guidelines for human research, such as the Declaration of Helsinki. All collected data were deidentified prior to analysis. No information that could directly or indirectly identify participants was stored or included in the manuscript. Data were handled in secure and access-controlled institutional repositories, following best practices for confidentiality protection. In addition, participants did not receive any monetary compensation for participation.

Serious Game and Interface Device

RehaBEElitation is a bee-themed serious game designed to rehabilitate and monitor people with PD. The bees represent diligence, commitment, and hard work, qualities that people with PD really value during their recovery. The game was developed by a multidisciplinary team using Unity 3D. The player has to control the movements of a bee in a 3D environment. The game tasks were designed to require users to perform the identical motions as those found in the reference tool used to evaluate individuals with PD (MDS-UPDRS Part III): hand opening and closing, wrist extension and flexion, wrist adduction and abduction, finger tapping, and forearm supination and pronation. RehaBEElitation presents 4 phases (Multimedia Appendix 1), and each one symbolizes a real-world bee worker's task [17]. The objectives of each phase are as follows:

- Phase 1: pollinating the flowers—The objective is to collect pollen from a flower and deposit it in another flower. To move the bee up and down, the player must perform the movements of wrist extension and flexion; and to move the bee to the left and right, the movements of wrist adduction and abduction. The player must move the bee to a flower containing pollen (indicated by yellow arcs) and close the hand to catch it. Then, with the hand closed, the player must move the bee to a flower that does not have pollen (with green arcs) and open the hand to deposit it.
- Phase 2: feeding the larvae—The objective is to feed the larvae. The bee moves around the scene (up, down, left, and right) only if the player's hand is closed. The player must place the bee in front of a larva and open and close his or her hand to feed the larva.
- Phase 3: collecting the nectar—The objective is to collect nectar from flowers. Flowers that have nectar are indicated by drops of water. The player must guide the bee to a flower that has nectar and perform the finger-tapping movement to collect it.
- Phase 4: drying the nectar—The objective is to dry the nectar to produce honey. The player must go to honeycombs containing nectar (indicated by a luminous reflection) and

XSL•FO
RenderX

perform forearm supination and pronation movement (as a single movement) to make the bee flap its wings faster and dry the nectar.

An HMI was created to promote communication between the movements of the real environment and the game (Multimedia Appendix 2). It consists of a glove with inertial sensors, housed in a small case attached to the glove on the back of the hand, capable of estimating hand orientation; and conductive thread sewn on the glove, toward the palm of the hand and the fingers, capable of estimating finger tapping movements and hand opening and closing.

Experimental Protocol

Overview

The experimental group (EG) in this study consisted of 15 participants with PD, while the control group (CG) consisted of 15 healthy participants. Age and gender pairs were formed among the group volunteers (10 men and 5 women; mean 66.27, SD 9.13 years; range 45 - 82 years). The eligibility criteria for participants were as follows: a clinically confirmed diagnosis of PD, be aged between 40 and 100 years of age, regular use of PD medication (typically levodopa and/or dopamine agonists), have a mild to moderate PD stage (Hoehn and Yahr levels I, II, and III) [30], score higher than 19 on the Mini Mental State Examination [31], not have severe hearing or vision impairments (hearing acuity was assessed using the Self-Declaration Questionnaire on Hearing Loss, and visual acuity was assessed using the Snellen Optometric Scale), and not have another neurological disease history.

A convenience sampling strategy was adopted due to the specific eligibility criteria and availability of participants in the recruitment context. The sample size was defined based on previous studies with similar experimental designs that investigated motor performance and bradykinesia or slowness of the upper limbs in PD, and which demonstrated adequate power to detect differences between groups in movement-related variables [22,27,28]. The survey was disseminated at care centers for people with PD and through the communication channels of the UFU. Those interested in participating contacted the research team directly to schedule an appointment.

Data collection was conducted in a controlled environment at the Centre for Innovation and Technological Assessment in Health at UFU between February and March 2022. Upon arrival at the site, participants were welcomed by the research team, who presented the study objectives and provided necessary clarifications before signing the Informed Consent Form. Only after formal agreement to participate and verification of the inclusion criteria did the experimental procedures and data collection begin.

The participants were instructed to sit on a chair a meter from the screen that displayed the serious game. The limb most affected by the disease, as identified by a clinical assessment, was then fitted with the HMI device. To isolate the necessary movements and prevent compensating with another body part during movement execution, the limb was placed on a forearm support (Multimedia Appendix 3).

The participants were asked to play each phase of the serious game for 5 minutes or until they fulfilled their objectives. Data collection was performed in the ON and OFF states of medication for the EG. The first session was performed with individuals in the OFF state, after arriving at the collection site, in the morning. The ON state occurs when disease symptoms are under medication control, and the OFF state occurs when symptoms are not properly controlled by medication [16]. The EG volunteers were instructed to arrive in the morning having abstained from their PD medication for at least 8 hours, ensuring the re-emergence of motor symptoms and standardizing the OFF condition. After completing the first session in the OFF state, the EG participants took their usual medication (levodopa-based, such as Prolopa BD or other Prolopa presentations), and approximately 45 minutes later (once the therapeutic effects began to emerge), they performed the second session in the ON state, when symptoms were expected to be adequately controlled by medication.

The MDS-UPDRS Part III [9] was applied to the EG by an independent physiotherapist, who was not involved in the development or execution of the intervention protocols. Assessments were conducted in each session, before starting the game, that is, in both the ON and OFF states of the medication. The MDS-UPDRS was not applied to the CG. The CG participants interacted with the RehaBEElitation serious game in a single session using their dominant upper limb. All participants played the game at the easiest difficulty level.

Slowness Evaluation

First, bradykinesia was clinically assessed using the scores related to items 3.4a to 3.6b of the MDS-UPDRS Part III for the EG in both the ON and OFF states of medication. These items assess: 3.4a and 3.4b—tapping the fingers of the right and left hands, respectively; 3.5a and 3.5b—movements of the right and left hands, respectively; and 3.6a and 3.6b—pronation-supination movements of the right and left hands, respectively. The average scores of these items were considered for each medication state. In addition, slowness was objectively assessed for all participants of the study in 2 ways: by calculating the RT and by estimating the individuals' angular velocity (AV) of movement. Methodological details on how each variable was estimated are provided in the subsequent sections.

As described previously, RT involves both reaction and movement time, since RT is equal to reaction time added to movement time (Multimedia Appendix 4). Across all phases, when the participant correctly positioned the avatar on the target, a stimulus was presented to indicate the precise moment for movement execution. Accordingly, participants learned to align the avatar with the designated location and to initiate the movement only after stimulus onset.

AV (in degrees per second) represents the speed of movement execution [32] (ie, in relation to the RT variable, AV is linked to movement time). For a given movement, the higher the AV, the shorter the time taken to perform the voluntary movement. Thus, if it is verified that the velocity of movement execution was reduced after the use of medication, that is, in the ON state,

XSL•FO
RenderX

the time to perform the movement increased, which may suggest a failure in the medication effect.

In addition, RT allows considering aspects related to the player's reaction time, such as the learning acquired after the first section of interaction with the game. The participant may, for example, decrease his reaction time in the second game session (in the ON state) by learning that, immediately after receiving the visual and sound stimuli, he should perform the movement required to score points in the game in the shortest possible time.

Descriptive and inferential statistical analyses were performed to compare RT and AV between the EG and CG. The normality of data distribution was verified by the Shapiro-Wilk test prior to comparisons between groups, and appropriate parametric or nonparametric tests were adopted according to this result. In this study, the nonparametric Kruskal-Wallis test was used, followed by Wilcoxon signed rank tests with Bonferroni correction for pairwise group comparisons. The effect size was estimated using eta square (η^2) and interpreted according to Cohen criteria [33], with η^2 values of approximately 0.01 considered small, around 0.06 considered moderate, and values of ≥0.14 considered large.

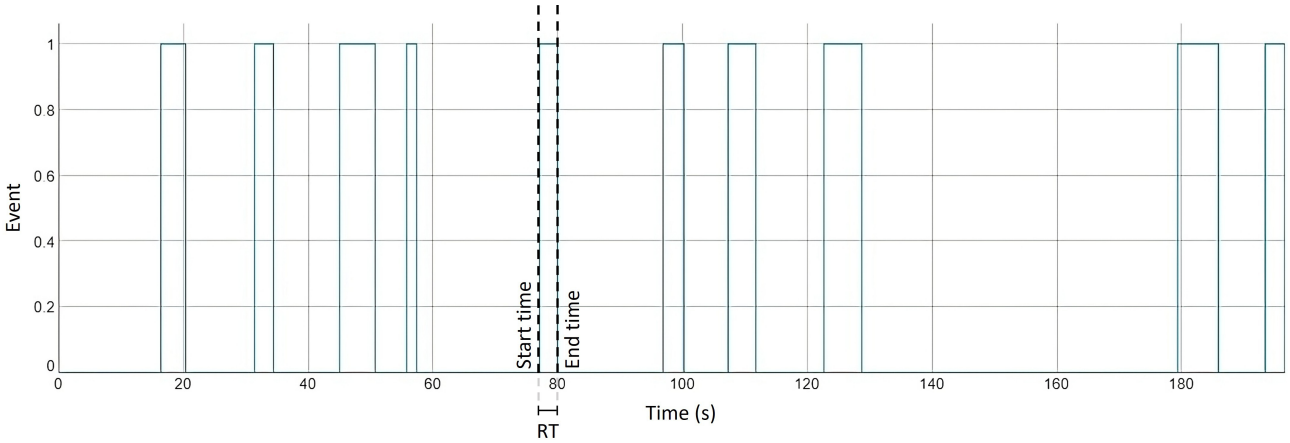
Spearman rank-order correlation analyses were conducted to examine associations between the RT and AV variables and the MDS-UPDRS motor items previously described (items 3.4a/b, 3.5a/b, and 3.6a/b), as well as with the summed score of these items (BRADINDEX). For each participant, the median value of the estimated RT and AV data was calculated and used in the correlation analyses. The correlation coefficient (ρ) was classified into 5 categories: very weak (0.00 - 0.19), weak (0.20 - 0.39), moderate (0.40 - 0.59), strong (0.60 - 0.79), and very strong (0.80 - 1.00) [34]. Signal processing and statistical procedures were performed using the R language for statistical computing (R Foundation for Statistical Computing).

Matching by age and gender during recruitment was used to minimize possible confounding factors, and no subgroup or interaction analyses were conducted due to the exploratory nature of the study and the matching strategy used. There were no missing data, as all attempts were successfully completed and validated during acquisition. Considering that sampling was by convenience, statistical analyses considered independent samples without additional weighting. Sensitivity analyses were not necessary, as all data were maintained and processed consistently throughout the study.

RT Estimation

RT was measured by defining a binary event in the game that signaled when the player approached the target and executed the movement. This event began when the player was supplied with visual and auditory stimuli, indicating that he or she could perform the movement and ended when the player performed the movement and scored in the game. Figure 1 shows the game screen (during phase 1) at the moment when the event responsible for calculating the RT occurs.

Figure 2 illustrates the occurrence of the described event of a volunteer from the EG in the OFF state during phase 4. This player arrived at the target and executed the movement 10 times (10 occurrences of the binary event). The start and end of each event were identified to determine the start and end times of the event. The duration of each event was then estimated by calculating the difference between the end and start times.



Thus, as RT is the sum of reaction time and movement time, both reaction time and movement time were taken into consideration to estimate the slowness of the individuals. This evaluation was performed for the 4 phases of the game.

Figure 1. Game screen showing the event to response time estimation. (**A**) Game screen while the player freely controlled the bee in the scenario. In this case, the player has not yet approached the target. (**B**) Game screen when the player reached the target and received the visual and sound stimuli, indicating that he/she could start executing the required movement. At this point, the bee remained static, the screen subtly changed color, a virtual hand appeared in the right corner of the screen, indicating to the player the movement to be performed, and a sound effect was emitted.

XSL•FO
RenderX

Figure 2. RT estimation from the defined event. Each blue rectangle represents an occurrence of the event, which indicates the duration of the RT. As stated, in this phase, the player hit the target and completed the expected movement 10 times, producing 10 RT values; the fourth occurrence showed the minimum RT, indicating that the player was faster in this instance. RT: response time.

AV Estimation

Overview

Gyroscope signals were used to measure the AV around a reference axis, which indicated how fast the movement was performed [32]. This characteristic was estimated only for phase 4 of the game because it is the only phase that requires the execution of a movement performed around one of the measurement axes of the inertial sensor (forearm supination and pronation) to score in the game. In Multimedia Appendix 5, which shows the reference axes of the inertial sensor, it is observed that the supination and pronation movements occur around the Y axis.

As previously described, the motor symptoms of PD can be detected by inertial sensors and recorded as time-series data. These movement signals recorded by the sensors include both voluntary movements of the player to control the bee in the scenario and involuntary movements caused by the disease (such as tremor). The presence of involuntary movements may interfere with the estimation of slowness; hence, they should be disregarded from the collected signals. Thus, to extract only information related to players' voluntary movements, it was necessary to use a signal processing method capable of performing time series decomposition.

Time series decomposition involves decomposing a time series into several components, each representing one of the underlying oscillatory patterns in a signal. Singular spectrum analysis (SSA) is a decomposition method frequently used in several fields, such as economics, physics, and geography [35]; however, no study applying this method to signals collected from individuals with PD was found in the literature. In view of this gap and the technique's capacity to robustly decompose complex temporal signals, the SSA method was adopted in this study.

Singular Spectrum Analysis

SSA is a nonparametric method for the analysis of time series and digital images. This method decomposes a time series into a set of components that are grouped and interpreted, and the original time series is recovered by summing all its components [35]. SSA can be used to remove all periodic and trend components from a time series, leaving only a particular component, which may have real and interpretable meaning [35]. In this study, decomposition was performed so that slowness could be evaluated objectively by using only the signals of voluntary movement, that is, excluding the influence of tremor.

A general description of the method is presented below [35-37]. SSA performs the 4 steps illustrated in Multimedia Appendix 6. The input X is an ordered collection of N real numbers (eg, a time series or a digital image), and the output is a decomposition of X into a sum of identifiable components: X=X1+ +Xm.

- Step 1: embedding: The starting point of SSA is the embedding of the time series X into a vector space of dimension L. As an example, X = (x1,...,xN) and *T*=SSA maps R^N to the space of Hankel matrices L×K with equal values on the antidiagonals. Thus, the embedding procedure constructs a sequence of vectors of the original time series using lagged copies of the scalar data. N is the length of the series, L is the length of the window (which is a parameter), and K=N-L+1.

  T(SSA)(X)=(x1x2x3xkx2x3x4xk+1x3x4x5xk+2 xLxL+1xL+2xN)
- Step 2: decomposition: The result of this step is the decomposition X=∑iXi,Xi=σiUiViT, where Ui∈ R^L and Vi∈ R^K are vectors such that || Ui ||=1 and || Vi||=1 for all i and σi are nonnegative numbers. This step performs the singular value decomposition (SVD) of the trajectory matrix and represents it as a sum of rank-one biorthogonal elementary matrices. Let S=XXT, λ1≥ ≥λL≥0, be eigenvalues of the matrix **S**, d=rank X=max{ j:λj>0 }, U_1 ,...,Ud be the corresponding eigenvectors, and Vj=X Uj / λj, j=1,...,d be factor vectors. Denote Xj=λj UjVjT. Then, the SVD of the trajectory matrix **X** can be written as X=X1+ +Xd. The triple (λi, Ui,Vi) consisting of the singular value σj=λj , the left singular vector Uj, and the right singular vector Vj of **X** is called the *j*th eigentriple.
- Step 3: grouping: The grouping step corresponds to the division of the elementary matrices Xj into several groups and summing the matrices within each group. The grouping procedure partitions the set of indices {1,...,d} into *m* disjoint subsets {I1,…,Im}, with each group Ik containing

XSL•FO
RenderX

a set of principal components {i1,…,ip}, representing specific components of the signal. Let Ik={i1,…,ip}. Then, the resulting matrix XIk corresponding to the group Ik is defined as XIk=Xi1+ +Xip. These matrices are computed for Ik=I1,…,Im, and the SVD expansion leads to the decomposition X=XI1+ +XIm . Each XIk represents a set of eigentriples, which describes a specific component series in the original time series.

- Step 4: reconstruction: The last step is to reconstruct the components of the original series. This is achieved by diagonal averaging of each XIk to provide the *k*th component of the series X, where the *n*th sample is obtained by averaging over the cross-diagonal i + j = const = n + 1 of XIk . This is because each XIk can be seen as the Hankel matrix for the corresponding embedded component series. Then, the resulting decomposition of the initial object X is X=X1+ +Xm.

The SSA procedure was applied to identify the tremor-related oscillatory components, which were subsequently removed from the original time series. The resulting residual signal, obtained by subtracting the tremor components from the original data (since the original signal can be reconstructed as the sum of all SSA-decomposed components), represents the tremor-free voluntary movement used for slowness evaluation.

The estimate of SSA was computed in the R language by using the method ssa (from the *Rssa* package), which constructs the ssa object that holds the decomposition and various auxiliary information. The typical call of the ssa function in R is:

s <- ssa(x, L = (N+1) %/% 2, neig=NULL)

The main arguments are (N is the length of the series):

- x is an object to be decomposed (eg, time series).
- L is a window length, which by default is fixed to half the length of the series. However, it is also recommended to use a proportional value to the periodicity of the time series. Very high values of L may mix the trend component with the periodicity components. Therefore, L=250 was used (the sampling frequency of the data).
- neig is the number of eigentriples desired. If neig=NULL, a default value, which depends on L and N, will be used. It was considered neig=NULL.

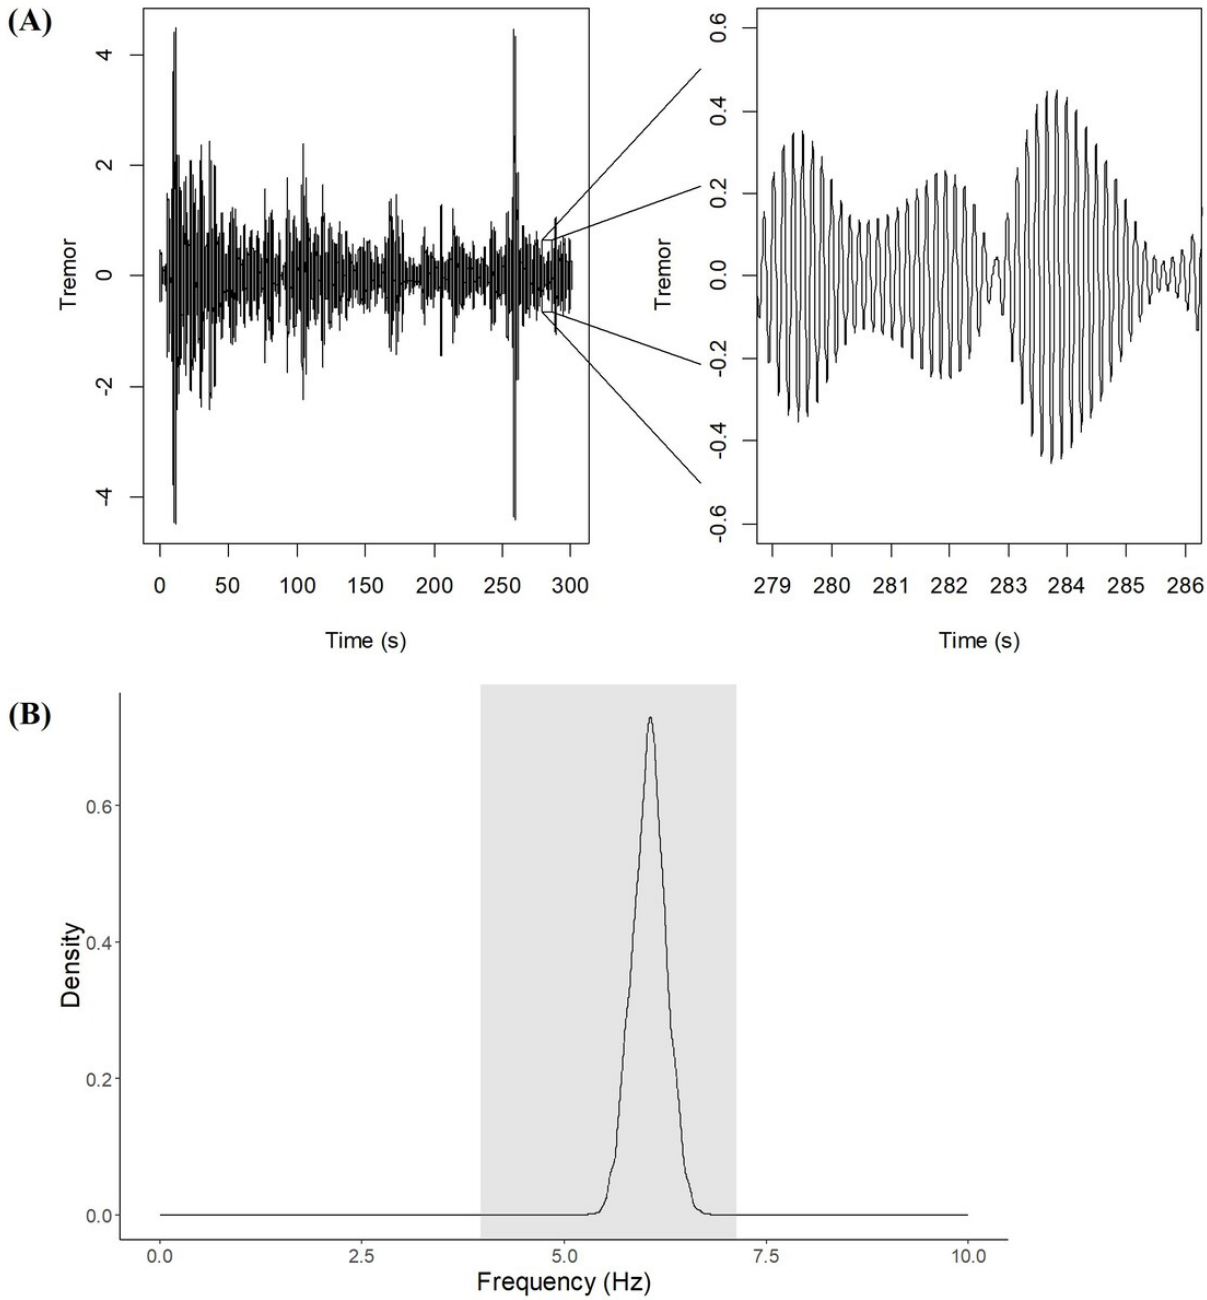
The function returns an ssa object. The precise layout of the object is hidden, but identifying the indices of the elementary components is necessary for the next step (reconstruction). This identification is performed to find the selection parameters of the principal components to group the elementary time series. The indices of the elementary components can be identified by using the $ operator and by analyzing the plots of the eigenvalues and the correlation matrix of the eigenvalues, namely, s$sigma returns the vector of single values, $(s$sigma)^2$ returns the vector of eigenvalues, plot(s) plots the eigenvalues, and plot(wcor(s)) plots the w-correlation matrix.

By definition, components that have similar eigenvalues are used for the grouping of elementary time series that represent the periodic or oscillatory components of the original time series. In other words, eigenvalues with very similar magnitudes are associated with a periodic or sinusoidal component of the signal, in this case, the PD tremor, which represents an involuntary movement.

The reconstruction step is performed with the reconstruct function. The typical call in R is:

r <- reconstruct(s, groups=list(Tremor=c(3:5, 13:16))

The main arguments are as follows:



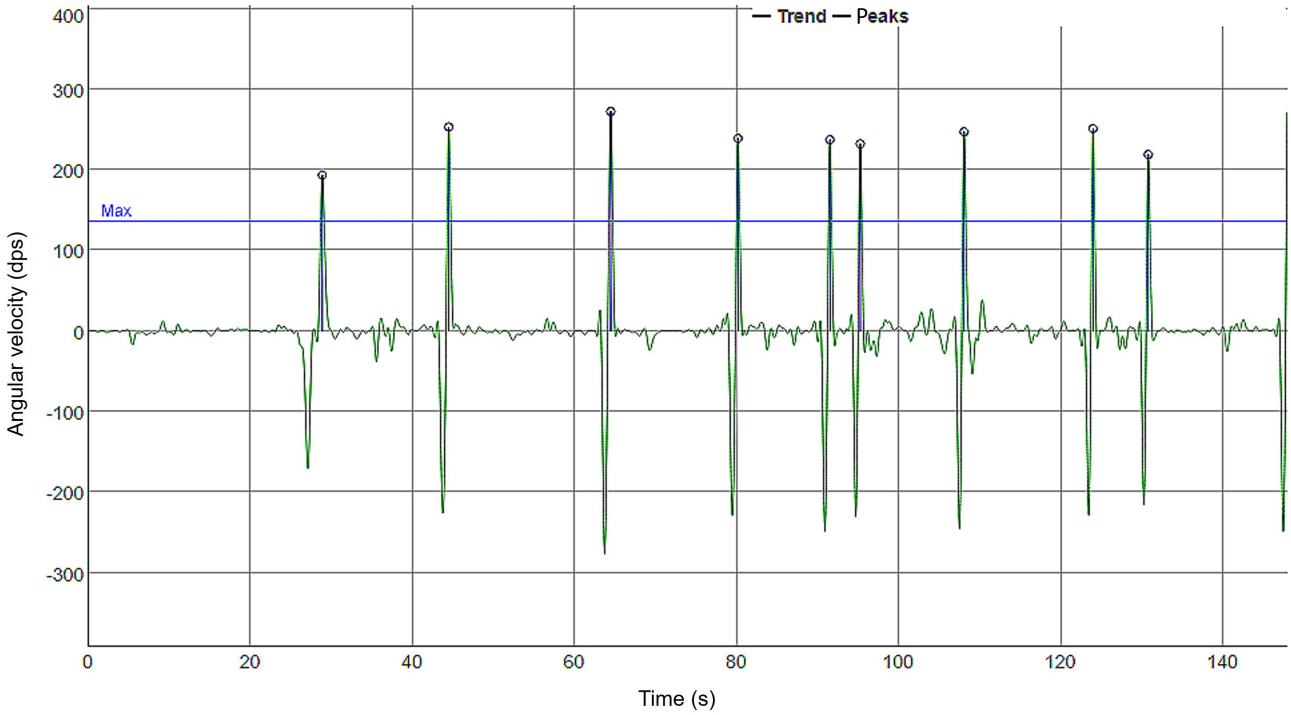
- s is an ssa object that holds the decomposition.
- groups is a list of numeric vectors consisting of the indices of the elementary components used for the reconstruction; the list entry can be named, and in this example, it was called Tremor. The elementary components with indices 3, 4, and 5 and 13, 14, 15, and 16 (which have similar magnitudes) represent the oscillatory component of the time series, which characterizes the player's involuntary movement (tremor).

Thus, SSA was applied to the original signal collected during the experiment to extract the tremor. The residual signal after extraction of the involuntary movement represents the voluntary movement used to quantify the slowness of the participants. In other words, the decomposition allowed us to exclude the frequency range associated with tremor while retaining the frequencies representing voluntary motion, which were then used to quantify participants' slowness. Multimedia Appendix 7 illustrates the decomposition of a gyroscope signal from a participant of the EG. The sum of the voluntary movement and tremor signals results in the original signal.

Figure 3 illustrates a typical tremor signal resulting from the use of SSA. An enlarged view of the tremor signal extracted by the decomposition is shown in Figure 3A (on the right), and the power spectral density of the tremor is depicted in Figure 3B. Figure 3B shows that the density of the tremor extracted by the decomposition ranges between 4 and 7 Hz, which is the frequency range of a tremor originating from PD. This indicates that the method is robust in cleanly separating the oscillatory components of the original signal that truly correspond to PD tremor.

XSL•FO
RenderX

Figure 3. Characteristics of the signal extracted by the singular spectrum analysis decomposition method. (**A**) On the left, the complete tremor signal, and on the right, a zoomed view of the signal. (**B**) Power spectral density of the tremor, confirming that it corresponds to a Parkinsonian tremor, as its dominant frequency lies within the characteristic 4 - 7 Hz range.



By minimizing the contribution of the higher-frequency components associated with tremor in the spectral profile of the movement, it becomes possible to isolate the signal that truly represents the participant's voluntary motion. Removing these high-frequency components is essential to ensure that slowness, which is manifested within the voluntary movement itself, can be estimated in a pure and uncompromised manner, without interference from other motor symptoms such as tremor. This allows the control signal used in the game to reflect only the participant's voluntary movement characteristics, particularly their slowness.

After applying SSA for signal decomposition, the peaks of the signals representing the voluntary movement were identified and discriminated by using a threshold of 0.5 to capture only the regions of interest and evaluate the participants' slowness of movement, as depicted in Figure 4. The higher the peak value, the faster the movement was executed.

XSL•FO
RenderX

Figure 4. Peak detection in the gyroscope signal, representing the angular velocity of hand movement. Each peak corresponds to a directional change or a complete movement cycle, and higher peak amplitudes indicate faster and more vigorous motion execution.

On the basis of the processes outlined earlier, the influence of involuntary movement arising from PD was mitigated for the assessment of slowness.

To minimize potential sources of bias, certain methodological precautions were implemented. First, standardized protocols were applied during all data collection procedures, including instructions, task execution, and environmental conditions, ensuring consistency among participants. Assessment sessions were conducted individually to avoid external interference and influence from other participants' performance. Disease severity was controlled by including only individuals classified as having mild to moderate PD (Hoehn and Yahr I-III), thereby reducing heterogeneity in motor impairment. After taking their regular antiparkinsonian medication, the researchers waited for a period of time until each participant subjectively reported improvement in motor symptoms, indicating perception of adequate motor control caused by the medication, minimizing drug-related performance fluctuations. In addition, data processing followed predefined criteria, and the researcher responsible for extracting and organizing the results was unaware of the participants' identities to reduce observer bias.

Results

All individuals who expressed interest in participating in the study and were evaluated for eligibility criteria met the established requirements. In total, 15 participants with PD and 15 healthy participants were included and analyzed in the study. Samples from healthy participants were collected only after the participation of an individual with PD of the same age and gender, ensuring pairing between the groups. There were no dropouts or exclusions during the collection process, so all participants fully completed the experimental protocol.

The primary demographic and clinical characteristics of the sample are presented in Table 1. To assess potential differences in age between the PD group and the healthy CG, an ANOVA was conducted, showing no statistically significant difference between the groups (P>.05). The Kruskal-Wallis rank-sum test was applied to compare the total MDS-UPDRS Part III scores in the ON and OFF medication states, demonstrating a significant difference between these conditions (P<.05). Additionally, an ANOVA performed on the Hoehn and Yahr scores across medication states indicated no significant variation (P>.05).

Table 2 displays the slowness assessment results for both the EG and CG. The average RT and AV values for each participant, considering the 4 phases of the game, are presented. The RT values were generally lower for the CG than for the EG, while the AV values were higher for the CG than for the EG in both the ON and OFF states. It is noteworthy that the CG participant with the highest RT also showed the lowest AV (participant 3). However, it is important to emphasize that RT and AV do not have a linear relationship; changes in one measure do not necessarily correspond proportionally to changes in the other, as they capture different aspects of movement performance.

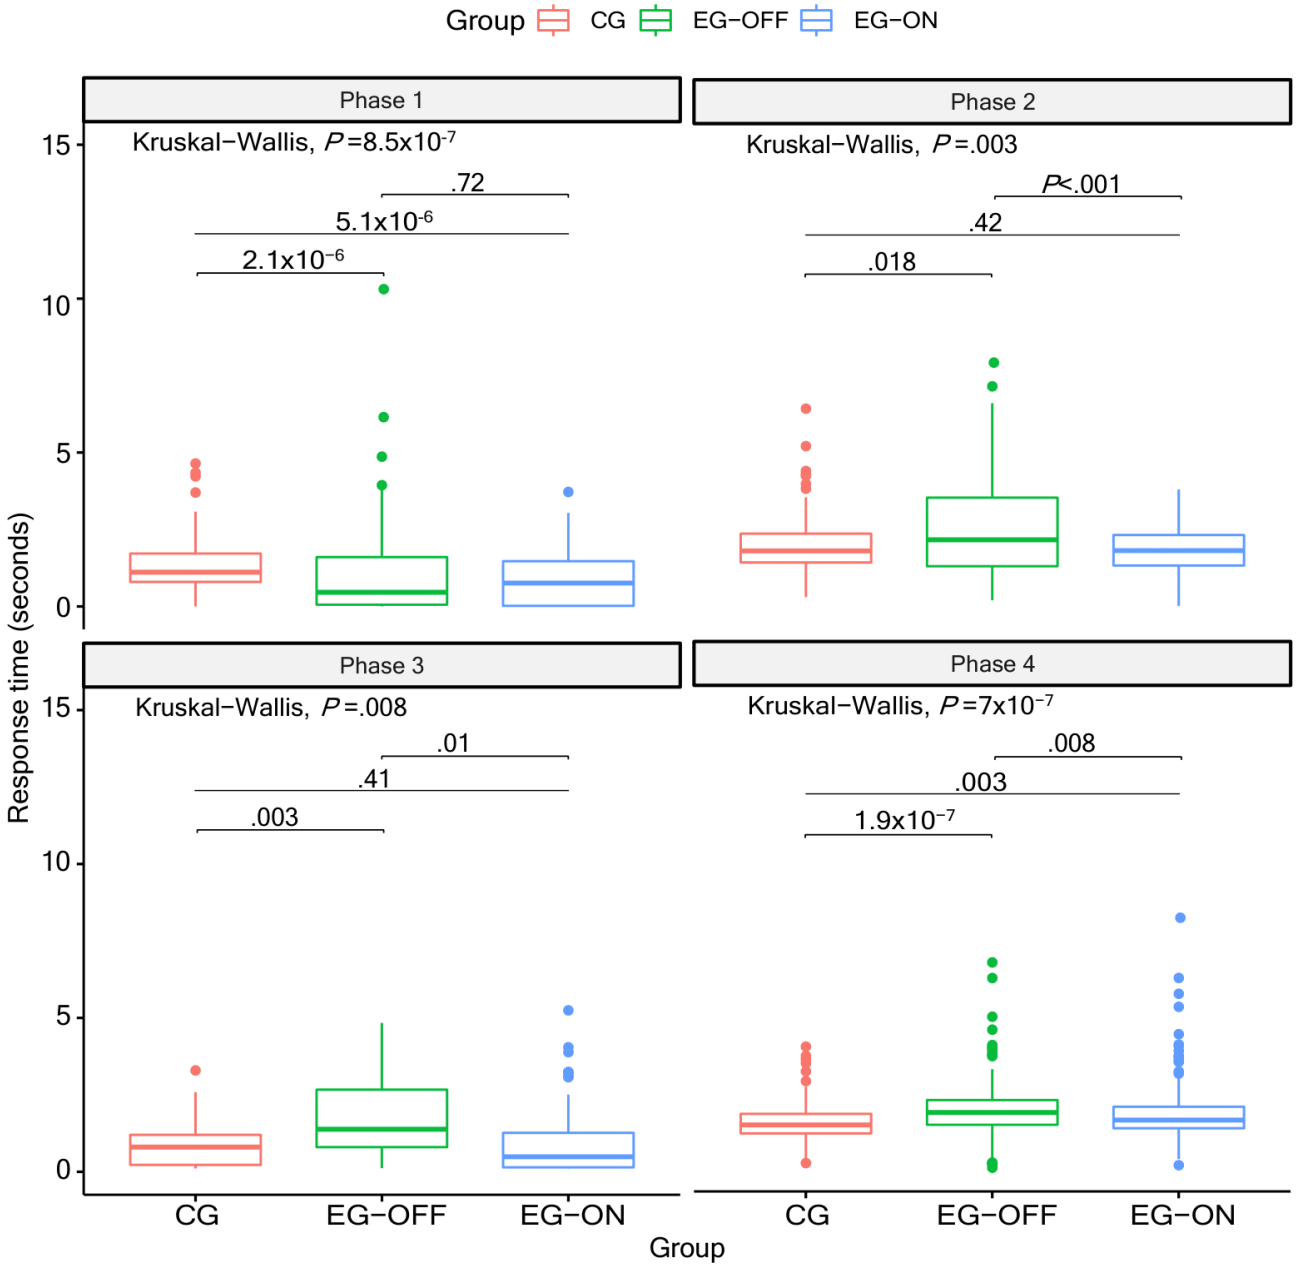
[a]Higher RT and lower AV indicate greater slowness, and higher MDS-UPDRS scores reflect worse motor impairment.

[b]ID denotes participant identifier.

[c]RT: response time.

[d]AV: angular velocity.



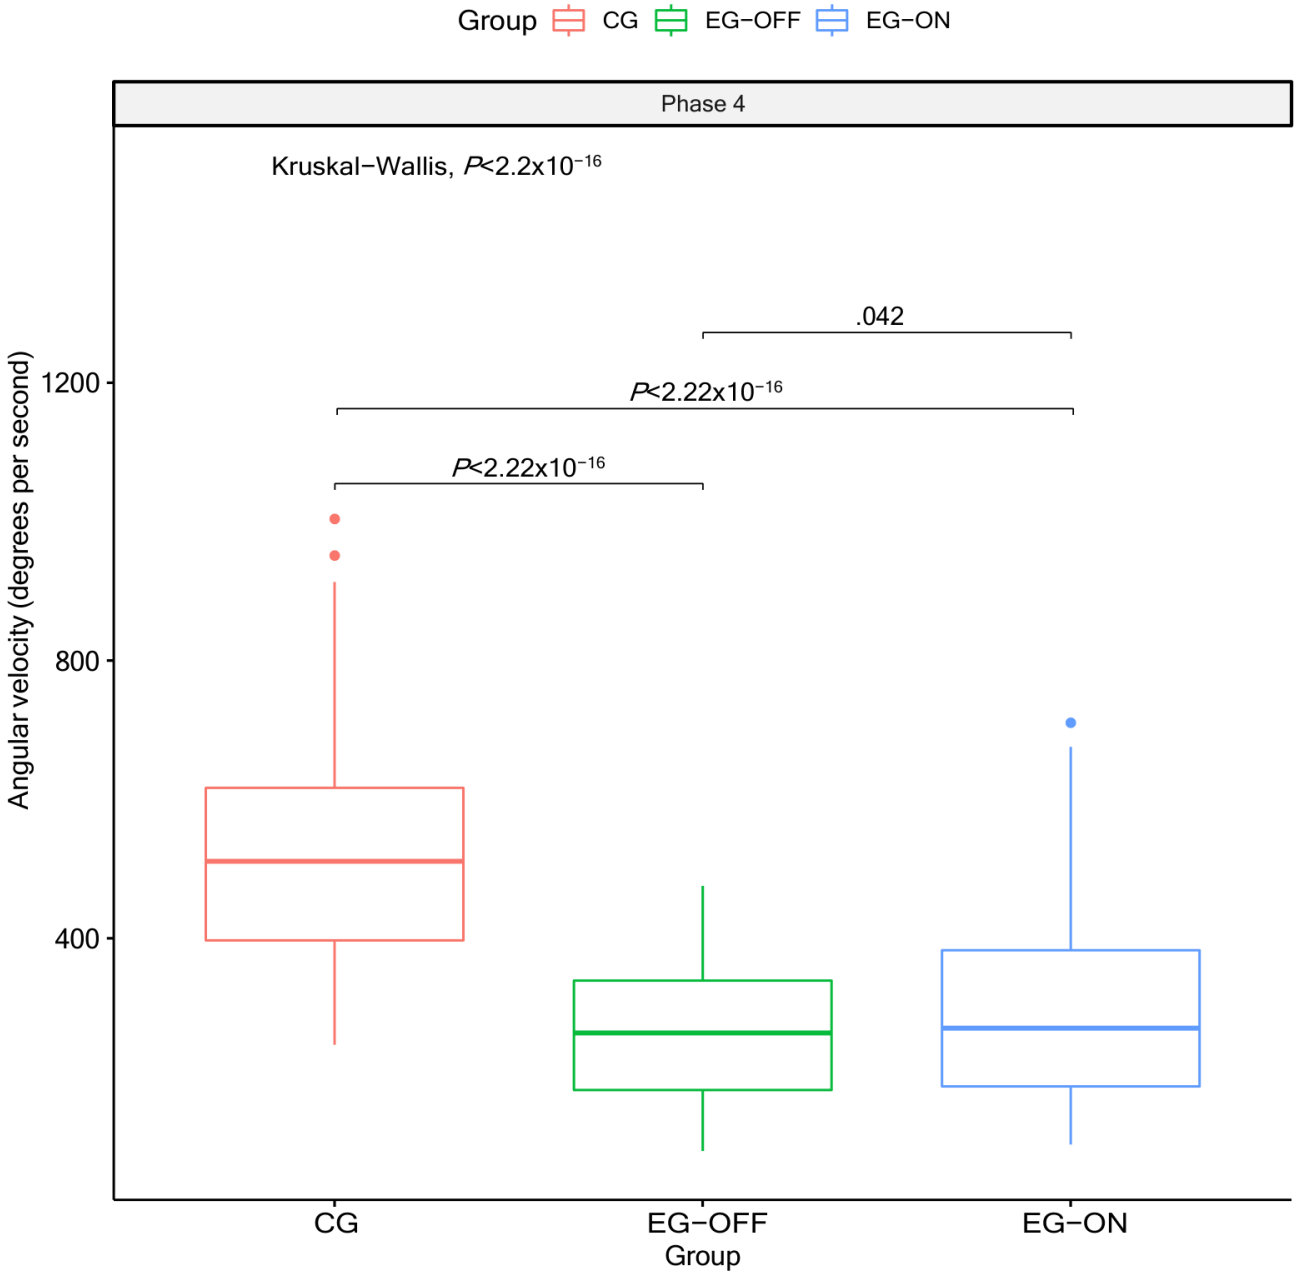
[e]MDS-UPDRS: Movement Disorder Society-Unified Parkinson's Disease Rating Scale.

Regarding the EG, participants 1, 5, 6, 9, 11, 12, and 15 in the ON state of medication presented lower RT scores and higher AV scores compared to the OFF state. In the OFF state, the individual with the highest degree of disease impairment, according to the clinical evaluation, also presented the largest RT and the smallest AV (participant 12). Participants 3 and 14 increased their AV in the ON state compared to the OFF state but also increased their RT; and participants 2, 7, and 10 decreased their RT in the ON state compared to the OFF state but also decreased their AV. Participants 4, 8, and 13 increased their RT and decreased their AV in the ON state compared to the OFF state.

The distribution of RT values for all participants is depicted in Figure 5. Except for phase 1, in all other phases, the CG had the lowest RT, followed by the EG in the ON and OFF states. In phase 1, the EG in the ON state produced the best RT values, followed by the CG and then the EG in the OFF state.

XSL•FO
RenderX

Figure 5. Distribution of estimated response time across participants for each of the 4 game phases, comparing the CG and the EG in the ON and OFF medication conditions. CG: control group; EG: experimental group.

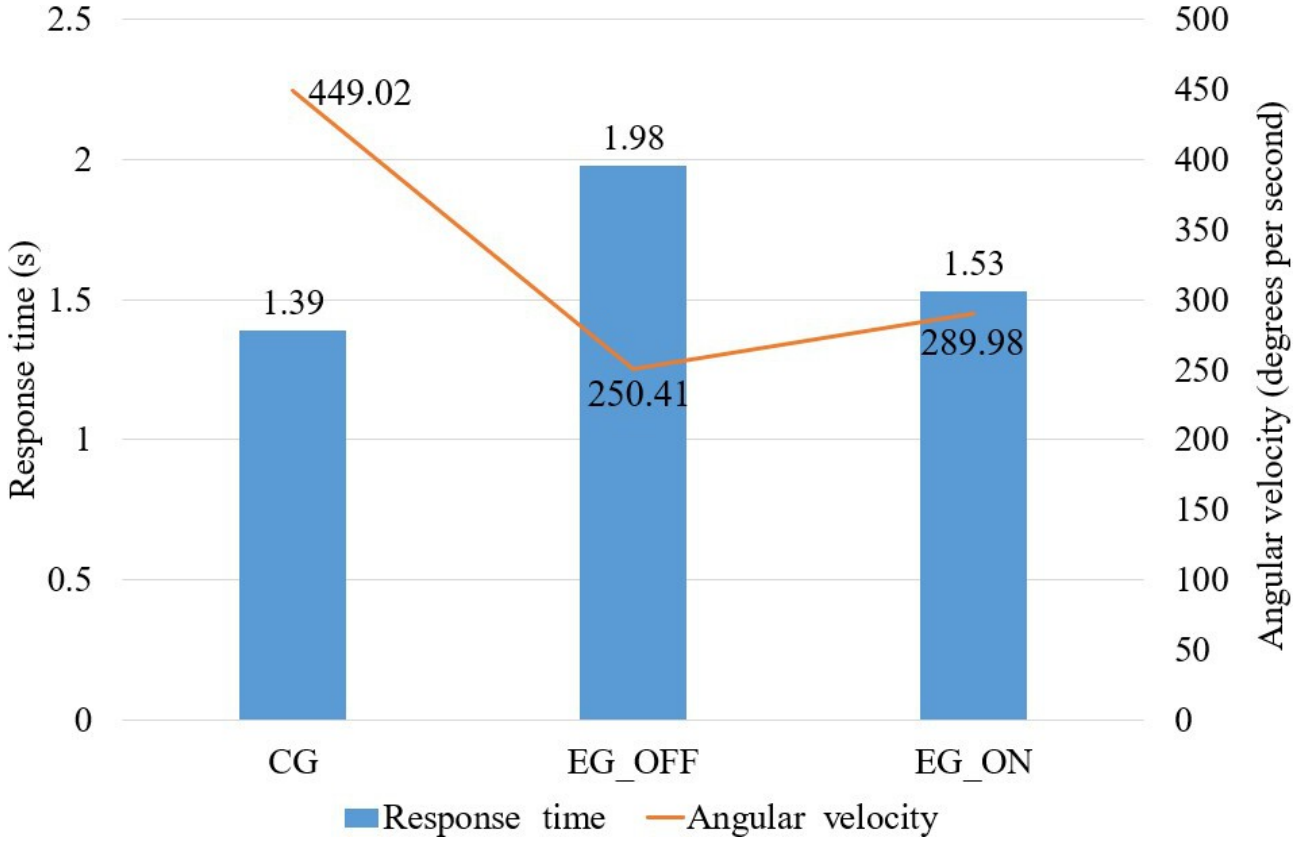


The Kruskal-Wallis test indicated statistically significant differences in RTs among the groups across all phases. Specifically, phase 1 showed $P=8.5\times10^{-}$ with a small-to-moderate effect size ($\eta^2=0.0591$), and statistically significant differences were found among all groups except between the EG-OFF and EG-ON; phase 2 showed $P=.0028$ with a small effect size ($\eta^2=0.0239$), and no statistically significant differences were observed between the CG and the EG-ON; phase 3 showed $P=.0081$ with a small effect size ($\eta^2=0.0419$), and the comparison between the CG and the EG-ON did not reach statistical significance; and phase 4 showed $P=7\times10^{-}$ with a moderate effect size ($\eta^2=0.0650$), and statistically significant differences were observed among all groups.

The distribution of AV data for all participants is shown in Figure 6. Again, the CG had the largest AV, followed by the EG in the ON state, and then by the EG in the OFF state.

XSL•FO
RenderX

Figure 6. Distribution of angular velocity among participants, comparing the control group and experimental group in both medication states. As noted, angular velocity was estimated exclusively for phase 4.



A statistically significant difference in AV among the groups was observed using the Kruskal-Wallis test ($P<2.2\times10^{-16}$), with a large effect size ($\eta^2=0.404$).

It is worth noting that the analyses presented in Figures 5 and 6 were not conducted based on individual trials but rather using aggregate measures per group. Specifically, both figures were constructed based on the median values of each variable within each group, ensuring that differences in the number of trials per participant did not influence the results. Thus, Figure 5 represents the median RT per group in each phase, while Figure 6 presents the median AV per group in phase 4. This procedure ensures a more robust and consistent interpretation of the data, minimizing biases related to intraindividual variability.

Figure 7 shows the mean values of RT and AV for all groups. This grouped visualization of the estimated variables (RT and AV) reflects an overall trend in motor performance between the groups. On average, healthy individuals performed faster movements in less time during interaction with the game when compared to participants with PD. In addition, for the EG, the RTs decreased from the OFF state to the ON state, and AVs increased from the OFF state to the ON state. This visualization highlights the overall difference between the groups in terms of RT and AV measurements.

XSL•FO
RenderX

Figure 7. Mean response time and angular velocity values for each group. The CG showed the fastest responses and highest movement speeds, while EG exhibited improved performance in the ON state compared to the OFF state, with lower response times and higher angular velocities. These values provide a quantitative overview of motor performance in all conditions. CG: control group; EG: experimental group.

The correlation analysis revealed distinct association patterns between RT and AV and the motor items of the MDS-UPDRS. Table 3 summarizes the corresponding correlation coefficients along with their classifications. RT showed very weak to weak positive correlations with all individual items and with BRADINDEX. In contrast, AV demonstrated strong negative correlations across all MDS-UPDRS items and with the composite bradykinesia index.

Table . Spearman correlations (ρ) between response time (RT), angular velocity (AV), and the Movement Disorder Society-Unified Parkinson's Disease Rating Scale (MDS-UPDRS) items.

MDS-UPDRS item	ρ (RT×MDS-UPDRS)	ρ (AV×MDS-UPDRS)
3.4a	0.058	−0.656
3.4b	0.217	−0.617
3.5a	0.114	−0.687
3.5b	0.216	−0.625
3.6a	0.118	−0.725
3.6b	0.215	−0.665
BRADINDEX[a]	0.147	−0.698

[a]BRADINDEX is the summary of the 3.4a to 3.6b item scores.

Discussion

On the basis of movement data collected by inertial sensors during participants' interaction with the serious game, it was possible to measure indicators of slowness in PD. These results demonstrate that metrics extracted from a gamified environment can capture motor changes characteristic of the disease and differentiate individuals with PD from participants in the CG.

Comparison to Prior Work

Unlike existing literature that relies on subjective scales or external motor tests, RehaBEElitation records inertial signals during gameplay for dual-purpose rehabilitation and monitoring. While the MDS-UPDRS remains the gold standard, its high interexaminer variability and inability to capture daily symptom fluctuations highlight the need for more reliable, objective tools [38,39]. Our system addresses this by capturing direct

XSL•FO
RenderX

neuromuscular data through a sensor-integrated glove, ensuring a more precise assessment of impairment.

Despite not addressing the use of serious games, recent studies have demonstrated the use of wearable sensors to assess and monitor the motor signs and symptoms of PD [40,41]. Such technologies can help researchers and health care professionals obtain a more reliable and objective view of disease progression and the severity of motor symptoms. Furthermore, according to Bhidayasiri and Tarsy [16], the successful implementation of wearables to evaluate PD symptoms, in conjunction with the use of established scales such as the MDS-UPDRS, promises to improve the quality of medical care for people with PD. However, despite numerous efforts to create new technologies for bradykinesia assessment, it has not yet been possible to establish one that performs this evaluation objectively, as considerable experience and effort are still required to operate the available technologies [10].

In this study, slowness was assessed using the individuals' RT, which was calculated by the duration of an event indicating the moment when the player reaches the target and performs the movement, as well as the gyroscope signal collected by the wearable HMI device, which represents the AV of movement. Statistical analysis indicated that the groups of healthy individuals and patients with PD were comparable in terms of age. Overall, as reflected by the MDS-UPDRS III and Hoehn and Yahr scores (Table 1), patients with PD in the OFF medication state exhibited greater impairment than in the ON state.

To obtain a reliable AV estimation, the SSA method was applied to the gyroscope signals to isolate voluntary activity. Several techniques can be used for time series decomposition, such as Fourier analysis, empirical mode decomposition, wavelet transform, kinematic decomposition by submovements, and singular spectrum decomposition (SSD). However, as the recorded signals are nonstationary time series, Fourier analysis is not the ideal option [42]. This approach assumes stationarity, risking the loss of transient information [43]. Moreover, Fourier analysis and empirical mode decomposition can provide data decomposition results with limited physical sense, that is, components with unclear physical meaning. The components retrieved by these techniques can also be affected by mode mixing, again interfering with the physical meaning of individual components, especially in cases where abrupt variations in movement occur [37]. Techniques such as wavelet transform, although suitable for nonstationary data, depend heavily on the prior choice of a mother wavelet, which can introduce bias and hinder the physiological interpretation of the extracted components [40]. The kinematic decomposition by submovements approach is limited by its dependence on ideal models that do not always represent real movements and by its sensitivity to noise during segmentation, which can lead to the misidentification of submovements [44]. Finally, the SSD technique was initially applied to decompose the original signal, but no successful results were obtained. The selection of fundamental parameters in SSD, including window length and elementary component indices, is completely automated, which generated components with no physical meaning.

The SSA method was able to satisfactorily disregard the signal that represents the involuntary movement of the players. The results suggested that this method is particularly useful for this application, as the extracted tremor signal represents a disease-induced tremor (Figure 3). Due to the decomposition, it is possible to separately and independently study the characteristics of the pure movement and of the tremor of individuals with PD by analyzing only the extracted signal of interest.

Principal Findings

The results indicated in Table 2 showed that participants 1, 5, 6, 9, 11, 12, and 15 in the ON state of medication presented lower RT scores and higher AV scores compared to the OFF state. This result was already expected, since EG participants in the ON state of medication have more reduced motor symptoms than in the OFF state [45]. However, in the ON state, some situations also occurred: participants 2, 7, and 10 reduced RT but also reduced AV, participants 3 and 14 increased AV but also RT, and participants 4, 8, and 13 increased RT and reduced AV. It is known that RT is the sum of reaction time and movement time; AV is more related to movement time.

After taking the medication, participants 2, 7, and 10 had lower RT but performed the movements more slowly; that is, they increased the movement time, which consequently resulted in a decrease in reaction time. Movement time may have increased because the medication is probably not bringing benefits regarding the improvement of motor symptoms in these individuals, which suggests the need to readjust the dosage of the medication or change it for another medication. The reaction time may have been reduced by the learning acquired in the first session of interaction with the game, that is, the players learned that after reaching the target and receiving the visual and sound stimuli, they should perform the required movement. Thus, although the player performed the movements more slowly, he was able to initiate the execution of the movements earlier.

After participants 3 and 14 took the medication, the movements were performed faster, that is, movement time was decreased, but RT increased, which consequently resulted in increased reaction time. Movement time may have been reduced due to the medication's effectiveness in reducing motor symptoms. The reaction time may have increased due to the lack of learning that could have been acquired in the first session; that is, the participants did not understand that the visual stimulus indicated the exact moment to start the execution of the movement. Thus, although the motor symptoms were reduced, the players did not learn enough, making them start the execution of the movements later.

Finally, after participants 4, 8, and 13 took the medication, their RT increased, and they performed the movements more slowly, that is, they increased the movement time. It can be suggested that the medication does not reduce the motor symptoms of these individuals; therefore, a readjustment of the medication dosage should be performed. Moreover, these individuals probably did not acquire learning in relation to the game.

XSL•FO
RenderX

Medication is the key treatment for the motor symptoms of PD, but the pharmacological response inevitably diminishes over time [46]. Following these results, it is possible to identify the individuals who possibly need medication adjustments, as well as those who require additional training with the serious game to better understand its features and rules. These findings may provide a more personalized patient follow-up by health care professionals and assist them in assessing individuals and monitoring the disease.

In phase 1, the median RT of the EG-OFF was lower than that of both the EG-ON and the CG. The EG-ON also showed lower RTs compared to the healthy controls. However, no statistically significant differences were found between the EG-OFF and EG-ON groups, whereas both EGs differed significantly from the CG. One possible explanation for this pattern is that participants in the EG had already been exposed to the RehaBEElitation serious game, which may have provided a degree of familiarity with the task demands. This prior exposure may have facilitated faster motor planning and reduced hesitancy during the initial phases of interaction, even among participants in the OFF-medication condition. In contrast, healthy controls, despite not presenting motor symptoms, were inexperienced with the task and may have required additional time to internalize the stimuli and response mapping, resulting in comparatively longer reaction times. It is worth noting, however, that the CG exhibited a narrower or flatter boxplot distribution in phase 1, indicating lower variability and greater consistency in performance compared to the EGs. A similar trend was observed in phase 3, in which the EG-ON demonstrated lower RTs than the healthy controls, although without reaching statistical significance. Together, these findings suggest that task familiarity may have contributed to the observed differences in RT performance.

Furthermore, the information indicated by Figures 5-7 showed that, in general, the RT and AV scores for the CG participants were better than those for the EG in the ON state, which in turn were better than those for the EG in the OFF state, as already expected. In addition, EG participants in the OFF state of medication and CG participants who presented the worst results for RT also presented the worst results for AV, which reveals that the measures used for the assessment of slowness were quite consistent.

According to Figures 5 and 6, phase 4 is the most suitable for assessing slowness using the RehaBEElitation serious game. Figure 5 shows that, in this phase, the differences between the groups were better detected, since the boxplots overlapped less, and only in phase 4 was it possible to estimate the intentional AV of the participants (Figure 6). Movements performed around the other axes, such as flexion-extension around the X axis and adduction-abduction around the Z axis, were not used to score points but to steer the bee within the scenario. Because these actions served navigation, players could deliberately modulate them (eg, moving more slowly or with reduced amplitude) to fine-tune the bee's positioning. Consequently, AV derived from these axes would not reflect performance intent and was not analyzed. In contrast, when a movement is executed to score points, it is performed with intentional speed and amplitude, which are suitable for AV estimation. For this, AV analyses were restricted to the gyroscope signals recorded in phase 4.

A further point to discuss is that phase 4 required the execution of the forearm supination and pronation movement, a more complex movement than the others and one that is not often performed during daily activities. This may have encouraged players to focus on the execution of the movement, which may have influenced a better estimation of the variables used in the study. These findings agree with those reported by Summa et al [47].

Effect size estimates provide important information about the practical relevance of the differences observed between groups. Although all phases of the RT analysis showed statistically significant differences, the associated effect sizes were small for phases 2 and 3, small-to-moderate for phase 1, and moderate for phase 4, suggesting that group membership explains only a limited part of the variability in RTs. This indicates that, although the groups are different, other factors such as individual variability, familiarity with the task, or motor strategy may play a substantial role in RT performance. In contrast, the AV results revealed a large effect size (η^2=0.404), indicating that the differences between groups in AV are not only statistically significant but also of great practical magnitude. This pattern also confirms that AV is a more sensitive marker of group-specific motor behavior than RT and, therefore, may serve as a stronger discriminator of motor performance differences in this context.

The grouped visualization shown in Figure 7 highlights an overall pattern of motor performance between groups but does not capture individual nuances or intrasubject variations. These differences may be related to the heterogeneity of symptoms among people with PD, variability in response to medication, level of familiarity with the game, motivation, rigidity, and different difficulties present in tasks at each phase of the game. Thus, although the overall trend indicates greater slowness in the Parkinson group, future studies should consider more detailed analyses at the individual level, as well as increasing the number of trials per participant, to reduce motor compensations or momentary fluctuations and obtain even more robust measures.

Correlation analysis revealed distinct patterns between RT and AV variables and the motor items of the MDS-UPDRS. While RT showed very weak to weak correlations with items that reflect slowness on the clinical scale, AV showed strong and consistent correlations, indicating, once again, greater sensitivity of this metric to the typical motor impairment of PD. In this study, slowness was estimated from the sum of reaction time and movement time (RT variable), although reaction time is not part of the clinical assessment of this symptom. This conceptual difference may have contributed to the weaker correlations observed between RT and MDS-UPDRS scores. Additionally, RT seems to reflect broader aspects of interaction with the task, such as attention, familiarity, and individual strategies, which may explain the lower magnitude of the associations.

XSL•FO
RenderX

Strengths and Limitations

An important contribution of this study is the definition of a specific event within the game that functions as a behavioral marker, allowing the estimation of a variable indicative of slowness (RT) during task execution. Although not a biological marker, this event provides a structured and reproducible reference point from which RT can be calculated. As already discussed, this variable, despite not showing a strong correlation with the MDS-UPDRS, captures a central component of motor slowness, as it reflects both the preparation and initiation of movement, processes known to be impaired in PD. Without this event, it would not be possible to quantify slowness with the RT variable in the simple way that was carried out. There is a total of 23 predefined markers in the game, which were detailed in a study describing the architecture and organization of our system [17]. Thus, the game's internal markers play a key role in providing objective anchors within the interaction, allowing the derivation of meaningful measures of motor performance.

Study limitations include the lack of prior training for the CG and the single-day assessment for the EG in both ON and OFF medication states. While this scheduling avoided collection bias, the cumulative duration of tasks may have impacted performance during the ON-state trials for some participants. Additionally, the PD group used their most affected limb, while the CG used their dominant limb. Although this introduces variability, it preserves ecological validity, as bradykinesia is characteristically asymmetric. Since our goal was to characterize game interaction under realistic clinical conditions rather than compare absolute performance, we consider the impact of this difference on our findings to be limited.

Future Directions

In this study, the generalization of the results is influenced by the sample characteristics. Although the use of a serious game that presents a well-established motor task favors broader applicability, the results should be interpreted, considering that participants presented mild to moderate PD (Hoehn and Yahr I-III) and that all interactions with the system were conducted in a controlled environment. Therefore, extrapolation to individuals with advanced disease, other clinical contexts, or unsupervised home use should be done with caution. Future studies with larger and more heterogeneous samples are needed to confirm the external validity of these results.

In comparison to other methodologies, using serious games is an appealing option for measuring Parkinson motor symptoms. This game can be applied frequently and easily in clinics and hospitals, which demonstrates excellent accessibility and is cost-effective. In addition, the methods applied can isolate voluntary activity from involuntary activity. Severe tremor interferes with the classification of bradykinesia.

This study advances the current literature by proposing a novel and objective method to quantify slowness in PD using inertial sensor data acquired during interaction with a serious game. While previous studies have explored serious games for PD assessment and rehabilitation, most relied on subjective clinical scales, questionnaires, or conventional physical tests to evaluate motor symptoms. In contrast, our approach directly analyzes sensor-derived metrics obtained during gameplay, enabling the extraction of quantitative measures of RT and AV without interrupting the user experience. To the best of our knowledge, this is the first study to evaluate slowness in PD by processing inertial sensor data collected during interaction with a serious game. This contribution strengthens the role of serious games as potential digital biomarkers and highlights their value as engaging tools for continuous and sensitive motor assessment. From a real-world perspective, this approach may facilitate remote monitoring in home environments, complement clinical evaluations, and support personalized follow-up of motor symptom progression, thereby expanding access to objective and technology-driven care for individuals with PD.

Conclusions

The findings of this study suggest that the RehaBEElitation serious game is a promising tool for objectively assessing motor slowness in individuals with PD. Interaction-derived variables, particularly AV, showed strong correlations with MDS-UPDRS motor scores, capturing motor impairment sensitively. The game also detected differences between ON and OFF medication states, reinforcing the ability of the serious game to detect changes associated with treatment. Overall, these results indicate that the RehaBEElitation serious game represents a viable and potentially valuable approach for the objective monitoring of slowness and for supporting strategies for tracking the progression and therapeutic management of PD.

Acknowledgments

The developed serious game won the prize at the 11th edition of the "Challenge Handicap & Technologie" event in Metz (France) on May 12, 2023. The first-place prize was awarded in the "Autonomy" category, related to promoting the autonomy of people in situations of dependency [48]. The project also received the Brazilian Society of Biomedical Engineering (SBEB) Boston Scientific Award for Innovation in Biomedical Engineering 2023. The award, created in a partnership between the SBEB and Boston Scientific, aims to value and encourage the academic production of projects and work in biomedical engineering aimed at tackling the difficulties of the Brazilian health system and public health services in Latin America [49]. No generative artificial intelligence was used in any part of this manuscript.

Funding

The work was carried out with the support of the National Council for Scientific and Technological Development (CNPq—444437/2024-0, 442150/2023-7, and 405365/2023-3), the Coordination for the Improvement of Higher Education

Decomposition of a gyroscope signal from an experimental group participant. The top signal represents the original time series, containing both components of voluntary movement (from gameplay) and involuntary movement (tremor). The middle signal isolates the voluntary movement, that is, the intentional control of the bee. The bottom signal isolates the disease-related tremor, that is, only the oscillatory or periodic components of the original time series.

Abstract

Background: Serious games offer promising avenues for clinical care by enhancing patient engagement and delivering therapeutic benefits. In psoriatic arthritis (PsA), chronic pain contributes to emotional distress, functional limitations, and reduced well-being. While symptom-tracking apps exist, few digital interventions directly address chronic pain through engaging, therapeutic experiences tailored to patients' cognitive and physical needs.

Objective: This study aimed to co-design mobile serious games—NoPain Games—to support patients with PsA in managing chronic pain. Conducted within the iPROLEPSIS Horizon Europe project, the study involved a multidisciplinary cocreation session with rheumatologists, researchers, and technical experts, followed by a usability feedback session with patients with PsA. The goal was to identify therapeutic priorities, refine game mechanics, and assess usability to inform the development of personalized, accessible digital interventions.

Methods: A sequential mixed methods design was used. First, a 90-minute remote cocreation session was held with 14 experts (6 rheumatologists, 4 technical experts, and 4 researchers) from 3 European countries. Participants reviewed game storyboards and discussed therapeutic and design priorities. Thematic analysis of transcribed discussions identified key insights. Next, a 60-minute remote usability feedback session was conducted with 5 patients with PsA (aged 25 - 64 y), who interacted with 2 high-fidelity game prototypes (Space Oddity and Four Seasons). Usability was assessed using the System Usability Scale (SUS), and qualitative feedback was collected through moderated discussion. Item-level analysis using item characteristic curves provided deeper insight into usability perceptions and item sensitivity. All ethics requirements were met for both study phases.

Results: Thematic analysis of the transcribed dialogs of the cocreation session revealed three core themes: (1) therapeutic benefits (pain distraction, memory enhancement, cognitive stimulation, stress reduction, and creative engagement); (2) game difficulty (balancing duration and complexity to sustain engagement without fatigue); and (3) accessibility and interaction (addressing physical limitations, optimizing touchscreen usability, and ensuring inclusive design). These insights informed the development of 2 NoPain Game prototypes, which received a SUS score of 79 (SD 10.4; 95% CI 69.89 - 88.11), indicating good usability. Item characteristic curve analysis showed strong discrimination for learnability, while ease of use and confidence exhibited ceiling effects. Items like support needs and inconsistency showed minimal variability, and the learning curve demonstrated delayed but meaningful responsiveness at higher usability levels. Qualitative feedback reinforced the relevance of difficulty adjustment, technical refinements, and game mechanics, offering actionable insights for future iterations and broader implementation.

Conclusions: This study uniquely contributes to the field by co-designing mobile serious games specifically for patients with PsA, integrating expert and patient input to address chronic pain through accessible, cognitively engaging digital interventions—an approach not previously explored in this population. Future work will refine game mechanics, integrate adaptive difficulty, and conduct clinical trials to evaluate therapeutic efficacy. NoPain Games may serve as complementary tools within digital care ecosystems, offering support tailored to the therapeutic needs and physical limitations of patients with PsA underserved by conventional therapies.

Introduction

In health care, serious games—designed for purposes beyond entertainment—have generated considerable interest and sparked ongoing debate [1]. Their potential has often been overlooked due to the still prevailing perception of games as purely recreational objects rather than valuable tools for skill development and health rehabilitation [2]. Research studies, however, have demonstrated the benefits of serious games, particularly their ability to reduce stress [3], enhance mobility [4,5], and alleviate pain [6,7].

Many of these benefits align with the symptomatology of rheumatic diseases, making it possible to use serious games as health care tools for conditions such as psoriatic arthritis (PsA). PsA, a degenerative rheumatic disease, is marked by joint stiffness and persistent pain, significantly affecting patients' quality of life [8]. As there is no cure, treatment primarily focuses on managing symptoms and holistically improving patients' well-being, often through interventions like physical therapy [9]. However, these traditional approaches can feel repetitive or burdensome for patients, leading to low adherence and reduced effectiveness. While various digital tools, particularly mobile apps for disease management, have been proposed [10], they primarily serve as symptom-tracking solutions and fail to address the ongoing joint pain experienced by patients.

Serious games offer a compelling alternative to complement traditional treatments by creating experiences that are both engaging and therapeutic [11]. For example, DaktylAct, a touch-based serious game, has been proposed as an innovative tool for assessing fine motor skills in PsA using novel digital biomarkers [12]. Furthermore, immersive experiences in chronic pain management have been extensively studied, with strong evidence supporting their pain-relieving capabilities, particularly in virtual reality (VR) environments [6,13]. Building on this, previous research has highlighted the effectiveness of exergames in altering pain perception by engaging multiple sensory modalities [14]. For instance, Gold et al [13] highlighted how VR can influence neurobiological mechanisms, showing that auditory, visual, and tactile stimuli reduce activity in pain-processing areas. In addition, Hoffman et al [15] further validated the effectiveness of immersive digital interventions by comparing VR and opioids in pain relief. Their findings suggest that while both approaches are beneficial independently, their combination leads to even greater analgesic effects. These findings, derived from subjective pain scales and functional magnetic resonance imaging, highlight the potential of mobile-based alternatives with similar engagement mechanisms to perform effectively without the need for specialized hardware.

Moreover, recent studies have further expanded the evidence base for serious games in pain management. Beltran-Alacreu et al [16] developed a task-oriented serious game for older adults with chronic neck pain, demonstrating its suitability and therapeutic potential. Saragih et al [7] conducted a systematic review and meta-analysis confirming the efficacy of serious games in managing chronic pain among older adults, reinforcing their clinical relevance. Additionally, Peña et al [17] explored the use of digital art and attachment priming in a web-based serious game, showing promising results in reducing both pain and social disconnection in individuals with chronic pain and loneliness.

Immersion remains a critical factor in pain management games. Gromala et al [6] emphasized that realistic visual environments, sound effects, and interactive storytelling contribute significantly to the overall therapeutic experience. Their concept of imaginary immersion introduces in-game threats and challenges to sustain player focus and engagement. We believe that translating these principles into mobile platforms requires innovative game mechanics that maintain immersion despite limited sensory channels. For instance, the MyRelief smartphone app presents a serious game to relieve chronic low-back pain through physical and psychological activities [18]. Although their analysis suggests that serious games can help improve patient status, the authors recognize that further research is needed to validate all game components.

Incorporating motivational elements in mobile pain management games is another critical design consideration. In this line, Ijaz et al [19] demonstrated the power of competitive motivation in their cycling game, which used on-screen scores of real and artificial competitors to enhance user engagement. Similarly, Tuah et al [20] reviewed common gamification elements in rehabilitation games, identifying key components such as points, leaderboards, badges, progression systems, and avatars that contribute to sustained participation.

To the best of our knowledge, no serious game has been specifically designed to target the chronic pain experienced by individuals with PsA. This study aims to explore the co-design and development of mobile serious games, referred to as NoPain Games, specifically tailored to support patients with PsA in managing chronic pain. Developed using an agile co-design methodology [21], these serious games represent a new approach to chronic pain management, as part of the Horizon Europe iPROLEPSIS project [22,23], which aims to create a personalized suite of games tailored to the needs of individuals with PsA. The primary objective of this study is to assess the therapeutic potential, usability, and design requirements of these games through a multidisciplinary cocreation process involving clinicians, researchers, and technical experts, along with the patients' usability feedback. By integrating cognitive stimulation, stress reduction, and inclusive interaction mechanics, the study seeks to establish foundational design principles for mobile-based digital interventions that enhance patient engagement and well-being. The underlying hypothesis is that co-designed serious games incorporating adaptive difficulty and accessible interfaces can serve as effective pain

XSL•FO
RenderX

distractors and cognitive enhancers for individuals living with PsA.

Methods

Overview

In this study, we followed a sequential mixed methods design, integrating qualitative and quantitative data to inform the co-design and evaluation of mobile serious games for patients with PsA. This sequential design was selected to allow expert-derived qualitative insights to inform prototype development prior to patient usability testing. Integration occurred through iterative refinement of game mechanics based on themes from the cocreation session, followed by triangulation of usability scores and patient feedback to validate design decisions. In the qualitative phase, 14 experts (6 rheumatologists, 4 technical experts, 4 researchers) were recruited via purposive sampling from the iPROLEPSIS Consortium and participated in a 90-minute remote cocreation session. Eligibility required domain expertise in rheumatology, digital health, or game development. Participants reviewed game storyboards and contributed to design refinement through moderated discussion. In the quantitative phase, 5 patients with PsA (age 25 - 64 years) from 4 countries were recruited through targeted outreach. Eligibility required a confirmed PsA diagnosis and the ability to interact with mobile devices. Patients participated in a 60-minute remote usability session, interacting with 2 high-fidelity game prototypes. Usability was assessed using the System Usability Scale (SUS), and qualitative feedback was collected through a structured discussion. Study outcomes included: (1) identification of therapeutic priorities and design requirements (qualitative), (2) usability scores and item-level sensitivity analysis (quantitative), and (3) patient feedback on game experience and accessibility (qualitative). Thematic analysis followed Braun and Clarke's framework, and SUS data were analyzed using descriptive statistics and item characteristic curves (ICCs). The study received ethical approval, and informed consent was secured from all participants.

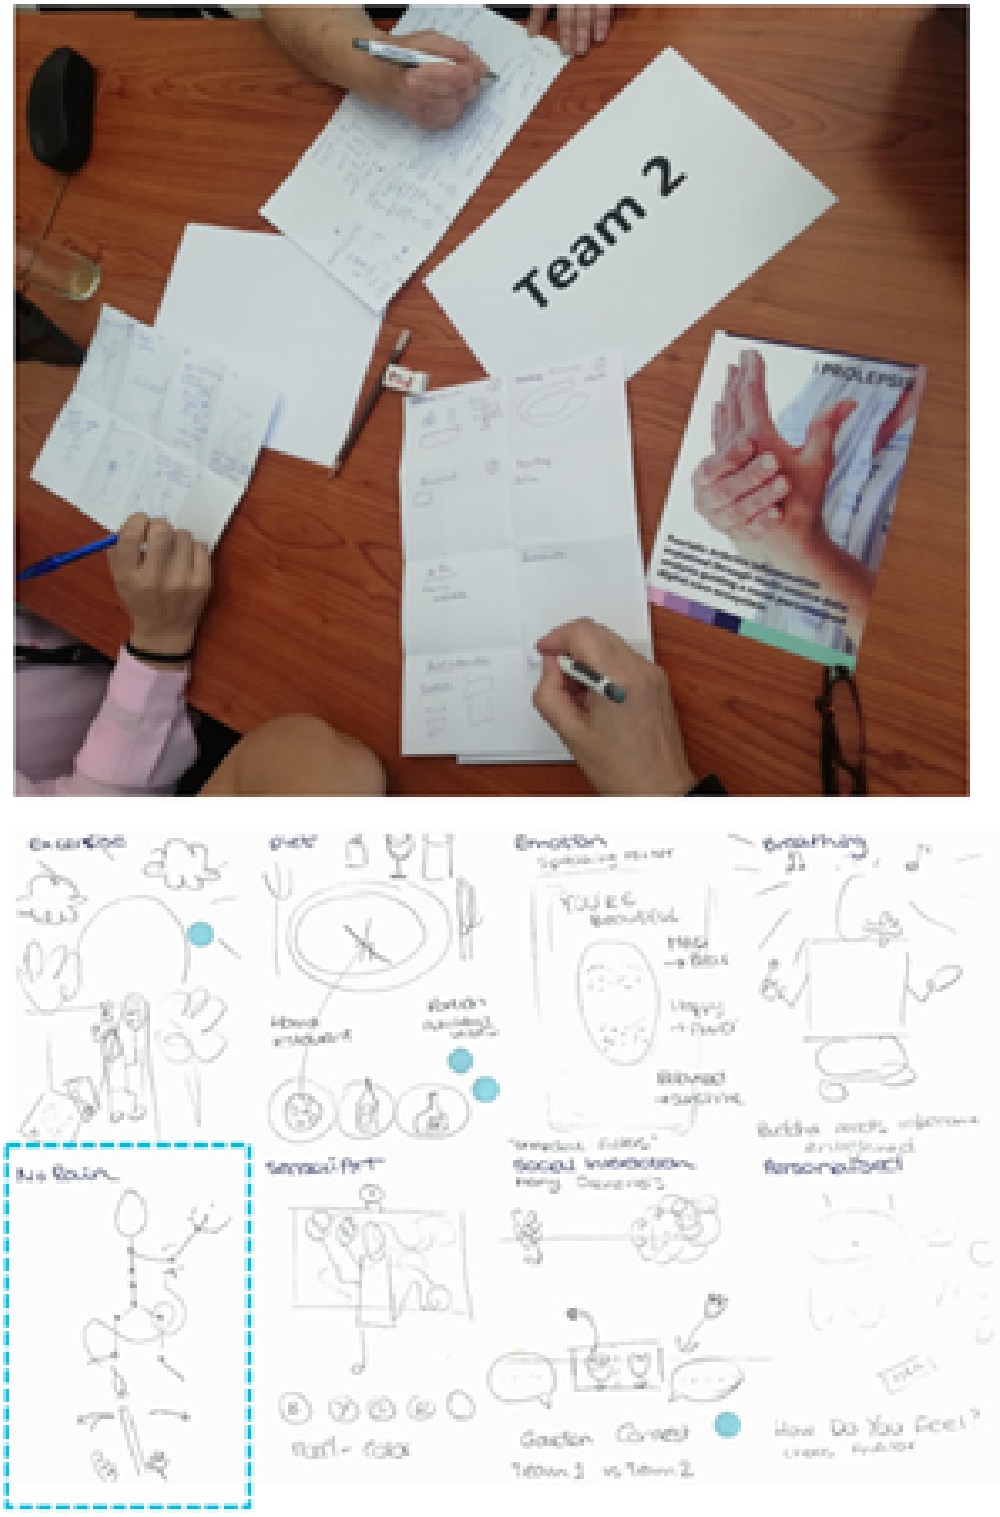
The following subsections provide a detailed account of the study context, co-design procedures, participant characteristics, data collection instruments, ethics, and analytic strategies used to generate and interpret the findings.

Study Context

This study is part of the iPROLEPSIS Horizon Europe research project, which seeks to investigate the progression from general health to PsA through multi-source data analysis, ultimately creating an innovative, personalized digital care ecosystem. Within the framework of iPROLEPSIS, the project focuses on designing, developing, and validating cutting-edge digital biomarkers to assess and address PsA using an Artificial Intelligence-Personalized Game Suite (AI-PGS). Developed collaboratively with key stakeholders, the AI-PGS takes a comprehensive, multitargeted approach to managing PsA symptoms. It includes intervention activities aimed at enhancing breathing, mobility, stiffness, balance, coordination, fitness, diet, and mood. By embracing a holistic perspective, the AI-PGS addresses stress, anxiety, fatigue, and pain through various categories of serious games, such as NoPain Games, Exercise Games [24], Sensorimotor Art Games [25], Breathing Games [26], Dietary Games, and Emotional Games. This study emphasizes NoPain Games, showcasing the critical role of engaging patients in therapeutic activities that incorporate cognitive processes—such as memory, coordination, and visual perception tasks—to help alleviate and manage chronic pain and discomfort associated with PsA symptoms.

NoPain Games Agile Co-Design Process

The design and development process for the proposed games followed an agile approach [21], emphasizing early feedback to iteratively refine game concepts and prototypes. The ideation and storyboards phase will guide the foundation for subsequent stages, including prototyping, software development, and expert evaluation, while ensuring continuous cocreation efforts aimed at clinical validation (see Figure 1). Following the product backlog, sprint planning meetings, and backlog refinement phases, the design process began with the Crazy8s ideation approach [27]. More specifically, stakeholders—including patients, clinicians, researchers, and technicians—collaboratively sketched ideas for various game categories within the AI-PGS framework, including NoPain Games (see Figure 2). This phase captured diverse requirements and expectations, culminating in the initial development of a game design document outlining the NoPain Games' key aspects, such as their concepts, mechanics, design, controls, and clinical relevance. This study highlights the subsequent agile cocreation sessions that brought together health care professionals, researchers, and technical experts as active cocreators and co-designers (see "Study participants and data collection" section) and patients with PsA as usability feedback providers (see "Feedback From Patients With PsA" section). In particular, using the storyboard technique [28], a collaborative session focused on refining and assessing the proposed designs for the NoPain Games (Figure 3), while another later session focused on the usability and general feedback of functional prototypes (Figure 4).



XSL•FO
RenderX

Figure 1. Schematic representation of the development framework for the proposed NoPain Games, illustrating the cocreation and agile methodologies used to achieve a minimum viable product. The process includes iterative 2 - 3 month sprints involving product backlog refinement (led by a technical coordinator), sprint planning, ideation, game development, expert evaluation, and clinical validation. All phases, except product backlog refinement, actively engaged patients, clinicians, researchers, and developers to ensure a multidisciplinary and user-centered approach.

XSL•FO
RenderX

Figure 2. Co-design session involving patients with psoriatic arthritis during the ideation process of the games using Crazy8s method. The initial sketch of the NoPain Games category is marked with a dashed blue square.

Initially Proposed NoPain Games Storyboards

Three different NoPain Games were initially designed: "Lightning," "Flashing Stars," and "The Garden" with related storyboards (Figure 3). In the "Lightning" game, players/patients are required to replicate a given pattern by lighting up rooms in a 2D house, reinforcing memory and coordination (Figure 3A). The "Flashing Stars" game engages players in counting falling stars within a night-sky scenario, fostering relaxation through gentle visual and cognitive stimulation (Figure 3B). Finally, "The Garden" game involves identifying a specific flower type within a vast field of blooms, promoting a sense of calm and concentration (Figure 3C). Overall, by incorporating the repetitive and rhythmic interactions of identifying flowers, lighting up rooms, or counting falling stars, the proposed NoPain Games encourage users to engage in predictable, structured

XSL•FO
RenderX

movements that promote relaxation and a sense of control. These are simple and rewarding mechanics aimed to provide immediate feedback, reinforcing positive engagement, and promoting a sense of accomplishment, while enabling a calm environment. Designed for both iOS and Android operating systems, the proposed NoPain Games high-fidelity prototypes present similar interaction controls, with players/patients using a touchscreen for interaction, with calming audio to match each scenario.

Study Participants

Cocreation Session

To obtain feedback on the related storyboards, a cocreation session was held. The latter occurred in October 2023 and was conducted digitally via the Microsoft Teams platform with shared storyboard visuals. The session included 14 experts from 3 European countries, namely the United Kingdom, Greece, and Portugal. Participants were selected using purposive sampling [29], intentionally inviting individuals with expertise in relevant fields. They were identified through institutional affiliations within the iPROLEPSIS Consortium and invited via email by the coordinating team. Participation was based on voluntary engagement and without the provision of compensation. Exclusion criteria for experts included a lack of direct experience with PsA or digital health interventions. The group included 6 rheumatologists, 4 researchers, and 4 technical experts from the iPROLEPSIS Consortium, with multidisciplinary perspectives, enriching the discussions. The cocreation session was moderated by the last author, a qualitative researcher with expertise in participatory design. To minimize bias, the moderator did not participate in game development. Two qualitative coders (first and last author) independently reviewed transcripts and discussed potential biases during theme development (see Results).

Feedback Session

To maintain a patient-centered and clinically relevant design process, individuals living with PsA were actively engaged in a dedicated feedback session conducted in May 2025. During the session, participants evaluated a pilot version of Space Oddity and a design prototype of Four Seasons (Figure 4). A 60-minute remote feedback session was conducted via Zoom with 5 patients with PsA from Portugal, the United Kingdom, the Netherlands, and Greece, using screen sharing for gameplay and an embedded SUS questionnaire via Google Forms. Similar to the cocreation session, participants were recruited through targeted outreach within the iPROLEPSIS network, through clinician referrals and patient advocacy networks affiliated with the project, using email and phone outreach. Participation was based on voluntary engagement and without the provision of compensation. For patients with PsA, exclusion criteria included cognitive impairments, severe visual/motor limitations preventing touchscreen interaction, or the inability to participate in digital sessions. The feedback session was also moderated by the last author, who did not participate in the quantitative analysis to minimize bias in the findings.

Data Collection

Cocreation Session

Audio recordings of the cocreation session were transcribed verbatim and then pseudoanonymized to preserve participant confidentiality. The digital setting facilitated active engagement from all attendees. The session was led by a female researcher specializing in qualitative research (last author), who guided discussions by posing questions and fostering group interactions to gather participants' opinions and experiences. To enhance participants' understanding of the session topics, relevant storyboards for each NoPain game were presented (Figure 3). The session followed a semistructured script with key questions designed to explore participants' views on the design of the proposed NoPain Games (Multimedia Appendix 1). A 90-minute timeframe was allowed for in-depth discussions and thorough exploration of the main topics.

RenderX

Figure 3. Screenshot of the storyboards for the proposed NoPain games: (A) The "Lightning" game illustrates a memory challenge where players light up rooms to replicate a specific pattern; (B) The "Flashing Stars" game presents a relaxation activity focused on counting falling stars; and (C) "The Garden" game features a calming experience in which players identify specific flowers in a vibrant field.

XSL•FO
RenderX

Figure 4. Screenshot of the prototypes used in the usability evaluation, featuring (A) the "Space Oddity" rockets minigame and (B) "The Four Seasons" design prototype.

Feedback Session

At the feedback session, after the playing experience and discussion, participants completed a System Usability Score (SUS) questionnaire [30,31], and verbally provided their feedback on refinements for improving game experience and accessibility. SUS comprises 10 statements, each evaluated on a 5-point Likert scale ranging from "Strongly Disagree" to "Strongly Agree." It serves as a standardized tool for assessing user experience and pinpointing usability challenges. Widely adopted across academic and industry settings, the SUS has been validated as a reliable benchmark for interface evaluation [32]. Final scores range from 0 to 100, with values above 68 and above 80.3 generally indicating acceptable and excellent usability, respectively [32].

Table 1 tabulates the Implementation Matrix of the study. In the latter, qualitative and quantitative data sources are systematically organized by type, timing of data collection, participant group, and associated research aims. The matrix also outlines anticipated outcomes for each data stream, facilitating transparency in methodological integration and supporting the interpretive logic of the mixed methods design.

XSL•FO
RenderX

Table . Implementation matrix: overview of qualitative and quantitative data sources, collection timelines, participants, and study aim.

Data source	Type of data	Timing of collection	Participants	Study aim or research question	Anticipated outcome
Expert cocreation session	Qualitative	October 2023	14 experts (6 rheumatologists, 4 researchers, 4 technical experts)	What therapeutic priorities and design requirements should guide the development of NoPain Games?	Identification of core themes: therapeutic benefits, game difficulty, accessibility
Transcribed session dialogs	Qualitative	Postsession (Oct 2023)	Same as above	How do experts perceive the cognitive and physical needs of patients with PsA[a] in game design?	Thematic analysis yielding subthemes across cognitive and emotional engagement, gameplay adaptability, and inclusive interaction
Patient usability feedback session	Quantitative and qualitative	May 2025	5 patients with PsA (Portugal, the United Kingdom, Netherlands, Greece)	How usable and engaging are the NoPain Game prototypes from a patient perspective?	SUS[b] score, feedback on game mechanics, difficulty, and interaction design
SUS	Quantitative	May 2025	Same as above	What is the perceived usability of the NoPain Games?	Average SUS score >68
Patient feedback discussion	Qualitative	May 2025	Same as above	What refinements do patients suggest for improving game experience and accessibility?	Insights into difficulty adjustment, technical refinements, and inclusive interaction

[a]PsA: psoriatic arthritis.

[b]SUS: System Usability Scale.

Data Analysis

Qualitative Analysis

The qualitative data analysis process used an inductive thematic approach, with 2 independent researchers (first and last authors) analyzing all qualitative data. After thoroughly familiarizing themselves with the data, the researchers developed an initial set of codes, which were subsequently organized into themes and subthemes. These were carefully reviewed to ensure alignment with the data. The final themes and subthemes were crafted using clear and precise language, adhering to the methodology established by Braun and Clarke [33]. To enhance credibility and reliability, the themes underwent cross-validation, and agreement on code assignment was assessed using the Kappa statistic [34], with a threshold of 0.80 deemed acceptable [34]. The finalized themes were determined through consensus-building among the researchers. This approach provided a comprehensive understanding of the participants' perspectives, ensuring the analysis accurately captured their experiences and insights.

Quantitative Analysis

Quantitative data from the SUS questionnaire were analyzed with descriptive statistics, that is, mean, SD, median, IQR, showing how data spread out the central values, and 95% CIs quantifying the uncertainty in estimating the mean. Moreover, SUS 2D (average) and 3D (per patient with PsA) radar plots were estimated along with the SUS ICCs. The ICC is a foundational concept in item response theory, that is, a statistical framework used to model how individuals respond to test items based on an underlying trait or ability [32]. An ICC is a curve that shows the probability p(θ)that a person with a given level of a latent trait θ (eg, usability perception, ability, attitude) will agree with or correctly answer a specific item. The probability p(θ)is given by a 2-Parameter Logistic (2PL) model [35] as

$$(1) p(\theta) = \frac{1}{1+e^{-a(\theta-b)}}$$

where a denotes the discrimination (slope), b the difficulty (threshold), and θ the latent trait value. A steep ICC (high a) means the item is highly sensitive to changes in usability perception, that is, ideal for detecting subtle shifts. A right-shifted ICC (high b) means the item is harder to agree with, that is, it activates only at higher usability levels. Finally, a flat ICC (low a) suggests the item does not discriminate well, that is, users across trait levels respond similarly. The whole quantitative analysis was carried out in Matlab 2025a (The MathWorks, Natick, USA).

Integration of Findings

Integration of qualitative and quantitative findings occurred through a sequential interpretive process that linked expert-derived design insights to patient-centered usability evaluation. Specifically, themes identified during the expert cocreation session—such as the need for cognitive stimulation, stress reduction, and adaptable difficulty—directly informed the development of 2 new game prototypes (Space Oddity and Four Seasons in the Results section). These prototypes operationalized therapeutic priorities and interaction mechanics discussed during the qualitative phase. In the subsequent feedback session, patients with PsA interacted with these games and provided both quantitative usability ratings via the SUS

XSL•FO
RenderX

and qualitative feedback through moderated discussion. The SUS scores offered a standardized measure of perceived usability, while the qualitative comments contextualized these scores by highlighting specific design strengths (eg, intuitive controls, calming visuals) and areas for refinement (eg, onboarding clarity, difficulty pacing). Item-level analysis using ICCs further revealed how individual SUS items aligned with patient-reported experiences, enabling cross-validation of usability dimensions such as learnability and confidence (see Results). This integration strategy ensured that the design decisions were not only expert-informed but also empirically validated through patient engagement, reinforcing the iterative and user-centered nature of the development process.

Ethical Considerations

This study involved 2 distinct data collection sessions conducted under the iPROLEPSIS Horizon Europe project. They involved members of the iPROLEPSIS Consortium participating in the 2 sessions, complying with the iPROLEPSIS-received ethical approval from the Ethics Committee of Erasmus Medical Center, Rotterdam, Netherlands (MEC-2023 - 0470). The first session was a cocreation workshop with members of the iPROLEPSIS Consortium, invited in their professional capacity. The second session was a usability feedback study involving patients with PsA. Neither session involved clinical procedures or the collection of sensitive personal health data. Participation in both sessions was entirely voluntary. For the cocreation session, verbal informed consent was obtained prior to participation. For the usability feedback session, informed consent was obtained via an embedded web-based form presented on the introductory page of the SUS questionnaire (Multimedia Appendix 2), which participants reviewed and accepted before proceeding. In both cases, participants were not compensated for their involvement. To ensure privacy and confidentiality across both phases, all audio recordings were transcribed verbatim and subsequently pseudo-anonymized. SUS survey responses were collected anonymously, with no identifying information linked to individual responses. All data were handled in accordance with General Data Protection Regulation–compliant data protection standards. No personally identifiable individuals appear in any images or supplementary materials.

Results

Qualitative Analysis

The cocreation session consisted of 14 participants, including 6 health care professionals, 4 technical experts, 3 observers, and one facilitator. The rheumatologists, all female, had a mean age of 36.3 (SD 7.2) years and over 10 years of professional experience, although most reported a basic level of technology literacy. The technical experts, all male, had a mean age of 44.8 (SD 7.9) years, with more than 15 years of experience and advanced-level technology literacy. The researchers, whose mean age was 28.5 (SD 7.0) years, included 3 females, each with over 4 years of experience and advanced-level technology literacy.

Thematic Analysis

Overview

Thematic analysis across all resolution scales, including themes and subthemes, revealed an almost perfect level of agreement between the 2 independent researchers (first and last authors), as indicated by a Kappa statistic of 0.90. In cases of uncertainty, discussions between researchers led to revisions, ultimately achieving 100% consensus across all subthemes. Data saturation was reached during the final stages of the cocreation session, as no new themes or subthemes emerged despite continued participant engagement. The structured yet open-ended nature of the sessions enabled iterative exploration of perspectives, and the consistency of responses across diverse stakeholders indicated that the thematic landscape had been sufficiently mapped. This saturation supports the robustness and completeness of the qualitative findings. From the thematic analysis, 3 primary themes emerged:

- Therapeutic benefits (Theme 1): This theme included subthemes such as pain distraction, memory enhancement, cognitive stimulation, stress reduction, and creative engagement, emphasizing the games' potential to help patients with PsA manage both mental and physical challenges.
- Game difficulty (Theme 2): This theme centered on subthemes like balancing gameplay duration, complexity, and adaptive difficulty levels to sustain engagement while avoiding fatigue or diminished therapeutic impact.
- Accessibility and interaction (Theme 3): This theme highlighted subthemes addressing physical limitations, optimizing touchscreen usability, and implementing inclusive design to meet the specific needs of patients with PsA.

The key findings for each identified subtheme are summarized below.

Theme 1: Therapeutic Benefits

Overview

The therapeutic value of NoPain Games was a recurring topic during the discussions, underlining their role in addressing both physical and mental health challenges. Overall, the NoPain Games were admired not only for their ability to distract patients from pain but also for enhancing cognitive functions like memory. This dual benefit positions them as a promising digital intervention, especially for patients with PsA, who often face fatigue and mental health issues.

Subtheme 1: Cognitive Stimulation, Stress Reduction, and Pain Distraction

Specifically, participants emphasized the dual benefits of NoPain Games in providing cognitive stimulation and serving as effective pain distractors. Engaging in memory-focused activities not only addresses the psychological burden of chronic illnesses but also shifts focus away from physical discomfort, ultimately promoting holistic well-being. In particular, the unique appeal of the "Lightning" NoPain Game exemplifies these combined benefits, as one clinician noted:

XSL•FO
RenderX

> *I'm just thinking the 'Lightning' game is really interesting in the way that besides distracting, it's also a memory game […] because our patients are depressed, and this can be very helpful.* [Rheumatologist #2]

This sentiment highlights the potential of such games to uplift patients' moods and combat depression, showing the therapeutic value of cognitive engagement. Some participants further reinforced this aspect by stating,

> *I like this game [the 'Lightning' game], it promotes memory skills, which can be seen as pain distractors.* [Rheumatologist #3]

> *[…] the underlying mechanisms for this game [The Garden], is the memory, the mental stimulation in a way as part of the pain distractor.* [Researcher #2]

By promoting cognitive stimulation, these serious games can also contribute indirectly to pain management, reducing the focus on discomfort. Additionally, many participants acknowledged these games as powerful tools for pain distraction and stress reduction. One participant summarized this aspect succinctly, as follows:

> *The NoPain Games are intended to act as a pain distractor, allowing the patient to focus on it as a means of distraction, which in turn can support pain management and stress reduction.* [Researcher #1]

Overall, NoPain Games intends to integrate calming experiences and mentally stimulating activities, offering therapeutic benefits that extend beyond traditional treatments. By providing a distraction from chronic illness discomfort, these games shift patients' focus to engaging tasks that can alleviate stress, improve mood, and foster a sense of achievement. Their holistic approach addresses cognitive, emotional, and physical well-being that can enhance therapy outcomes and empower patients with PsA to actively participate in their care journey.

Subtheme 2: Promoting Creativity

This subtheme explores the integration of creativity into gameplay as a strategy for enhancing both physical and mental engagement in therapeutic contexts. Incorporating creative elements, such as drawing flowers in The Garden game, can introduce a unique combination of movement and creativity, directly supporting therapeutic objectives. As highlighted by one clinician:

> *Incorporating creative elements, such as drawing flowers, combines movement with creativity, stimulating the mind and physical tasks. Maybe the patient could draw the flower in this game [The Garden]. So you can combine in this way the movement and the creativity.* [Rheumatologist #6]

Furthermore, another clinician proposed expanding this creative aspect, as follows:

> *[…] maybe there is a stage where somehow someone can use this kind of flowers to build something […] more constructive.* [Rheumatologist #5]

Incorporating creative tasks into gameplay can potentially enhance interaction and personalization, encouraging active patient engagement in rehabilitation. Activities like drawing or constructing can stimulate fine motor skills, hand-eye coordination, cognitive focus, and emotional well-being. This creative emphasis can expand the NoPain Games' role, making them valuable tools that complement traditional treatments while combining therapeutic movement with self-expression for a more meaningful and enjoyable therapeutic experience.

Theme 2: Game Difficulty

Overview

Balancing the duration and complexity of gameplay emerged as a crucial aspect of game design during the cocreation session. Clinicians expressed concern that both extremes—prolonged sessions and overly simplistic mechanics—could undermine the games' therapeutic and engagement potential.

Subtheme 1: Managing Fatigue and Engagement

Prolonged gameplay or repetitive motions might exacerbate fatigue, reducing the games' effectiveness as therapeutic tools. One clinician pointed out the following:

> *For instance, it could be interesting to know how long the game sequences of the game [The 'Lightning' game] are, so how long should it last.* [Rheumatologist #5]

This indicates the need for carefully tailored session lengths to prevent overstimulation. On the other hand, overly simple game mechanics might fail to captivate players or provide meaningful stimulation. In this line, one clinician also highlighted this issue, noting:

> *So, I'm just thinking about the complexity of the game [The 'Lightning' game], in particular the duration of the sequence and the number of repetitions to play the game. […] have you decided or thoughts regarding the game duration?* [Rheumatologist #1]

This perspective highlights the need for future work to focus on designing gameplay that achieves the optimal balance—sufficiently challenging to maintain engagement, yet not so demanding as to provoke frustration or exhaustion.

Subtheme 2: Customizable Difficulty Levels

This subtheme introduces customizable difficulty levels and adjustable session durations as effective solutions. These features enable players to adapt gameplay to their individual needs, thereby enhancing both satisfaction and therapeutic outcomes. Furthermore, the significance of gradual progression in difficulty is emphasized by one participant:

> *For each level of difficulty, different coordination movements can be incorporated to offer a light yet progressively challenging experience, possibly linked to timing.* [Researcher #1]

This highlights how incorporating varied coordination movements fosters engagement while simultaneously supporting therapeutic goals, such as enhancing refined motor skills and cognitive reaction time. By offering challenges that escalate at an adaptable pace, players can feel a sense of growth and accomplishment, reinforcing motivation and adherence to therapeutic activities. Additionally, incorporating a time-based

XSL•FO
RenderX

element was suggested as a potential customization option. As noted by one technical expert:

> *Can I also ask if the game [The 'Lightning' game] is connected to time? Does it involve reaction time that progressively get faster? For example, if there's a time limit, would it require completing the task within 5 seconds, then 10 seconds?* [Technical expert #1]

Together, these insights can suggest that customization in difficulty and session dynamics is vital for creating a flexible and impactful game experience.

Theme 3: Accessibility and Interaction

Overview

Accessibility was identified as another pivotal theme, reflecting the need for an accessible design to accommodate the physical limitations of patients with PsA. Symptoms like joint stiffness, swelling, and reduced dexterity can significantly impact interaction with digital tools, including games.

Subtheme 1: Physical Limitations and Interface Challenges

Overall, many clinicians highlighted specific challenges related to physical symptoms. For example, one clinician commented:

> *I guess if people have swollen fingers, the accuracy for this game ['The Garden' game] might be a problem, in the sense that you're trying to get quite a small area when you've got lots of flowers like this and the accuracy is potentially trickier.* [Rheumatologist #6]

This underlines the need for larger touch targets and simplified game interactions to accommodate patients with swollen fingers or a limited range of motion. Similarly, another clinician noted:

> *Sometimes, on a small screen, it's quite difficult to drag a marker to a particular point or to be very accurate with where we're pressing if we've got bad hand arthritis.* [Rheumatologist #2]

This observation points to the importance of designing user interfaces (UIs) that minimize the need for precise movements, making the games more accessible to those with severe joint issues.

Subtheme 2: Enhancing Inclusivity

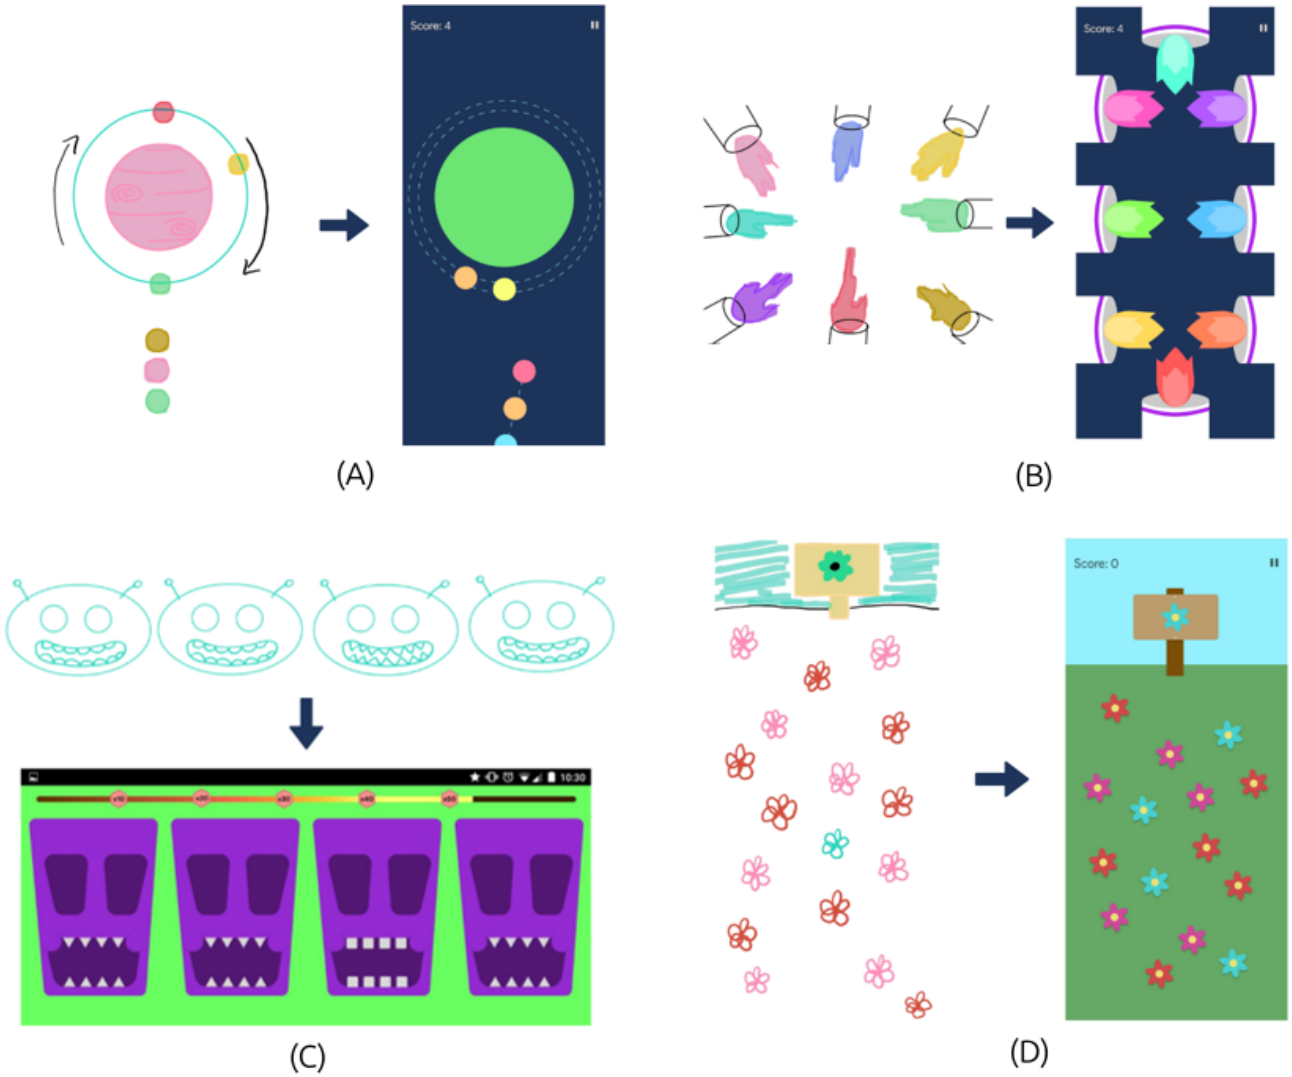
To make the games more inclusive, developers could implement features such as adjustable touch sensitivity, alternative input methods (eg, voice commands), and options to magnify specific screen elements. These adaptations would enhance usability and ensure that the games can be enjoyed by a wider range of patients, regardless of their physical limitations.

These features foster a more inclusive experience for users with diverse needs, particularly those with conditions impairing their motor skills or visual acuity. For instance, adjustable touch sensitivity would allow users with reduced dexterity to interact with the interface more comfortably, while alternative input methods, such as voice commands, could provide a hands-free option for individuals unable to perform precise touch gestures. Similarly, magnification options for specific screen game elements could support users with visual impairments, ensuring they can navigate the game environment with ease and confidence. As suggested by one participant:

> *In fact, the levels of difficulty and synchronization with the user profile, as suggested before using the adaptation algorithm of the games (…) includes the patient's disease status, and eventually align with the hand or finger exhibiting better conditions in terms of symmetry and functionality.* [Researcher #1]

This highlights the potential for an adaptive system that tailors the gameplay experience to the specific physical conditions of the player. By considering factors such as hand symmetry, finger functionality, or disease progression, the game could dynamically adjust its mechanics to align with each patient's capabilities. For example, if a player has difficulty using one hand due to PsA, the game could prioritize interactions that favor the less-affected hand or allow for single-hand play. This ensures an engaging experience, minimizes frustration, and enhances therapeutic outcomes. Furthermore, a robust adaptation algorithm could learn and evolve with the player's needs, offering more personalized solutions over time by focusing on inclusive design principles.

Summarizing, these detailed insights into each theme emphasize the multifaceted nature of NoPain Games' design and impact. By addressing therapeutic benefits, gameplay balance, and accessibility, these games have the potential to make a meaningful difference in the lives of patients with PsA. Although the feedback from this session highlighted the clinical value of the storyboard elements and provided suggestions for design enhancements, there remains an opportunity to develop prototypes that integrate all these ideas to guide future development. The storyboards were revised based on the feedback collected, and a wider range of game mechanics was incorporated to improve the overall design and gameplay. Consequently, 2 NoPain game prototypes—Space Oddity Game and Four Seasons Game—have been conceptualized, as detailed next.



Prototyping the NoPain Games

Overview

Building on the subsequent phase of the agile approach after the ideation and storyboard design phase, 2 NoPain Games prototypes for pain relief were developed, incorporating targeted feedback gathered during the cocreation session (Development phase in Figure 1). These prototypes include Space Oddity (Figure 5), a space-themed serious game featuring 3 minigames that engage players in memory, coordination, and visual perception tasks; and Four Seasons (Figure 5D), a nature-themed game designed to promote repetitive, soothing movements. Tables 2 and 3 provide an overview of the key characteristics of the proposed NoPain Game prototypes, including their game concepts, clinical value, visual design, game mechanics, and difficulty progression.

XSL•FO
RenderX

Figure 5. Refined storyboards for the proposed NoPain Games: (A) Space Oddity coordination challenge, (B) Space Oddity memory challenge, (C) Space Oddity visual perception challenge, and (D) Four Seasons.

XSL•FO
RenderX

Table . Main characteristics of the proposed Space Oddity game prototypes, featuring 3 distinct mini-game–related areas, that is, memory-based challenge, coordination skills, and visual perception, each designed to target specific cognitive and motor functions associated with psoriatic arthritis. For each area, the game concept, intended clinical value, visual design elements, core gameplay mechanics, and difficulty progression are described.

	Memory-based challenge	Coordination skills	Visual perception
Game concept	Players memorize and reproduce a sequence of ignited spaceships.	Players launch asteroids into orbit while avoiding collisions.	Players identify the odd creature among a group.
Clinical value	Strengthening cognitive and memory sequencing skills.	Developing motor coordination by improving reaction timing and precision.	Improving focus, visual perception, and cognitive processing speed.
Visual design	Embracing the game's space esthetic, the spaceships' ignition includes vibrant and distinct hue colors to strengthen visual memory cues during gameplay, with clear contrast against the background for easy recognition.	A central, colorful planet with orbiting asteroids stands out against a calm-toned universe, with new asteroids emerging from below to ensure an intuitive and structured gameplay flow.	Aligned with the futuristic theme, alien robot-like creatures were chosen as the main characters, since various features (such as eye color, teeth shape, and accessories) can be easily modified for a dynamic experience.
Game mechanics	At the start of each round, a sequence of rockets lights up. The player must replicate the sequence by tapping the rockets in the correct order. The game verifies the input, granting progression if correct. If incorrect, the sequence repeats for the player to try again.	The game consists of multiple stages, each with a set number of asteroids. Players must launch asteroids into orbit while ensuring they do not collide. When all asteroids are placed successfully, a new planet appears. If 2 asteroids collide, the game ends.	A set of creatures is displayed, with one differing in subtle ways. The player must identify the intruder. Feedback is given through color and audio cues.
Difficulty progression	The sequence length increases as the game progresses, making it more challenging. An easier mode maintains the sequence and adds only one new element per round, while a harder mode randomizes the sequence each time, increasing difficulty.	Initially, asteroids move in a straight path toward the orbit. At higher difficulty levels, additional asteroids move dynamically, requiring more precise timing. Some areas on the planet may be restricted (eg, mountains), and color-coded zones may require matching asteroids.	At lower difficulties, the creatures' differences are more apparent. At higher levels, the distinctions become more subtle, requiring greater attention to detail.

Table . Main characteristics of the proposed Four Seasons Game prototypes, targeting 2 distinct areas, that is, visual perception and coordination skills, each designed to support stress reduction, focus, and motor precision in individuals with psoriatic arthritis. For each area, the game concept, intended clinical value, visual design elements, core gameplay mechanics, and difficulty progression are described.

	Visual perception	Coordination skills
Game concept	Players identify specific flower species on a garden field.	The player has to select fruits to fall from a tree, while ensuring they fall into a basket and not on the floor.
Clinical value	Stress reduction, improved focus, and coordination.	Reaction time and precision.
Visual design	A relaxing nature-based theme in the form of a garden. Various colorful plants and flowers populate the garden, giving it a vibrant atmosphere.	A nature-based theme with fruit trees in the background full of colorful fruits.
Game mechanics	The player is instructed to find and tap a chosen flower species, in a garden scenario full of various plants. Feedback is provided to let the player know if they selected the correct flower. As the game progresses, the seasons change, creating a dynamic environment and increasing the level of challenge.	The player has to select fruits to fall from a tree, as a rolling bucket passes underneath. The player gains points if they correctly calculate the timing of the falling fruit, making them land in the basket. They lose points if the fruits miss the basket instead.
Difficulty progression	As the game progresses, some elements become more challenging. For example, the flowers are no longer static; they start moving or become more similar to each other.	As difficulty rises, the number of fruits increases, the basket moves faster, and the basket becomes smaller.

XSL•FO
RenderX

Space Oddity

The Space Oddity NoPain Game was inspired by the space theme expressed in Figure 3B and incorporated a memory-based challenge with a patterns-matching mechanic similar to that in Figure 3A. Based on clinician feedback provided at the second design phase, other game tasks related to coordination and visual perception were added, while maintaining the overall space thematic and base mechanics. Table 2 links the specific game tasks with the themes highlighted at the second cocreation session. Throughout the game, players should experience all these tasks in the form of minigames. Therefore, as the players enter Space Oddity and select a difficulty level, 3 minigames appear in a different order to avoid monotony and ensure that the game will be played various times without getting repetitive.

The first minigame is designed to train coordination skills (Figure 5A). A main planet stands at the center of the screen, while being surrounded by a fixed-speed orbit of asteroids. As new asteroids emerge from below, the player/patient must launch them into orbit one at a time, ensuring they do not collide with existing asteroids. Success depends on precise timing, requiring the player/patient to tap the screen at the right moments to avoid collisions. After a certain number of asteroids are launched, a new planet emerges with new challenges. Additional features to add diversity to the game include areas on the planet with mountains where asteroids cannot be placed, or color-coded zones to correspond to asteroids of the same color (Figure 5A). The second minigame, depicted in Figure 5B, features 8 spaceships scattered across the screen, all starting with their engines turned off. It operates, like the Simon game [36], in rounds where players watch as a sequence of rockets ignite and then are required to replicate the sequence by selecting the rockets in the correct order. The first round begins with a single randomly ignited rocket. In each subsequent round, the previous sequence repeats in the same order, with one additional rocket added. The minigame continues until a certain number of rounds is successfully completed. To enhance memorization, unique colors and musical notes can be attributed to each rocket, providing both visual and auditory stimuli. Figure 5B illustrates the core prototype elements and an example screen in which all rockets are ignited with their distinct colors. The third minigame focuses on memory, concentration, and visual perception, where a player/patient performs several rounds of identifying from a set of 4 creatures, the one that differs from the others (intruder) (Figure 5C). Overall, various features may be modified to create distinctions, such as the creatures' shape or variations in their elements.

Four Seasons

The Four Seasons NoPain Game builds upon the concepts illustrated in the storyboard of Figure 3C. Similarly, Tables 2 and 3 link the specific game tasks with the themes highlighted at the second cocreation session. During gameplay, the players/patients explore a garden filled with various flowers and are asked to identify a specific one (Figure 5D). As the game progresses, the seasons change, affecting both the environment's aesthetic and the challenges presented. Each season introduces unique difficulties and advantages, adding variety to the game. The Four Seasons game was designed to distract players from pain by offering 2 distinct modes to suit individual preferences. The Relax Mode allows players to peacefully search for flowers in a garden across different seasons, while the Party Mode introduces added excitement with minigames at the end of each season for a more dynamic experience. Overall, this game, designed to reflect the unique characteristics of each season, has the potential to offer a refreshing gameplay variety while introducing an element of dynamism for players/patients seeking a more immersive experience.

Feedback From Patients With PsA

Quantitative Analysis

The patients with PsA feedback group included 2 women and 3 men, with ages ranging from 25 to 64 years, split into age groups of 25 - 34 years (1), 35 - 44 years (1), 45 - 54 years (2), and 55 - 64 years (1). All patients had been diagnosed with PsA for more than 8 years; had an average experience in gaming, and good experience in smartphone usage. During the session, 4 participants (1-4) reported experiencing a PsA flare.

The session first focused on "Space Oddity" through a playable version developed in Unity3D (Figure 4A). Participants played the game and then evaluated its usability by completing the SUS questionnaire. Table 4 tabulates the derived descriptives from the SUS data, that is, mean (SD), 95% CI, and median (IQR). From the latter, it is seen that an average SUS score of 79 (SD 10.4; 95% CI 69.89 - 88.11) was reached, suggesting good overall usability, with some variation in individual user perceptions.

XSL•FO
RenderX

Table . Descriptives of the System Usability Scale (SUS).

Item definitions	Mean (SD)	95% CI	Median (IQR)
Frequency Use (1)	3.80 (0.84)	3.07 - 4.53	4 (3-4)
Complexity (2)	2.40 (1.95)	0.69 - 4.11	1 (1-4)
Ease of Use (3)	4.60 (0.55)	4.12 - 5.08	5 (4-5)
Support Needs (4)	1.00 (0.0)	1.00 - 1.00	1 (1-1)
Functionality Integration (5)	3.80 (0.84)	3.07 - 4.53	4 (3-4)
Inconsistency (6)	2.00 (1.0)	1.12 - 2.88	2 (1-3)
Confidence (7)	4.40 (0.55)	3.92 - 4.88	4 (4-5)
Cumbersomeness (8)	1.60 (0.90)	0.82 - 2.38	1 (1-2)
Learnability (9)	4.20 (0.84)	3.47 - 4.93	4 (4-5)
Learning Curve (10)	2.20 (1.64)	0.76 - 3.64	2 (1-2)
Total SUS	79 (10.4)	69.89 - 88.11	75 (75 - 82.5)

Moreover, Figure 6 displays a 2D radar plot of average SUS responses across all participants, with each axis representing a usability factor mapped to its corresponding SUS item number (eg, Frequency Use (1), Cumbersomeness (8), etc). The radial layout allows for intuitive comparison of agreement levels across items, with values ranging from 1 (“Strongly Disagree”) to 5 (“Strongly Agree”). Peaks in the plot are observed around positively worded items such as Ease of Use (3), Confidence (7), and Learnability (9), indicating strong agreement and direct contributions to higher SUS scores. Conversely, troughs appear around negatively worded items like Support Needs (4), Cumbersomeness (8), and Learning Curve (10), where low agreement is desirable and reflects positive usability perceptions. The overall shape of the radar plot reveals a balanced usability profile, with high agreement on core interaction elements and consistent disagreement with statements implying complexity or poor integration.

In addition, Figure 6B presents a 3D radar surface plot where axes radiate outward from the center, each labeled with a usability factor and its corresponding SUS item number, for example, Consistency (6) and Learning Curve (10). The surface height represents participant index, while the color gradient (blue to yellow) encodes response values from 1 to 5. The plot reveals structural patterns in usability perception, with elevated regions around Ease of Use (3), Confidence (7), and Learnability (9), positively worded items where high agreement directly contributes to higher SUS scores. Conversely, lower scores on negatively worded items such as Complexity (2), Support Needs (4), Inconsistency (6), Cumbersomeness (8), and Learning Curve (10) are desirable, as they reflect disagreement with statements implying poor usability. Notably, Support Needs (4) received a uniform score of 1 across all participants, indicating unanimous disagreement with the notion that external support was required to use the system, an encouraging signal of intuitive design and self-sufficiency. Participant-level differences are also evident. In particular, Participants 1 - 4, who reported experiencing PsA flare episodes during evaluation, showed slightly more variability in items such as Functionality Integration *(5)* and Inconsistency *(6)*, suggesting that symptom severity may influence perceptions of system responsiveness and coherence. In contrast, Participant 5, who did not report a flare, exhibited consistently high agreement on positively worded items and low agreement on negatively worded ones, resulting in a smoother and more elevated usability profile across the radar surface. Together, Figure 6A and B offer complementary perspectives on usability perception, highlighting both structural consistency and individual-level nuances.

XSL•FO
RenderX

Figure 6. (A) Radar chart of mean SUS item scores arranged clockwise, highlighting usability strengths and weaknesses. (B) 3D radar surface plot of individual SUS responses, showing participant-level variation across usability dimensions. SUS: System Usability Scale.

XSL•FO
RenderX

Furthermore, Figure 7 illustrates a detailed visualization of item-level behavior across the latent usability trait spectrum. The left panel presents 2D ICCs for selected SUS items, each labeled by item index. These curves illustrate the probability of agreement p(θ) (see (1)) as a function of latent usability (θ), revealing distinct patterns of discrimination and difficulty. The right panel complements this view with a 3D ICC ribbon plot, where each SUS item is vertically separated and labeled by its full descriptor. This format enhances interpretability by exposing how response probabilities vary not only across θ but also across items. Moreover, Table 5 includes the corresponding parameters (a,b) (see (1)) of the ICCs depicted in Figure 7. Analytically, from Figure 7 and Table 5, the following observations can be derived per SUS item, revealing their heterogeneity:

- Frequency of Use (1)-positive wording: With a = 1.29 and b = –1.10, this item shows moderate discrimination and early activation. The curve is gently sloped and elevated across the trait spectrum, indicating consistent agreement even at low usability levels. This suggests it reflects habitual or contextual familiarity rather than sensitivity to usability changes. Its contribution is stable but diagnostically limited.
- Complexity (2)-negative wording: With a = 0.67 and b = 0.49, the curve rises gradually and activates in the mid-range of θ. Users increasingly disagree as usability improves, aligning with expected polarity. However, the low a value indicates weak discrimination. The ribbon is broad and shallow, offering general friction-related information but lacking precision.
- Ease of Use (3)-positive wording: Despite its conceptual importance, $a = 1.73\times10^{13}$ and $b = -5.93\times10^{14}$ suggest a modeling anomaly, likely due to uniform agreement across participants. The curve appears flat and saturated, with no meaningful slope. While users universally endorse this item, its statistical discrimination is negligible, making it confirmatory rather than diagnostic.
- Support Needs (4)-negative wording: With $a = -8.72\times10^{14}$ and $b = -1.18\times10^{1}$, this item exhibits modeling instability. The curve is flat and extremely right-shifted, indicating that nearly all users disagreed regardless of usability level. In fact, all users disagreed. This uniform rejection aligns with high usability but limits the item's ability to differentiate experiences. It may be conceptually relevant but statistically redundant.
- Functionality Integration (5)-positive wording: With a = –0.11 and b = 3.48, the curve is shallow. The negative a suggests an inverse slope, possibly due to inconsistent response patterns. The ribbon is low and delayed, indicating poor discrimination and limited responsiveness.
- Inconsistency (6)-negative wording: Like item 4, $a = -8.72\times10^{14}$ and $b = -1.18\times10^{1}$ reflect modeling collapse. The curve is flat and nondiscriminative, with uniform disagreement across users. While this aligns with high usability, the lack of slope or variability renders it statistically inert.
- Confidence (7)-positive wording: With $a = 1.73\times10^{13}$ and $b = -5.93\times10^{14}$, this item shows extreme early activation and saturation. The curve is flat and elevated, indicating universal agreement. Like *Ease of Use (3)*, it functions as a strong confirmatory item but lacks statistical discrimination due to the ceiling effect.
- Cumbersomeness (8)-negative wording: Again, $a = -8.72\times10^{14}$ and $b = -1.18\times10^{1}$ suggest modeling failure. The curve is flat and low, with near-universal disagreement. While this reflects low friction, the lack of variability limits its diagnostic value.
- Learnability (9)-positive wording: With a = 59.00 and b = –2.28, this item shows extremely high discrimination and early activation. The curve is steep and sharply contoured, making it the most responsive item in the set. The ribbon is narrow and elevated, indicating strong sensitivity to usability perception across the trait range. This item is statistically and conceptually robust.
- Learning Curve (10)-negative wording: With a = 0.33 and b = 4.33, this item exhibits low discrimination but great difficulty. The curve rises gradually and activates only at the upper end of the usability trait spectrum. The ribbon in Figure 7 is delayed but upward-sloping, confirming that the item captures late-stage usability clarity, particularly in systems that excel in onboarding. While its responsiveness is limited at lower θ levels, it still contributes meaningful coverage of the high-usability tail, making it useful for identifying systems with strong learnability.

From the aforementioned, we can identify four interpretive categories: (1) Statistically robust item: "Learnability (9)" shows exceptional discrimination and early activation, making it the most diagnostically powerful item. (2) Confirmatory but saturated items: "Ease of Use (3)" and "Confidence (7)" are universally endorsed but exhibit near-zero discrimination due to ceiling effects. They confirm high usability but offer limited differentiation. (3) Low-performing or inert items: "Support Needs (4)," "Inconsistency (6)," and "Cumbersomeness (8)" show flat, nonresponsive curves and modeling collapse, limiting their diagnostic utility. (4) Mid-range and coverage items: "Frequency of Use (1)," "Complexity (2)," and "Learning Curve (10)" contribute moderate or delayed responsiveness, offering coverage across the trait spectrum but with limited precision. This item-level interpretation supports evaluation of the SUS, guiding decisions on item weighting and further scrutiny for potential refinement.

XSL•FO
RenderX

Figure 7. 2D Item characteristic curves (left) showing agreement probability p(θ) across latent usability trait (θ), with each curve labeled by item index, along with the 3D item characteristic curve ribbons (right) for all System Usability Scale items, visualizing response probabilities across θ and item index, with full item labels on the horizontal axis.

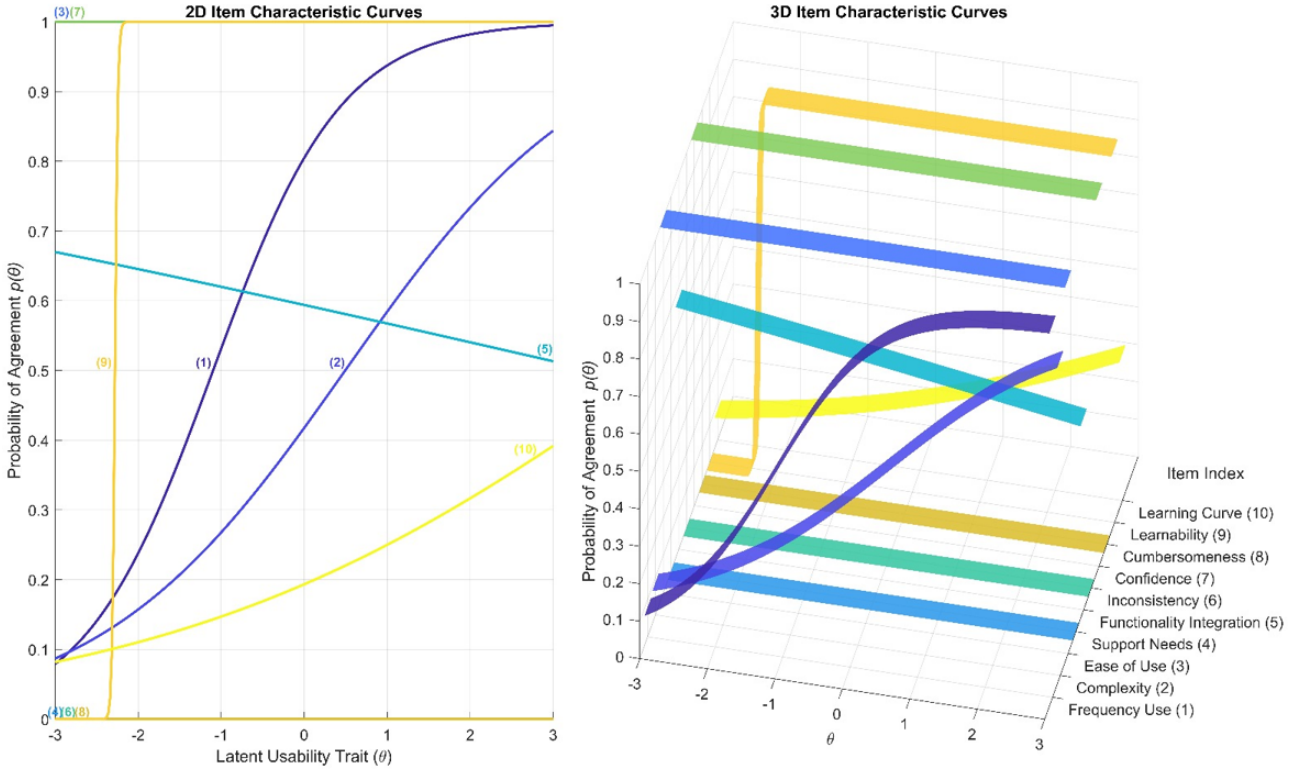


Table . Estimated parameters (a, b) of the corresponding item characteristic curves of Figure 7 for each System Usability Scale (SUS) item.

SUS item	Alpha (a)	Beta (b)
Frequency Use (1)	1.29	–1.10
Complexity (2)	0.67	0.49
Ease of Use (3)	1.73×10^{-13}	-5.93×10^{14}
Support Needs (4)	-8.72×10^{-14}	-1.18×10^{15}
Functionality Integration (5)	–0.11	3.48
Inconsistency (6)	-8.72×10^{-14}	-1.18×10^{15}
Confidence (7)	1.73×10^{-13}	-5.93×10^{14}
Cumbersomeness (8)	-8.72×10^{-14}	-1.18×10^{15}
Learnability (9)	59.00	–2.28
Learning Curve (10)	0.33	4.33

Qualitative Analysis

During the patients with PsA feedback session, the group was guided through a design prototype demonstration of the Four Seasons (Figure 4B), covering its tutorial, practice session, navigation, gameplay, bonus level, and scoring. Feedback was generally positive and constructive, with discussions focusing on several key areas across the 2 games. In particular, they proposed:

- resolving iOS compatibility issues to improve accessibility,
- modifying difficulty levels and incorporating adaptive artificial intelligence (AI) in “Space Oddity” to tailor challenges to individual player profiles,
- transitioning “The Four Seasons” from prototype to full interactive development with seasonal mechanics and high-quality 3D rendering, and
- introducing smartwatch integration to track stress levels before and after gameplay in both games.

From a combined perspective, the derived average SUS score of 79 reflects a generally positive user experience, placing the NoPain Games within the “good” usability range according to established benchmarks. This score suggests that core interaction elements, such as navigation, responsiveness, and interface clarity, were well-received across a diverse group of patients with PsA, even during flare episodes. To better understand how this overall score reflects item-level behavior, we examined the

XSL•FO
RenderX

individual ICC profiles. The accompanying ICC analysis revealed several positive outcomes. These item-level patterns help contextualize the overall SUS score of the NoPain Games, revealing how specific usability dimensions contributed to the positive user experience. This is combined with the feedback provided during the session, which revealed that usability alone does not fully capture user expectations in therapeutic contexts. Participants articulated a clear desire for functional enhancements and personalization features that extend beyond baseline usability. Their suggestions, ranging from adaptive AI and platform compatibility to immersive rendering and biometric integration, indicate that patients are not merely evaluating ease of use, but actively envisioning how the system could evolve into a more responsive and clinically meaningful tool. This feedback reveals the importance of interpreting usability scores in tandem with qualitative insights, especially when designing interventions for chronic conditions where therapeutic relevance and emotional engagement are critical.

Discussion

Main Findings

This study aimed to explore expert perspectives on the design of 2 serious games, that is, NoPain Games, intended to alleviate chronic pain and improve quality of life for individuals with PsA. The cocreation session revealed 3 key thematic areas: therapeutic benefits, game difficulty, and accessibility and interaction. These themes directly informed modifications to the game prototypes, aligning with the study's objective to develop personalized, user-centered digital interventions for chronic pain management. Moreover, the usability assessments of patients with PsA using SUS and feedback further supported the design approach, indicating generally positive perceptions of the game prototypes and reinforcing their potential as accessible and engaging tools for digital pain management. The extended quantitative analysis of SUS responses, including item-level discrimination and difficulty modeling via ICCs, provided deeper insight into usability perceptions. These findings offer item-level insights that can guide targeted enhancements to interface design and interaction mechanics. This quantitative granularity complements the thematic findings, particularly those related to therapeutic intent and user engagement.

Therapeutic benefits were a major focus, with the games designed to provide pain distraction and cognitive engagement. For example, the "Lightning" game focuses on memory enhancement, which can help distract from pain and improve cognitive function [3]. Additionally, the games incorporate soothing and repetitive mechanics, such as in the "Flashing Stars" game, which promotes relaxation and stress reduction [6]. Moreover, previous studies had also suggested a link between serious games and improvements in working memory [37], prompting further research on this topic.

Game difficulty was another critical theme, with feedback emphasizing the need to balance game duration and complexity to maintain engagement without causing fatigue. This led to the development of adaptive difficulty levels that adjust to the player's abilities [38]. The games were designed to be challenging enough to keep players engaged but not so difficult that they become frustrating. This balance is crucial for maintaining the therapeutic benefits of the games [39]. In fact, the challenge of balancing game difficulty has been identified in previous studies [38,39], yet it remains complex due to the need to provide therapeutic benefits while maintaining player engagement. When designing serious games, it is essential to balance activity levels, as over-exercise can cause fatigue and frustration, while insufficient activity may reduce therapeutic benefits. Adaptive difficulty levels aligning with players' abilities and goals could ensure engagement, gradual improvement, and overall well-being.

Accessibility and interaction were also key considerations. Overall, the game design considered the physical limitations of patients with PsA, such as joint stiffness and swelling. This led to the optimization of touchscreen usability and the inclusion of larger touch targets to accommodate swollen fingers [40]. Ensuring that the games are accessible to all patients with PsA, regardless of their physical abilities, was a key focus. This included designing intuitive and easy-to-use interfaces [41]. Moreover, smartphone accessibility has been analyzed in various domains [40,41] due to the fine motor skills required for small touchscreen interactions. However, its impact on patients with PsA could be investigated further.

The alterations in game design during the cocreation workshops align with findings from existing literature on serious games and digital health interventions. Studies have shown that serious games can reduce stress, enhance cognitive function, and provide pain relief through immersive and engaging experiences [3,6]. The NoPain Games leverage these benefits by incorporating memory and relaxation activities. The importance of balancing game difficulty to sustain engagement and therapeutic efficacy is well-documented. Adaptive difficulty levels, planned for implementation in the NoPain Games, are crucial for maintaining player interest and ensuring the games' effectiveness [38,39]. Research highlights the need for accessible game design, especially for individuals with physical limitations. The NoPain Games' focus on optimizing touchscreen usability and inclusive design reflects these findings [40,41]. Furthermore, the conceptual framework (2D-ME) for explaining self-first and self-third person views of prototyping dynamics in serious games design highlights the importance of iterative feedback and dynamic constructs in the game design process [42]. This framework supports the iterative refinement seen in the NoPain Games development, ensuring that the games are both engaging and therapeutic.

Furthermore, the design of NoPain Games leverages key insights into how the human brain pays attention to various aspects of game design. By understanding and applying principles related to perception, memory, attention, and emotional engagement, the developers can create games that are both therapeutic and engaging.

For example, perception plays a crucial role in how players interact with NoPain Games. The brain processes visual and auditory information to understand and navigate the game world. For instance, the "Lightning" NoPain game uses effective visual cues and sound effects to guide players' attention and enhance

XSL•FO
RenderX

their immersion [43]. The UI design is also critical, ensuring that players can easily access information and controls without being distracted by confusing or cluttered interfaces. This is particularly important for patients with PsA, who may have physical limitations affecting their game interaction [40].

Memory is another essential aspect of the proposed NoPain Games. Players rely on short-term memory to remember recent actions, objectives, and game mechanics. This is particularly important in fast-paced games where quick decision-making is required. For example, the "Lightning" NoPain Game focuses on memory enhancement, helping players to distract from pain and improve cognitive function [3]. Long-term memory is engaged when players learn and remember game rules, storylines, and strategies. By reinforcing learning through repetition and rewards, NoPain Games can enhance player retention and engagement [43].

Attention is also vital for maintaining focus and engagement in the proposed NoPain Games. The brain's ability to maintain focus is critical for sustained engagement, and the developers have used various techniques to capture and hold players' attention. This includes compelling narratives and dynamic gameplay [44]. Managing cognitive load is essential to prevent player fatigue. NoPain Games balance complexity and simplicity to keep players engaged without overwhelming them. This involves designing intuitive controls, clear objectives, and manageable challenges, ensuring that the games are accessible and enjoyable for patients with PsA.

Emotional and motivational factors significantly influence the brain's attention to NoPain Games. Emotions play a significant role in how players experience the games. Engaging storylines, relatable characters, and emotional rewards enhance player immersion and satisfaction. The brain responds to rewards and achievements, which can motivate players to continue playing. NoPain Games use various reward systems, such as points and progression systems, to keep players motivated and engaged [43].

Achieving a flow state is another critical aspect of NoPain Games. The concept of "flow" refers to a state of deep focus and immersion where players lose track of time [45]. Achieving flow involves balancing challenge and skill, providing clear goals, and offering immediate feedback. NoPain Games successfully induce flow by creating a balance between challenge and skill, ensuring that players remain deeply engaged and enjoy the therapeutic benefits of the games [43].

Approaching the aforementioned from the lens of the 3 themes identified, that is, therapeutic benefits, game difficulty, and accessibility and interaction, a deep interwovenness can be identified with sustained engagement, player attention, cognitive load, player fatigue, emotions, and flow state in the context of NoPain Games for patients with PsA. In particular:

1. Therapeutic benefits: NoPain Games aim to alleviate pain and improve emotional well-being by providing cognitive stimulation, stress reduction, and memory enhancement. These benefits are crucial for fostering sustained engagement as players find therapeutic value in their activity, which keeps their attention fixed on the games. The soothing and predictable mechanics of games like "Flashing Stars" reduce *cognitive load* by presenting clear objectives and repetitive tasks, allowing players to focus without being overwhelmed. This emotional engagement also helps maintain the ideal flow state, where players are immersed in gameplay and distracted from their chronic pain.
2. Game difficulty: Balancing and adapting difficulty levels directly supports sustained engagement by keeping tasks manageable yet stimulating. Customizable difficulty prevents player fatigue, ensuring sessions remain enjoyable rather than exhausting. A dynamically adjusted challenge ensures that attention is maintained without inducing frustration, helping to optimize both players' attention and cognitive effort. Gradual progression of difficulty, such as increasing complexity in the "Lightning" game, enhances emotions of achievement and satisfaction, which is key for reinforcing engagement and maintaining the flow state.
3. Accessibility and interaction: The design considerations in this theme, such as larger touch targets and intuitive interfaces, ensure that physical limitations do not hinder participation. This inclusivity supports sustained engagement by enabling patients to interact easily and prevent frustration. These accommodations reduce the cognitive load on players, allowing them to focus on the tasks rather than overcoming interface challenges. This theme also reduces players' fatigue by minimizing physical strain and frustration, helping to maintain a relaxed state essential for emotional well-being and immersion into a flow state.

Together, these themes create a synergistic experience where accessibility removes barriers, therapeutic benefits uplift emotional and cognitive states, and adaptive difficulty sustains attention and motivation, all of which harmonize to engage patients with PsA while mitigating pain effectively.

The iterative optimization process in developing NoPain Games prototypes involved refining visual cues, simplifying the UI, balancing cognitive load, and incorporating emotional and motivational elements. By understanding how the brain pays attention to different aspects of game design, the designers/developers were able to create games that are both effective and enjoyable for patients with PsA. This approach ensured the potential for the proposed NoPain Games to provide therapeutic benefits while maintaining high engagement and satisfaction levels.

Overall, the cocreation themes guided the iterative refinement of the NoPain Games, confirming they are both engaging and therapeutic for patients with PsA. The integration of feedback from the cocreation session with insights from the relevant literature review resulted in 2 game prototypes that are well-suited to the needs of their target audience, as expressed via the feedback from patients with PsA. In fact, the patient feedback session extended the thematic framework by introducing concrete implementation priorities that reflect lived experience and technical expectations. The mean effective SUS score (79) confirmed good usability, yet the qualitative suggestions revealed areas for refinement that map directly onto the 3 core themes.

XSL•FO
RenderX

First, the recommendation to resolve iOS compatibility issues reinforces theme 3 (accessibility and interaction). While the expert session emphasized touchscreen optimization and inclusive design, patients highlighted platform-specific barriers that could limit access. This aligns with Beltran-Alacreu et al [16], who emphasized the importance of device-level accessibility in digital interventions for chronic pain populations. Addressing cross-platform compatibility is essential to ensure equitable access, particularly for older adults or those with limited digital literacy.

Second, the proposal to incorporate adaptive AI into Space Oddity to tailor difficulty to individual profiles directly advances theme 2 (game difficulty). This feedback moves beyond static balancing and introduces personalization as a therapeutic strategy. It resonates with Tuah et al [20], who identified progression systems and adaptive mechanics as key to sustaining engagement in rehabilitation games. In the context of PsA, where symptom severity and cognitive capacity fluctuate, AI-driven difficulty modulation could enhance both usability and therapeutic relevance.

Third, the suggestion to transition the Four Seasons from prototype to full interactive development with seasonal mechanics and high-quality 3D rendering reflects an evolution of theme 1 (therapeutic benefits). While experts emphasized cognitive stimulation and stress reduction, patients implicitly called for deeper immersion and aesthetic refinement. This aligns with Gromala et al [6], who argued that realistic environments and sensory richness contribute to pain relief. The seasonal metaphor may also support emotional regulation by anchoring gameplay in familiar, cyclical rhythms.

Finally, the idea of integrating smartwatch-based stress tracking introduces a novel extension to Theme 1, bridging subjective experience with physiological feedback. This aligns with recent findings by Pinge et al [46], who systematically reviewed wearable-based stress detection and highlighted the clinical potential of physiological signals such as heart rate variability and electrodermal activity for real-time stress monitoring. By capturing pre- and post-game stress levels, future iterations of NoPain Games could offer biofeedback-informed personalization, enhancing therapeutic precision and enabling longitudinal tracking within digital care ecosystems.

Overall, these patient-driven suggestions not only validate the thematic structure but also push its boundaries toward real-world deployment. They emphasize the importance of technical adaptability, personalized challenge design, and physiological integration in therapeutic game development. More broadly, they demonstrate how participatory feedback can transform conceptual frameworks into actionable design trajectories, ensuring that digital health tools remain grounded in both clinical insight and patient reality.

Limitations

Although this study offers important insights, it is essential to acknowledge certain limitations. The study engaged a limited sample of 14 experts from 3 European countries in one session, followed by 5 patients with PsA from 4 European countries in a subsequent session, including SUS-based evaluation. While the results offer initial insights into usability perceptions, the limited sample size may have constrained variability, leading to some of the ICC curves being saturated, reducing the ability to detect item-level differentiation. Future research can build on this by involving a broader and more diverse participant pool to deepen understanding of the varied needs and experiences of individuals living with PsA. Particularly, including more testing with patients is necessary, which is essential to the proper design and effectiveness of the games despite the recruiting challenges associated with this task. Disparities in technology literacy among participants, especially health care professionals, also posed a challenge. Providing training or educational materials on the technologies used in the serious games could bridge this gap and improve feedback quality. Moreover, as the study is still at the prototype stage, further testing and clinical validation with patients with PsA through pilot studies and trials will be essential to refine the games based on real-world usability data. Finally, the proposed game designs may not fully consider the physical limitations of patients with PsA, such as joint stiffness and swelling, which can affect usability. Future iterations should incorporate adaptive game design features like customizable controls to improve accessibility.

Implications

The research on co-designing serious mobile games for patients with PsA presented here has several important implications across various domains.

From a managerial standpoint, the study underlines the importance of interdisciplinary collaboration in developing effective digital health interventions. Managers in health care and technology sectors should foster partnerships between clinicians, researchers, and game developers to leverage their combined expertise. This collaborative approach can lead to more innovative and user-centered solutions [47]. Additionally, the agile co-design methodology highlighted in the study can be adopted by managers to ensure continuous feedback and iterative improvements, enhancing the overall quality and relevance of the developed digital solutions [48]. By promoting a culture of collaboration and iterative development, managers can drive the successful implementation of digital health tools that meet the specific needs of patients [48,49].

From a financial perspective, the development and implementation of NoPain Games for patients with PsA could lead to significant cost savings in health care. By providing an engaging and effective tool for pain management and cognitive stimulation, these games can reduce the reliance on more expensive treatments and interventions [50]. Improved patient adherence to therapeutic activities can also lead to better health outcomes, potentially decreasing the frequency of hospital visits and the need for additional medical support. Furthermore, the scalability of mobile games means that they can be distributed widely at a relatively low cost, making them an economically viable option for health care providers and patients alike [51]. Investing in the development of such digital health solutions can yield long-term financial benefits for both health care systems and patients.

From the clinical point of view, while the NoPain Games presented here are still in the prototype stage and have not yet

XSL•FO
RenderX

been used in clinical practice, their potential therapeutic benefits are promising. The proposed serious games are designed to provide pain distraction, cognitive stimulation, and stress reduction, which could significantly improve the quality of life for patients with PsA. Future clinical trials and real-world testing will be crucial to validate these benefits and refine the game mechanics based on patient feedback [52]. If proven effective, these serious games could be integrated into treatment plans as complementary therapy, offering a novel approach to managing chronic pain and enhancing cognitive function. This research also highlights the importance of adaptive difficulty levels and personalized gameplay experiences, which could be further explored in clinical settings to tailor the interventions to individual patient needs [53].

Finally, from a societal perspective, the emphasis on accessibility and inclusive design in the NoPain Games highlights the importance of creating digital health solutions that are usable by individuals with varying physical abilities. By addressing the specific needs of patients with PsA, the games promote greater equity in health care access and support for chronic pain management. This inclusive approach can serve as a model for developing other digital health interventions that address the needs of diverse patient populations [54]. Moreover, the widespread adoption of such games can raise awareness about the potential of serious games in health care, encouraging further innovation and investment in this field [51]. By making effective pain management tools accessible to a broader audience, the research can contribute to improved health outcomes and quality of life for many individuals living with chronic conditions.

In contrast to prior studies that focus on general chronic pain, this research is the first to co-design mobile serious games specifically for patients with PsA, integrating both expert and patient perspectives. It contributes to the field by demonstrating how agile, participatory design can yield tailored, accessible, and therapeutically meaningful digital interventions for a rheumatic population largely overlooked in serious game development.

Conclusions

The proposed NoPain Games hold significant potential for alleviating chronic pain in individuals with PsA by providing engaging and immersive gameplay experiences aimed at reducing discomfort. This study highlights the collaborative efforts of researchers and clinical/technical experts in designing NoPain Games as cocreators. It introduces 2 serious game prototypes developed using agile methodology and co-design principles, incorporating expert feedback. The study explores the cocreation process, presenting initial findings through storyboards, game visualizations, and prototypes informed by the collected input. Future work includes obtaining further patient feedback on the prototypes and conducting real-world testing to evaluate their feasibility, acceptability, and overall user satisfaction. The findings highlight the critical role of managing game difficulty, which can be addressed through the integration of a dynamic difficulty adjustment system [38,39] in developing the game to customize challenges based on each patient's condition. Moreover, potential additional features could include integrating smartwatch-based biometric data, such as stress levels and heart rate, to personalize gameplay experiences and provide valuable clinical insights.

Acknowledgments

The authors would like to thank and acknowledge all members of the iPROLEPSIS Consortium for their valuable contributions. Views and opinions expressed are, however, those of the authors only and do not necessarily reflect those of the European Union or European Health and Digital Executive Agency. Neither the European Union nor the European Health and Digital Executive Agency can be held responsible for them. The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Funding

This work received funding from the European Union under the Horizon Europe Grant agreement number 101095697 (iPROLEPSIS: Psoriatic Arthritis Inflammation Explained through Multi-Source Data Analysis guiding a Novel Personalized Digital Care Ecosystem).

Data Availability

The datasets generated or analyzed during this study are not publicly available due to privacy restrictions and consortium policies on data sharing, but are available from the corresponding author on reasonable request.

Authors' Contributions

BR and SBD contributed to the study conceptualization and design; BR and SBD collected the data; BR, S Gomes, and SBD contributed to project administration. BR, S Gomes, MSV, FM, RGC, and SBD contributed to data curation and formal analysis; LH and SBD contributed to funding acquisition; BR, S Gomes, MSV, FM, RGC, LH, and SBD contributed to the methodology; BR, S Gomes, and SBD contributed to writing the original draft; BR, S Gomes, MSV, FM, RGC, S Gama, LH, and SBD contributed to reviewing and editing the paper; all authors reviewed and approved the final version of the manuscript.

Abstract

Background: The digital therapy of attention-deficit/hyperactivity disorder (ADHD) based on a "self-adaptive multitasking training paradigm" has been developed to improve the cognitive functional impairments and attention deficits of children with ADHD. However, the efficacy and safety of such treatment for Chinese patients remain untested.

Objective: This study aimed to preliminarily evaluate the actual intervention effects of a video game–like training software (ADHD-DTx) for children with ADHD aged 6-12 years as the first nationally certified digital therapeutics medical device for ADHD in China. We performed a single-arm, open-label efficacy and safety study.

Methods: This is a single-arm, open-label, pre-post efficacy and safety study. A total of 97 participants were included in the analysis. Participants received digital therapy (ADHD-DTx) and basic behavioral parent training for 4 weeks (25 min/day, ≥5 times/week) without medication. The efficacy outcomes included the Test of Variables of Attention (TOVA), Swanson, Nolan, and Pelham Questionnaire, version 4 (SNAP-IV), Weiss Functional Impairment Rating Scale (WFIRS), and Conner's Parent Symptom Questionnaire (PSQ). Safety-related events were monitored during and after the trial.

Results: From day 0 (baseline) to day 28, the population TOVA Attention Performance Index exhibited statistically significant improvement (from mean –4.15, SE of the mean [SEM] 0.32 to mean –1.70, SEM 0.30; t_{94}=–8.78; n=95; P<.001); the population total, inattention (AD), hyperactivity/impulsivity (HD), and oppositional defiant disorder (ODD) scores of SNAP-IV all significantly improved (total: from mean 1.33, SEM 0.05 to mean 1.09, SEM 0.05; t_{96}=5.32; P<.001; AD: from mean 1.71, SEM 0.06 to mean 1.44, SEM 0.06; t_{96}=4.44; P<.001; HD: from mean 1.38, SEM 0.07 to mean 1.05, SEM 0.06; t_{96}=5.96; P<.001; ODD: mean 0.84, SEM 0.05 to mean 0.75, SEM 0.05; Z=2.47; P=.03; n=97); for WFIRS results, domains of "family" and "social activities" showed significant population improvement (family: from mean 0.75, SEM 0.05 to mean 0.65, SEM 0.04; Z=2.80; P=.01; social activities: from mean 0.56, SEM 0.05 to mean 0.45, SEM 0.05; Z=2.91; P=.01; n=97); for PSQ results, domains of "learning problem,"

XSL•FO
RenderX

"psychosomatic problem," "impulsivity-hyperactivity," and "hyperactivity index" showed significant improvement (learning problem: from mean 1.72, SEM 0.06 to mean 1.57, SEM 0.06; *Z*=2.42; *P*=.03; psychosomatic problem: from mean 0.40, SEM 0.03 to mean 0.32, SEM 0.03; *Z*=2.66; *P*=.02; impulsivity-hyperactivity: from mean 0.94, SEM 0.06 to mean 0.80, SEM 0.06; *Z*=2.49; *P*=.03; hyperactivity index: from mean 1.06, SEM 0.05 to mean 0.92, SEM 0.05; *Z*=2.90; *P*=.01; n=97). No device-related adverse event or severe adverse event was observed or reported during or after the intervention.

Conclusions: This study preliminarily suggested the significant improvements of ADHD symptoms and attention function after 4 weeks of ADHD-DTx digital therapy combining basic behavioral parent training with satisfying safety outcomes.

ADHD; attention; attention-deficit/hyperactivity disorder; cognitive training; digital therapy; rehabilitation

Introduction

Attention-deficit/hyperactivity disorder (ADHD) is a neurodevelopmental disorder that commonly occurs in childhood and is characterized by inattention, hyperactivity, and impulsivity. The primary treatment for ADHD is pharmacotherapy, using methylphenidate, dexamphetamine, or atomoxetine as the first-line drugs [1]. However, pharmacotherapy for ADHD could cause adverse drug reactions such as digestive system issues, irritability, palpitations, and headaches, and more importantly, pharmacotherapy does not target the core functional deficits of patients with ADHD [2]. A recent study also suggested that beginning treatment with behavioral intervention may produce better outcomes overall than beginning treatment with medication [3]. Therefore, many patients with ADHD and their parents are looking forward to alternative interventions [4] like behavior therapy, neurofeedback, counseling, and, more recently, digital therapy [5].

The digital therapy of ADHD has been developed to improve the cognitive functional impairments and attention-control deficits of children with ADHD. In 2020, the US Food and Drug Administration (FDA) approved EndeavorRx (AKL-T01), the first video game–like training software for children with ADHD aged 8-12 years. Growing evidence has suggested that digital therapy could provide a safe and effective intervention to improve functional performance (such as attention, working memory, etc) and problematic behavior of children with ADHD, with minimal risk of adverse events (AEs) compared to pharmacotherapy [6-9]. In 2023, the Chinese National Medical Products Administration (NMPA) approved the "Attention Enhancement Training Software" (ADHD-DTx), a video game–like training software for children with ADHD aged 6-12 years, as the first nationally certified digital therapeutics medical device for ADHD in China.

The neurophysiological mechanisms of EndeavorRx and ADHD-DTx are both based on the self-adaptive multitasking training paradigm (NeuroRacer), which consists of 2 tasks: the "driving task" (sustained attention) and the go/no-go "sign task" (signal detection, attention-shifting, and inhibition control). Multiple studies have revealed that this training paradigm could improve participants' cognitive control abilities (enhanced sustained attention and working memory) after 1-month training [6-8,10], as well as increase the frontal midline theta (FM) power, the neuromarker of sustained attention and cognitive control [9,10]. Therefore, this paradigm has been used for the intervention of ADHD in a video game–like form to improve compliance in children. Besides the "driving task" and "sign task," ADHD-DTx also included a third task: the "digit cancellation task" (a widely used attention assessment and training method in clinical practice) [11] to further enhance the training effect of attention function.

To preliminarily evaluate the actual intervention effects of ADHD-DTx in Chinese children with ADHD aged 6-12 years, we performed a single-arm, open-label efficacy and safety study in the Children's Hospital of Zhejiang University School of Medicine (Hangzhou, China) in 2021. This study provided valuable efficacy and safety data of ADHD-DTx (and ADHD digital therapy based on the self-adaptive multitasking training paradigm) for the first time in Chinese children with ADHD. The efficacy data suggested by this pilot study provided a critical contribution to the design of the following randomized, double-blinded, parallel-controlled clinical trials, which were conducted during 2022 and 2023 (Feng S, PhD, unpublished data, 2025). The Chinese NMPA approval of ADHD-DTx (as the first Chinese ADHD digital therapy medical device) was based on the results of a key Good Clinical Practice clinical trial conducted during 2022-2023 (Feng S, PhD, unpublished data, 2025).

All participants had to be off any ADHD medication and without other significant comorbid psychiatric diagnoses. Included participants were treated with ADHD-DTx therapy and basic behavioral parent training (BPT; positive reinforcement training at home, required according to the ethical consideration of the regulatory agency) [12,13]. Efficacy outcomes included the computerized attention test: Test of Variables of Attention (TOVA) [14,15] and classic scales: (1) the Swanson, Nolan, and Pelham Questionnaire, version 4 (SNAP-IV) [16-18]; (2) the Weiss Functional Impairment Rating Scale (WFIRS) [19]; and (3) the Conner's Parent Symptom Questionnaire (PSQ) [20,21]. Safety outcomes included the proportions of device-related AEs or severe AEs.

Methods

Overview

This study was a single-arm, open-label study in children (aged 6-12 years) with a confirmed diagnosis of ADHD (as per the DSM-5 [*Diagnostic and Statistical Manual of Mental Disorders* {Fifth Edition}) in the Children's Hospital of Zhejiang

XSL•FO
RenderX

University School of Medicine (Hangzhou, China) in 2021. Participants had to be off any ADHD medication and not present other significant comorbid psychiatric diagnoses. All participants had an IQ score of ≥80 (per the Wechsler Intelligence Test) and an Attention-Deficit/Hyperactivity Disorder Rating Scale IV (ADHD-RS-IV) total score of >28.

Study Design

The study planned to enroll about 100 participants with a confirmed diagnosis of ADHD. Participants received digital therapy (ADHD-DTx, a video game–like training software running on an Android tablet) and basic BPT (positive reinforcement training at home) for 4 weeks (25 min/day, ≥5 times/week). Efficacy outcomes were measured on day 0 (baseline visit) and day 28 (after 4-week treatment). Safety-related events were monitored during and after the trial.

Participants

Eligible patients were male or female children aged 6-12 years with a confirmed diagnosis of ADHD (as per the DSM-V). Participants had to be off any ADHD medication (for at least 4 weeks before the baseline visit) and not present other significant comorbid psychiatric diagnoses. All participants had an IQ score of ≥80 (per the Wechsler Intelligence Test) and an ADHD-RS-IV total score of ≥28. Complete inclusion and exclusion criteria are in Multimedia Appendix 1.

Procedures

The ADHD-DTx intervention was preinstalled on Huawei MatePad tablets (Huawei). At the baseline visit, eligible patients were instructed to use ADHD-DTx for about 10 minutes while a study coordinator monitored the session to ensure that patients could follow the rules of ADHD-DTx. Patients were further assessed by ADHD-related scales (symptoms and impairments) and TOVA (attention functioning) at the baseline visit.

Afterward, patients received the ADHD-DTx digital treatment and basic BPT at home for 4 weeks (25 min/day, ≥5 times/week). Basic BPT was required according to the ethical considerations of the regulatory agency. The daily training task consisted of five 4- to 5-minute multitasking missions (total time on task was about 25 minutes). Compliance was monitored remotely using the network by investigators, and daily training reminders were sent to patients' caregivers manually or automatically. In accordance with a strict, predefined protocol, any participant who failed to complete the required training (25 min/day, ≥5 times/week) and persistently ignored reminders was classified as noncompliant and withdrawn from the trial.

ADHD-DTx is a digital therapeutic that uses a proprietary algorithm designed to improve attention control by training interference management (multitasking). ADHD-DTx mechanisms have been described previously. In brief, users multitask by responding to a perceptual discrimination targeting task and a simultaneous sensory motor navigation task. Users advance by reducing interference costs (closing the performance gap between multitasking and single-tasking), and real-time and periodic recalibration occurs to maintain an optimal difficulty level.

BPT consisted of parent-training courses (focusing on teaching parents specialized child management techniques primarily involving contingency management, such as behavior management principles, parental attending skills and home token system), aerobic exercises (such as jogging, swimming, or rope-skipping 40 min/day, ≥4 times/week), listening-retelling training (the child was asked to accurately retell sentences presented orally by parent, and the sentences were gradually made longer and more detailed to train the child's auditory attention and memory span), and reading-aloud training (the child was asked to read texts aloud to maintain focus and reduce mind-wandering, thereby promoting the child's sustained attention) [22-24]. BPT is a regular basic treatment for all children with ADHD in clinical practice.

Safety-related events such as vomiting, dizziness, headache, palpitation, addiction, frustration, eye discomfort, and other similar symptoms were monitored during and after the trial, as described: (1) during the 4-week intervention period, all participants' parents were contacted daily by a research assistant using online social software to collect safety-related events; and (2) after the intervention period, all participants' parents were contacted monthly by a research assistant using the telephone for 3 months to collect long-term safety-related events.

Outcomes

To effectively evaluate the impact of treatment on the core symptoms, problematic behaviors, and functional deficits of children with ADHD, and also ensure the reliability, validity, and objectivity of data, we chose both the computerized attention test and classic scales as the efficacy outcomes.

The primary end point was the improvement of attentional functioning as measured by TOVA from baseline to day 28. TOVA is a computerized, objective test of attentional functioning and has been globally used in clinical and academic institutions [22-24]. The outcomes of TOVA could objectively reflect the functional training effect of ADHD-DTx and provide essential information about the efficacy of the intervention.

Secondary end points included the improvements of classic scales that assess ADHD-related symptoms, functional impairments, and problematic behaviors from baseline to day 28. The SNAP-IV is widely used as the key assessment of ADHD core symptoms, including 3 subsets: (1) inattention (AD), (2) hyperactivity/impulsivity (HD), and (3) oppositional defiant disorder (ODD) [16,17]. WFIRS is a multidimensional, ADHD-specific, functional impairment assessment scale, including 6 domains: family, school, life skills, child's self-concept, social activities, and risky activities [19]. The PSQ has been widely used to assess problematic behaviors related to ADHD, including 6 domains: conduct problem, learning problem, psychosomatic problem, impulsivity-hyperactivity, anxiety, and hyperactivity index [20,21]. The selection of classic, widely validated scales could provide rich information about the behavioral symptoms, and importantly, the outcomes of these scales could reflect the influence of daily life by the training of ADHD-DTx, which is crucial for the rehabilitation of children with ADHD. More detailed descriptions of the outcome measurements can be found in Multimedia Appendix 2.

RenderX

Statistical Analysis

All analyses were performed according to a prespecified statistical analysis plan. Unless otherwise indicated, statistical comparisons used a 2-tailed significance test evaluated at the 95% level of confidence. All analyses were conducted using a complete case analysis. In no situation were missing data to be imputed. Student *t* test was performed only if the analyzed data passed the normality test (Shapiro-Wilk test); otherwise, the Wilcoxon nonparametric test would be used. The chi-square test was used for the statistical inference for counting data. Multiple comparisons corrections (using the false discovery rate method) were performed for all the secondary efficacy end points [25].

The primary efficacy end point for each participant was the change in the TOVA Attention Performance Index (API) from baseline to day 28, defined as the score on day 28 minus the score at baseline. Missing data were not imputed. Participants with missing data either on day 0 or day 28 would be excluded from the paired significance analysis. Unless otherwise indicated, the results of the efficacy analysis were summarized as mean (SE of the mean [SEM]). Significance was assessed with a 2-sided paired *t* test evaluated at the 95% level of confidence.

The following secondary efficacy end points were tested using the same technique outlined for the primary efficacy analysis: (1) change in SNAP-IV from baseline to day 28, (2) change in WFIRS from baseline to day 28, and (3) change in PSQ from baseline to day 28.

Ethical Considerations

The study was conducted in accordance with the International Conference on Harmonisation Regulations and was approved by the Institutional Review Board of Children's Hospital of Zhejiang University School of Medicine. All participants and their caregivers provided written informed consent prior to any study activities being conducted. The data of all participants were anonymous throughout the study. All participants received compensation for the examination fees. The study was subject to independent supervision by regulatory agencies (the Institutional Review Board and the Office of Clinical Trial Institution of Children's Hospital of Zhejiang University School of Medicine) throughout the entire process. Authors who were employed by SDO Digital Therapeutics (the developer of ADHD-DTx) did not participate in any data collection process, and the data analysis results were checked and confirmed by authors from the Children's Hospital of Zhejiang University School of Medicine. To safeguard the design details and clinical parameters of the investigational product (ADHD-DTx) and mitigate potential commercial risks, the producer requested a delay in the clinical trial registration until after market approval was obtained from the NMPA of China. Following the product's market approval in 2023, the trial was submitted for registration with the Chinese Clinical Trial Registry, where it is currently pending review.

Results

Participants

A total of 114 participants were screened for inclusion in this study, with 110 meeting eligibility criteria (Figure 1). The sample size was determined comprehensively, referring to previous research using similar digital therapy for children with ADHD [8], the power of statistics, and the amount of available resources. The mean age of included participants was 7.78 (SD 1.14) years, and 90% (99/110) were male. The vast majority (106/110, 96.36%) of included participants were of the Han ethnic group, and other involved ethnic groups included She (2/110, 1.82%), Korean (1/110, 0.91%), and Tujia (1/110, 0.91%). The educational status of participants' parents: postgraduate (6/110, 5.45%), graduate or junior college (62/110, 56.36%), high school or vocational school (28/110, 25.45%), middle school (12/110, 10.91%), primary school, and below (2/110, 1.82%). Demographic characteristics of included participants are listed in Table 1.

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram of the single-arm, open-label study of children with attention-deficit/hyperactivity disorder in China during 2021. TOVA: Test of Variables of Attention.

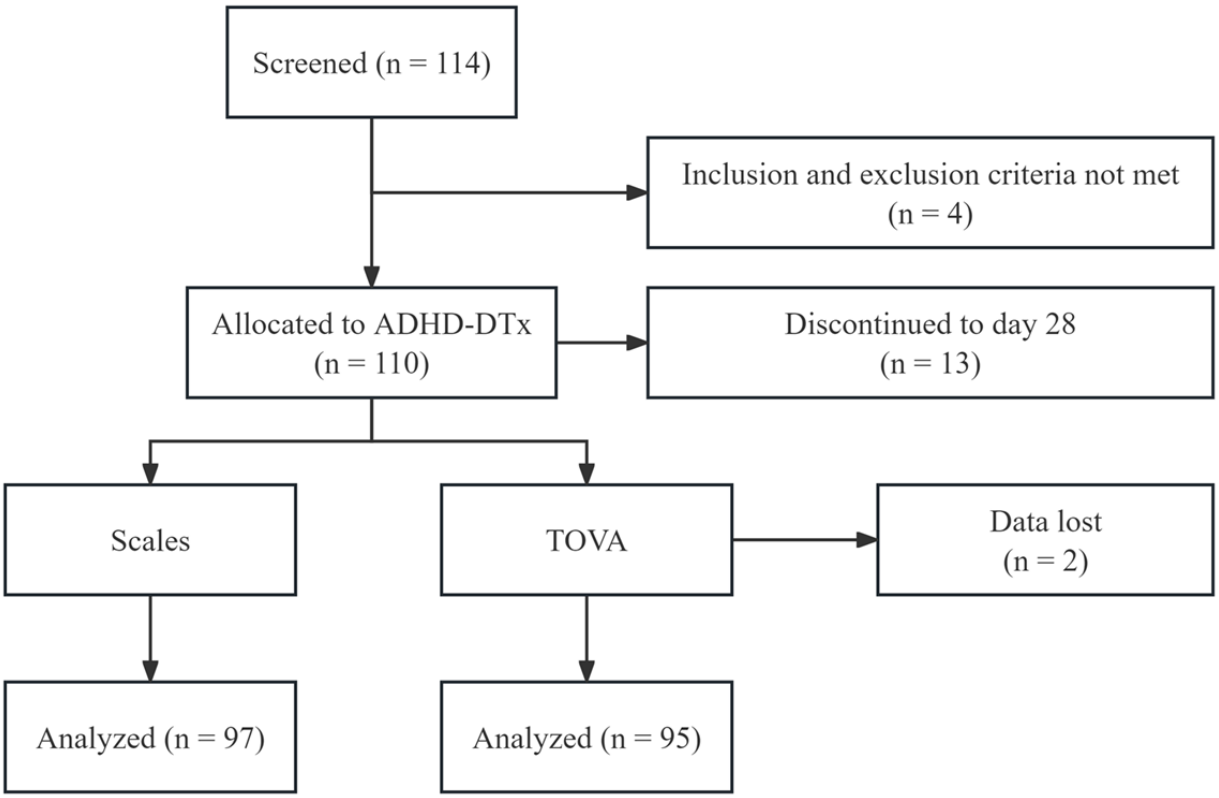

Table 1. Demographic characteristics of included participants.

Demographic	Value (n=110)
Age (years), mean (SD)	7.78 (1.14)
Gender, n (%)	
Male	99 (90)
Female	11 (10)
Ethnicity, n (%)	
Han	106 (96.36)
She	2 (1.82)
Korean	1 (0.91)
Tujia	1 (0.91)
Parental education level, n (%)	
Postgraduate	6 (5.45)
Graduate or junior college	62 (56.36)
High school or vocational school	28 (25.45)
Middle school	12 (10.91)
Primary school and below	2 (1.82)

Overall, 97/110 (88%) participants completed the study, 13 participants did not complete the study (lost to follow-up or noncompliance), and the TOVA data of 2 participants were lost due to device failure. All 97 participants who completed the study adhered strictly to the training protocol (25 min/day, ≥5 times/week for 4 weeks), and the average number of actual training days completed per participant was 20. Therefore, we finally collected and analyzed 97 participants' scales data, as well as 95 participants' TOVA data. All participants received

XSL•FO
RenderX

ADHD-DTx digital therapy (combined with basic BPT) in 2021 and remained off medication during the treatment period.

Efficacy Outcomes

In this study, efficacy outcomes were measured using the computerized attention test (TOVA) and classic scales: SNAP-IV, WFIRS, and PSQ. After a 4-week intervention, we found that the treatment significantly improved ADHD-related symptoms and impairments (all detailed statistical results are present in Table 2).

XSL•FO

[a]TOVA: Test of Variables of Attention.
[b]API: Attention Performance Index.
[c]*t* test (*df*).
[d]SNAP-IV: Swanson, Nolan, and Pelham Questionnaire, version 4.
[e]AD: inattention subscale of SNAP-IV.
[f]HD: hyperactivity/impulsivity subscale of SNAP-IV.
[g]ODD: oppositional defiant disorder subscale of SNAP-IV.
[h]*Z* value of Wilcoxon nonparametric test.
[i]WFIRS: Weiss Functional Impairment Rating Scale.
[j]PSQ: Conner's Parent Symptom Questionnaire.

Primary End Point: TOVA-API

We chose TOVA (an objective measurement of attention function) as the primary measurement of intervention efficacy, and the TOVA-API was chosen as the primary end point of this study (Figure 2).

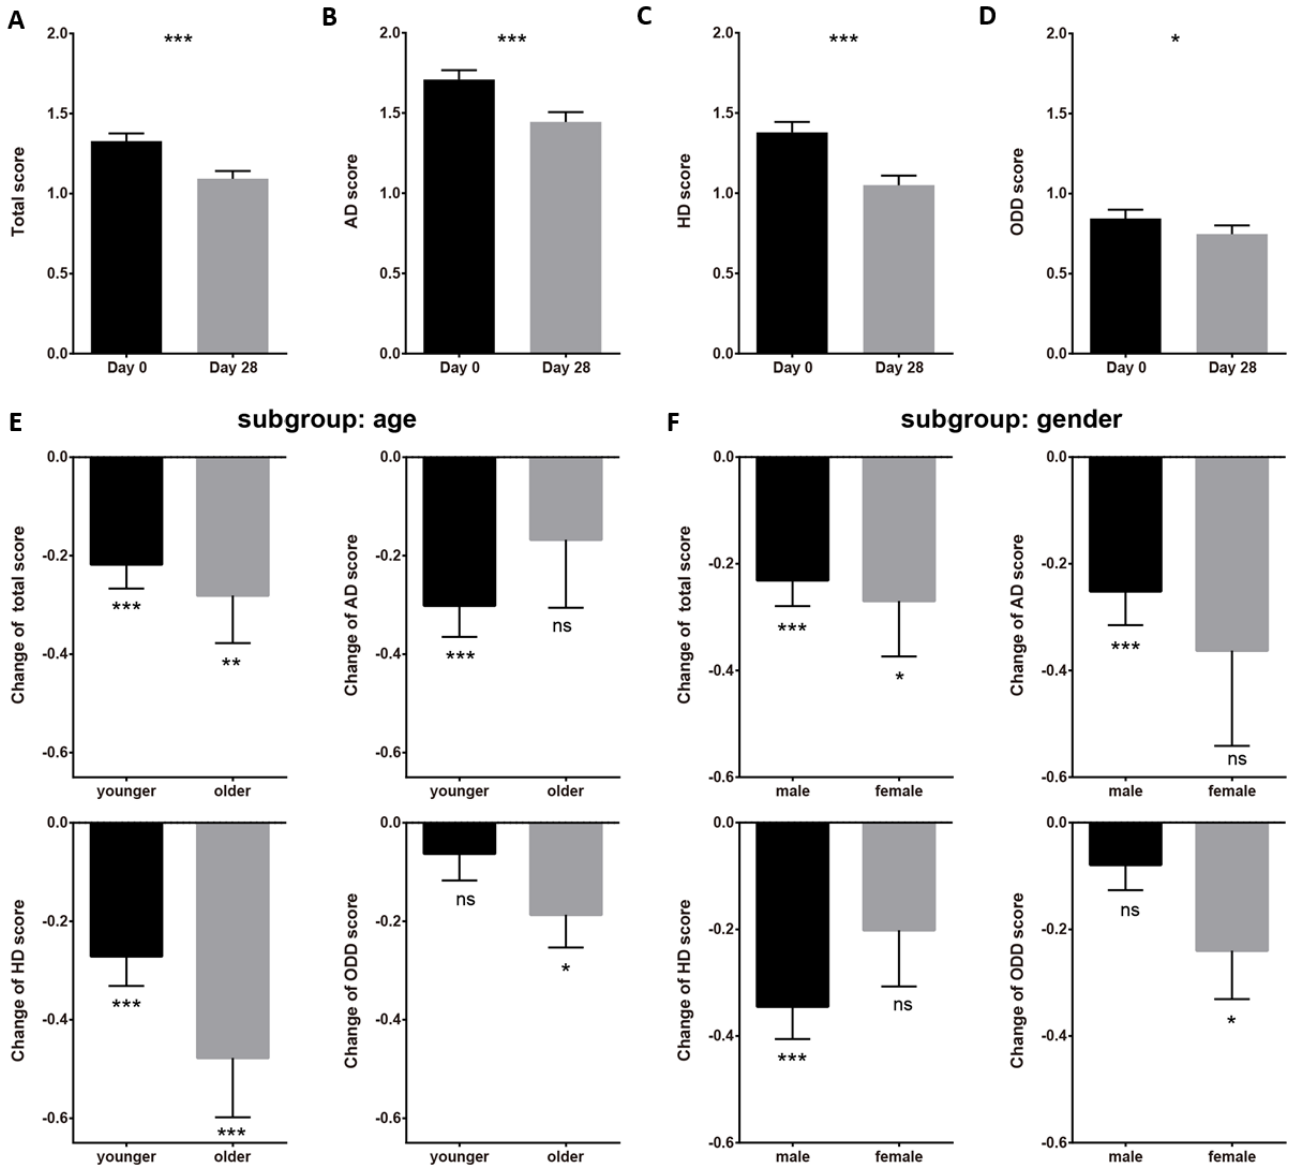
Figure 2. Statistical results of the Test of Variables of Attention (TOVA) suggested significant improvement after 4 weeks of intervention. (A) TOVA Attention Performance Index (API) outcomes from day 0 to day 28; (B) TOVA-API of younger (aged 6-8 years) and older (aged 9-12 years) groups from day 0 to day 28; (C) TOVA-API of male and female groups from day 0 to day 28. Error bars indicate SEM. ***P*<.01, ****P*<.001.

The baseline data of TOVA-API passed the normality test (n=95; *P*=.36). From day 0 (baseline) to day 28, the population TOVA-API exhibited statistically significant improvement (Figure 2A, from mean –4.15, SEM 0.32 to mean –1.70, SEM 0.30; T=–8.78; n=95; *P*<.001), suggesting the efficacy of objective functional improvement of attention.

We conducted subgroup analysis of TOVA-API on age (Figure 2B; younger: 6-8 years; older: 9-12 years) and gender (Figure 2C; male and female) to investigate more detailed efficacy characteristics. We found that from day 0 (baseline) to day 28, both the younger and older groups exhibited statistically significant improvement (younger group: from mean –4.15,

XSL•FO
RenderX

SEM 0.35 to mean –1.59, SEM 0.35; T=–7.90; n=69; *P*<.001; older group: from mean –4.15, SEM 0.73 to mean –2.00, SEM 0.59; T=–3.90; n=26; *P*=.001). The improvement of the younger group (pre-post difference=2.56) slightly exceeded that of the older group (pre-post difference=2.15), but no statistical difference was found (*P*=.53). As for the gender analysis, from day 0 (baseline) to day 28, both the male and female groups exhibited statistically significant improvement (male group: from mean –4.18, SEM 0.34 to mean –1.74, SEM 0.31; T=–8.11; n=84; *P*<.001; female group: from mean –3.89, SEM 1.08 to mean –1.38, SEM 1.19; T=–3.31; n=11; *P*=.008). The improvements of both groups showed no statistical difference (*P*=.93). We also analyzed the potential influence of parental education level (college degree or above: n=56; below college level: n=39) on TOVA-API and found no statistically significant difference (*P*=.78).



The above findings suggested that the 4-week intervention could significantly improve the attention function of children with ADHD (regardless of age or gender), as measured by TOVA-API.

Secondary End Points: SNAP-IV, WFIRS, and PSQ

We chose the results of classic clinical scales (SNAP-IV, WFIRS, and PSQ) as the secondary end points. Multiple comparisons corrections were performed for the statistical analysis results of the scale scores (see Methods section).

Using the SNAP-IV scale, we measured the treatment effect of ADHD core symptoms (Figure 3). The baseline data of the SNAP-IV total score, AD subscale, and HD subscale passed the normality test (n=97; P_{total}=.19; P_{AD}=.09; P_{HD}=.25), while that of the ODD subscale did not (n=97; P_{ODD}<.001). Therefore, we used the Student *t* test for total score, AD, and HD data, and the Wilcoxon nonparametric test for ODD data.

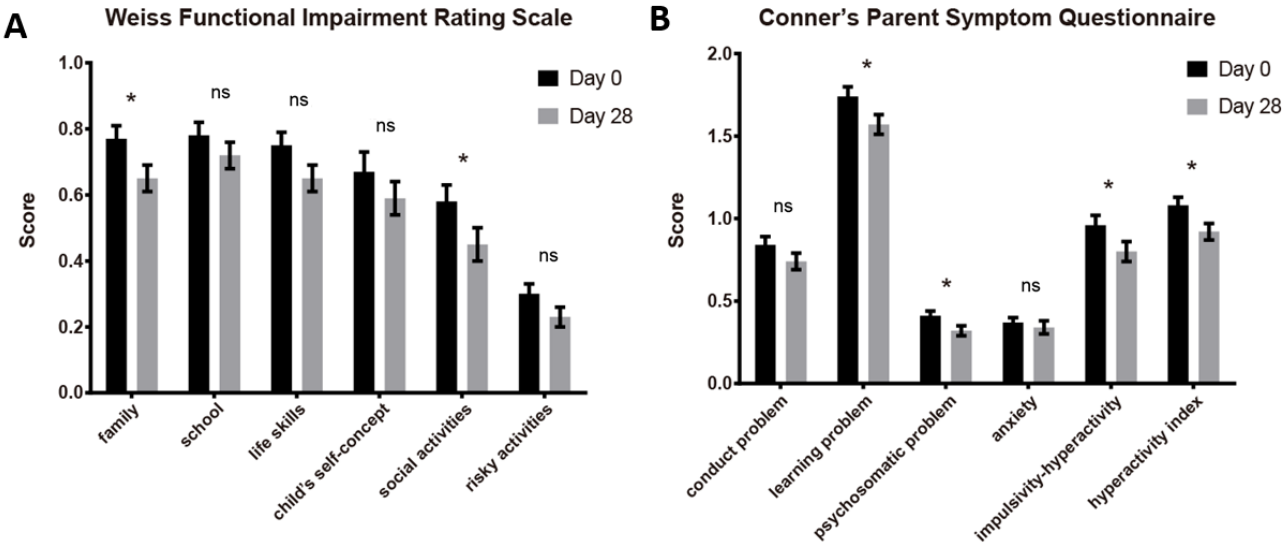
Figure 3. Statistical results of the Swanson, Nolan, and Pelham Questionnaire, version 4 (SNAP-IV), suggested significant improvement after 4 weeks of intervention. (A) SNAP-IV total score from day 0 to day 28; (B) SNAP-IV inattention (AD) score from day 0 to day 28; (C) SNAP-IV hyperactivity/impulsivity (HD) score from day 0 to day 28. (D) SNAP-IV oppositional defiant disorder (ODD) score from day 0 to day 28. (E) Subgroup analysis of age (younger: 6-8 years; older: 9-12 years) of SNAP-IV scores from day 0 to day 28. (F) Subgroup analysis of gender (male and female) of SNAP-IV scores from day 0 to day 28. Error bars indicate SEM. ns: nonsignificant. *P<.05, **P<.01, ***P<.001.

XSL•FO
RenderX

From day 0 to day 28, the population total score of SNAP-IV significantly improved (descended) from mean 1.33, SEM 0.05 to mean 1.09, SEM 0.05 (Figure 3A; T=5.32; n=97; *P*<.001); the population AD score of SNAP-IV significantly improved (descended) from mean 1.71, SEM 0.06 to mean 1.44, SEM 0.06 (Figure 3B; T=4.44; n=97; *P*<.001); the population HD score of SNAP-IV significantly improved (descended) from mean 1.38, SEM 0.07 to mean 1.05, SEM 0.06 (Figure 3C; T=5.96; n=97; *P*<.001); the population ODD score of SNAP-IV significantly improved (descended) from mean 0.84, SEM 0.05 to mean 0.75, SEM 0.05 (Figure 3D; *Z*=2.47; n=97; *P*=.03). The above results suggested that the treatment could significantly improve the core symptoms (attention deficit and hyperactivity) of children with ADHD.

We also conducted subgroup analysis of SNAP-IV on age (Figure 3E; younger: 6-8 years; older: 9-12 years) and gender (Figure 3F; male and female). It was notable that due to the small sample size of the female group (n=11) and older group (n=27), the efficacy of statistical inference might be limited.

For the SNAP-IV total score, all the subgroups exhibited statistically significant improvement (younger group: from mean 1.30, SEM 0.05 to mean 1.09, SEM 0.06; T=4.44; n=70; *P*<.001; older group: from mean 1.39, SEM 0.11 to mean 1.11, SEM 0.09; T=2.91; n=27; *P*=.007; male group: from mean 1.35, SEM 0.05 to mean 1.12, SEM 0.05; T=4.78; n=86; *P*<.001; female group: from mean 1.14, SEM 0.08 to mean 0.87, SEM 0.16; T=2.59; n=11; *P*=.03 paired *t* test). No statistical difference was found between different age and gender groups (age: *P*=.56; gender: *P*=.74).



For the SNAP-IV AD score, only the younger group and male group exhibited statistically significant improvement (younger group: from mean 1.72, SEM 0.07 to mean 1.42, SEM 0.07; T=4.77; n=70; *P*<.001; male group: from mean 1.73, SEM 0.06 to mean 1.48, SEM 0.07; T=3.97; n=86; *P*<.001), while the older group and female group did not (older group: from mean 1.68, SEM 0.11 to mean 1.51, SEM 0.12; T=1.22; n=27; *P*=.23; female group: from mean 1.57, SEM 0.11 to mean 1.20, SEM 0.19; T=2.04; n=11; *P*=.07). No statistical difference was found between different age and gender groups (age: *P*=.39; gender: *P*=.57).

For the SNAP-IV HD score, the younger, older, and male groups exhibited statistically significant improvement (younger group: from mean 1.34, SEM 0.07 to mean 1.07, SEM 0.08; T=4.53; n=70; *P*<.001; older group: from mean 1.49, SEM 0.14 to mean 1.01, SEM 0.09; T=3.98; n=27; *P*<.001; male group: from mean 1.42, SEM 0.07 to mean 1.07, SEM 0.06; T=5.69; n=86; *P*<.001), while the female group did not (n=11; *P*=.09). No statistical difference was found between different age and gender groups (age: *P*=.94; gender: *P*=.26).

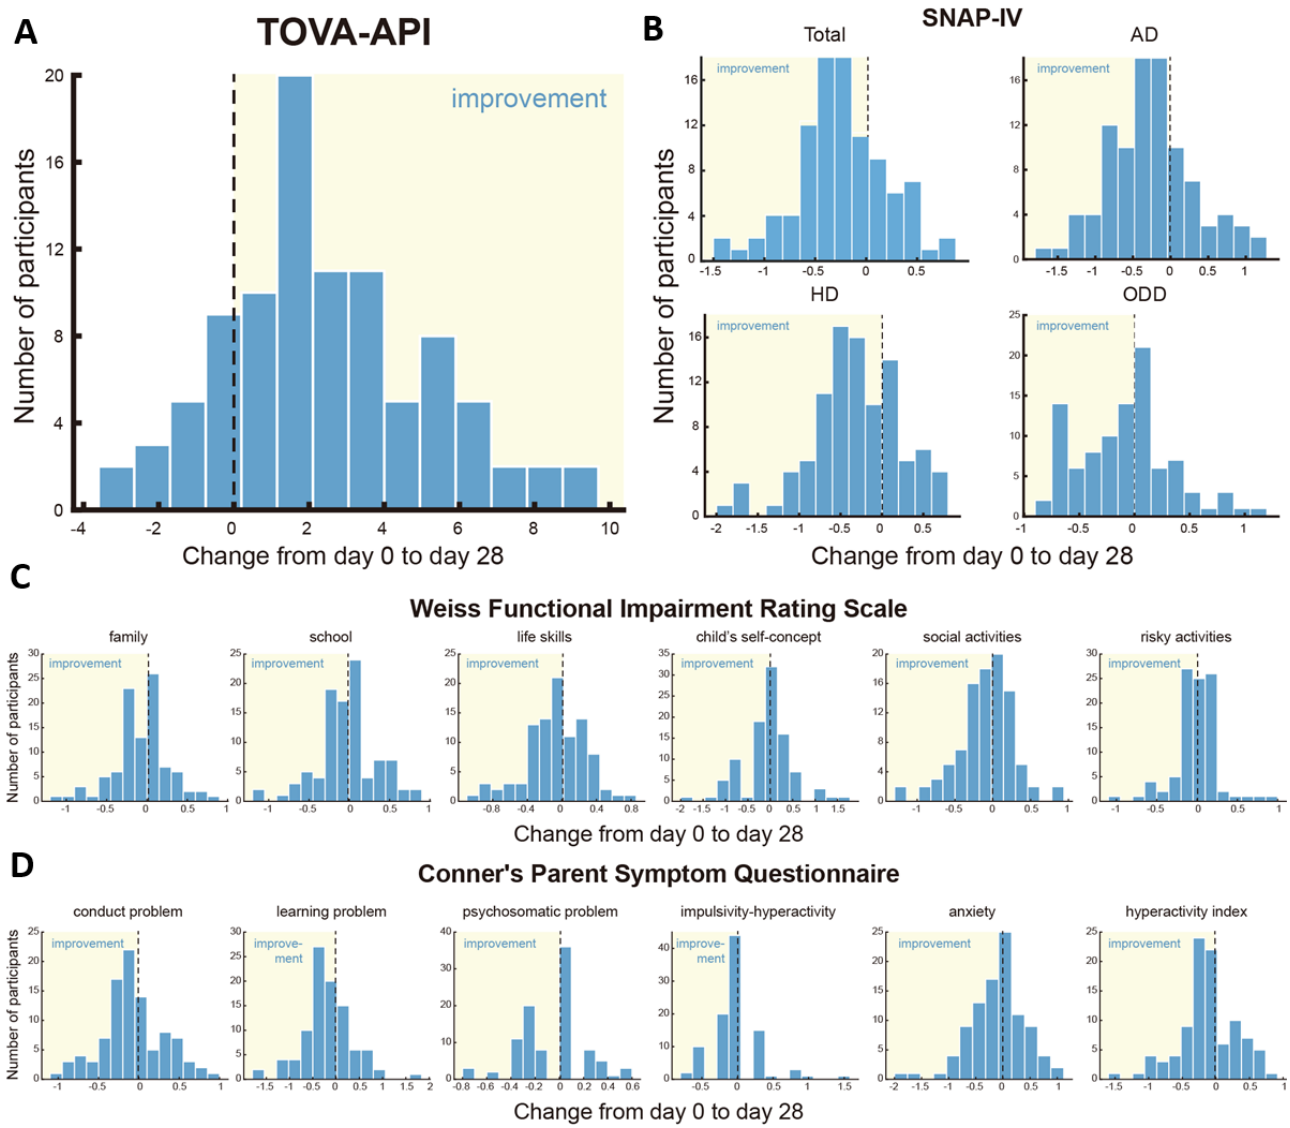
For the SNAP-IV ODD score, only the older group and female group exhibited statistically significant improvement (older group: from mean 0.95, SEM 0.13 to mean 0.76, SEM 0.11; T=2.50; n=27; *P*=.01; female group: from mean 0.70, SEM 0.10 to mean 0.47, SEM 0.08; T=2.02; n=11; *P*=.04), while the younger group and male group did not (younger group: T=1.38; n=70; *P*=.17; male group: T=1.88; n=86; *P*=.06). No statistical difference was found between different age and gender groups (age: *P*=.17; gender: *P*=.22).

The functional impairments of participants were measured using WFIRS (Figure 4A). WFIRS data did not pass the normality test; therefore, the Wilcoxon signed-rank test was used. We found that after 4 weeks of treatment, the impairments of the "family" and "social activities" domains were statistically significantly improved (family: from mean 0.75, SEM 0.05 to mean 0.65, SEM 0.04; *Z*=2.80; *P*=.01; social activities: from mean 0.56, SEM 0.05 to mean 0.45, SEM 0.05; *Z*=2.91; n=97; *P*=.01), while the domains of "school," "life skills," "child's self-concept," and "risky activities" exhibited nonsignificant improvement (school: *P*=.14; life skills: *P*=.09; child's self-concept: *P*=.34; risky activities: *P*=.14; n=97).

Figure 4. Statistical results of the Weiss Functional Impairment Rating Scale and Conner's Parent Symptom Questionnaire suggested significant improvement after 4 weeks of intervention. (A) Weiss Functional Impairment Rating Scale outcomes (scores) from day 0 to day 28. (B) Conner's Parent Symptom Questionnaire outcomes (scores) from day 0 to day 28. Error bars indicate SEM. ns: nonsignificant. *P<.05, **P<.01, ***P<.001.

XSL•FO
RenderX

We also analyzed the number of items scored ≥2 in WFIRS to investigate the treatment effect on severe functional impairments using the chi-square test. We found that the correlation between the intervention and the number of items scored ≥2 of "child's self-concept" was statistically significant (Pearson χ^2_1=7.249; *P*=.007). There were also almost significant correlations between the intervention and the number of items scored ≥2 of "family" and "life skills" (family: Pearson χ^2_1=3.183; *P*=.07; life skills: Pearson χ^2_1=3.071; *P*=.08). While there were no significant correlations between the intervention and the number of items scored ≥2 of "school," "social activities," and "risky activities" (school: Pearson χ^2_1=0.949; *P*=.33; social activities: Pearson χ^2_1=0.899; *P*=.34; risky activities: Pearson χ^2_1=0.519; *P*=.47).



The problematic behaviors of participants were measured using PSQ (Figure 4B). PSQ data did not pass the normality test; therefore, the Wilcoxon signed-rank test was used. After 4 weeks treatment, the domains of "learning problem," "psychosomatic problem," "impulsivity-hyperactivity," and "hyperactivity index" were statistically significantly improved (learning problem: from mean 1.72, SEM 0.06 to mean 1.57, SEM 0.06; *Z*=2.42; *P*=.03; psychosomatic problem: from mean 0.40, SEM 0.03 to mean 0.32, SEM 0.03; *Z*=2.66; *P*=.02; impulsivity-hyperactivity: from mean 0.94, SEM 0.06 to mean 0.80, SEM 0.06; *Z*=2.49; *P*=.03; hyperactivity index: from mean 1.06, SEM 0.05 to mean 0.92, SEM 0.05; *Z*=2.90; *P*=.01; n=97). While the domains of "conduct problem" and "anxiety" exhibited nonsignificant improvement (conduct problem: *P*=.06; anxiety: *P*=.17).

The above findings suggested that the 4-week intervention could significantly improve the core symptoms of children with ADHD (measured by SNAP-IV), as well as a few domains related to functional impairments and problematic behaviors (measured by WFIRS and PSQ).

Table 2 summarizes the statistical results of efficacy outcomes during the 4-week treatment. The distributions of efficacy-outcome improvements (from day 0 to day 28) among the participants are shown in Figure 5. The proportions of participants whose efficacy outcomes showed improvements were 80% (76/95 in TOVA), 71.13% (69/97 in SNAP-IV total), 70.1% (68/97 in SNAP-IV AD), 70.1% (68/97 in SNAP-IV HD), 55.67% (54/97 in SNAP-IV ODD), 54.64% (53/97 in WFIRS-family), 52.58% (51/97 in WFIRS-school), 52.58% (51/97 in WFIRS-life skills), 38.14% (37/97 in WFIRS-child's self-concept), 54.64% (53/97 in WFIRS-social activities), 42.27% (41/97 in WFIRS-risky activities), 58.76% (57/97 in PSQ-conduct problem), 48.45% (47/97 in PSQ-learning problem), 45.36% (44/97 in PSQ-psychosomatic problem), 32.99% (32/97 in PSQ-anxiety), 47.42% (46/97 in PSQ-impulsivity-hyperactivity), and 57.73% (56/97 in PSQ-hyperactivity index).

Figure 5. Distributions of efficacy-outcome improvements (from day 0 to day 28) among the participants suggest significant improvement of symptoms. (A) Distribution of Test of Variables of Attention (TOVA) Attention Performance Index (API) changes from day 0 to day 28; (B) Distributions of Swanson, Nolan, and Pelham Questionnaire, version 4 (SNAP-IV) score changes from day 0 to day 28; (C) Distributions of Weiss Functional Impairment Rating Scale score changes from day 0 to day 28; (D) Distributions of Conner's Parent Symptom Questionnaire score changes from day 0 to day 28. The ranges corresponding to improvement are highlighted. AD: inattention; HD: hyperactivity/impulsivity; ODD: oppositional defiant disorder.

Safety Results

Parents and participants were informed to report any safety concerns and discomfort during the study. Any concerns and discomfort reported by parents and participants during the study were recorded. Overall, no device-related AE or severe AE was observed or reported during the 4-week intervention and the 3-month follow-up period, suggesting the safety of treatment.

Discussion

Principal Findings

This paper reports the first Chinese clinical trial outcomes of an adaptive multitasking training paradigm for the treatment of children with ADHD without medication. This study preliminarily suggested the significant improvements of ADHD symptoms and attention function after 1-month digital therapy (combined with basic BPT, without medication) using the "Attention Enhancement Training Software" (ADHD-DTx), a video game–like training software for children with ADHD aged 6-12 years, with satisfying safety outcomes.

Comparison to Prior Work

The efficacy results are consistent with previous studies using an adaptive multitasking training paradigm [7,8,10], indicating the potential application value (as an individual or adjuvant treatment) of video game–like digital therapy for children with ADHD. The potential contribution of game-like cognitive training on attention has been reported both in children and adults [26-30], which suggests a new digital solution for attention-related deficits (such as ADHD, mild cognitive impairment, etc) across age groups [31,32].

The BPT has been extensively studied, and the overall effect size was estimated by previous researchers. Gubbels and colleagues [33] suggested that the overall effect of parent training was 0.416 (Cohen *d*) in their meta-analysis research, while Zwi and colleagues [23] suggested that the effect size

XSL•FO
RenderX

might be "between small and medium" in their review. In comparison, we calculated the effect size (Cohen *d*) of the intervention in this study, based on TOVA-API and SNAP-IV data. We found that the effect size of TOVA-API was 0.80, while that of SNAP-IV total score was 0.50. These results exceeded the effect sizes of BPT estimated by previous researchers, suggesting that the ADHD-DTx digital therapeutic, when integrated with BPT, may yield superior outcomes to BPT alone. However, such cross-study comparisons are informal and cannot independently establish the efficacy of ADHD-DTx. More rigorously controlled trials—directly comparing the combined intervention against BPT alone—are needed to draw definitive conclusions regarding the stand-alone contribution of the digital therapy.

Compared with the FDA-approved EndeavorRx (AKL-T01) software, the "Attention Enhancement Training Software" (ADHD-DTx) added the "digit cancellation task" (a widely used attention assessment and training method in clinical practice [11]) to further enhance the training effect on attention function. The "digit cancellation task" was simplified from the clinical version and consisted of 5 different types of tasks: (1) choose a specific number (eg, "choose 3"), (2) choose the adjacent (left or right) number of a specific number (eg, "choose the adjacent number on the left of 3"), (3) choose a specific number adjacent (left or right) to a specific number (eg, "choose 2 on the left of 3"), (4) choose the number in the middle position of 2 specific numbers (eg, "choose the number in the middle position of 2 and 3"), and (5) choose a specific type (even or odd) of number in the middle position of 2 specific numbers (eg, "choose the even number in the middle position of 2 and 3"). These tasks targeted multiple dimensions of attention (such as pointing, shifting, selection, span, and allocation), aiming to activate extensive attention-related brain regions and achieve the training effect of attention function.

Limitations

The key objective of this study was to explore the clinical safety and efficacy of ADHD-DTx digital therapy. However, considering that this study was single-armed and did not use a control group, it would be meaningful to attempt to exclude the influence of basic BPT from the final therapeutic effect. We suggest that further research should use a randomized, double-blinded, parallel-controlled design, which could provide the most reliable data reflecting the actual effect of ADHD-DTx.

In this study, several potential confounding factors should be considered. First, the subjective evaluation bias was caused by the open-label design, the subjective parent-reported scales for all secondary outcomes, and the large research time span. Open-label design and subjective scales could introduce a significant risk of reporter bias or placebo effect, while the 1-year time span of this study might further enhance the potential subjective bias due to the fluctuating behavior patterns of children between school and vacation periods. These confounding factors could not be separated from the intervention's true effect, and future studies should adopt a double-blind, randomized controlled design to mitigate these biases.

Second, heterogeneity in the effectiveness of BPT may have contributed to variability in outcomes. The actual effect of BPT largely depended on the performance of parents when providing behavioral guidance to children with ADHD. However, due to differences in educational level, professional skills, and training quality, the actual effectiveness may vary among different parents, resulting in population heterogeneity. During the study, all parents were asked to daily report their home-based training progress, and all participants exhibited high adherence to both ADHD-DTx and BPT. And the subgroup analysis focusing on parental education level did not show a significant difference in efficacy outcome. Therefore, the potential influence of adherence and parental education level may be limited. However, the potential impact of training quality differences between parents still existed.

Third, the potential contribution of BPT was not excluded in this single-arm study design, which might amplify the effectiveness results. As a standard foundational treatment for ADHD, BPT was mandated by the regulatory agency for all participants due to ethical considerations. While its efficacy was well-established, albeit generally mild, its concurrent implementation with the investigational digital therapy (ADHD-DTx) introduced a considerable confounding effect that may inflate the perceived effectiveness of the intervention. Improved study design should include a control group (providing BPT equally to both test and control groups, while only the test group is treated with ADHD-DTx) so as to effectively control the confounding influence of BPT, allowing for a more precise assessment of the benefit of ADHD-DTx.

Fourth, the generalizability of the results was constrained due to limited sample diversity. The included participants were predominantly male (99/110, 90%) and of Han ethnicity (106/110, 96.36%), which weakened the interpretability of outcomes for females and other ethnicities. Future research should prioritize enrolling more representative samples with balanced gender distribution and greater ethnic diversity to ascertain the efficacy of the intervention across the broader population with ADHD.

Fifth, the rigorously monitored and controlled conditions of a clinical trial may not perfectly predict the intervention's effectiveness in real-world clinical practice. The high adherence observed in this study was facilitated by intensive monitoring and support, which limited the direct translation of these efficacy results into real-world practice, where effectiveness might be weaker. Consequently, future investigation should involve pragmatic trials to generate robust evidence on the actual efficacy and implementation of the intervention.

Finally, the subgroup analyses for age and gender were likely underpowered due to the small sample sizes in the female and older groups. Consequently, any observed differences (or lack thereof) between these subgroups should be considered preliminary and interpreted with caution. Further research specifically designed to investigate these demographic groups is needed to advance our understanding of digital therapeutics for ADHD.

RenderX

Future Directions

Further improvements could still be carried out in future research. In this single-arm, open-label study, we preliminarily revealed the safety and efficacy of ADHD-DTx digital therapy. While future research should use a randomized, double-blinded, parallel controlled design so as to prevent potential placebo effect and rule out the effect of basic BPT at home, it will achieve a better evaluation of the actual effect size of ADHD-DTx. Further study could also investigate the effect of a prolonged treatment period (>4 weeks) to study the long-term influence of digital therapy. Longer safety monitoring after the intervention period is also needed to reveal potential effects on visual acuity, daily activities, sleep quality, screen usage time, and so on. The independent ethical oversight should continue to be valued and implemented to avoid potential conflicts of interest. Future studies should include comparisons with well-established interventions like pharmacotherapy, psychological behavioral therapy, and so on, to obtain more informative evidence for better clinical practice.

There is psychological and neurophysiological evidence suggesting the potential mechanisms of ADHD treatment by the adaptive multitasking paradigm. According to electroencephalogram studies focusing on the neural mechanisms of the adaptive multitasking paradigm, after 4 weeks of training, participants' FM significantly enhanced [9,10]. The FM is a well-established neural marker of attention control [34-38], and its enhancement is related to the suppression of a key node of the "default mode network" [10,39,40], leading to a reduction of the susceptibility to internal distraction, resulting in better task performance and sustained attention. To explore potential neural mechanisms of digital therapy, physiological measurements of brain function (such as electroencephalogram, functional magnetic resonance imaging, functional near-infrared spectroscopy, functional ultrasound, etc) could provide irreplaceable insight and should be considered in future studies.

The evaluation methods used in this study were limited, and further study could include other powerful tools such as other neuropsychological tests (eg, the Integrated Visual and Auditory Continuous Performance Test, the Wisconsin Card Sorting Test, the Cambridge Neuropsychological Test Automatic Battery, etc), classic scales (eg, the Execution Function Parent Questionnaire, the Vanderbilt ADHD Parent Rating Scale, etc).

Due to the limited data on female patients, we suggest that further research could include a higher proportion of female patients so as to make the results more representative. The inclusion and exclusion criteria set strict restrictions on comorbidity, which, on the one hand, could reduce potential confounding factors; however, on the other hand, it would limit our knowledge of real-world situations. We suggest that subsequent research can specifically investigate the effect of ADHD digital therapy involving comorbidities. We also suggest including the examination of visual acuity in further study to investigate the potential impact of long-term electronic device training on vision.

Conclusions

According to our pilot study on the Attention Enhancement Training Software (ADHD-DTx), we suggest that it could be used as a daily home-training tool for children with ADHD as an adjunct therapy to medication or other behavioral therapies, thereby further improving the intervention efficacy and reducing potential adverse drug reactions.

Abstract

Background: Nature experiences may have a positive impact on mental health. Innovative alternatives, such as immersive virtual reality (iVR), can have similar effects. In previous studies on embodying a tree in virtual reality, connectedness to nature has been induced in healthy participants and shown to be influenced by compassion. Compassion and empathy, however, can be altered in psychiatric disorders, leading to impaired relationships with fellow human beings. The potential effect of nature experiences in iVR on compassion, empathy, and nature connectedness in mental health disorders has not yet been investigated.

Objective: This study aims to examine the development of nature connectedness, compassion, empathy, and individual symptom load in patients with depression (n=20), schizophrenia (n=20), and healthy controls (n=20), measured pre and post 1 session of virtual embodying a rainforest tree.

Methods: We conducted an explorative clinical trial, comparing 3 groups (depression, schizophrenia, and healthy control), using repeated measures ANOVA and multiple regression analysis. Effect sizes (η_p^2) and 95% CIs were reported where applicable. We assessed the impact of iVR-exposure on nature connectedness, empathy, compassion, individual symptoms, spirituality, cybersickness, presence, and virtual body ownership. Electrodermal activity was measured to capture physiological correlates of emotional arousal.

Results: Individual symptom load decreased significantly through the experience of embodying a growing tree in iVR in both patient groups ($F_{1,38}$=40.93, η_p^2=0.52, 95% CI 0.29-0.67; P<.001). All groups benefited equally from the iVR experience regarding a change in nature connectedness ($F_{1,57}$=100.12, η_p^2=0.637, 95% CI 0.48-0.74; P<.001) and compassion ($F_{1,57}$=12.86, η_p^2=0.18, 95% CI 0.04-0.36; P<.001). The change in empathy did not differ significantly between the 3 groups. The analysis of electrodermal activity during iVR showed significantly higher nonspecific skin conductance response numbers than at the beginning of the iVR (2-tailed t_{53}=4.40, mean difference=2.38, 95% CI 1.30-3.46; P<.001). Changes in compassion were predicted by spirituality (β=–0.35, 2-tailed t_{59}=–2.89, η_p^2=0.13, 95% CI 0.01-0.30; P=.005) and virtual body ownership (β=0.29, 2-tailed t_{59}=2.15, η_p^2=0.08, 95% CI 0.00-0.23; P=.04) but not by the feeling of presence.

Conclusions: Our results indicate that virtually embodying a tree seems to have a positive effect on individual symptoms. Patients with depression and schizophrenia were able to receive an iVR-based intervention and benefited from the experience.

XSL•FO
RenderX

Our results provide a deeper understanding of the phenomenon of virtual body ownership of nature, a specific affordance of iVR, thereby laying the groundwork for future innovative body psychotherapy interventions for individuals with mental health disorders.

KEYWORDS

immersive virtual reality; nature connectedness; psychosis; depression; compassion; empathy; symptom burden; virtual body ownership

Introduction

Background

Positive effects of nature experiences on mental health have been shown by numerous studies and meta-analyses, especially in depressive and anxiety disorders [1-3]. However, a recent systematic review by Paredes-Céspedes et al [4] from 2024 concluded that outcomes of nature-based therapy studies were inconclusive in regard to definitive effects on stress, anxiety, or depression, for example, due to varying interventions, sample sizes, and methods, thereby highlighting the need for further studies on this topic [4]. Regarding the potential therapeutic effects of experiencing nature, the practicability of potential interventions in everyday clinical routines for patients, which sometimes take place far away from nature (eg, in hospitals), has to be considered. Additionally, urbanization means that fewer and fewer people are able to experience nature directly [5].

Virtual reality (VR)–based applications are becoming increasingly important in the development of innovative, easily accessible, therapeutic procedures in mental health care [6,7]. Patients can immerse themselves in various computer-generated environments with the help of a head-mounted display (HMD), ranging from, for example, exposure scenarios for anxiety disorders or substance use disorders to avatar-based interventions for psychotic disorders [6]. Exploring these 3D scenarios, a feeling of "presence," of being in this virtual world, can arise, the subjective correlate of "immersion" as the computer system's capacity to deliver a vivid experience [8]. Related to the sense of presence, "embodiment" is another key concept in immersive virtual reality (iVR), with one of its subcomponents being "virtual body ownership" [9]. Although an experience in iVR cannot replace real experiences in nature [10], a recent study in healthy volunteers compared specific emotions, presence, and immersion in iVR with real natural environments and found that only some aesthetic emotions, state anxiety, and presence, but not immersion, were significantly more intense in real situations than in iVR environments [11]. Studies show that the level of immersion and realism is highly relevant for affective responses to nature scenarios, underlining the importance of iVR over, for example, videos [12]. Especially, virtual body ownership seems to be a promising approach to foster affective and cognitive processes relevant to the feeling of nature connectedness [13,14]. Hence, it is not surprising that interest in iVR-based nature exposure is also increasing in the field of mental health.

Ilioudi et al [15] described the patient experiences of 20 patients with bipolar and unipolar depression who used an iVR calm room with relaxing nature scenarios in an inpatient psychiatric setting. Qualitative interviews showed an increase in awareness, calmness, and well-being as well as patients' gratefulness about these nonpharmacological alternatives for anxiety relief [15].

Another pilot study on the feasibility and acceptability of an iVR relaxation intervention in an acute psychiatric setting showed a statistically significant increase in relaxation, happiness, and connectedness to nature and a decrease in stress, anxiety, and sadness, all measured by visual analog scales (VASs) [16]. Even effects on violence were shown—according to the authors, violent incidents and restrictive practices decreased during the implementation of this iVR-application. The intervention consisted of 1 session, maximum 1 hour, with several possible scenarios open for exploration (eg, a beach and scuba diving with dolphins [16]).

Despite these promising examples, the induction of affective processes and their effects on different psychiatric disorders of such iVR-based nature experiences remain relatively unexplored. In a preceding study with healthy students embodying a tree in a virtual rain forest, previous studies could show that compassion is a crucial influencing factor for the development of nature connectedness [17]. However, deficits in compassion and empathy are described in several psychiatric disorders, whereas patients with schizophrenia, examined with the Multifaceted Empathy Test (MET) and Interpersonal Reactivity Index, showed impairments in cognitive empathy but not emotional empathy [18]; patients with persistent or recurrent depression completing the same tests had deficits in emotional but not cognitive empathy [19]. The importance of these abilities for psychosocial functioning, or on the other side, isolation and social withdrawal is obvious [18,19]. Whether these impairments also influence connectedness to nature in patients with psychotic or depressive disorders remains unclear.

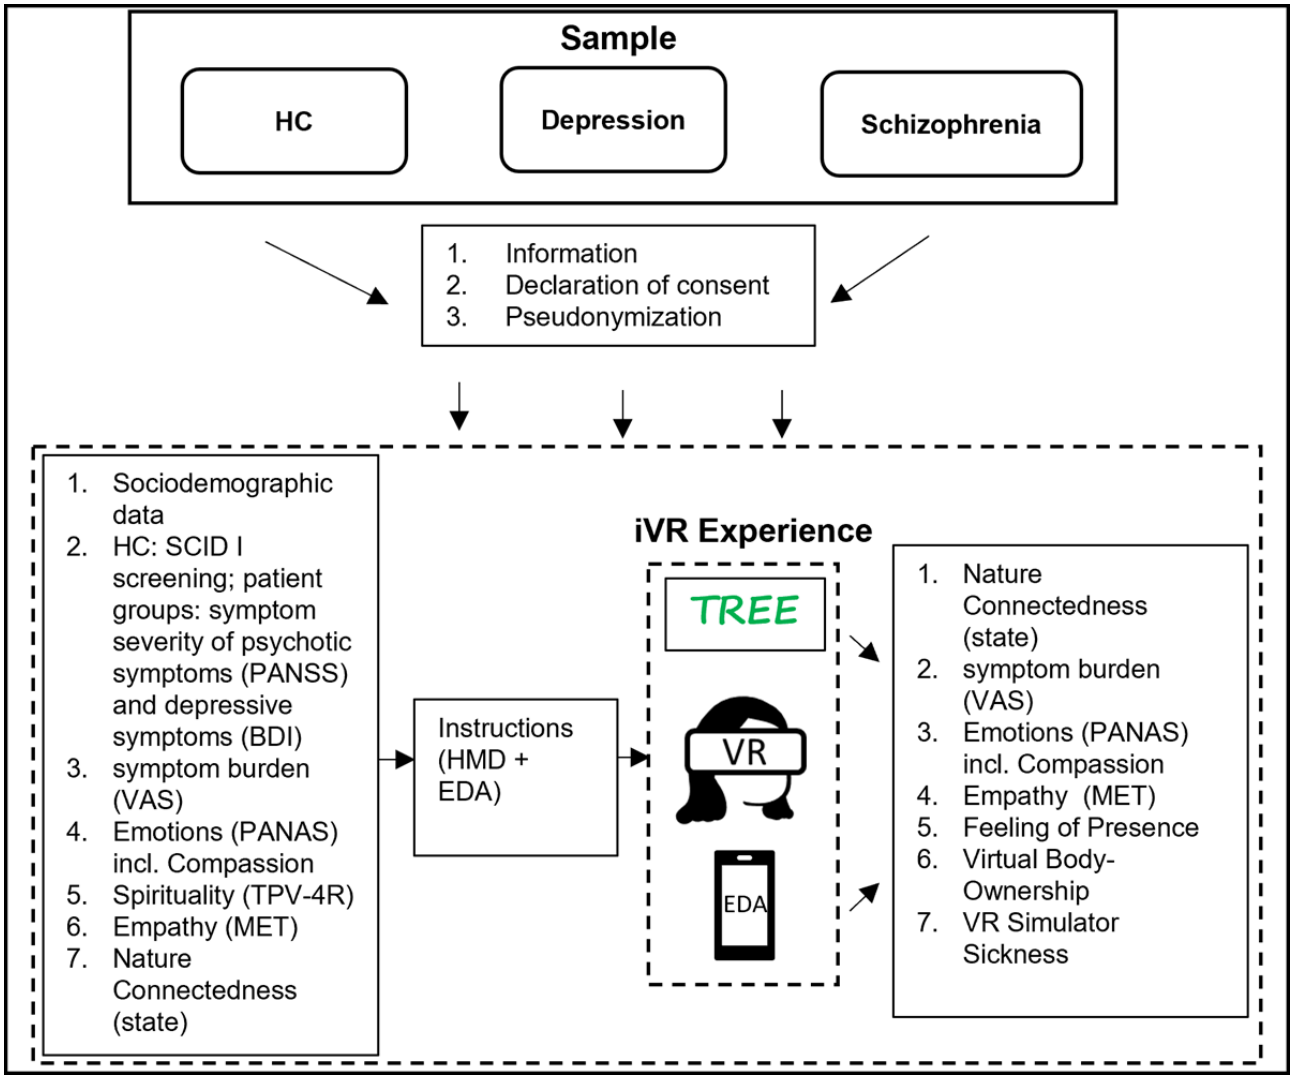
In addition to the development of nature connectedness, iVR-based interventions, especially the experience of virtually embodying a tree, could lead to an enhancement of body experiences, which are also the focus of body psychotherapy interventions [20]. The question arises whether a single iVR intervention is already associated with changes in affect and symptom load, thereby indicating a potential therapeutic effectiveness of such interventions, which could then be investigated in further studies.

Objective of the Study

This explorative study aims to examine the effect of 1 session of an iVR-based nature experience in 2 different patient groups

XSL•FO
RenderX

with highly prevalent serious mental illnesses, patients with depressive disorders, and patients with schizophrenia, compared with a healthy control (HC) group. We test our hypotheses that patients with a depressive or psychotic disorder and HCs show differential effects of the iVR intervention on (1) nature connectedness, (2) empathy, and (3) compassion. In addition, we hypothesize that (4) patients with psychotic or depressive disorder have a lower symptom burden after the iVR experience than before the iVR experience. On an explorative basis, we test the hypothesis that (5) the measurement of electrodermal activity (EDA) before, during, and after the iVR application allows emotional arousal to be objectified. Additionally, we test the explorative hypothesis (H6) that spirituality, presence and virtual body ownership have an influence on nature connectedness, empathy and compassion in all 3 groups.



Methods

Study Design

This clinical trial study aimed to evaluate symptom load, empathy, compassion, and nature connectedness before and after an iVR experience in patients with depressive disorder, patients with schizophrenia, and HC participants (participants between 18 and 65 years of age).

The study was designed as follows. Before participating in the study, participants were informed about the nature of the experiment and declared consent (Figure 1). Symptom severity was assessed with the Beck Depression Inventory (BDI) for depressive symptoms and the Positive and Negative Syndrome Scale (PANSS) for psychotic symptoms. HCs were screened with the Structured Clinical Interview for *DSM-IV* (*Diagnostic and Statistical Manual of Mental Disorders* [Fourth Edition]; SCID I). Being a pre-post intervention, participants filled out an online questionnaire before the VR-exposure, containing questions on sociodemographics, symptom burden perceived in the moment with a VAS, as well as perceived nature connectedness (state), spirituality, and emotions, including compassion (Positive and Negative Affect Schedule [PANAS]) and empathy (MET). After filling out the questionnaire, participants put on the VR headset and were equipped with an EDA measurement device attached to the arm and fingers. After experiencing the VR application for 4 minutes and 20 seconds, participants filled out the post-VR questionnaire, containing items on symptom burden (VAS), nature connectedness (state), emotions including compassion (PANAS), feeling of presence, virtual body ownership, VR simulator sickness, and empathy (MET).

Figure 1. Study Design.

XSL•FO
RenderX

Setting

The experimental setting included a notebook for questionnaire administration and the VR hardware (refer to Material section), arranged in a setting that provided sufficient space for participants. Data collection took place at the Psychiatric University Hospital Charité at St. Hedwig Hospital, Berlin, Germany, over a 4-week period (May 23-June 19, 2024), during which participants were recruited, and data were assessed. Participants were reimbursed with €15 (approximately US $17).

Material

The iVR application "Tree" was used, developed by a group of researchers from the Massachusetts Institute of Technology and filmmakers [21,22]. This application has been used in previous studies to examine its impact on nature connectedness within healthy individuals, observing a positive effect on nature connectedness [13,14,17]. In the application, users explore the growth of a rainforest tree, starting from the viewpoint of a seed under the earth to a fully-grown tree reaching the sky (refer to Figure 2 for a screenshot from the VR application). The illusion of virtual body ownership was induced by synchronous movements of, for example, the arms of participants and the corresponding branch of the tree. While users embody the growing tree, they can watch various animals (eg, ants, birds, and monkeys) around them, as well as other trees in the jungle. In the original version, a forest fire occurs at the end of the experience. However, in this study, we used only the nonthreatening part of the iVR experience, stopping the application after 4 minutes and 20 seconds. The VR sessions were conducted by a psychiatrist (AL) and a second trained experimenter (KL) with experience in VR application and treatment of patients with acute psychiatric conditions. The hardware used for the VR exposure consisted of an HMD (HTC Vive Focus 3, including controllers, field of view 120°, resolution of 2448×2448 pixels per eye, 6DoF, 90Hz refresh rate), a notebook, an Android smartphone, and an EDA device. Patients were standing throughout the exposure and were able to move. The HMD was connected to an Alienware notebook during the entire experiment (Intel Core i9-8 8950HK processor, 16 GB RAM, NVIDIA GeForce GTX 1080, Windows 10 Home). The smartphone was a Samsung S10e running on Android 12, connected to the Mindfield eSense Skin Response Meter (recording at 10Hz).

Figure 2. Own Screenshot of the VR-application Tree purchased from VIVEPORT developed by New Reality Co. (http://newreality.co) [21, 22]. Used under quotation exception for research purposes.

Participants

Participants were inpatients or outpatients and HCs recruited via an open call (purposive sampling) at the Psychiatric University Hospital Charité at St. Hedwig Hospital, Berlin, Germany. Interested parties were invited to a brief information session (approximately 5-10 minutes), during which it was also assessed whether the inclusion criteria were met. The following inclusion and exclusion criteria (Textbox 1) were binding for participating in the study.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Age: 18 to 65 years
- Inpatients or outpatients of the Psychiatric University Hospital Charité at St. Hedwig Hospital
- Diagnosis of schizophrenia (F20; schizophrenia) or unipolar depressive disorder according to the *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*; F32, F33; depression) or healthy controls between 18 and 65 years
- Ability to provide written informed consent after receiving study information

Exclusion criteria

- Acute suicidality or endangerment of others
- Primary eating disorder requiring treatment
- Acute dermatological condition affecting the hands that could interfere with electrodermal activity measurement
- Healthy control group: Diagnosis of a psychiatric or psychosomatic disorder; additional exclusion criteria corresponding to those of the patient group

Assessments

All participants were exposed to the virtual body ownership experience as described in the previous sections. Hypotheses of this study can be found in the Introduction section. Outcomes and methods of assessment are described in detail in the Data Sources section.

Data Sources

Nature Connectedness

Measurement of nature connectedness as a state variable with the "Inclusion of Nature in Self" (INS) scale [23] before and after iVR exposure, based on the German version by Spangenberger et al [13]. The item consisted of a slider based on percentages (0%=zero overlap of "I" and "nature" and 100%=total overlap). Calculating the test-retest reliability revealed a satisfying Pearson correlation of r=0.64.

Empathy

Evaluation of cognitive empathy and emotional empathy explicit with the MET [24], before and after the iVR exposure. Questions on emotional empathy implicit (levels of arousal) were excluded. The questionnaire was divided into 2 equal parts, which the patients completed in pseudorandomized order before and after the iVR exposure. Internal reliability measures were conducted for both pseudorandomized orders and both subscales. The cognitive empathy scale revealed an acceptable internal reliability for both pseudorandomized orders (Order A: pre iVR McDonald ω=0.64, post iVR McDonald ω=0.74; and Order B: pre iVR McDonald ω=0.75, post iVR McDonald ω=0.73). The emotional empathy scale revealed an excellent internal reliability for both pseudorandomized orders (Order A: pre iVR McDonald ω=0.97, post VR McDonald ω=0.97; and Order B: pre iVR McDonald ω=0.95, post iVR McDonald ω=0.97).

Compassion

Evaluation of compassion (state compassion) pre and post the iVR exposure with the PANAS and 5 integrated items measuring compassion based on Pfattheicher et al [25]. The compassion scale revealed a good internal reliability for pre (McDonald ω=0.85) and post iVR exposure (McDonald ω=0.85).

Symptom Burden

Symptom burden was assessed with the VAS (0-10) measuring the burden of the individual 3 main symptoms, previously specified during assessment of symptom severity (PANSS based on Kay et al [26]) and BDI based on Beck et al [27]. Calculating the test-retest, the VAS reliability revealed a satisfying Pearson correlation of r=0.62.

Explorative EDA

EDA was analyzed using the counted number of nonspecific skin conductance responses (NS-SCRs) provided by the Mindfield eSense Skin Response device during iVR exposure.

Structured Clinical Interview for DSM-IV (SCID I)

The screening with SCID I was conducted before the iVR exposure to screen for psychiatric symptoms in the HC group based on First and Gibbon [28]. The SCID I revealed an excellent internal reliability (McDonald ω=0.90; item 3 excluded due to an SD 0).

VR Simulator Sickness

Motion sickness as a potential side effect of iVR, measured with the Virtual Reality Sickness Questionnaire based on Kim et al [29], after exposure. This questionnaire revealed an acceptable internal reliability (McDonald ω=0.70).

Definition of Covariates

Embodiment was assessed as the feeling of virtual body ownership with an adapted and translated subscale of the Embodiment scale by Spangenberger et al [13], based on Ahn et al [30] and Slater et al [31], consisting of 5 items. This questionnaire revealed an excellent internal reliability (McDonald ω=0.95).

Spirituality was assessed using the 4-item short version of the questionnaire "Transpersonales Vertrauen" based on Hampel et al [32] before iVR exposure. This questionnaire revealed a good internal reliability (McDonald ω=0.81).

Feeling of presence in iVR: Scale according to Ahn et al [30], adapted from the "Spatial Presence scale" by Bailenson et al [33], German translation by Spangenberger et al [13], adapted

XSL•FO
RenderX

to the virtual Amazon forest area after exposure. The internal reliability of this questionnaire was acceptable (McDonald ω=0.79).

PANSS was based on the study by Kay et al [26]. Furthermore, 5 subscores according to van der Gaag et al [34] were calculated to better differentiate between positive symptoms, negative symptoms, disorganization, excitement, and emotional distress. The PANSS total internal reliability was excellent (McDonald ω=0.93).

BDI was based on the study by Beck et al [27]. The BDI revealed a good internal reliability (McDonald ω=0.87).

Study Size

Due to the exploratory nature of this study and the lack of comparable studies, the number of cases is not based on a sample size calculation but based on a consideration of feasibility (given the technically complex preparation and implementation), and is intended to provide a basis for subsequent follow-up studies. Effect sizes in the 3 groups could be used in a follow-up study for power analyses and thus for calculating sample size.

Data Analysis

All outcome variables were checked for outliers and extreme values before conducting the analyses. The assumptions for analysis of variance were also examined [35]. The results are presented in the Multimedia Appendix 1.

Baseline characteristics between the 3 groups were compared using either the chi-square test or, if cell counts were less than 5, the Fisher exact test.

To analyze hypothesis 1 (differences in nature connectedness), hypothesis 2 (differences in cognitive empathy and emotional empathy explicit), hypothesis 3 (differences in compassion), and hypothesis 4 (differences in mean VAS scores pre- vs post-iVR exposure), we calculated a repeated measures ANOVA and post hoc tests (Tukey [36]). Additionally, we conducted ANCOVA with depressive (BDI sum score) and psychotic symptom severity (PANSS subscales according to the 5-factor solution by van der Gaag et al [34]) as covariates and delta VAS as the dependent variable.

To test for physical emotional arousal (hypothesis 5), EDA was recorded throughout the experience using the eSense skin-response device from Mindfield, capturing data in µS at a 5 Hz sampling rate. Then, 2 electrodes were attached to the participants' index and middle fingers on the palm side and connected by cable to a smartphone that used the eSense App to measure EDA through skin conductance and NS-SCR. The number of NS-SCRs at the end of the first full minute was set as the baseline. Paired-samples *t* tests were conducted to examine the difference between the mean of the number of NS-SCRs per minute during the iVR and the baseline.

We tested the direct effects postulated in hypothesis 6 with 4 multiple linear regression analyses, examining the influence of each independent variable as a predictor (spirituality, presence, and virtual body ownership) and the combination of them on the dependent variables (nature connectedness, empathy, and compassion).

Ethical Considerations

The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008. The study was approved by the Ethics Committee of Charité - Universitätsmedizin Berlin Institutional Review Board (EA2/04/24; April 26, 2024) and preregistered on ClinicalTrials.gov. All participants gave written informed consent after a previous verbal explanatory discussion and the opportunity to ask questions. They received compensation of €15 (approximately US $17) for their participation. All study data were pseudonymized by sequential numbering (without using initials or dates of birth), and no identification through images or supplementary material is possible.

Results

Descriptive Statistics

Baseline descriptive characteristics of the study participants are displayed in Table 1. One participant stopped the application early due to general discomfort. All other participants completed the full VR application. Mean Virtual Reality Sickness Questionnaire scores were 1.40 (SD 0.301, range 1.00-2.22) for the patient groups, including 3 outliers, and 1.26 (SD 0.173, range 1.00-1.56) for the HC group. Patients showed a mean value of the virtual body ownership items of 4.36 (SD 1.36, range 2.00-7.00), and HCs showed a mean value of 5.35 (SD 1.37, range 1.60-7.00). The presence questionnaire post VR resulted in a mean value of 3.65 (SD 0.708, range 2.40-5.00) for patients and a mean value of 3.60 (SD 0.676, range 2.40-5.00) for HCs.

Hypothesis Outcomes

Hypothesis 1: Patients With a Depressive or Psychotic Disorder and HCs Show Differential Effects of the iVR Intervention on Nature Connectedness

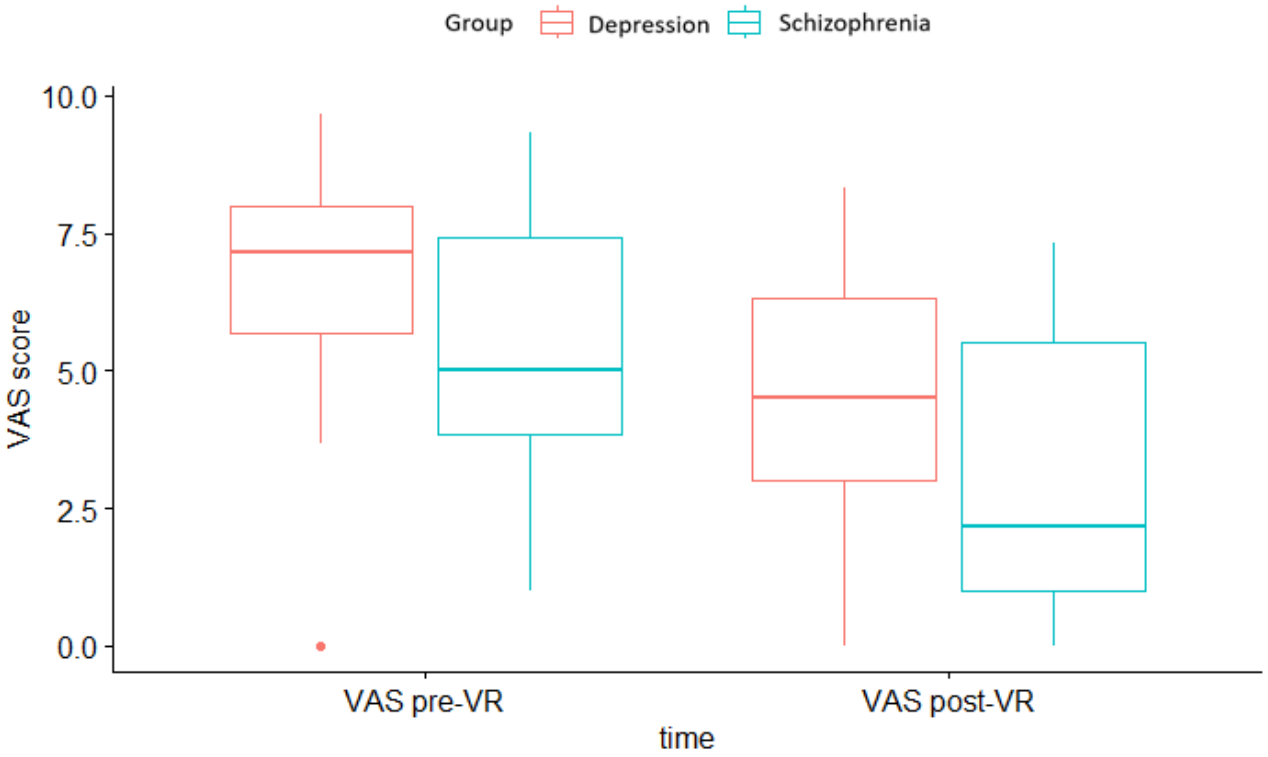
We found a strong increase in nature connectedness on comparing before and after experiences for all groups. Nature connectedness from before to after the iVR experience, INS delta, increased for participants with depression (mean 28.85, SD 26.55), psychotic disorder (mean 32.65, SD 25.86), and HCs (mean 30.70, SD 18.00). The repeated measures ANOVA showed a significant effect of time on changes in nature connectedness with a narrow CI, suggesting a high degree of precision in the effect size estimate ($F_{1,57}$=100.12, η_p^2=0.637, 95% CI 0.48-0.74; *P*<.001) but no significant interaction of group and time ($F_{2,57}$=0.128, η_p^2=0.004, 95% CI 0.00-0.11; *P*=.88). Hypothesis 1 has to be rejected.

Hypothesis 2: Patients With a Depressive or Psychotic Disorder and HCs Show Differential Effects of the iVR Intervention on Empathy

The repeated measures ANOVA showed neither significant effects of time on emotional empathy explicit ($F_{1,57}$=0.03, η_p^2=0.001, 95% CI 0.00-0.06; *P*=.86) or cognitive empathy ($F_{1,57}$=0.77, η_p^2=0.013, 95% CI 0.0-0.1; *P*=.38) for the 3 groups, nor significant interaction of group and time (emotional empathy explicit: $F_{2,57}$=0.68, η_p^2=0.023, 95% CI 0.00-0.22; *P*=.51; and cognitive empathy: $F_{2,57}$=0.54, η_p^2=0.018, 95% CI 0.0-0.2; *P*=.59). Hypothesis 2 has to be rejected.

Hypothesis 3: Patients With a Depressive or Psychotic Disorder and HCs Show Differential Effects of the iVR Intervention on Compassion

The repeated measures ANOVA revealed a significant effect of time ($F_{1,57}$=12.86, η_p^2=0.18, 95% CI 0.04-0.36; *P*<.001) for the change in compassion but no significant interaction of group×time ($F_{2,57}$=1.48, η_p^2=0.05, 95% CI 0.0-0.3; *P*=.24). Hence, compassion increased for all participants after iVR exposure but did not differ significantly between groups. Calculations were repeated after the removal of 3 outliers, showing no significant differences. Hypothesis 3 has to be rejected.



Hypothesis 4: Patients With Psychotic or Depressive Disorder Have a Lower Symptom Burden After the VR Experience Than Before the iVR Experience

Repeated measures ANOVA revealed a significant effect of time—both groups, patients with psychotic and depressive disorders, showed significantly fewer symptoms after iVR exposure ($F_{1,38}$=40.93, η_p^2=0.52, 95% CI 0.29-0.67; *P*<.001), indicating a large and precisely estimated effect. There was also a significant effect of group ($F_{1,38}$=4.68, η_p^2=0.11, 95% CI 0.000-0.314; *P*=.04), indicating significant differences between the groups, but no interaction effect of group and time ($F_{1,38}$=0.021, η_p^2=0.001, 95% CI 0.000-0.074; *P*=.89). Patients diagnosed with depression had a mean VAS score of 6.58 (SD 2.21) before and a mean VAS score of 4.42 (SD 2.50) after the iVR experience. Patients diagnosed with schizophrenia had a mean VAS score of 5.18 (SD 2.31) before and 2.92 (SD 2.52) after iVR. Hypothesis 4 was confirmed. Figure 3 illustrates a

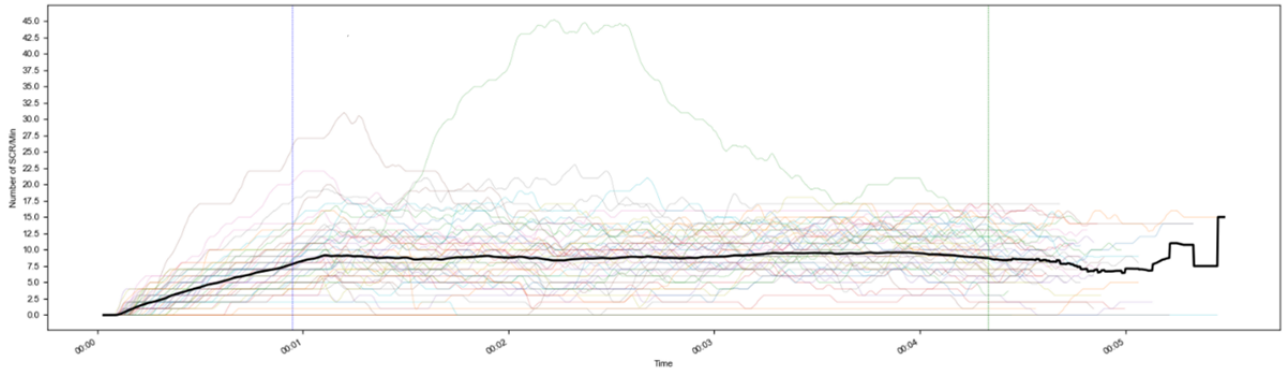
XSL•FO
RenderX

boxplot of pre- and post-VR VAS measures as a measure of symptom burden in both patient groups.

Figure 3. Boxplot of pre- and post-VR VAS measures in both patient groups.

To further explore the influence of the iVR intervention on the change in symptom load of patients with psychosis or depression measured by VAS of the 3 individual main symptoms, we performed an ANCOVA controlling for the covariates, psychotic and depressive symptom severity as assessed with the PANSS, and the BDI before the iVR experience.

The overall model was not statistically significant ($F_{7,32}$=1.44, R^2=0.239, 95% CI 0.000-0.364; *P*=.23). Furthermore, 2 covariates, however, emerged as significant—PANSS factor excitement (β=–0.198, η_p^2=0.127, 95% CI 0.000-0.353, ω^2=0.086; *P*=.03) and PANSS factor negative symptoms (β=0.165, η_p^2=0.063, 95% CI 0.00-0.27, ω^2=0.096; *P*=.03). This suggests that higher levels of excitement symptoms are rather associated with a decrease in change of symptom load (delta VAS), whereas higher levels of negative symptoms are rather associated with an increase in change of symptom load (delta VAS).



Hypothesis 5: The Measurement of EDA Before, During, and After the iVR Application Allows Emotional Arousal to Be Objectified

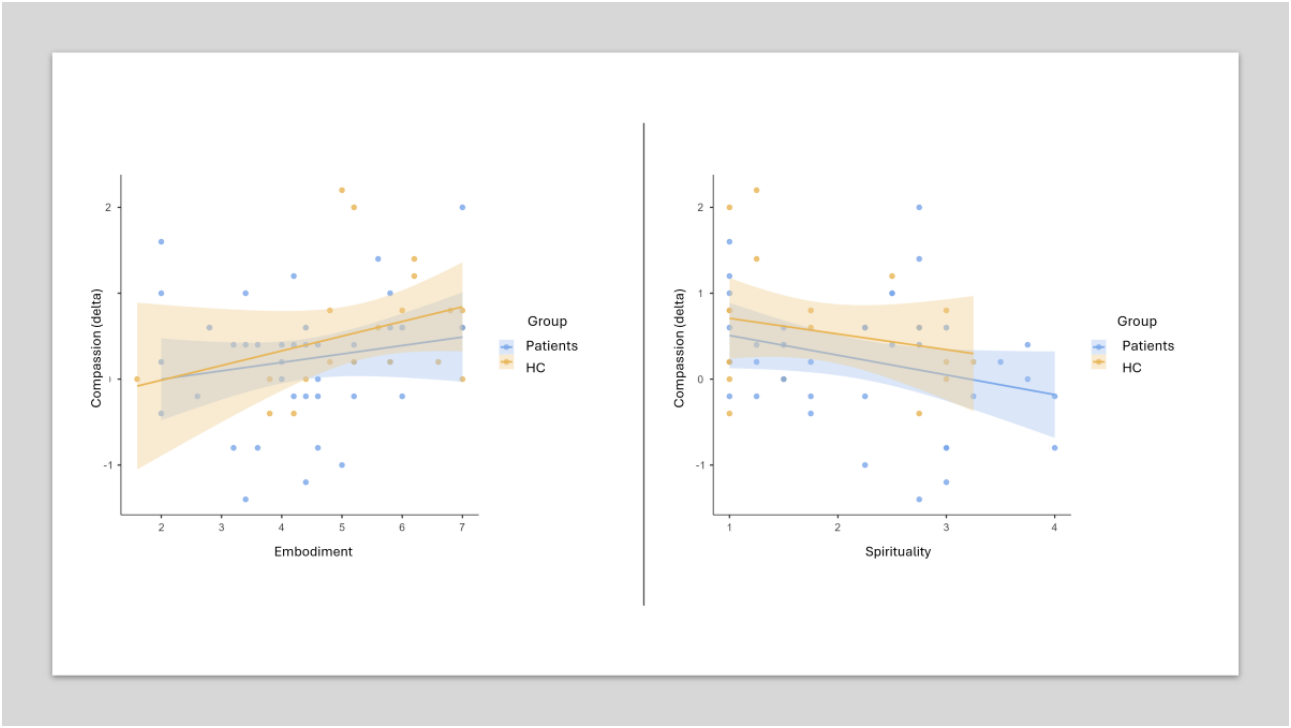
In total, 59 participants were tested for emotional arousal. In 1 case, the EDA device did not work properly because it lost connectivity during the intervention after 3 minutes. In 4 cases, the EDA device recorded no change over time, hinting at a bad connection of the sensor. The average number of counted NS-SCRs at the end of the first full minute in iVR of the remaining 54 participants was interpreted as a baseline (mean 6.92, SD 3.65, 95% CI 5.93-7.90). A relatively low level of physical arousal (mean of the average number of NS-SCRs per minute) during the experience was measured over time (mean 9.30, SD 4.27, 95% CI 8.13-10.05). A paired-samples *t* test was conducted to examine the difference between the average number of counted NS-SCRs at baseline (point 1) and the mean of NS-SCRs during iVR (point 2). The analysis showed that the difference between point 1 (baseline) and point 2 (during) was statistically significant but with a wide CI (2-tailed t_{53}=4.40, *P*<.001, mean difference=2.38, 95% CI 1.30-3.46). EDA before the iVR session was not assessed. Therefore, hypothesis 5 was partly confirmed, as analysis of EDA during iVR showed significantly higher NS-SCR numbers than at the beginning of the iVR application.

In Figure 4, the black line presents the average number of NS-SCRs per minute of all participants, whereas the colored lines are the individual numbers of NS-SCRs per minute. One point in time is marked as the first event when breaking through the soil. The second point in time is marked as an event by means of the end of the scenario.

XSL•FO
RenderX

Figure 4. Number of NS-SCRs per minute.

Hypothesis 6: Spirituality of the Participants, Presence, and Virtual Body Ownership in iVR Have an Influence on Intervention-Induced Changes in Nature Connectedness, Empathy, and Compassion in all 3 Groups



The multiple linear regression analyses revealed that the combination of the 3 predictors (spirituality, presence, and virtual body ownership) did not explain changes in nature connectedness (state; R^2=0.04, $F_{3,56}$=0.72, 95% CI 0.00-0.13; *P*=.55).

The multiple linear regression analysis also revealed that the combination of the 3 predictors (spirituality, presence, and virtual body ownership) did not explain changes in emotional empathy (state; R^2=0.06, $F_{3,56}$=1.21, 95% CI 0.00-0.18; *P*=.31).

Similar results were observed for changes in cognitive empathy. The test revealed that the combination of the 3 predictors (spirituality, presence, and virtual body ownership) did not explain changes in cognitive empathy (state; R^2=0.02, $F_{3,56}$=0.382, 95% CI 0.0-0.09; *P*=.77).

For compassion, the test revealed that the combination of the 3 predictors (spirituality, presence, and virtual body ownership) explained 20.2% of the variance in participants' change in compassion (state; R^2=0.20, $F_{3,56}$=4.73, 95% CI 0.04-0.34; *P*=.005). Whereas the predictor variable virtual body ownership was a predictor of participants' change in compassion (β=0.29, 2-tailed t_{59}=2.15, η_p^2=0.08, 95% CI 0.00-0.23; *P*=.04) and the predictor variable spirituality was a predictor of participants' change in compassion (β=–0.35, 2-tailed t_{59}=–2.89, η_p^2=0.13, 95% CI 0.01-0.30; *P*=.005), the feeling of presence was not a significant predictor (β=0.08, 2-tailed t_{59}=0.6, η_p^2=0.001, 95% CI 0.00-0.10; *P*=.55). This means that the changes in compassion were predicted by participants' spirituality and perceived level of virtual body ownership with moderate to large effects, but not by the perceived feeling of presence (Figure 5).

Discussion

Principal Findings

The study results indicate that engaging with the iVR nature embodiment scenario led to an increase in participants' sense of nature connectedness, as well as a rise in compassion levels across all groups, despite no corresponding change in empathy, and no differential effects between groups (hypotheses 1, 2, and 3). Regarding the effect on symptom load (hypothesis 4), participants reported a reduction in subjective symptom load, as measured by VAS. Complementing these self-reported data, exploratory physiological measures via EDA revealed consistent arousal during the iVR application (hypothesis 5), highlighting that the immersive environment elicited a substantial affective response. Finally, changes in compassion were influenced by individual differences in spirituality and the degree of perceived virtual body ownership (hypothesis 6). Together, these results add further support to the multifaceted effects of iVR interventions on emotional and physiological states.

In general, the investigation of iVR nature exposure on symptom load was an important aim of this study. Here, we could show a significant decrease in individual symptom load in both patient groups, independent of previous symptom burden in the overall model, but significantly influenced by 2 covariates. The significant influence of the 2 PANSS factors, excitement and negative symptoms, calculated according to van der Gaag et al [34], is notable. In view of the known relationship of negative symptoms with poor treatment response [37], this positive association between negative symptoms and change in symptom load gives hope for a potentially effective intervention. Response of different symptom groups to comparable iVR interventions and individual characteristics influencing this response should be further studied, as it is still an insufficiently studied but promising field. Besides the above-mentioned study by Riches et al [16] with n=42 who found a decrease in VAS-measured stress, anxiety, and sadness [16], Ilioudi et al [38] conducted a quasi-randomized cross-sectional trial with 60 patients and compared the effects of iVR and physical calm rooms in acute psychiatric settings. Similar to our study, the authors not only use self-report questionnaires but also physiological parameters (blood pressure and heart rate). Of the 60 patients, 40 used the iVR environment, and 20 entered the physical calm room. Both groups showed an improvement in well-being, measured by VAS, after the intervention without showing significant differences between the 2 options [38]. Considering the potential benefits of iVR, as a cost-effective and space-saving tool, this study gives hope for an easily accessible nondrug therapeutic option. In a second study by the authors, this gratefulness of patients about nonpharmacological options was an important result, speaking for the good acceptance of such approaches [15]. In a longitudinal study over 3-4 weeks, Browning et al [39] examined the effect of daily iVR nature experiences on anxiety, depression, and rumination (n=24 in the iVR intervention group vs n=16 in the control group); however, not in a clinical cohort but in college students. Symptoms of anxious arousal and anxious apprehension decreased, whereas the VR nature experience did not influence anhedonia or rumination, thereby underlining the importance of specifying different symptom groups in a longitudinal setting [39].

Additionally, we could replicate findings from our earlier investigations [13,17] showing that using the *Tree* application fosters nature connectedness assessed with the INS scale. With this study, more than 200 participants tested the application, and in all studies, a significant increase in INS was found [13,17]. We also replicated the finding of an increase in compassion after exposure found in Spangenberger et al [17], as well as the perceived virtual body ownership of participants being a predictor for compassion. As an embodiment of a tree was an integral component of the used iVR scenario (embodying a tree) and a predictor of the changes in compassion, its role should be further studied with a focus on its potential in body psychotherapy, an established approach in the treatment of severe mental disorders [40]. Psychotic negative symptoms in particular are sometimes understood as a form of disembodiment and alienation from the self and are therefore addressed in body-oriented therapies [41]. Even though the relationship between nature embodiment, especially the feeling of growing virtually in this study, and specific symptoms or symptom load in the long term has not yet been sufficiently researched, the promising results from previous studies and this study provide grounds for more detailed investigations.

In this study, we also assessed empathy and observed that it is rather compassion than emotional or cognitive empathy that is elicited by the perceived virtual body ownership experience [17]. Again, we were able to support earlier findings that while compassion has some overlaps with the concept of empathic concern, it is recognized as a distinct emotion, separate from empathy, and is associated with activation in different brain regions [42-44]. Although different impairments of empathy are described in the 2 examined disorders [18,19], we could not find any differences regarding the change of empathy through the exposure between the 3 groups in our study.

Limitations

Several limitations should be acknowledged when interpreting the findings of this study. First, our data were derived from an explorative study with a relatively small sample size, which restricts the generalizability of our results. Thus, further research with larger sample sizes is needed to assess the effects of iVR exposure on emotional or clinical aspects, for example, different categories of individual symptoms. The groups in this study were too small for the latter. Second, singular interventions do not allow for drawing conclusions about the long-term impact of this intervention. Longitudinal studies are necessary to clarify whether these effects change over time. Third, we did not ask participants' previous iVR experience, which may influence observed outcomes. Fourth, we did not include a control group (eg, a different VR scenario) to differentiate between the effects of nature embodiment in iVR and the general effects of iVR, which should be supplemented in future studies. Fifth, the absence of systematic psychological side effect monitoring is due to the exploratory design of this study, but should be addressed in the following studies. Finally, the quality of EDA data collected was limited, likely due to issues related to the lack of a pre-VR baseline, sensor placement, signal noise, or

XSL•FO
RenderX

participants' movement. Even though the decision to not integrate a pre-VR baseline measure of EDA was made in order to limit the time commitment of the patients in this explorative study, future studies should integrate a pre-exposure baseline and separate tonic and phasic activity as recommended [45,46]. Larger samples might be essential for obtaining more reliable physiological measures.

Conclusions

To conclude, the experience of embodying a tree in iVR had immediate benefits, as indicated by positive effects on individual symptoms, an increase in participants' sense of nature connectedness, and a rise in compassion levels. It can be highlighted that patients with psychiatric conditions during inpatient treatment, including patients diagnosed with psychosis, were able to receive an iVR-based intervention and profited from the experience. Despite a still high technological effort to implement VR applications into therapeutic sessions, our study suggests that even a short exposure to becoming a virtual tree can elicit a strong affective response in patients. Given that some clinical facilities in urban areas offer little opportunity for recreation in natural surroundings, and that patients with acute psychiatric disorders are sometimes not able to seek out these surroundings on their own, the use of virtual nature experiences appears to be a promising approach. While these findings are a starting point, long-term effects in follow-up examinations remain to be investigated. Additional research examining sustained outcomes, different intervention dosages (longer or repeated sessions), sham or alternative VR control conditions, as well as the integration of such virtual embodiment practices into established body therapy interventions, would help determine whether this innovative form of iVR exposure can become an effective and easily accessible nonpharmacological tool for patients with severe mental disorders.

Abstract

Background: Few game-based digital mental health interventions have been adopted in clinical practice, where mental health professionals (MHPs) play a critical role in the uptake of new technologies. Existing evidence suggests that MHPs' views on game-based interventions and entertainment video games are mixed, reflecting broader tensions surrounding video games, which are perceived as both harmful and beneficial. However, the underlying reasons for these perceptions have remained unclear, even though they may substantially influence MHPs' willingness to adopt or refuse new clinical solutions.

Objective: This qualitative cross-sectional study investigates how MHPs view entertainment video games and gaming in clinical contexts. By examining these perceptions, the study aims to inform the implementation of game-based digital mental health interventions in health care.

Methods: This study combined 3 qualitative interview datasets (n=19, n=16, and n=6) capturing Finnish MHPs' views on video games and gaming, resulting in a combined sample of 41 participants, of whom 56% (n=23) were women and 59% (n=24) reported playing games. The interview data were analyzed using reflexive thematic analysis. Additionally, 2 post hoc analyses were conducted with complementary qualitative questionnaire data (n=80) collected alongside the first dataset.

Results: In total, 3 themes were generated to reflect the MHPs' views. First, personal recreation, clinically harmful: MHPs demonstrated a self-client attitude asymmetry, describing their own gaming primarily as positive and recreational, while associating clients' gaming with problems. Second, adverse technology and meaningful culture: MHPs expressed attitudinal ambivalence, making sense of gaming through conflicting frames as both potentially harmful technology and meaningful culture. Third, holistic exploration of clients' gaming: MHPs evaluated their clients' gaming within the broader context of the clients' lives. The first post hoc analysis reinforced the observed self-client attitude asymmetry, showing that MHPs associated their own gaming experiences with more positive and fewer negative meanings compared to their clients' gaming. The second post hoc analysis suggested that MHPs expected game-based interventions to be approachable, motivating, and complementary to other treatments, and particularly suited for children and youth, people with strong digital competencies, and clients who were withdrawn.

Conclusions: Existing qualitative research on MHPs' perceptions of video games remains limited and has not examined clinicians' broader sense-making of gaming to inform the implementation of game-based interventions. This study identifies how clinician education can build on MHPs' existing perceptions while addressing potential misconceptions by clearly differentiating game-based interventions from entertainment games, clarifying their clinical aims and mechanisms of action, situating them within clients' broader care and recovery processes, and challenging narrow assumptions about their target audience. Together, these contributions address a critical gap in the literature and inform strategies to improve clinician education, communication, and the adoption of game-based interventions in mental health care.

Introduction

Game-Based Interventions as a New Treatment Modality

Game-based digital mental health interventions use elements from entertainment games to achieve health-related aims [1]. They include both fully fledged serious games and gamified interventions [2], and here we focus on the former category, referred to as game-based interventions. The rationale for designing such interventions includes increasing intervention appeal to facilitate treatment access [3], increasing user engagement with digital interventions to alleviate the well-known challenge of low user engagement [4], and establishing new modes of treatment to complement psychological interventions and pharmacotherapy, which do not help all patients [5,6]. Preliminary evidence supports the efficacy of game-based interventions for depression [7], anxiety [8], and other mental disorders [9,10]. Game-based interventions include, for instance, SPARX for adolescent depression [11]; StarStarter for social anxiety disorder [12]; Embers the Dragon, a child-parent intervention supporting children's emotional development [13]; and EndeavorRx, which has received Food and Drug Administration authorization for the treatment of pediatric attention-deficit/hyperactivity disorder [14]. However, most interventions are still in the research and development stage, few commercial game-based therapeutics are available, and few have been broadly or routinely integrated into clinical practice [15]. Best practices around their use are thus only emerging. The translation from the controlled research environments to real-world settings remains a central challenge for many digital interventions [16], including game-based interventions.

Beyond clinical efficacy, the success of game-based interventions depends on their acceptability [17-19]. The evaluation of acceptability has typically focused on end users [18], but in health care, clinical stakeholders also hold sway; they act as gatekeepers who recommend and prescribe digital interventions [20]. As health care providers' attitudes and consequent behavior can make or break the implementation of novel digital tools [21,22], it is vital to understand their perceptions and consider them in intervention implementation [23-27]. This is particularly significant considering that game-based interventions suggest a change of meaning [28]—what looks like an entertainment video game can be therapeutic. Such a category shift offers opportunities for reconceptualizing and renewing mental health interventions [29], but it can also provoke hesitancy and resistance. Our aim in this study is to examine mental health professionals' (MHPs') views on entertainment video games and gaming in clinical contexts to inform the implementation of game-based interventions.

MHPs' Views on Games Are Mixed

Game-based interventions are still uncommon in clinical practice, and there are few studies examining MHPs' views on them. Surveys indicate that only 12%-16% of psychotherapists know of the existence of such treatments, and only 1%-7% use them [30-32], while there are no data on the uptake of game-based interventions in the regional context of this study, Finland. Game-based interventions are perceived to offer opportunities for clients to engage with therapeutic content, foster self-efficacy and responsibility, and improve therapy access and patient motivation [31]. However, they are also viewed as potentially increasing avoidance and isolation, promoting addictive gambling habits, and devaluing therapy. Moreover, another study found that 5% of psychotherapists exhibit unfavorable and 10% highly favorable attitudes toward game-based interventions [32]. However, the previous studies do not capture the reasons for MHPs' sentiments, which are particularly important to understand when implementing novel solutions in health care contexts.

MHPs' mixed views on game-based interventions may arise from their perceptions of the underlying media, namely, video games. They may associate video games with addictive and violence-inciting potential, while simultaneously being open to using them in clinical contexts [33]. MHPs recognize both disadvantages and benefits related to gaming: "*Paradoxically, it seems that the way gaming benefits one individual may disrupt another and vice versa*," summarize Alho and Mankinen [34]. Such conflicting attitudes mirror lay perspectives regarding video games [33,35] that they are associated with aggressive [36,37] and addictive behavior [38,39], while also being popular entertainment [40,41] and linked to positive effects on affective well-being [42], cognitive skills [43,44], and even intelligence [45,46]. Przybylski [47] encapsulates this attitudinal tension concisely: "*Whether electronic games are on balance a good or bad thing remains an open question, but is a topic about which people hold strong opinions*." This contradiction may be a key distinction between MHPs' views on game-based and non–game-based interventions and underscores the need for further qualitative research to explore the tensions MHPs may perceive. Because most Finnish MHPs do not have first-hand experience with game-based interventions, this study focuses on their views of entertainment video games, the medium on which these interventions are based, and the activity of playing entertainment video games, that is, gaming.

Research Question

The research question guiding this study is as follows: How do MHPs view entertainment video games and gaming in clinical contexts? By examining these perceptions, the study aims to advance understanding of gaming in clinical contexts for researchers and designers involved in the creation, evaluation,

XSL•FO
RenderX

and implementation of game-based digital mental health interventions in health care.

Methods

Research Design Overview

This qualitative cross-sectional study investigated the views of Finnish MHPs on entertainment video games and gaming. This aimed to inform the implementation of game-based interventions, where designers and developers interact with health care professionals and need to be mindful of their perceptions. Aligned with this aim, the research paradigm was interpretive [48], seeking to understand the meanings MHPs assign to video games and gaming. The study data included 3 distinct interview datasets, which were gathered independently by Lukka et al (dataset 1, n=19) [20], Alho and Mankinen (dataset 2, n=16) [49], and Siutila et al (dataset 3, n=6) [50], for a total of 41 MHP interviews. All 3 datasets concerned MHPs' views on video games but used slightly different interview guides as described further in this study in detail. The combined datasets were analyzed using reflexive thematic analysis (RTA) [51,52], which led to the generation of 3 themes. After the interview data analysis, 2 post hoc analyses were conducted using questionnaire data (n=80) that were gathered with dataset 1.

Ethical Considerations

The study and data gathering for dataset 1 were reviewed and approved by the Aalto University research ethics committee (D/508/03.04/2022), and the study was preregistered on the Open Science Framework [53]. The study involving the gathering of dataset 2 did not involve any of the 6 criteria that lead to ethics review in Finland, and therefore, ethics review was not required or applied for [54]. The study gathering dataset 3 was reviewed and approved by the Human Sciences and Ethics Committee of the University of Jyväskylä (80/13.00.04.00/2021).

Dataset 1 is stored securely on Aalto University servers with restricted access to only the researchers of this study, while datasets 2 and 3 are anonymized and stored securely in the Finnish Social Science Data Archive (FSD). The dataset 2 has been published in FSD with permission for secondary analysis [49], and the dataset reuse [55] was justified by the rationale that this study was guided by a different and more interpretive research question. The dataset 3 has also been published in FSD with permission for secondary analysis [50]. The dataset 3 reuse was justified because it was earlier analyzed via completely different research questions and analytical process, which focused primarily on players rather than MHPs.

In all 3 studies, the participants provided informed consent in Finnish. For studies generating datasets 2 and 3, the original informed consent allows for the secondary analysis without additional consent. No compensation was provided to the participants. All data have been reported in a manner that ensures no individual participant can be identified from the study results.

Study Participants

The study participants were Finnish MHPs or psychology students (Table 1). Dataset 1 was gathered to study the role digital tools and video games had on Finnish MHPs' clinical practices. Dataset 2 was gathered to study clinical psychologists' and psychology students' attitudes toward video games, problematic gaming, and gaming disorder [34]. The second author acted as the supervisor for this work. Dataset 3 was gathered to study the difference between 2 types of intensive play—one related to treatment-seeking and the other related to thriving well-being. The research effort was led by the second author (VMK) [56]. The primary participants in the study were people who played digital games actively and had sought help for their gaming-related problems, and those who actively played esports without health problems. These 2 samples of video game players were contextualized with interviews from Finnish MHPs (n=6) who had experience in treating at least 1 client with gaming-related health problems (3 MHPs were therapists, others were clinical psychologists).

[a]MHP: mental health professional.

Participant Recruitment

For dataset 1, the study participants were recruited using a questionnaire distributed through professional associations, health care organizations, social media, and snowballing. A total of 80 MHPs completed an online questionnaire; 46 (58%) wanted to participate only in the questionnaire, and 34 (43%) also in the interview. The first author (LL) contacted 24 MHPs in the latter group via email, primarily in registration order, and received 21 (88%) responses, of whom 2 withdrew before the interview. For dataset 2, the study recruitment occurred in 2 parts. First, psychology students were recruited through the university email list, which led to 8 responses, of whom 6 were interviewed. Then, gaming and nongaming licensed psychologists were recruited using social media and emails. For dataset 3, the participants were recruited through health care institutions and snowballing.

Data Collection

For dataset 1, the first author (LL) conducted the semistructured interviews [57] with the initial aim of examining MHPs' views and needs regarding game-based digital interventions. The researcher's preinterview assumptions and perspectives are described in the study preregistration [53]. The original interview guide consisted of 4 sections—MHP background, views on digital interventions, views on digital games, and views and needs concerning game-based digital interventions. During the early interviews, it became evident that participants had very limited first-hand experience with digital interventions or game-based digital interventions. Consequently, the interview guide was revised (available in the study by Lukka et al [20]) to focus on MHP background, digital tools more broadly, and video games and gaming. The interviews were conducted as a dialogue in which meaning was actively cocreated, and shared understanding was confirmed through the interviews. Member checking was not conducted [58]. The interviews were conducted in Finnish via Zoom (Zoom Video Communications Inc) between May and September 2022, and they had an average duration of 57 (SD 9) minutes. They were audio-recorded with the interviewee's explicit permission, and the first author (LL) transcribed the recordings verbatim for analysis.

For dataset 1, data sufficiency was evaluated using the concept of saturation, such that data collection was concluded when no substantively new information emerged. Saturation was evaluated through analytic memoing conducted during and after the interviews [59]. After 12 interviews, diminishing returns in new information were observed, and the first (LL) and second (VMK) authors agreed that 19 interviews were sufficient to address the original research questions. Data analysis then

XSL•FO
RenderX

commenced, focusing first on the digital tools used by the MHPs, which were reported elsewhere [20]. This analysis did not examine MHPs' views on video games and gaming, because this topic was found to be largely independent of how MHPs used digital tools in their clinical practice.

Subsequently, when preparing the analysis of MHPs' perceptions of video games and gaming, the second author (VMK), who had been involved in the studies gathering datasets 2 and 3, proposed the use of data triangulation. Incorporating datasets 2 and 3 allowed for the inclusion of material gathered by different researchers and using slightly different interview guides and recruitment networks. Consequently, dataset 1 was complemented with these additional datasets to enable data source and investigator triangulation [60], thereby enhancing data richness and credibility.

For dataset 2, the development of the interview guide was guided by the aim of investigating psychology students' and psychologists' views on video games, problematic gaming, and gaming disorder. To study these topics, the interview guide (Alho et al [34]) included 4 sections, that is, background questions to explore participants' clinical background and gaming experience; an adapted version of the Attitudes Toward Gambling Scale 8 [61], in which the word "gambling" was replaced by the word "gaming," to study attitudes toward gaming; follow-up questions on attitudes toward video games; and questions about the new diagnostic category of gaming disorder. The interviews had an average duration of 35 minutes, and they were conducted in Finnish via Zoom between February and March 2021. The interviews were audio-recorded with permission from the interviewee and transcribed verbatim.

For dataset 3, the development of the interview guide was guided by the aim of contextualizing problematic and esports play through interviews with MHPs who had worked with at least 1 individual experiencing gaming-related problems. VMK and Miia Siutila conducted interviews with MHPs using a semistructured 12-item interview guide (Siutila et al [50]), which examined their work context, clinical experiences, practices related to treating clients who lived with gaming-related problems, their personal gaming experiences, and their perceptions of gaming disorders. The interviews had an average duration of 48 (SD 8) minutes, and they were conducted remotely via Zoom between June and November 2021. The interviews were recorded with the interviewees' permission and transcribed verbatim.

Interview Data Analysis

The interview data analysis approach was inductive, interpretive, and pragmatic. This approach was selected due to the characteristics of the research domain [62]; there is little previous research on MHPs' attitudes toward video games and game-based digital interventions, and the existing findings are mixed [63]. Therefore, it was logical to proceed with a ground-up data analysis approach [64] while acknowledging that no research can be fully inductive [65]. The study paradigm was interpretive [48] and aimed to understand the meanings MHPs attributed to video games and gaming in their clinical contexts. The analysis was also influenced by the pragmatic aim of furthering game-based digital intervention development, which is derived from the pragmatist stance in health care [66], which aims to alleviate suffering and improve well-being.

The data was analyzed using RTA [51,52]. The methodological choice was based on our overall evaluation of the research aims, the quality and nature of the data, and our familiarity with the method. We chose to use RTA over coding reliability, thematic analysis, or codebook thematic analysis [65] due to our inductive and interpretive approach. RTA emphasizes the researchers' active and reflexive role in the interpretation of data that occurs at the intersection of theoretical assumptions, analytic resources, and skills, and the data [65,67]. The researcher does not discover, but develops, constructs, and generates themes that are defined as "*patterns of shared meaning, united by a central concept or idea*" [65]. This should lead to a "*compelling, insightful, thoughtful, rich, complex, deep, and nuanced*" analysis, which acted as a quality criterion [68].

The first author (LL) conducted the analysis. It began with combining the datasets 1-3 and familiarization with them while making notes. Then, the combined data were coded using Atlas.Ti 23 software (ATLAS.ti GmbH). RTA emphasizes deep engagement with the data [65], and considerable time was given to generating the themes over a period of over half a year. During this time, the researcher engaged with the data, coded it, took a distance from it, and returned to review the themes several times. The second author (VMK) reviewed and helped revise the generated themes in 4 sense-making sessions with the first author (LL). Through this process, 3 themes were eventually considered to be meaningful and stable. They are illustrated with translated interview quotes and numbers (eg, #1) that connect them to a particular interviewee and dataset (Table 1).

We consider the combined sample and the data, diverse and adequate, to answer the research question. In RTA, it is not recommended to use the concept of saturation [69]. Given the exploratory nature of this study and the complexity of clinicians' perceptions of the topic of gaming, this study does not capture all possible views on the topic. For instance, this study did not gather data on MHPs' views on specific game platforms or genres, or on specific game-based interventions. However, we consider that the sample is sufficient to answer the research question of how MHPs view video games and gaming in clinical contexts. For reference, comparable qualitative research typically requires only 9-17 interviews [70,71], whereas our combined sample included 41 interviews. The inclusion of 3 complementary datasets enhanced the diversity and comprehensiveness of the qualitative material and enabled data source and investigator triangulation [60]. The manuscript was reviewed and revised in consultation with the Standards for Reporting Qualitative Research [72] (Multimedia Appendix 1) and Journal Article Reporting Standards for Qualitative Research [73].

The first author (LL) rooted the analysis in the data while being mindful that their own experiences in the domain inevitably contribute to their interpretations—in RTA, this awareness acts as a resource [65]. Considering positionality, the first author (LL) is a Finnish psychologist who has worked in Finnish mental health care, which allowed them to relate to the participant's

XSL•FO
RenderX

clinical working context. On the other hand, they are experienced in games; they play analog and digital games, have a degree in game design and production, and they have worked with entertainment games [74], gaming disorder [75], and game-based intervention for adult major depressive disorder [76]. This allowed them to connect with the participant's personal and professional experiences regarding video games. The second author (VMK) is an interdisciplinary researcher of play and games, with a specific focus on clinical and psychological approaches to gaming. A personal history of active gaming has also contributed to the second author's researcher position.

Post Hoc Analysis

After the interview data analysis, 2 qualitative post hoc analyses were designed to provide complementary perspectives to the primary interview data analysis. The post hoc data were gathered with dataset 1 using an online questionnaire (Multimedia Appendix 2). The respondent characteristics were 80% (64/80) identified as women, 81% (65/80) were 30-59 years old, 74% (59/80) were psychologists, 78% (62/80) worked full time, 40% (32/80) worked in specialized health care, 39% (31/80) played video games daily or weekly, 35% (28/80) did not play video games at all, and the respondents had an average of 16 (SD 12) years of mental health working experience (Multimedia Appendix 3).

The first theme generated via RTA revealed how MHPs' personal and professional gaming experiences differed, suggesting self-client attitude asymmetry. The gathered questionnaire data allowed for the methodological triangulation of this theme [60]. Therefore, the first post hoc analysis compared the questionnaire respondents' attitudes toward video games in their personal lives (question 22: "*What does playing digital games mean to you?*") and in their professional context (question 25: "*How does video game play exhibit itself in your client work?*"). All participants answered both questions. The analysis was conducted by deductively coding MHPs' open-ended responses by their emotional valence from positive to neutral to negative [59]. Responses containing multiple positions were coded as including multiple categories. For example, the statement "*[Gaming is] a way to spend time, a way to fill time, fun activity, numbing, something that you can use to avoid things and that you can get addicted to*" was coded as both positive and negative. The results were reported as domain summaries [67]. Because these post hoc analyses were qualitative and nonstatistical and used to illustrate patterns of meaning, CIs for coding frequencies are not reported.

The 3 RTA themes did not provide insights into what kind of benefits game-based interventions could have and for whom. Therefore, we decided to complement the interview data analysis with the second post hoc analysis, which analyzed MHPs' responses to the questions regarding the expected benefits of game-based interventions (question 27: "*What benefits in particular would you expect from game-based digital therapies?*") and their target audience (question 30: "*For whom do you think game-based digital therapies would be most useful and why?*"). In total, 79 (99%) participants answered question 27, and all participants answered question 30. The open-ended responses were categorized with descriptive coding [59] and reported as domain summaries.

Results

Overview

The RTA of interview data generated 3 themes (Table 2).

XSL•FO

Table 2. Reflexive thematic analysis of interview data generated 3 themes, which are illustrated with quotes.

Theme	Description	Illustrative quotes
Personal recreation, clinically harmful	MHPs'[a] views on video games were influenced by the context of their gaming experiences. MHPs' self-selected personal gaming experiences were typically positive and associated with recreation and pastime. In contrast, MHPs' professional experiences with gaming occurred in a problem-focused clinical environment, which associated their clients' gaming with mental health challenges, harm, and potential addiction. However, the client cases could also expand MHPs' views on gaming.	• "Games are close to my heart and I have played since I was a kid. My earliest memories are associated with gaming: I played Super Mario Bros 2 on the Nintendo Entertainment System when I was 4-5 years old." [#14] • "I have two children and they play video games. I see what they are doing, and I have learned about that world through them, and I know what it is about." [#17] • "In my work, I am mostly faced with the problems gaming causes." [#1] • "[In the clinical context] I have maybe seen the breadth of problematic gaming more than what I would have seen in a hobby. This has broadened my views on how different people benefit from and have problems with games." [#26]
Adverse technology and meaningful culture	MHPs framed video games as both adverse technology and meaningful culture. Here, framing refers to a process of meaning-making through comparison and association. When MHPs framed video games as technology, gaming was associated with smartphones and digital media, which were perceived to have the potential for excessive use and harms. When MHPs framed video games as culture, gaming was compared to storytelling, hobbies, and arts, which were characterized as meaningful activities and recreation. Many MHPs acknowledged the simultaneous presence of both frames, which reflected the complexity of gaming as a societal phenomenon.	• "We encourage people to read, watch movies, listen to music, and engage in other cultural experiences. I think games could very well be in the same category." [#27] • "I am occasionally frustrated that gaming is presented alongside snus, cannabis, and alcohol in a preventative substance abuse event. Gaming does not belong to that category, it is a hobby." [#40] • "Schools have pretty negative views on gaming. The teachers are concerned that children play a lot and spend a lot of time with digital devices." [#32] • "Games are not a black-and-white thing, but a new phenomenon to cope with. The same goes for smartphones, some people spend way too much time on them." [#16]
Holistic exploration of clients' gaming	MHPs explored their clients' lives holistically: their responsibilities, social interactions, rest, exercise, and recreation. Particular attention was paid to whether any of these activities, including but not limited to gaming, had a detrimental effect on other life domains. Thus, the positive and adverse effects of any activity could only be identified by examining life as a whole. The balance between activities could change over time, and MHPs identified two courses where gaming could evolve from a recreational activity to a problem: from connection to loneliness and from comfort to avoidance.	• "I try to think about life as a whole, about all the things that are important to the person. If you miss out on important because of playing, you play too much. This is true for other things as well: sleeping, working, seeing friends, and spending time with the spouse; so I don't think it merely concerns playing." [#33] • "I think more important than the hours played is whether gaming has a negative influence on other fields of life." [#24] • "I don't believe that [excessive] gaming is the root cause, but a symptom." [#14] • "Most people do not have problems [with gaming]. Those children who have, have other mental health problems or risk factors to them, such as anxiety disorders, social anxiety, maybe difficulties in forming friendships, domestic challenges." [#29]

[a]MHP: mental health professional.

Personal Recreation, Clinically Harmful

MHPs' views on video games depended on whether they considered their own experiences (as players or spectators) or those of their clients. Gaming represented a long-term interest and hobby for several MHPs. One interviewee explained:

> *I have played quite a lot, for as long as I can remember. My first memory, in fact, is of a video game.* [#23]

Such a close relationship with gaming was understandably associated with perceiving the activity positively, even enthusiastically. Other MHPs played digital games more casually or had a more distant, spectator relationship with gaming. Their second-hand gaming experiences involved observing the gaming of their friends, siblings, spouse, and children, and such connections fostered familiarity with gaming and the perception of it as a meaningful recreational activity. Few MHPs associated video games with themes of threat and control, and they discussed the necessity of and challenges with limiting their children's playtime to ensure moderation and daily rhythm.

The positive connotations associated with gaming in personal contexts were less present in problem-focused professional clinical contexts. Working with people who had mental health challenges often focused attention on problems, implicitly associating gaming with risks, harms, procrastination, interpersonal problems, and addictive behaviors. One participant reflected:

> *A psychotherapist always faces things that have become a problem. Then, the first association is that someone has a problem with games, that they are addicted or something.* [#17]

XSL•FO
RenderX

Such a perspective was reinforced by the clients having little need to explore gaming when it was recreational, positive, and meaningful. Therefore, MHPs' professional perspective on gaming could be limited, and some felt their views were not representative of the general population. However, this did not necessarily mean their views were negative. Many MHPs acknowledged that gaming could offer their clients a meaningful way to pass the time, relax, socialize, and manage emotional states, but they commonly considered gaming a conflicted or divided topic that was shadowed by its potential harms.

MHPs' personal gaming experiences were often self-affirmingly positive, whereas their professional context was associated with a greater possibility for attitudinal change and enrichment. Some MHPs, enthusiastic about video games, found that their professional experiences had made them more aware of potential problems associated with gaming. One participant described:

> *Before [running a video-game-related group intervention] I was more open-minded and liberal regarding problematic gaming. Now, I recognize and understand its divisiveness better: even if gaming is meaningful, it is potentially harmful.* [#27]

Conversely, a clinician with initial reservations about video games described how they came to appreciate the value gaming offered their clients:

> *If I was not working here at the neuropsychiatric clinic, I would probably think differently. I would think that games do more harm than good.* [#9]

These attitudinal changes stemmed from client cases that broadened MHPs' perspectives beyond their usual social circumstances. Indeed, some MHPs reflected on case stories, which included cautionary examples, such as a compulsively playing mother and a boy walking into a ditch while playing on their phone, but also inspiring anecdotes, such as a physically disabled youth who found rich social contact through games and highly talented players who earned their living from competitive gaming. These exceptional case stories expanded MHPs' views on gaming through idiosyncratic examples.

Adverse Technology and Meaningful Culture

MHPs framed games as both adverse technology and meaningful culture. By framing, we refer to a process in which the interviewee associated and compared gaming with other activities, thus establishing categorical similarity and connection. This allowed MHPs to make sense of gaming by positioning it within broader societal developments and phenomena, which in turn also rationalized their attitudes and cyclically maintained them. Some MHPs emphasized one frame over another, while others acknowledged that gaming exhibited characteristics of both frames. This introduced tension and made it difficult to make sense of gaming as it was not merely harmful or beneficial, but rather had the simultaneous potential for both. Thus, gaming was a complex, divisive, and even polarizing topic that could not be described in black-and-white terms.

When MHPs framed video games as technology, they grouped and compared them with smartphones, television, streaming services, and social media. Video games were viewed as an inseparable part of societal technologization and digitalization, as well as the growing use of digital media and smartphones, in a negative sense. One interviewee reflected:

> *I think that the problems with video game playing are part of a broader discussion on the use of technology. – – The same types of addictive features are also present in other digital software, not only in games. Therefore, examining video games independently does not capture the whole they are a part of.* [#23]

Some MHPs considered this change to be linked to the technology and gaming industries, which aimed to design highly engaging products to increase their revenues while presenting themselves favorably as providers of employment and tax revenue. The frame of technology was associated with concerns about excessive digital device use, which could disrupt sleep, detach patients from their bodily experiences, and encourage social withdrawal. One participant explained:

> *I am afraid of what kind of a country or world this will become if there is too much digital interaction. It feels as if there is a technological religiosity, and digital playing is only a part of it.* [#21]

When gaming was framed as technology, it was associated with the disproportionate, pervasive, and adverse influence of digital devices on society.

In contrast, some MHPs framed video games as culture. They described gaming as a hobby, pastime, and recreational activity, which associated it with widely accepted activities such as storytelling, reading, doing crossword puzzles, listening to music, going to the movies, and doing handcrafts. This normalized and depathologized gaming and linked it with positive, life-enriching, and meaningful experiences, relaxation, and ways to pass the time. Video games were seen as the latest manifestation of the continuous cultural evolution of recreational activities. One interviewee described:

> *My generation played with dolls, cars, and in sandboxes—these activities have shifted [to video games].* [#19]

Concerns regarding the ill influence of gaming were perceived as an instance of media panic, where the latest form of media was unnecessarily feared and blamed. Within the frame of culture, the distinct feature of video games was their capability to invite participation in an immersive and sensory-rich story. One clinician characterized this as follows:

> *Video games are a form of art that enables processing different themes, telling stories, and stepping into another person's shoes. They do it in a way that is different or unique compared to literature, movies, theater, or other forms of art.* [#31]

These features set video games apart from other forms of culture to which they were compared.

Holistic Exploration of Clients' Gaming

MHPs explored their clients' lives holistically. They found that the universal pillars of a good life consisted of sufficient sleep, nutrition, exercise, social relationships, pursuing livelihood through studies or work, and recreation. MHPs consistently positioned video games within recreation where gaming offered

XSL•FO
RenderX

challenges, feelings of competence, opportunities for social interaction, and a way to unwind and relax. However, they found that evaluating the overall impact of gaming required considering it against the other life domains, because well-being was a matter of balance. One participant described this as "*a golden middle way*" (#32). Another elaborated:

> *If you have a lot of social relationships, do sports, play an instrument, and then sometimes play video games, even a lot, things are in balance. [The influence of gaming] depends on the whole.* [#21]

Vice versa, MHPs agreed that disturbances to the balance between activities lead to problems. This meant that one activity, such as gaming, could cause "*harm to other fields of life*" (#9). This included negative influence on responsibilities, such as work or studies, or the fulfillment of basic human needs, such as nutrition, rest, daily rhythm, exercise, and social contact. Therefore, the activity itself was not perceived as a problem, but its influence on other necessary and intrinsically valuable domains of life. Moreover, the participants did not find that this principle was specific to video games, because anything in excess could be detrimental.

Therapeutic interaction included exploring the position and role video games played in the client's life. The interviewees found that challenges in regulating gaming were rarely the primary reason for help-seeking, but other mental health issues, such as depression and anxiety, were. These symptoms, in turn, had predisposing factors, such as developmental and neuropsychological problems, learning disabilities, and external stressors (such as challenging domestic environments, bullying, bereavement, breakup, and loneliness). From this perspective, an existing behavioral problem, such as excessive gaming, could be a coping attempt to an emotional, social, or cognitive issue. Over time, the role of playing may have changed from an initial solution to a rigid, unsuccessful coping mechanism. One clinician characterized:

> *The motivation to playing may not be the same as it once was. It may be more compulsive and routinized, and you may not enjoy it as much.* [#41]

Thus, using games as self-help could turn from the alleviation of symptoms to the maintenance of the client's issues.

MHPs described 2 problematic pathways in which initial recreational gaming could evolve into a problem—from connection to loneliness and from comfort to avoidance. Regarding the former, MHPs found that players may seek social connection from digital games, for instance, due to shyness or social anxiety. However, finding such online connections may lead to further withdrawal from social contacts outside gaming and exacerbate social anxiety, because the patients do not get exposure to real-life social situations. One clinician described:

> *Multiplayer games are an opportunity to find friends and community from the other side of the world – – but it can also offer an easy way out so that you don't have to think about your feelings of loneliness and find other solutions as you can withdraw to the game world.* [#31]

Considering the latter pathway, the clients may also struggle with stress and depression, and fail to experience meaning in their lives, which can lead to seeking comfort, feelings of competence, and motivation from digital games. However, because gaming requires less effort than studying or working, this may lead to detrimental avoidance behavior, which prevents solving the underlying issues. Using gaming to manage stress, anxiety, and depression may end up aggravating the problems through self-defeating behavior. One clinician portrayed:

> *At least initially, gaming may have been therapeutic. You may have anxiety, depression, or a life crisis, and then you seek comfort from playing. But over time the amount of gaming may increase and become a problem of its own.* [#37]

Differentiating between gaming as an avoidance behavior and a coping strategy could be challenging, but it was considered important in understanding the influence of gaming.

Post Hoc Analysis of Questionnaire Data

Do MHPs' Views on Their Own and Their Clients' Gaming Differ?

This first post hoc analysis triangulated the first theme generated in the RTA, investigating whether MHPs' views on their own and their clients' gaming differed. The post hoc analysis found that MHPs associated their own video game experiences with more positive meanings compared with their clients' gaming (Table 3). When thinking about their own life, 73% (58/80) of MHPs associated gaming with positive meanings, such as recreation, relaxation, benefits, and a way to spend time, whereas considering their clients, only 38% (30/80) made such positive associations. Examining their own life, 16% (13/80) viewed video games in a negative light as uninteresting, uninspiring, addictive, and a waste of time, whereas when thinking about their clients, 64% (51/80) were concerned about excessive gaming, gaming-related interpersonal problems, avoidance behavior, and problems with daily rhythm. Overall, this analysis provided further evidence of the self-client attitude asymmetry concerning video games.

XSL•FO
RenderX

Table 3. The post hoc analysis of open-ended questionnaire responses (n=80) with quotes annotated with the respondent number (eg, #q1). Responses could be coded into multiple categories, and therefore percentages do not sum to 100.

Question and category	Quote	n (%)
"What does playing digital games mean to you?" (question 22)		
Positive or beneficial	• "A way to spend time with my spouse and friends. Pleasant recreation." [#q54] • "An opportunity to momentarily disrupt my thoughts by intensively focusing on something else." [#q46]	58 (73)
Neutral	• "I don't have a relationship with playing." [#q29] • "It is not currently a part of my life at all. I last played in the 90s." [#q17]	19 (24)
Negative or harmful	• "They are something I don't want to give any time from my life." [#q6] • "Senseless waste of time and a residue of childhood." [#q64]	13 (16)
"How does video game play exhibit itself in your client work?" (question 25)		
Positive or beneficial	• "Some clients consider playing a meaningful hobby." [#q9] • "It offers many people a way to relax like watching TV did earlier." [#q39]	30 (38)
Neutral	• "It only shows itself in conversations with clients." [#q44] • "Almost all clients play." [#q21]	25 (31)
Negative or harmful	• "People increasingly use these games to avoid real social contacts." [#q6] • "It maintains insomnia." [#q20]	51 (64)

What Benefits Could Game-Based Interventions Have and for Whom?

This second post hoc analysis complemented the RTA of interview data. It used the open-ended questionnaire responses to investigate what kind of benefits game-based interventions could have and for whom. Many MHPs (n=37, 46%) found that game-based interventions could be approachable and lower the threshold to participate in treatment. Some MHPs (n=20, 25%) expected that game-based interventions could create therapeutic impact by motivating the client to take care of themselves, be more active, build new skills, and self-reflect. Some MHPs (n=18, 23%) found that game-based interventions could augment and complement traditional therapies by providing structured content between sessions. Few MHPs (n=4, 5%) considered that game-based approaches were not feasible because they do not incorporate the crucial salutatory component of therapeutic, interpersonal interaction.

Many MHPs (n=34, 44%) considered that game-based interventions were particularly suitable for children and youth. This view was occasionally rationalized with younger generations being digitally native, and many MHPs (n=33, 41%) considered that competence with computers or playing video games could facilitate the uptake of game-based interventions. While the mentions of gender were infrequent, MHPs exclusively mentioned boys and men (n=6, 8%) when making such remarks. The participants also considered that game-based interventions could be feasible for clients who were hard to reach, withdraw, or have challenges with interpersonal interaction (n=25, 31%), or have neuropsychological challenges (n=5, 6%). In contrast to these cases that exhibited rather severe psychiatric problems, some participants suggested that the client's symptoms should be mild and that the client should be proactive and capable of using such interventions (n=9, 11%). Refer to Multimedia Appendix 4 for quotes.

Discussion

Principal Findings

This qualitative study investigated Finnish MHPs' views on gaming to inform the implementation of game-based interventions in health care. Although previous research highlights the importance of clinicians' views on the adoption of new health care technologies [23-27], detailed accounts of how clinicians make sense of gaming within clinical contexts have remained limited. To address this gap, we analyzed 3 distinct qualitative interview datasets (n=41) using RTA, which converged into three themes: (1) MHPs exhibited a self-client attitude asymmetry where they associated their own gaming positively with recreation while linking their clients' gaming to problems; (2) MHPs' views expressed attitudinal ambivalence: they made sense of gaming through conflicting frames, viewing it simultaneously as harmful technology and meaningful culture; and (3) MHPs evaluated clients' gaming holistically within the broader context of clients' lives (Table 2). Furthermore, 2 complementary post hoc analyses of open-ended questionnaire responses (n=80) further contextualized these themes. The first corroborated the self-client attitude asymmetry identified in the interviews (Table 3). The second expanded the core findings by showing that MHPs expected game-based interventions to be approachable, motivating, and complementary to other treatments, and particularly suitable for children and youth, digitally native generations, and clients who were withdrawn or difficult to reach. Overall, these findings provide nuanced insights into the perceptions shaping MHPs' decisions to adopt and recommend game-based interventions in clinical practice.

XSL•FO
RenderX

Self-Client Attitude Asymmetry

In the first theme, we found that MHPs' personal gaming experiences were positive and associated primarily with recreation. This aligns with previous work showing that limited gaming experience is associated with negative assumptions [47] and that first-hand exposure to gameplay can shift these views. Ferguson et al [77] demonstrated that older adults developed more positive attitudes toward video games after playing one themselves, concluding that "*negative attitudes toward video games exists mainly in the abstract and do not survive direct exposure to individual games*." Because game-based mental health interventions are still rarely used in Finland, MHPs had no first-hand experience of such tools. Offering clinicians opportunities to try game-based interventions as they are introduced in health care may therefore help challenge preconceptions, improve acceptability, and support intervention uptake. These efforts may be further supported by lead users or internal champions [78] who have personal and professional experience of gaming and game-based interventions and can facilitate informed discussions within their organizations.

Previous research has shown that MHPs hold mixed views about gaming and game-based interventions [32,33], but the reasons underlying these perceptions have remained unclear. A key contribution of this study is the identification of a self-client attitude asymmetry; although MHPs viewed their own gaming positively, they tended to perceive their clients' gaming as potentially problematic. This discrepancy may reflect the problem-oriented nature of psychiatric practice [79], where clinical encounters focus on difficulties and challenges, leaving the potential benefits of gaming underrecognized, even when they contribute to clients' well-being. From an implementation perspective, these findings highlight the value of providing clinicians with concrete case examples that illustrate the therapeutic potential of game-based interventions.

Negotiating Attitudinal Ambivalence

The second theme illustrates how MHPs use 2 nonexclusive and at times conflicting frames to make sense of gaming—adverse technology and meaningful culture. Entman [80] defines framing as selecting: "*some aspects of a perceived reality and make them more salient in a communicating text, in such a way as to promote a particular problem definition, causal interpretation, moral evaluation, and/or treatment recommendation*." Thus, these frames allowed MHPs to interpret the complex phenomenon of video games within a broader societal context [81]. Previous research on serious games has identified 4 complementary frames [82]. This study expands the framing approach by focusing specifically on clinical contexts, revealing the 2 frames most salient to MHPs. Furthermore, these 2 frames exhibit attitudinal ambivalence [83], in which both positive and negative evaluations coexist, and suggest that MHPs' perspectives on gaming cannot be accurately represented on a simple positive-negative continuum or measured with a single-dimensional scale.

The conflicting frames may surface in the implementation of game-based interventions, particularly when MHPs draw from broader societal discourses about the risks or cultural significance of video games and apply these discourses to game-based interventions. It may therefore be beneficial to acknowledge these frames and the complexity surrounding the issue of gaming, and to exhibit that the frames applied to entertainment gaming are not necessarily sufficient when considering game-based interventions; entertainment games are used for a range of recreational reasons [84,85], whereas game-based interventions are designed to achieve health benefits [1]. Clients' expectations for game-based interventions are driven by a health-related need that the interventions aim to address through a therapeutic mechanism of action, which are not present in entertainment games. Thus, although game-based interventions may resemble commercial entertainment video games, they function as therapeutic tools or medical devices intended to meet specific health needs. Highlighting this distinction in clinician education and communications can help MHPs focus on the unique features of the technology and its intended purpose.

Contextualizing Gaming

The third theme illustrates how MHPs adopt a holistic view when assessing clients' gaming. They examined the role gaming played in clients' lives and sought to differentiate problematic gaming from gaming that functions as a personal resource [86]. MHPs did not single out video games as a unique threat to well-being [63] but viewed gaming as one influence among many. When gaming presented problems, clinicians often explored how the meaning and motivations behind gaming had changed. Here, we identified 2 pathways through which recreational gaming could evolve into problematic gaming—from connection to loneliness and from comfort to avoidance. These pathways highlight that the functions of gaming are not static, but dynamic, shifting by the players' life context.

The implementation of game-based interventions could benefit from adopting a similar holistic and temporal perspective. The educational and communication materials could emphasize the potential client-experienced benefits and position them within the broader context of their lives. To illustrate the role of game-based interventions in clients' health care and recovery processes, implementation efforts could apply a patient journey approach [87]. Case examples may be particularly effective in demonstrating how game-based interventions match diverse life trajectories and contribute to the lived experience of recovery [88], thereby adding detail to health-related claims.

Broadening Views on Users

The second post hoc analysis revealed that MHPs' attitudes reflected common stereotypes about video game players as male, young, and socially withdrawn—perceptions that have been upheld by media representations [89]. References to player gender were exclusively about boys and men (Multimedia Appendix 4), consistent with the marginalization of female video game players. While men may more commonly identify as gamers [90], approximately half of video game players are female [41], and 59% of Finnish women play video games at least monthly [40]. Given that depressive and anxiety disorders are more common in women [91], it is likely that potential users of game-based interventions for mood disorders may be disproportionately female. This is consistent with our previous

XSL•FO
RenderX

evaluation of a game-based intervention for adult depression, in which 57% (255/445) of participants identified as female, 34% (152/445) as male, and 7% (31/445) as nonbinary [76].

In this study, we also found common age-related stereotypes; many MHPs considered gaming to be an activity for children and youth. However, while the frequency of playing video games declines with age [40], an average player is 33 years old [41], and nearly half of Finns in their 30s play video games weekly [40]. Earlier, we found that a game-based intervention for adult depression attracted two-thirds of participants in their 20s and 30s, with a fourth aged 40-59 years [76], suggesting that there is an adult audience for these interventions.

Finally, some MHPs in this study associated video game playing with social anxiety, withdrawal, and awkwardness. However, previous work found no significant differences in social networks or exercise between online players, offline players, and nonplayers [89]. Overall, there appears to be a clear contrast between MHPs' expectations and the actual characteristics of many game-based intervention users.

This finding has significant implications for the implementation of game-based interventions; their potential target audience may be broader than clinicians assume, and inaccurate stereotypes may inadvertently limit who MHPs recommend such interventions to. To expand understanding of actual intervention users, researchers may need to identify who engages with and benefits from game-based interventions. Target audience profiling [76] and user-journey analyses [92] can help broaden clinicians' perceptions of the intervention user population and highlight cases in which interventions reach underrecognized patient groups, such as women older than 40 years.

Limitations

This study was conducted in Finland, a digitally advanced country [93] where digital solutions are widely used, including in health care [94]. Finland also has an active entertainment game industry, employing 4100 people in 2022 [95], which may contribute to higher digital and gaming familiarity. Regarding representativeness, interview participation may reflect self-selection bias, as individuals with an interest in or favorable attitudes toward the topic may be more likely to participate [96]. The interviews did not capture MHPs' perceptions of the regulatory status of digital interventions, which is a critical factor for their broader implementation. Regulatory frameworks differ across countries, are constantly evolving [97,98], and debate remains regarding which MHPs have the authority to prescribe such interventions [99], which warrant further investigation. Future research should also examine whether the identified frames and self-client attitude asymmetry are expressed in other cultural contexts. There are also opportunities for studying how MHPs' perceptions may differ across certain gaming platforms and genres. Additionally, subsequent studies could broaden the analytical focus from individual MHPs to organizational factors, exploring how clinicians are introduced to and supported in using game-based interventions.

Conclusions

Existing qualitative research on MHPs' perceptions of video games is scarce and has not examined clinicians' broader sense-making of gaming, limiting its usefulness for informing the implementation of game-based interventions. To fill this gap, this qualitative study explored the views of Finnish MHPs and suggests ways to improve clinician education by building on MHPs' existing perceptions while addressing potential misconceptions. Because many MHPs have limited experience with game-based interventions, they tended to interpret them either through their own, often positive, recreational gaming experiences or through clients' gaming-related problems, revealing a previously underexplored self-client attitude asymmetry. Their views also exhibited attitudinal ambivalence, such that they made sense of gaming through conflicting frames as both potentially harmful technology and meaningful culture. To alleviate these tensions, clinician education could more clearly differentiate game-based interventions from recreational entertainment games and highlight their clinical purpose, mechanisms of action, and expected benefits. This communication could be further enhanced by providing clinicians with first-hand exposure to these interventions and by illustrating their therapeutic potential with case examples.

MHPs also tended to evaluate the impact that video games had on their clients' lives holistically and temporally, and they identified two pathways through which gaming could evolve into a problem: (1) from connection to loneliness and (2) from comfort to avoidance. Clinician education could use a similar approach and situate game-based interventions within clients' broader health care and recovery processes. Finally, MHPs often assumed that game-based interventions are best suited for stereotypically male, young, and socially withdrawn individuals. Clinician communication could help challenge these preconceptions and demonstrate how game-based interventions are appealing and relevant to a wider range of users than MHPs may initially assume. Together, these findings address an important gap in the literature and offer practical guidance for improving clinician education, communication strategies, and the adoption of game-based interventions in mental health care.

Acknowledgments

The authors would like to thank the researchers who gathered dataset 2 (Joel Alho and Katja Mankinen), the researchers who gathered dataset 3 (Miia Siutila, Antti Päivinen, Soli Perttu, Tanja Laitinen, and Venla Korhonen), Otso Saariluoma for their comments on the article draft, and all the study participants for sharing their views. Artificial intelligence was not used in the preparation of this manuscript.

Authors' Contributions

The contributions are listed using the CRediT statement [100].
LL: Conceptualization, methodology, investigation, writing – original draft, writing – review and editing, visualization, project administration.
VMK: Writing – review and editing, supervision.
JMP: Funding acquisition, supervision, writing – review and editing.

Conflicts of Interest

LL and JMP are cofounders in Soihtu DTx Ltd, which develops game-based digital mental health interventions.

Abstract

Background: Alzheimer disease (AD) is increasingly conceptualized as a disorder of large-scale brain network disruption rather than isolated regional dysfunction. Immersive virtual reality (VR) may provide a controlled sensory challenge for neurophysiological assessment, but its association with whole-brain electroencephalography (EEG) functional network organization across AD and mild cognitive impairment (MCI) remains insufficiently characterized.

Objective: This study examined whether immersive VR exposure was associated with state-dependent changes in EEG-derived functional network organization among older adults with AD, MCI, and normal cognition (NC).

Methods: This exploratory single-session, 3-group repeated-measures EEG study included 60 older adults: 20 with AD, 20 with MCI, and 20 participants with NC. During a single visit, participants underwent repeated within-session EEG recordings during pre-VR resting, immersive VR exposure, and post-VR resting states. VR was delivered through a head-mounted display presenting a passive first-person roller-coaster environment. Functional connectivity was quantified using phase-locking value (PLV) across multiple frequency bands, and global efficiency (GE), modularity, and nodal strength were calculated to characterize network topology. Between-group differences within each state were assessed using 1-way ANOVA with post hoc pairwise comparisons, whereas within-group state changes were evaluated using paired-sample 2-tailed *t* tests. Benjamini-Hochberg false discovery rate (FDR) correction was applied to inferential graph-theoretical analyses. PLV matrices, nodal strength maps, and connectivity graphs were interpreted descriptively.

Results: In the broadband range, GE was higher in the AD group than in the NC group during the pre-VR resting state (raw *P*=.009; FDR-adjusted *P*=.04), whereas the AD-NC difference was not statistically significant during VR exposure or the post-VR resting state. Baseline modularity was also higher in AD than in NC and remained significant after FDR correction; no significant between-group modularity differences were detected during VR exposure. Within-group analyses showed an FDR-corrected

XSL•FO
RenderX

increase in GE from pre-VR to VR in NC participants and from pre-VR to post-VR in participants with MCI. No within-group GE change in AD remained significant after FDR correction. Descriptive PLV, nodal strength, and connection maps suggested state-associated changes in hemispheric distribution and high-frequency connectivity patterns. However, high-frequency GE findings did not remain significant after FDR correction and were therefore interpreted as exploratory.

Conclusions: In this exploratory single-session, 3-group repeated-measures EEG study, immersive VR exposure was associated with short-term, state-dependent changes in PLV-derived EEG functional network organization among older adults with AD, MCI, and NC. Graph-theoretical analysis demonstrated the feasibility of using repeated within-session VR-EEG measurements to characterize acute network responsiveness across cognitive groups. However, descriptive connectivity maps were not treated as confirmatory evidence, and the absence of a non-VR comparison condition and concurrent cognitive or clinical outcomes precludes conclusions regarding causality or therapeutic efficacy. Larger controlled and longitudinal studies are needed to establish the reproducibility and clinical relevance of these findings.

Introduction

Alzheimer disease (AD) is an insidious and progressive neurodegenerative disorder and the leading cause of dementia [1-3]. It is clinically characterized by progressive cortical atrophy, cognitive decline, and behavioral dysfunction [4,5]. More than 60 million people worldwide currently live with AD, and projections suggest this number will approach 80 million by 2030. AD remains incurable and predominantly affects older adults, with an average life expectancy of only 4 to 8 years after diagnosis [6]. Pharmacological therapies remain the standard approach for slowing disease progression, yet supportive care alone often fails to preserve quality of life [5,7]. Identification of effective nonpharmacological interventions therefore remains essential. Virtual reality (VR) technology has advanced substantially, and immersive neural stimulation may exert distinct modulatory effects on functional brain connectivity [8,9]. This study aims to characterize brain network differences among AD, mild cognitive impairment (MCI), and normal cognition (NC) groups and to investigate whether VR stimulation is associated with alterations in functional brain network organization [10,11]. Electroencephalography (EEG), which records cortical oscillations using scalp electrodes with high temporal resolution, provides a robust tool for this investigation [12-16].

Previous studies have identified hallmark network abnormalities in AD and MCI, including altered phase synchrony, reduced global efficiency (GE), disrupted modular organization, and interhemispheric connectivity imbalance [17,18]. Phase-based metrics such as phase-locking value (PLV) show reduced synchronization in AD, especially across long-range connections, indicating impaired large-scale coordination. GE measures show more complex patterns. Healthy aging typically correlates with reduced efficiency, whereas AD may show paradoxically increased resting-state GE, which may reflect pathological overintegration or loss of modular constraints rather than enhanced processing. Modularity analyses further indicate that AD networks become excessively segregated, with rigid community boundaries that restrict flexible reconfiguration [1,19,20].

MCI represents a transitional stage between healthy aging and dementia and is characterized by heterogeneous and often delayed network responses. Evidence shows that MCI exhibits network properties that are intermediate between those of NC and AD groups, but with significantly reduced dynamic adaptability [21,22]. Most existing EEG studies rely on resting-state recordings, which limit understanding of how pathological networks respond to external stimulation or cognitive engagement.

VR represents a promising nonpharmacological approach for modulating brain function in older adults and neurodegenerative populations. Through immersive, multisensory input, VR can simultaneously engage distributed perceptual, attentional, and sensorimotor networks. Neuroimaging studies suggest that VR stimulation may influence neuroplastic processes, alter hemispheric activity patterns, and promote functional reorganization [23-25]. However, the mechanisms through which VR dynamically modulates large-scale EEG networks in AD and MCI, particularly across frequency bands and temporal stages, remain poorly defined [26,27].

A key unresolved question is whether immersive VR exposure is associated with measurable changes in EEG functional network organization in AD and MCI and whether the observed within-session patterns differ descriptively from those in cognitively normal older adults. To address this question, we conducted an exploratory, single-session, 3-group repeated-measures EEG study using pre-VR resting, immersive VR exposure, and post-VR resting states. By integrating multiband PLV-derived connectivity with graph-theoretical metrics, we aimed to characterize group-related network organization, examine state-associated network changes, and evaluate the feasibility of VR-EEG as an experimental framework for assessing acute neurophysiological responsiveness [28-30]. We hypothesized that immersive VR exposure would be associated with state-dependent changes in EEG-derived functional networks and that the 3 diagnostic groups would show distinct within-session response patterns.

Methods

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and was approved by the Institutional Review Board (IRB) of Kwangwoon University, Republic of Korea, under IRB number 7001546-202300614-HR(SB)-005-01. Written informed consent was obtained from all participants before enrollment.

Participant confidentiality was strictly protected throughout the study. All EEG recordings and demographic information were anonymized and deidentified before analysis. No personally identifiable information was included in the study database, and no identifiable participant images are presented in this manuscript.

Participants were recruited on a voluntary basis and did not receive financial compensation for participation.

Study Design and Setting

This was an exploratory, nonrandomized, single-session, 3-group repeated-measures EEG study. Participants with AD, MCI, and NC underwent repeated EEG measurements during pre-VR resting, immersive VR exposure, and post-VR resting states within 1 experimental session. Diagnostic group constituted the between-participant factor, and experimental state constituted the within-participant repeated-measures factor. All participants underwent the same VR procedure. No randomization, treatment allocation, separate non-VR comparison condition, or longitudinal follow-up was included. The study was designed to characterize short-term EEG functional network responses rather than to evaluate therapeutic efficacy.

Sampling Procedures

Participants were recruited through advertisements at Chuncheon Sacred Heart Hospital within 1 month before the experimental sessions. Patients with AD and individuals with MCI were recruited from hospital patients whose diagnoses and clinical status were confirmed by experienced clinicians. Older adults with NC were recruited from the same hospital-based recruitment setting and were screened for the absence of neurological or psychiatric disorders.

Inclusion and Exclusion Criteria

Inclusion criteria were being aged 60 to 70 years, completion of at least secondary-school education, ability to complete EEG recording, and ability to tolerate VR stimulation. For the AD and MCI groups, participants were required to have a clinical diagnosis established by experienced clinicians. For the NC group, participants were required to have no history of neurological or psychiatric disorders.

Exclusion criteria included severe visual impairment preventing VR participation, inability to complete EEG recordings, severe psychiatric disorders, major neurological diseases other than AD or MCI, and intolerance to VR stimulation. Participants were instructed to avoid medications or substances that could acutely affect EEG activity for at least 24 hours before the experiment whenever clinically appropriate.

Participant Characteristics

A total of 60 older adults participated in this study, including 20 patients diagnosed with AD, 20 individuals with MCI, and 20 participants with NC. All participants were aged 60 to 70 years and had completed at least a secondary-school level of education. Sex distribution was balanced across groups, with 10 male and 10 female participants in each group.

Diagnoses of AD and MCI were established according to standard clinical diagnostic criteria by experienced clinicians. Although standardized cognitive screening scores such as the Mini-Mental State Examination (MMSE) were not available for all participants, the clinical recruitment process ensured that participants within each diagnostic group had comparable clinical presentations based on hospital assessment.

Prior to the formal experiment, all participants completed a 1-minute VR familiarization session using VR content different from that used during the main experiment. This procedure was performed to evaluate tolerance to VR stimulation and minimize adaptation effects. No participant reported dizziness, cybersickness, or other adverse reactions during the familiarization procedure. Visual function was screened prior to enrollment. All participants were able to complete the VR procedure without corrective eyewear and reported no visual difficulties during VR stimulation.

A participant flow diagram summarizing recruitment, eligibility screening, group allocation, VR-EEG recording, and final analysis is provided in Multimedia Appendix 1. Available demographic and clinical characteristics are summarized in Table 1.

Recruitment source	Chuncheon Sacred Heart Hospital	Chuncheon Sacred Heart Hospital	Chuncheon Sacred Heart Hospital
Clinical comparability	Comparable clinical presentation within the AD group based on hospital assessment	Comparable clinical presentation within the MCI group based on hospital assessment	Control participants with NC
Visual function for VR[d] participation	No severe visual impairment preventing VR participation	No severe visual impairment preventing VR participation	No severe visual impairment preventing VR participation
Corrective eyewear during VR	Not used during VR stimulation	Not used during VR stimulation	Not used during VR stimulation
VR familiarization	Completed 1-minute VR familiarization without adverse reaction	Completed 1-minute VR familiarization without adverse reaction	Completed 1-minute VR familiarization without adverse reaction
Final inclusion for EEG[e] network analysis, n	20	20	20

[a]AD: Alzheimer disease.

[b]MCI: mild cognitive impairment.

[c]NC: normal cognition.

[d]VR: virtual reality.

[e]EEG: electroencephalography.

Sample Size, Power, and Precision

Because this was an exploratory single-session, 3-group repeated-measures EEG study, no formal a priori power calculation was performed. The sample size was determined based on participant availability during the recruitment period and the feasibility of simultaneous VR-EEG recordings in older adults with cognitive impairment. The final sample included 20 participants in each diagnostic group, allowing balanced group-level exploratory comparisons of EEG-derived network metrics.

Experimental Design and VR Stimulation

EEG data were collected using a 3-phase experimental paradigm consisting of a pre-VR resting state, a VR stimulation state, and a post-VR resting state.

VR stimulation was delivered using a PICO 4 head-mounted display (PICO Technology). Participants viewed an immersive 3D roller-coaster environment from a first-person perspective. The VR environment consisted of a passive first-person roller-coaster scenario that provided dynamic visual motion cues within an immersive 3D space. The paradigm was designed to provide visual and vestibular-like motion stimulation through optic flow, but participants were not required to perform motor responses, make decisions, or complete memory tasks. The VR stimulation lasted approximately 5 minutes. Participants remained seated comfortably in an upright position throughout the experiment.

Participants were monitored for discomfort, dizziness, and cybersickness during both the familiarization procedure and the main VR stimulation session. No participant discontinued the experiment because of VR-related discomfort. After the removal of the VR stimulus, a post-VR resting state was conducted to evaluate subsequent changes in brain activity. Each phase lasted approximately 5 to 6 minutes, and a 15-minute interval was provided between phases to minimize potential carryover effects.

The pre-VR, VR, and post-VR recordings were repeated within-session experimental states and did not represent longitudinal follow-up assessments.

Measures and Covariates

The primary neurophysiological measures were EEG-derived graph-theoretical metrics, including GE, modularity, and nodal strength, calculated from PLV-based functional connectivity networks. Diagnostic group and experimental state were the main grouping variables. Standardized cognitive screening scores, such as MMSE, were not available for all participants and were therefore not included as covariates in the statistical analyses.

EEG Data Acquisition

EEG signals were recorded using a HydroCel Geodesic Sensor Net (Electrical Geodesics) coupled with an EGI NetAmps 300 amplifier (Electrical Geodesics). A total of 64 electrodes were placed according to the International 10-20 system. Signals were sampled at 1000 Hz, and Cz was used as the reference electrode throughout acquisition.

Electrode impedance was maintained within clinical recording standards during data acquisition. Participants were instructed to remain seated, relaxed, and to minimize head, facial, and limb movements throughout recording. EEG data were collected during all 3 experimental states: pre-VR resting, VR stimulation,

XSL•FO
RenderX

and post-VR resting. During the pre-VR and post-VR resting states, participants remained awake and visually fixated without active task performance. During VR stimulation, the headset was positioned carefully to avoid excessive pressure on the EEG electrodes and to minimize mechanical artifacts during simultaneous VR-EEG recording [31,32].

EEG Preprocessing

EEG preprocessing was performed using EEGLAB. Raw EEG data were imported from EGI MFF files, and electrode locations were assigned using a 68-electrode channel-location file. Before independent component analysis (ICA), the data were high-pass filtered at 1 Hz. The data were then rereferenced using T7 and T8 as reference channels; if the specified reference channels were unavailable or failed validation, average referencing was used instead.

ICA-based artifact correction was performed using the extended runica algorithm in EEGLAB. To account for rank reduction after rereferencing, ICA decomposition was performed with principal component analysis (PCA) dimensionality reduction, using up to 64 principal components. Independent components were classified using ICLabel. Components classified as muscle, eye, heart, line-noise, or channel-noise artifacts with a probability of 0.90 or higher were automatically flagged and removed, whereas components classified as brain or other were not automatically rejected. Across the analyzed ICA-cleaned EEG recordings, the number of removed independent components was 7.68 (SD 7.32) per recording, with a median of 6 and a range of 0 to 32 components. After ICA-based artifact correction, the data were low-pass filtered at 70 Hz and saved as ICA-cleaned EEG datasets.

Following artifact correction, EEG signals were decomposed into multiple frequency bands, including δ (1-4 Hz), θ (4-8 Hz), α (8-13 Hz), β (13-32 Hz), γ (32-70 Hz), and a full-spectrum band (1-70 Hz) [33]. After preprocessing, artifact-free 1-second epochs were extracted for further analysis. For each participant and experimental phase, 30 clean epochs were selected and used for subsequent functional connectivity analysis.

Functional Connectivity Analysis

Functional connectivity was quantified using the PLV, which measures the consistency of phase differences between 2 signals over time. For channels *i* and *j*, PLV was computed as:

where $\varphi_i(t)$ and $\varphi_j(t)$ denote instantaneous phases obtained using the Hilbert transform. PLV values range from 0 (no phase synchronization) to 1 (perfect synchronization) [34].

Network Construction and Thresholding

Functional brain networks were constructed based on PLV connectivity matrices derived from the preprocessed EEG signals. In the resulting network representation, each node corresponded to an EEG recording channel, and edges represented the PLV-based functional connectivity strength between pairs of channels.

For descriptive network visualization, a proportional thresholding approach was applied to the group-averaged PLV connectivity matrices. Specifically, only the top 5% of the strongest PLV connections were retained in the visualization graphs, while weaker connections were not displayed. This thresholding step was used to improve the interpretability of the network maps and to highlight the dominant spatial distribution of strong functional connections.

The 5% proportional threshold was selected as a literature-informed and visualization-oriented threshold. Previous EEG graph-theoretical studies have displayed only the strongest subset of functional connections to improve the interpretability of network topology and connection changes. For example, Liang et al [35] visualized only the upper 30% of mutual information values in a 19-channel EEG network to better illustrate network connection changes. In the present study, the number of EEG nodes and possible pairwise connections was substantially larger. Therefore, retaining higher proportions of connections, such as 20% or 10%, produced dense and visually cluttered graphs, with many overlapping edges that obscured the dominant spatial connectivity patterns. The 5% threshold provided the clearest visualization of the strongest PLV connections and regional network differences. Therefore, the top 5% of strongest PLV connections were retained only for network visualization and descriptive connectivity mapping. GE and modularity were calculated from weighted PLV matrices, whereas the top 5% proportional threshold was applied only to descriptive network visualizations.

Graph-Theoretical Measures

Overview

Graph-theoretical metrics were calculated to characterize the topological properties of the constructed brain networks. In particular, GE was used to evaluate the efficiency of information integration across the entire network.

GE quantifies the capacity of a network to support parallel information transfer between distributed brain regions and is defined as:

where represents the number of nodes in the network and L_{ij} denotes the shortest path length between nodes *i* and . A higher GE value indicates a more efficient network organization with stronger global integration and more effective communication between brain regions [36].

Modularity

Modularity measures the extent to which a network can be partitioned into densely connected modules with sparse intermodule connections. It is defined as:

where A_{ij} represents the edge weight between nodes *i* and *j*, k_i denotes node strength, *W* is the total edge weight, and $\delta(c_i,c_j)$ equals 1 when 2 nodes belong to the same module and 0 otherwise [37]. For modularity estimation, the Louvain

XSL•FO
RenderX

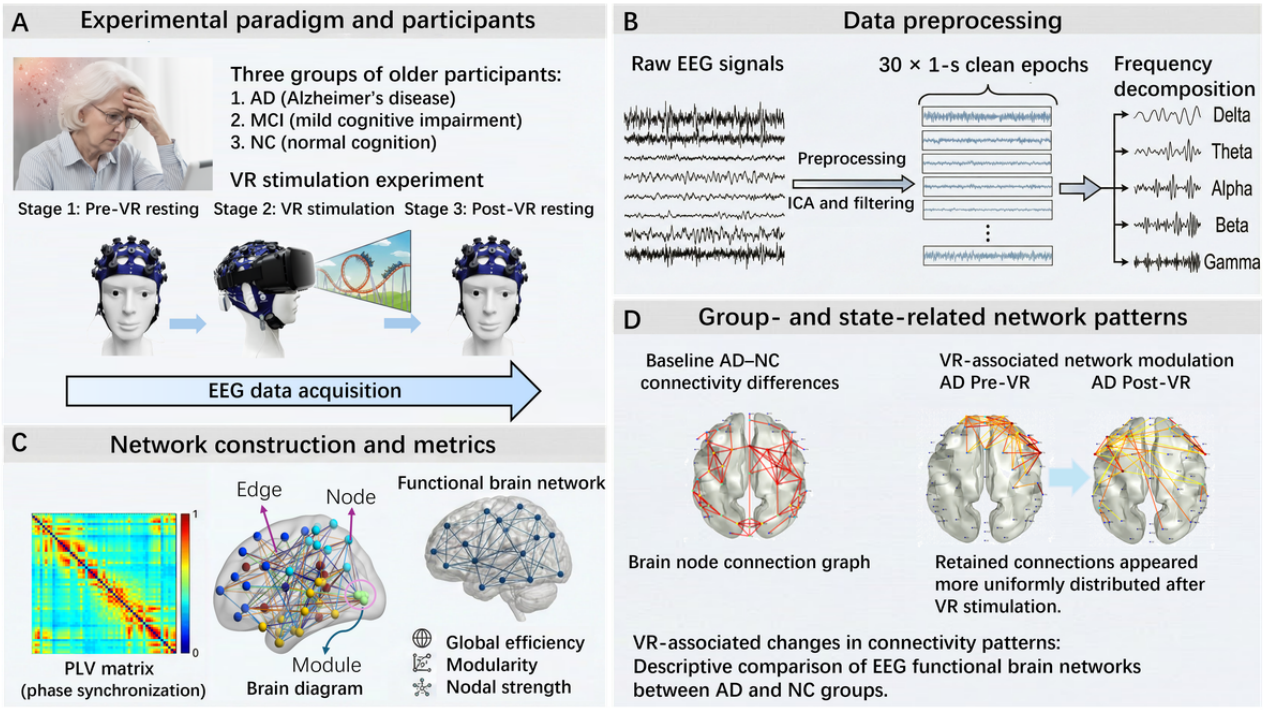
algorithm was repeated 30 times, and the highest Q value was retained for each epoch.

Nodal Strength

Nodal strength was calculated as the sum of the weights of all edges connected to a given node, reflecting the overall level of connectivity of that node within the network [38].

Visualization and Statistical Analysis

Brain network visualizations were generated to illustrate the spatial distribution of functional connectivity and to highlight long-range and interhemispheric connection patterns across experimental conditions. Connectivity graphs were projected onto scalp topography to provide an intuitive representation of network organization for each group and experimental state [35,39].



For statistical evaluation, graph-theoretical metrics were compared across diagnostic groups (AD, MCI, and NC) and experimental states (pre-VR resting, VR stimulation, and post-VR resting). Between-group differences within each experimental state were first assessed using 1-way ANOVA. When significant group effects were detected, post hoc pairwise comparisons using independent-sample 2-tailed *t* tests were performed to identify specific between-group differences. Within-group comparisons across experimental states were performed using paired-sample *t* tests. These statistical analyses were conducted to determine whether VR stimulation was associated with measurable modulation of brain network topology across the different cognitive states [40,41]. When reported, 95% CIs were calculated using the t distribution based on the corresponding group sample size.

Statistical significance was initially defined as $P<.05$. To control for multiple comparisons, *P* values were adjusted using the Benjamini-Hochberg false discovery rate (FDR) procedure [42]. FDR correction was applied separately within each graph-theoretical metric and comparison family. Specifically, between-group comparisons within the same experimental state and within-group comparisons across experimental states were treated as separate comparison families. Both raw *P* values and FDR-adjusted *P* values are reported where applicable.

Missing Data

No participant-level data were missing in the final dataset. During EEG preprocessing, artifact-contaminated segments were removed according to the predefined quality-control procedures. For each participant and experimental condition, 30 artifact-free epochs were retained for subsequent analyses, ensuring an equal number of observations across groups and experimental states. The overall VR-EEG experimental and functional network analysis workflow is shown in Figure 1.

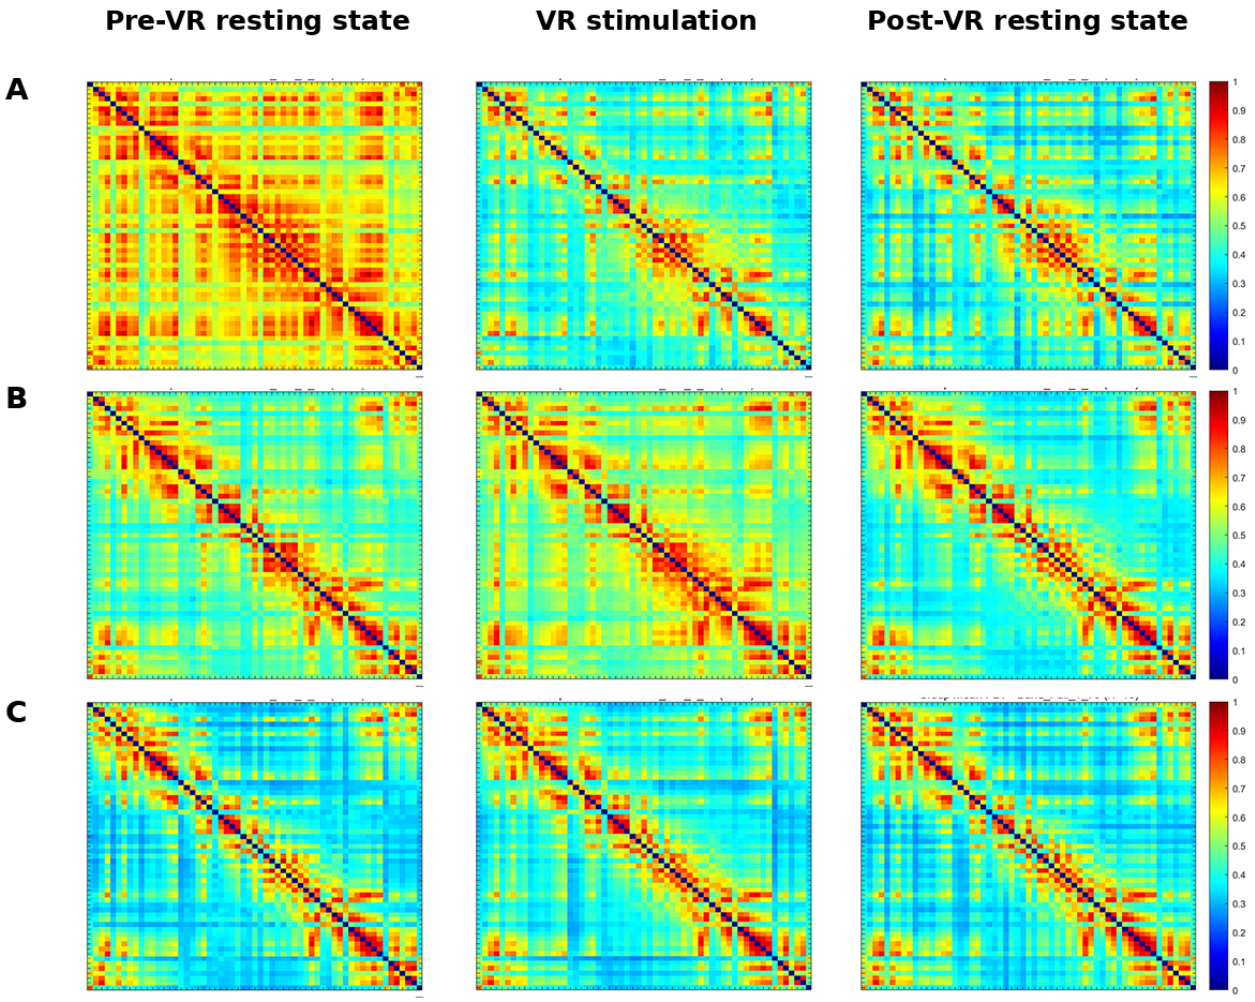
Figure 1. Virtual reality (VR)–based electroencephalography (EEG) network analysis workflow in AD. (A) Experimental paradigm and participants: EEG was recorded from AD, MCI, and NC groups during 3 stages: pre-VR resting, VR stimulation, and post-VR resting. (B) Data preprocessing: raw EEG signals were cleaned using preprocessing and independent component analysis (ICA) filtering, followed by frequency-band decomposition. (C) Network construction: functional brain networks were constructed using phase-locking value (PLV)–based connectivity, and graph metrics (global efficiency, modularity, and nodal strength) were calculated. (D) Group- and state-related network patterns: descriptive network differences between AD and NC were analyzed to illustrate VR-associated changes in connectivity distribution.

XSL•FO
RenderX

Results

Overview

Unless otherwise specified, inferential statistical conclusions were based on graph-theoretical metrics, including GE and modularity. PLV matrices, nodal strength distributions, and node connection graphs were used primarily as descriptive visualizations to illustrate spatial connectivity patterns and to support interpretation of the quantitative network results.



PLV Matrix

The PLV connectivity matrices were used as descriptive visualizations to illustrate broadband functional connectivity patterns across diagnostic groups and experimental states. In the pre-VR resting state, the NC group visually showed stronger broadband coupling, whereas the AD group showed weaker and less distributed connectivity patterns, with the MCI group showing intermediate features.

During VR stimulation, the PLV matrices suggested a change in broadband connectivity organization, particularly in the NC and AD groups. In the NC group, broadband PLV patterns appeared less globally dense during VR stimulation, whereas the AD group showed relatively limited changes in overall coupling strength. In the post-VR resting state, visual differences among the 3 groups appeared less pronounced than those observed at baseline.

Because these PLV matrices were intended primarily for visualization, formal statistical interpretation was based on subsequent graph-theoretical metrics, including GE and modularity. These descriptive PLV patterns provide spatial context for the quantitative network changes reported below. The broadband PLV connectivity matrices across diagnostic groups and experimental states are shown in Figure 2.

Figure 2. Phase-locking value (PLV)–based functional connectivity matrices across experimental stages. (A) PLV matrices of the normal cognition (NC) group. (B) PLV matrices of the Alzheimer disease (AD) group. (C) PLV matrices of the mild cognitive impairment (MCI) group. For each group, connectivity matrices are shown for 3 experimental stages: (1) pre–virtual reality (pre-VR) resting state, (2) during VR stimulation, and (3) post-VR resting state. The matrices represent functional connectivity in the full frequency band (1-70 Hz), where warmer colors indicate stronger phase synchronization between electroencephalography (EEG) channels.

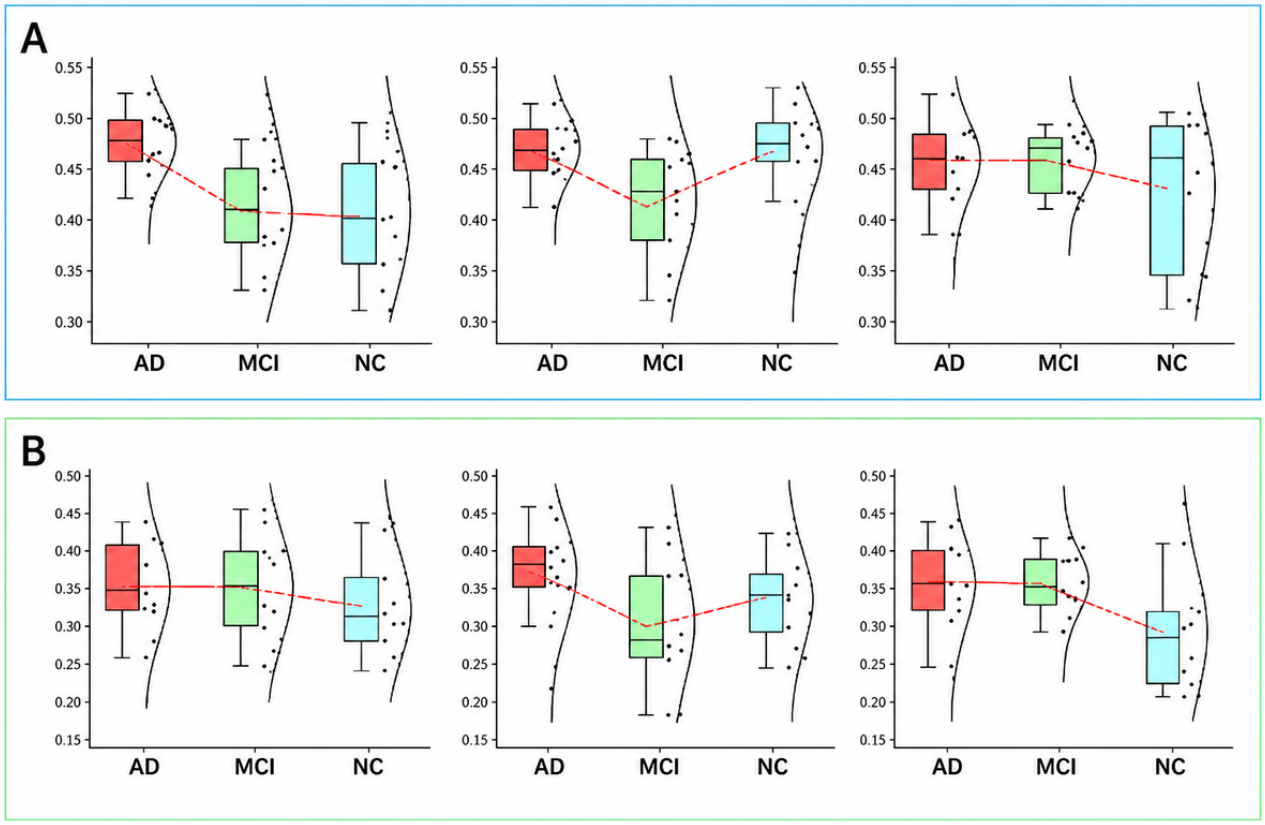
GE Values

Figure 3 illustrates GE values across frequency bands and experimental states in the NC, MCI, and AD groups. Descriptively, GE values tended to be higher in the 13 to 32 Hz range than in lower-frequency and higher-frequency bands across several groups and experimental states. This pattern suggests that beta-band activity may contribute to large-scale network integration in the present EEG dataset. However, because frequency-band comparisons were primarily descriptive, this observation should be interpreted cautiously and not as confirmatory evidence of a frequency-specific network mechanism.

Figure 3. Global efficiency across frequency bands and experimental states. (A) Global efficiency values of the normal cognition (NC) group across frequency bands during the 3 experimental states: pre–virtual reality (pre-VR) resting, VR stimulation, and post-VR resting. (B) Global efficiency values of the mild cognitive impairment (MCI) group across the same frequency bands and experimental states. (C) Global efficiency values of the Alzheimer disease (AD) group across the 3 states.

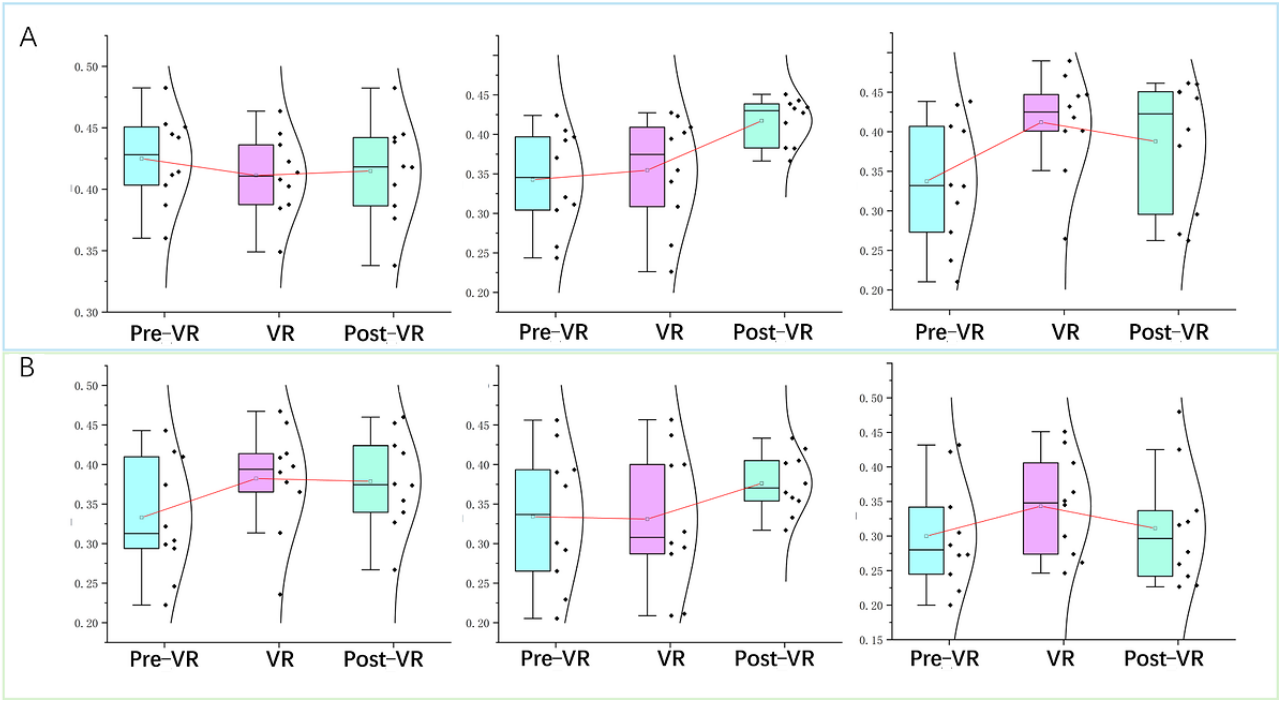


In the broadband frequency range (1-70 Hz), between-group differences in GE were most evident during the pre-VR resting state. In the pre-VR condition, patients with AD exhibited higher GE than both NC participants (AD: 0.425, SD 0.036, 95% CI 0.408-0.442; NC: 0.337, SD 0.081, 95% CI 0.299-0.375; raw P=.009; FDR-adjusted P=.04) and patients with MCI (MCI: 0.343, SD 0.064, 95% CI 0.313-0.373; raw P=.003; FDR-adjusted P=.03). During VR stimulation, the difference in GE between the AD and NC groups was no longer significant (AD: 0.411, SD 0.033, 95% CI 0.396-0.426; NC: 0.412, SD 0.065, 95% CI 0.382-0.442). GE in the AD group was higher than that in the MCI group during VR stimulation in the uncorrected analysis (MCI: 0.355, SD 0.071, 95% CI 0.322-0.388; raw P=.04); however, this comparison did not remain significant after FDR correction (FDR-adjusted P=.12) and was therefore interpreted as an exploratory trend. In the post-VR state, GE values in the AD and NC groups converged, and no significant difference was observed between the 2 groups.

A comparable descriptive trend was observed in the high-frequency band (32-70 Hz); however, no between-group or within-group state comparison in this frequency band remained significant after FDR correction. Therefore, high-frequency GE findings were interpreted as exploratory patterns rather than confirmatory statistical effects. Across all experimental states, the MCI group generally exhibited intermediate GE values between the AD and NC groups, accompanied by moderate state-dependent variations. These results suggest that VR stimulation was associated with dynamic changes in network integration, with reduced AD-NC group differences in GE during and after VR stimulation. Each panel shows the distribution of GE values for the 3 diagnostic groups, illustrating group-level differences in network integration under different VR conditions in Figure 4.

XSL•FO
RenderX

Figure 4. Group comparisons of global efficiency (GE) across experimental states. (A) GE comparisons among Alzheimer disease (AD), mild cognitive impairment (MCI), and normal cognition (NC) groups across the 3 experimental states (pre–virtual reality [pre-VR], VR stimulation, and post-VR) in the broadband frequency range (1-70 Hz). (B) Global efficiency comparisons among the 3 groups across the same experimental states in the gamma frequency band (32-70 Hz).



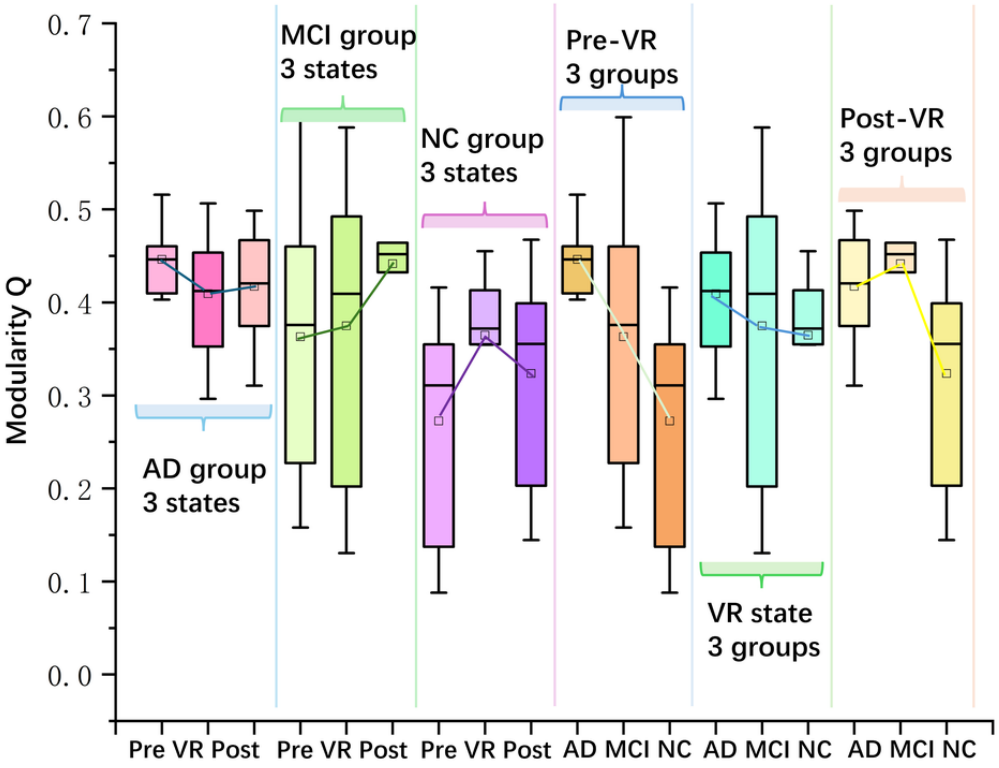
These findings suggest distinct patterns of GE modulation across the clinical groups. At baseline, patients with AD exhibited elevated GE, suggesting altered or dysregulated network integration. During VR stimulation, GE in the AD group showed a decreasing trend; however, within-group GE changes in the AD group did not remain significant after FDR correction.

In contrast, participants in the NC group demonstrated a significant increase in GE during VR stimulation (pre-VR: 0.337, SD 0.081, 95% CI 0.299-0.375; VR: 0.412, SD 0.065, 95% CI 0.382-0.442; raw *P*=.007; FDR-adjusted *P*=.04). This increase suggests state-dependent upregulation of large-scale functional integration in response to sensory stimulation. The MCI group did not show an immediate increase in GE during the VR phase; instead, GE increased from pre-VR resting to the post-VR state after FDR correction (raw *P*=.009; FDR-adjusted *P*=.04), suggesting a delayed network response following stimulation.

This temporal pattern suggests that network responsiveness in MCI may be partially preserved compared with AD, but that the dynamic regulation of global integration may occur more slowly. Taken together, these findings suggest a possible continuum of network dysfunction from NC to MCI to AD, characterized by rapid GE modulation in NC, delayed GE changes in MCI, and limited within-group GE modulation in AD. Each panel illustrates the distribution of GE values across experimental states, highlighting state-dependent modulation of network integration within the AD, MCI, and NC groups in Figure 5.

XSL•FO
RenderX

Figure 5. State-dependent changes in global efficiency (GE) within each clinical group. (A) GE across the 3 experimental states—pre–virtual reality (pre-VR) resting, VR stimulation, and post-VR resting—within each group (Alzheimer disease [AD], mild cognitive impairment [MCI], and normal cognition [NC]) in the broadband frequency range (1-70 Hz). (B) Global efficiency across the same experimental states within each group in the high-frequency band (32-70 Hz).

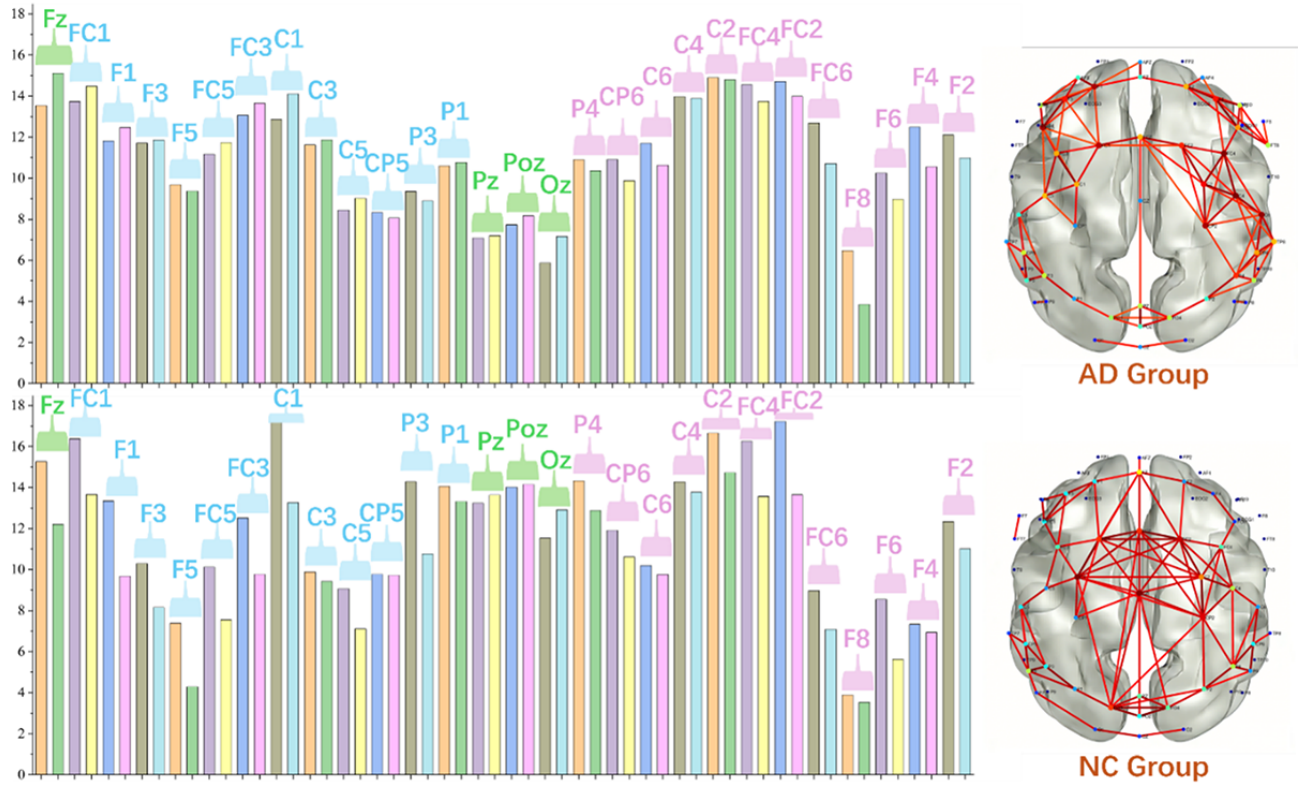


Modularity

Modularity analysis revealed a robust baseline group difference and descriptive state-dependent patterns across clinical groups, partially paralleling the patterns observed for GE [43]. In the pre-VR resting state, patients with AD exhibited higher modularity than NC participants, and this difference remained significant after FDR correction (AD: 0.446, SD 0.036; NC: 0.273, SD 0.120; raw *P*=.001; FDR-adjusted *P*=.01), while the MCI group showed intermediate values (0.363, SD 0.146). During VR stimulation, modularity values converged across the 3 groups, and no significant between-group differences were observed after FDR correction. In the post-VR state, modularity values in the AD and MCI groups were comparable, and both were numerically higher than those of the NC group. The MCI-NC difference was significant in the uncorrected analysis but did not remain significant after FDR correction (raw *P*=.02; FDR-adjusted *P*=.07); therefore, this result was interpreted as an exploratory trend, as shown in Figure 6.

XSL•FO
RenderX

Figure 6. Comparison of modularity values across groups and experimental states. Modularity values are compared across the 3 experimental states (pre–virtual reality [pre-VR], VR, and post-VR) and the 3 clinical groups (Alzheimer disease [AD], mild cognitive impairment [MCI], and normal cognition [NC]). Boxplots illustrate state-dependent changes within each group and group differences within each experimental state. Only the baseline AD–NC modularity difference remained significant after false discovery rate (FDR) correction; the remaining group and state patterns are presented descriptively.



Within-group comparisons across experimental states showed descriptive temporal modulation patterns, but no within-group state comparison remained significant after FDR correction. In the AD group, modularity numerically decreased during VR stimulation, suggesting a possible reduction of the highly segregated network organization observed at baseline. The MCI group showed minimal numerical change during VR but exhibited higher modularity in the post-VR phase, suggesting a possible delayed network reconfiguration pattern. In contrast, participants in the NC group showed a numerical increase in modularity during VR stimulation followed by a reduction in the post-VR state. These within-group modularity patterns should therefore be interpreted as descriptive trends rather than confirmatory statistical effects.

Nodal Strength

This study investigated alterations in EEG-based nodal connection strength during the pre-VR and VR conditions, illustrating VR-associated changes in functional brain network patterns in patients with AD. As shown in Figure 7, during the pre-VR resting state, the AD group exhibited pronounced right-lateralized connectivity, with higher nodal strength in the right hemisphere than in the left, whereas the NC group showed relatively balanced interhemispheric connectivity patterns.

XSL•FO
RenderX

Figure 7. Regional node strength distribution and connectivity patterns in the Alzheimer disease (AD) and normal cognition (NC) groups. The upper panel shows the AD group, and the lower panel shows the NC group. For each group, node strength values are presented for 2 experimental states: pre–virtual reality (pre-VR) resting (left) and VR stimulation (right). Bars represent node strength for individual electroencephalography (EEG) channels. Node labels are color-coded by anatomical region: blue indicates left-hemisphere nodes, green indicates midline (central) nodes, and pink indicates right-hemisphere nodes. The brain network diagrams on the right illustrate the corresponding connectivity patterns for each group.

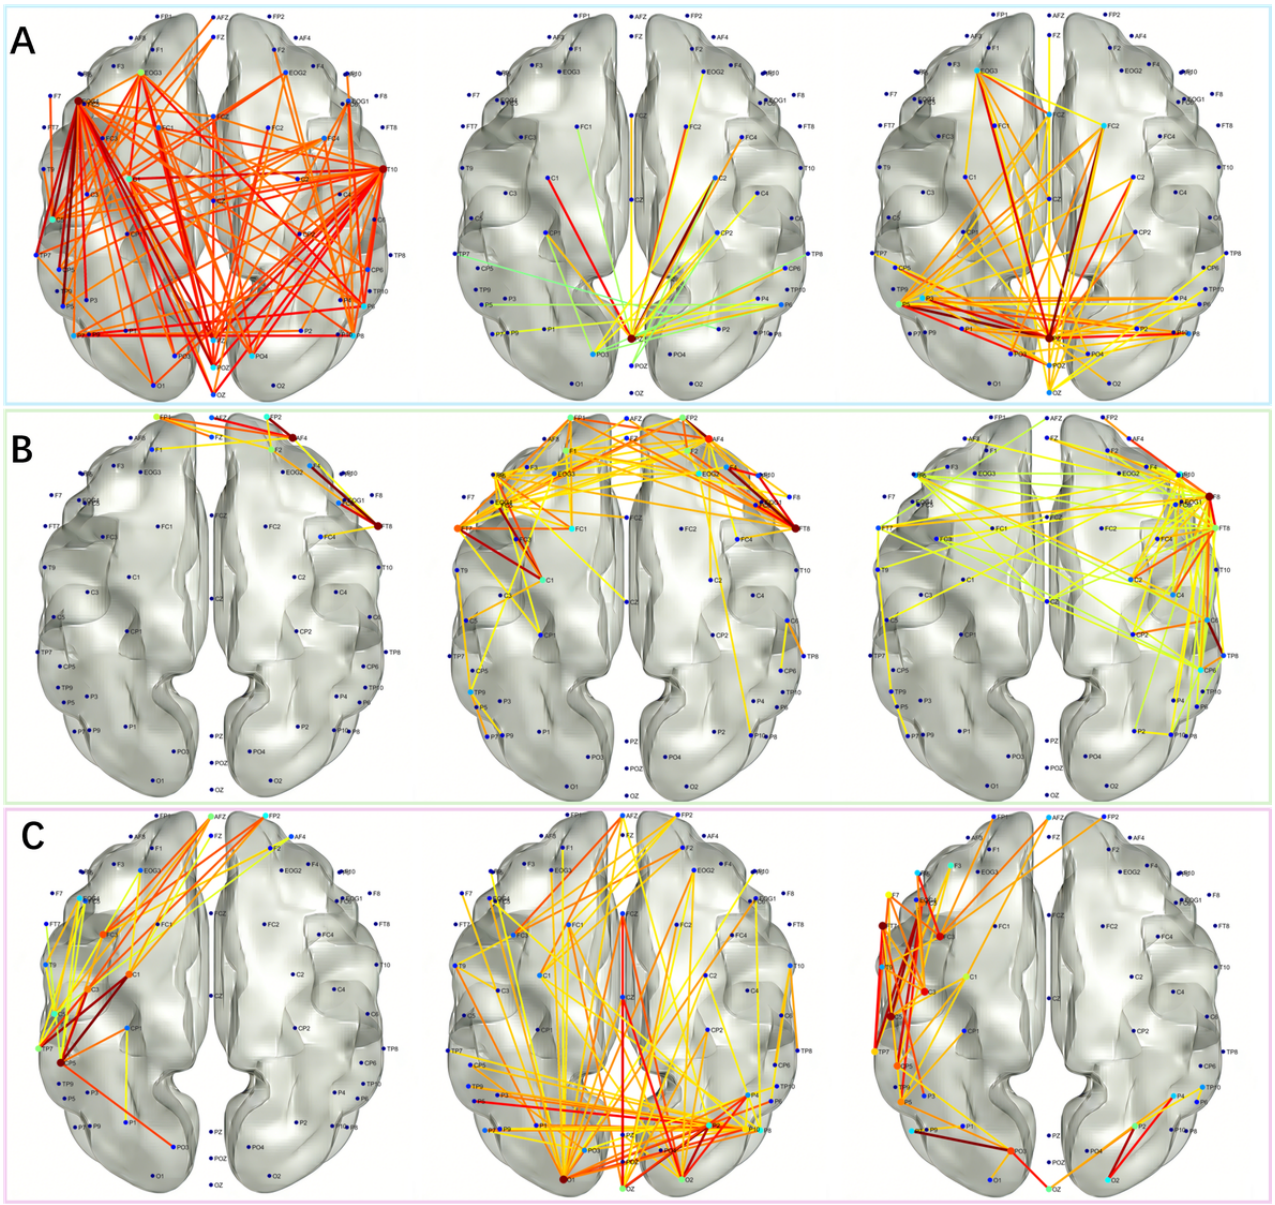
During VR stimulation, the AD group demonstrated a bidirectional modulation pattern: most nodes in the left hemisphere showed increased connection strength, while several nodes in the right hemisphere displayed decreased strength. This “left-up and right-down” pattern suggested a shift in interhemispheric connectivity distribution during VR stimulation, with the AD connectivity pattern appearing more balanced than in the pre-VR resting state.

Analysis of key midline hub nodes (Pz, POz, Fz, and Oz) further revealed that the NC group exhibited variable changes with generally higher nodal strength, whereas the AD group showed consistent increases in nodal strength across these central regions during VR stimulation. As illustrated in Figure 7, these changes appeared to reduce visual group differences in these core integration nodes.

Taken together, these descriptive nodal strength patterns suggest that VR stimulation was associated with a shift in nodal connectivity distribution in AD, characterized by increased left-hemisphere and midline involvement and reduced apparent right-lateralized dominance. Because nodal strength maps were used primarily for descriptive visualization, these findings should be interpreted as spatial patterns of regional connectivity rather than evidence of therapeutic efficacy or functional improvement. These descriptive findings provide spatial context for the quantitative GE and modularity results, which indicated state-dependent changes in large-scale network organization.

Node Connection Graph

Node connection graphs were used as descriptive visualizations of the top 5% strongest PLV connections and were not treated as independent inferential statistical tests or threshold-sensitivity analyses. Using preprocessed EEG data in the .set format and retaining the top 5% of strongest connections, the NC group showed stronger and more spatially distributed retained PLV connections than the MCI and AD groups, with relatively balanced interhemispheric organization. During VR stimulation, the retained connections in the NC group appeared more selective and spatially distributed across the network, suggesting a descriptive shift in the organization of strong PLV connections under sensory stimulation [44].



In contrast, the AD group exhibited marked hemispheric asymmetry at rest, with connectivity predominantly concentrated in the right hemisphere, particularly in central and centroparietal regions. This central and centroparietal concentration may reflect compensatory reliance on sensorimotor integration hubs and midline relay regions when distributed long-range coordination is reduced, consistent with more locally constrained coupling in disease. During VR stimulation, hemispheric asymmetry decreased, and the network adopted a more symmetric configuration, suggesting a state-associated shift toward a more bilateral distribution of retained connections and redistributed connectivity away from an overly lateralized resting-state pattern. The MCI group showed intermediate features between NC and AD but lacked a stable configuration across states,

XSL•FO
RenderX

consistent with a transitional and heterogeneous network phenotype.

Overall, VR stimulation was associated with a more selective and spatially balanced distribution of retained connections in NC networks. In AD, VR stimulation was associated with reduced apparent resting-state lateralization and a more bilateral distribution of retained connections. These connectivity reorganization patterns across groups and states are illustrated in Figure 8.

Figure 8. Brain network connectivity differences across groups and experimental states. The panels correspond to 3 frequency ranges: broadband (1-70 Hz), gamma band (32-70 Hz), and alpha band (8-13 Hz). For descriptive visualization, each network displays the top 5% of the strongest phase-locking value (PLV) connections. The maps were not treated as independent inferential evidence. (A) Connectivity difference maps obtained by subtracting the Alzheimer disease (AD) group from the normal cognition (NC) group across the 3 experimental states. (B) Connectivity difference maps obtained by subtracting the NC group from the AD group across the 3 experimental states. (C) Connectivity differences between the VR stimulation state and the resting state within the AD group.

To further evaluate VR-related network changes in AD, differential connectivity maps were generated by subtracting the pre-VR network from the VR-state network within the AD group across frequency bands. In the broadband range (1-70 Hz) and in the mid-frequency band (8-13 Hz), VR-related connectivity increases were mainly localized to the left hemisphere, with prominent involvement of central and centroparietal regions. This pattern contrasts with the right-hemisphere dominance observed at rest and suggests a state-associated shift toward more bilateral hemispheric distribution.

In the high-frequency band (32-70 Hz), descriptive maps showed a different spatial distribution of retained long-range connections during VR stimulation. Because high-frequency GE findings did not remain significant after FDR correction, this pattern should be interpreted as visualization-based spatial context rather than confirmatory evidence of enhanced high-frequency communication.

XSL•FO
RenderX

Taken together, the node connection graphs descriptively suggested that VR stimulation was associated with a shift in AD connectivity patterns from a more lateralized resting-state configuration toward a more bilateral distribution. These visualization-based observations should be interpreted together with the quantitative GE and modularity findings rather than as independent statistical evidence. Overall, the connectivity maps provide spatial support for the interpretation that VR stimulation was associated with short-term changes in large-scale functional network organization.

Discussion

Across the 3 within-session experimental states, this exploratory single-session, 3-group repeated-measures EEG study identified FDR-corrected baseline group differences in broadband GE and modularity, together with FDR-corrected within-group changes in GE in the NC and MCI groups. Descriptive connectivity maps also suggested state-associated changes in hemispheric distribution and high-frequency connectivity; however, the corresponding high-frequency GE findings did not survive FDR correction and were therefore treated as exploratory. Collectively, these results support the feasibility of using immersive VR as a controlled challenge for examining acute EEG network responsiveness, while not establishing a therapeutic effect.

At baseline, the AD group showed elevated GE and modularity relative to the NC group, indicating altered organization of network integration and segregation. Prior EEG network studies and reviews have similarly reported disease-related changes in synchronization, coherence, efficiency, modular organization, and hub connectivity in AD and MCI [20,45-47]. During VR exposure, the apparent separation between groups was reduced for some measures; however, the absence of a statistically significant difference should not be interpreted as normalization, equivalence, or functional recovery.

Although higher GE is commonly interpreted as greater network integration, elevated GE in AD does not necessarily represent beneficial or more efficient neural processing. In a disrupted neurodegenerative network, greater apparent integration may reflect altered synchronization, compensatory recruitment, reduced modular constraints, or pathological overintegration [20,36,45-47]. Accordingly, the elevated baseline GE observed in AD is interpreted as altered network organization rather than enhanced functional performance.

Descriptive maps suggested that the spatial distribution of strong connections became more bilateral during VR exposure than during the pre-VR resting state. Previous work has linked AD and MCI to hemispheric imbalance and disrupted interhemispheric coordination [40,41,45]. Because the present maps were descriptive and dependent on the selected display threshold, they provide spatial context for the quantitative findings rather than confirmatory evidence of hemispheric rebalancing.

Descriptive high-frequency maps suggested state-associated redistribution of strong connections; however, high-frequency GE findings did not remain significant after FDR correction. Task-based and connectivity-focused EEG literature supports the possibility that cognitive or sensory challenges may reveal neurophysiological features not evident during resting-state recording [46-49]. Nevertheless, the present high-frequency observations should be considered hypothesis-generating rather than evidence of a confirmed frequency-specific mechanism.

The NC and MCI groups showed FDR-corrected within-group GE changes at different phases of the experiment, whereas no within-group change in AD remained significant after correction. These findings may indicate group-related differences in acute network responsiveness, consistent with the heterogeneity described across NC, MCI, and AD [21,22,45-47,49]. However, without a direct group-by-state interaction test, the observed patterns should not be interpreted as a confirmed progression continuum or as proof that one group responded more strongly than another.

A contribution of the present study is the application of a common graph-theoretical framework across 3 clinical groups and 3 within-session experimental states. Prior EEG studies have demonstrated the relevance of spectral and connectivity measures for identifying cognitive decline in MCI and AD [46-52], whereas VR studies in older adults have primarily emphasized cognition, usability, training outcomes, or regional activation [10,11,23-25]. The present work extends this literature by examining acute, large-scale EEG network organization during and after immersive VR exposure.

Because concurrent cognitive, behavioral, functional, and clinical outcomes were not collected, the observed EEG changes cannot be directly linked to cognitive improvement, symptom severity, daily functioning, or therapeutic benefit. The practical significance of the study therefore lies in demonstrating the feasibility of combining immersive VR with EEG graph-theoretical analysis as an experimental challenge paradigm for characterizing short-term neurophysiological responsiveness. Future controlled and longitudinal studies should test whether these network measures are associated with standardized cognitive and everyday-functioning outcomes [10,11,23-25,49].

Methodological factors may also contribute to the observed connectivity patterns. PLV-based connectivity can be influenced by volume conduction, common-reference effects, signal leakage, filtering, and preprocessing decisions [34]. Graph-theoretical findings may further depend on edge weighting, node and edge definitions, network density, and proportional threshold selection [35,53]. The top 5% threshold was used only for descriptive visualization; because formal threshold-sensitivity analysis was not performed, the spatial maps should not be interpreted as threshold-independent biomarkers. Replication using multiple network densities, alternative connectivity estimators, and independent datasets is required.

Several limitations should be considered. First, the modest sample and convenience recruitment may limit generalizability, and complete individual-level demographic and standardized cognitive data were unavailable for all participants. Second, the study used a single-session repeated-measures design without a separate non-VR comparison condition; therefore, VR-specific

XSL•FO
RenderX

effects cannot be separated from repeated recording, visual stimulation, novelty, arousal, fatigue, or other time-related influences. Third, connectivity was estimated using PLV, which can be affected by volume conduction, reference selection, and signal leakage [34]. Fourth, the top 5% proportional threshold was used only for descriptive visualization, and formal threshold-sensitivity analysis was not performed [53]. Fifth, a standardized cybersickness questionnaire was not administered, so mild discomfort or vestibular symptoms could not be quantified. Finally, no concurrent cognitive, behavioral, functional, or clinical outcomes or longitudinal follow-up were available. These limitations support interpreting the findings as exploratory and hypothesis-generating.

In conclusion, this exploratory single-session, 3-group repeated-measures EEG study identified short-term, state-associated changes in PLV-derived EEG functional network organization across older adults with AD, MCI, and NC. The findings support the feasibility of combining immersive VR with EEG graph-theoretical analysis to characterize acute network responsiveness. However, the descriptive connectivity maps were not treated as confirmatory evidence, and the lack of a non-VR comparison condition and concurrent cognitive or clinical outcomes precludes conclusions regarding causality, functional benefit, or therapeutic efficacy. Larger controlled and longitudinal studies are required to determine the reproducibility, functional significance, and potential clinical value of these network responses.

Acknowledgments

Abstract

Background: People with multiple sclerosis (MS) are at high risk of falls, with approximately half experiencing at least 1 fall within 6 months. Multidirectional step training has shown potential for fall prevention, but evidence in people with MS remains inconsistent. Mixed reality (MR) offers adaptive and home-based rehabilitation opportunities. However, successful implementation of MR-based serious games requires structured co-design processes integrating patient, clinician, and technical perspectives.

Objective: This qualitative study describes the co-design and prototyping of a home-based MR serious game called Head Your Limits for volitional step training in people with MS, aiming to identify patient-, clinician-, and technology-driven design requirements and translate them into an MR rehabilitation application.

Methods: We implemented a cross-sectional qualitative user-centered co-design process. Phase 1 involved 2 online focus groups with people with MS to identify experiential and design preferences related to MR-based training. Phase 2 included a focus group with 4 clinicians and 1 engineer to define clinical and technical requirements. Phase 3 consisted of in-person hands-on testing of 2 MR prototypes (“clock” and “grapes”), developed in Unity and deployed on Meta Quest 3. Twenty people with MS were purposively screened from among individuals referred for motor rehabilitation; 14 participated in the online focus groups and 9 in in-person prototype testing (mean age 56.2, SD 7.0 years; mean Expanded Disability Status Scale score 5.1, SD 1.3; 6/9, 66.7% female). Iterative refinement followed each phase, translating stakeholder-derived requirements into architectural modifications of the MR application. Focus group recordings and moderator notes were reviewed to identify themes and design requirements guiding iterative prototype refinement.

Results: Five primary patient-derived requirements emerged: multisensory feedback, gamification, progress tracking, visual accessibility, and ergonomic comfort. Clinicians emphasized adaptive difficulty, cognitive-motor integration, biomechanical validity, and caregiver compatibility. Prototype comparison showed that floor-level targets induced cervical discomfort and postural compensation, whereas auditory guidance reduced head flexion. The final application repositioned targets at eye level and implemented head-mounted display tracking to ensure appropriate center-of-mass displacement, preserve proprioceptive engagement, enable caregiver proximity, and integrate gamified feedback and performance reporting.

Conclusions: Iterative stakeholder engagement resolved key design tensions related to ergonomics, sensory reliance, biomechanical validity, and motivation. The transition to eye-level, head-mediated interaction emerged as a core solution integrating therapeutic and user-experience goals. Through a rigorous user-centered co-design process, aligned with contemporary human-centered

XSL•FO
RenderX

development models, we developed an MR serious game for volitional step training in people with MS. This study contributes to the field by providing a transparent methodological framework integrating biomechanical validity, usability, and engagement. Although clinical effectiveness remains to be tested, these findings may inform the design of accessible, personalized home-based rehabilitation for people with MS and other neurological populations.

Introduction

Description of Research Problem

Multiple sclerosis (MS) is a complex neurological disorder that leads to cognitive and motor deficits [1]. Cognitive deficits affect up to 60% of people with MS, limiting their activities of daily living and capacity for work [2]. The most prevalent cognitive dysfunctions are slowing of information processing speed and impairments in episodic memory, attention, and executive functions [3]. Motor dysfunction is a highly disabling feature of MS, resulting from the multifocal involvement of the central nervous system. Damage to motor, sensory, cerebellar, and brainstem pathways leads to impairments in strength, coordination, balance, and gait, which often coexist and interact, producing highly variable motor phenotypes across individuals [4,5]. These motor deficits significantly impact functional independence and quality of life and represent one of the main drivers of disability progression in people with MS [6]. Importantly, the expression of motor dysfunction in MS is not static but evolves over time, reflecting disease course, lesion distribution, and the deployment of compensatory mechanisms [7]. Consistent with this multifactorial impairment, cognitive and motor disorders are strongly associated with an increased risk of falling [8,9]. Indeed, at least 50% of people with MS experience 1 or more falls within a period of 3 to 6 months, with a large proportion sustaining concomitant injuries ranging from mild trauma to injuries requiring hospitalization [10]. Beyond the immediate physical consequences, falls often lead to activity restriction, which in turn contributes to reduced social participation and decreased levels of physical activity, further exacerbating disability and negatively impacting quality of life [10,11].

Several approaches have been proposed to prevent falls in people with MS, including balance rehabilitation, combined motor and sensory training, mind-body exercises, functional electrical stimulation, and education-based programs [12]. However, although there is strong evidence that these interventions can improve balance in people with MS, clear effectiveness in reducing falls has not yet been demonstrated [12]. In the absence of clear evidence on how to effectively reduce falls in people with MS, insights from fall-prevention research in older adults may provide important indications. In this population, the systematic review by Sherrington et al [13] recommends engaging in balance-challenging exercise for at least 2 hours per week for a minimum of 6 months to achieve meaningful reductions in falls [13]. Beyond the training dose, emerging evidence suggests that the content of balance training is also critical. A systematic review by Okubo et al [14] demonstrated that multidirectional step training can prevent falls by approximately 50%.

In this context, there is a clear need for rehabilitation interventions that can be safely performed at home, without continuous direct supervision by a physiotherapist, to achieve the high training volumes required for effective fall prevention [13]. Furthermore, these interventions should be sufficiently task-specific, challenging, and engaging to be effective and to promote long-term adherence [14]. In response to these requirements, volitional multidirectional step training interventions have been proposed for people with MS [15-17], with the aim of training stepping responses, which represent the final opportunity to recover stability following a perturbation [18]. Hoang et al [16] developed a large-scale stepping-based training program for people with MS. Despite a large sample size and an extended intervention duration, this program did not demonstrate a reduction in fall rates. A potential limitation may be the spatial organization of the stepping task, which is constrained by the stepping mat and limited to 4 predefined directions. Such a spatial constraint may reduce the ecological validity of the task, as balance recovery during everyday tasks requires steps in all directions. In this regard, task specificity has been identified as a critical factor in reactive balance training [19].

Among technological solutions, emerging extended reality (XR) technologies offer new approaches for people with MS, especially in motor rehabilitation [20]. XR technologies, which include virtual reality, mixed reality (MR), and augmented reality, combine virtual and physical worlds to provide immersive, realistic experiences in which users can practice specific skills or behaviors [20,21]. Several studies have shown that the sense of presence and immersion elicited by XR environments may influence performance and rehabilitation outcomes in people with MS. XR systems also facilitate the replication of task-oriented activities related to daily living, ensuring ecological validity [22]. XR-based applications often incorporate serious game (SG) frameworks to enhance patient engagement and motivation, particularly during prolonged or repetitive training [22]. Furthermore, given the challenges that people with MS face in adhering to rehabilitation programs due to personal, social, and economic factors, XR-based SGs can help reduce barriers to accessing rehabilitation programs [23]. Another important feature is the ability to customize extended environments and design applications that adapt in real time to the patient's performance [24]. The ability to create enriched and highly adaptable environments, tailored to individual postural control abilities [25], is particularly important in MS, as motor phenotypes are highly variable, reflecting differences

XSL•FO
RenderX

in lesion location, disease course, and compensatory mechanisms [26]. Second, XR can provide rich audiovisual cues [25] and closed-loop feedback [27], both of which are pivotal for promoting motor learning [28]. Motor learning is the mechanism underlying the production of more effective movement [28], and it is preserved even in people with MS with higher levels of disability [29]. Among XR environments, MR has been shown to elicit higher levels of spatial presence [30]. Spatial presence is critical for the execution of confident body movements [30]. This increased confidence in movement may encourage people with MS to explore the limits of their motor abilities within the MR environment, which is critical for driving functional improvements [31]. Spatial presence is also an essential element of embodiment [32], a process that is commonly disrupted in people with MS when interacting with virtual environments [33].

While MR offers significant technological potential for motor rehabilitation in MS, its successful translation into clinical practice depends on development strategies that effectively integrate the perspectives of end users and other key stakeholders [20]. Co-design methods are increasingly acknowledged as essential in the development of health care technologies, especially when multiple stakeholder perspectives, including patients, clinicians, and engineers, must be integrated [34,35]. In the context of MR-based rehabilitation devices for individuals with MS, a co-design framework ensures that experiential, clinical, and technical requirements inform all stages of the design process, in line with biopsychosocial models of care and patient-centered innovation [35,36]. Various co-design approaches are available, including participatory design, cooperative inquiry, and living lab methods, which differ in stakeholder composition, duration, and tools [37-39]. The selection of a specific approach should reflect the number and diversity of stakeholders involved, the complexity of the technology, regulatory and safety constraints, and the development timeline, as these factors critically influence the real-world adoption and sustained use of rehabilitation technologies [34,40,41].

Among the available co-design tools, focus groups are particularly well suited to the development of complex health care technologies that require the integration of experiential, clinical, and technical perspectives [35,42]. Focus groups facilitate interactive discussions in which stakeholders can articulate needs, negotiate priorities, and collectively surface design ideas [43,44]. Unlike individual interviews or survey-based approaches, they enable the emergence of themes shaped by group dynamics, such as trade-offs between clinical safety parameters and usability, or between technical feasibility and patient motivation [42,45]. This dialogic format is especially appropriate for harmonizing the perspectives of patients, who may experience fatigue, sensory discomfort, or motivational challenges, with those of clinicians, who prioritize therapeutic efficacy and safety, and engineers, who focus on system performance, latency, motion tracking, and real-time feedback [34,35]. The iterative use of focus groups further supports the progressive refinement of design assumptions and the exploration of usability and acceptability across multiple development stages, consistent with human-centered and participatory design frameworks [36,40]. In health care co-design, focus groups are frequently used in early design phases because they support rapid sense-making across stakeholder groups and enable the identification of tacit assumptions that may not emerge through individual methods. Their capacity to approximate real-world decision-making processes makes them particularly relevant for the initial development of medical devices and digital health interventions [34,45].

Research Goals

The aim of this qualitative study was to describe the user-centered co-design, iterative prototyping, and conceptual development of a home-based MR SG for volitional step training in people with MS. Specifically, we aimed to identify patient-, clinician-, and technology-driven design requirements and translate these into an MR rehabilitation application integrating therapeutic relevance, usability, safety, and engagement. The application was designed for patients not requiring bilateral support to walk. The development of SGs for rehabilitation benefits from a structured, human-centered methodology that ensures usability, acceptability, and alignment with patients' needs. In this work, the ideation and refinement of our MR-based motor training application were inspired by the International Organization for Standardization (ISO) 9241-210 framework for human-centered design of interactive systems [46]. The standard outlines the following six core principles: (1) explicit understanding of users, tasks, and context of use; (2) user involvement throughout the design and development process; (3) iterative refinement driven by user-centered evaluation; (4) design responding to user needs and requirements; (5) consideration of the whole user experience; and (6) multidisciplinary design teams that guide the structure and logic of the co-design pathway. These principles guided the structure and logic of the co-design pathway.

Methods

Research Design Overview

This study used a cross-sectional qualitative, user-centered co-design approach involving iterative prototype development. The methodology was operationalized through a 3-phase pipeline using focus groups with distinct stakeholder categories at each stage, with the overall aim of informing the design, refinement, and evaluation of the MR application for volitional step training.

Phase 1 aimed to explore the perspectives of individuals with MS regarding their rehabilitation experiences, expectations, preferences, and perceived acceptability of MR-based training. The focus groups were designed to elicit participants' views on practical aspects of use, including comfort, fatigue, and preferred feedback modalities, as well as broader considerations related to motivation and engagement.

Phase 2 aimed to gather interdisciplinary input from health care professionals and an engineer to contextualize patient perspectives within clinical and technical constraints. This phase focused on discussing clinical applicability, safety

XSL•FO
RenderX

considerations, and feasibility aspects relevant to the development of the MR application.

Phase 3 aimed to evaluate user interaction with the MR application through hands-on testing with individuals with MS. This phase was designed to collect both quantitative and qualitative feedback on usability, user experience, perceived usefulness, motivation, and intention for future use, in order to support iterative refinement of the system.

Study Participants

Researcher Description

Each focus group was moderated by a psychologist and a physiotherapist with previous research experience in MS rehabilitation. Their understanding of balance training, rehabilitation technologies, motivation, and human-technology interaction informed the development of the focus group structure. The broader research team was multidisciplinary and included a rehabilitation physician with extensive experience in MS rehabilitation and translation of rehabilitation technologies into clinical practice (SS), as well as engineers with expertise in digital health technologies, XR systems, and human-computer interaction for health care applications. The different backgrounds allowed the individual disciplinary assumptions to be balanced and ensured that decisions regarding prototype refinement were guided by stakeholder feedback rather than by the prior expectations of any single researcher.

Researcher-Participant Relationship

The psychologist had no prior therapeutic relationship with the participants and therefore acted as the primary moderator of the focus groups to ensure independent facilitation of the discussions. The physiotherapist had an existing therapeutic relationship with the participants, as all had previously received care at the rehabilitation unit. His role was primarily supportive, using the established rapport to facilitate open communication and encourage participants to share their experiences. The other members of the research team had no relationship with the participants.

Participant Recruitment

For the patients' focus groups, people with MS were recruited among individuals who had been referred to the Ferrara University Hospital for motor rehabilitation in the previous year. Eligible participants were contacted by telephone and invited to participate. For the health care professionals and engineer focus group, colleagues and external collaborators working in the field of rehabilitation technology and with expertise in neurological rehabilitation were invited via email.

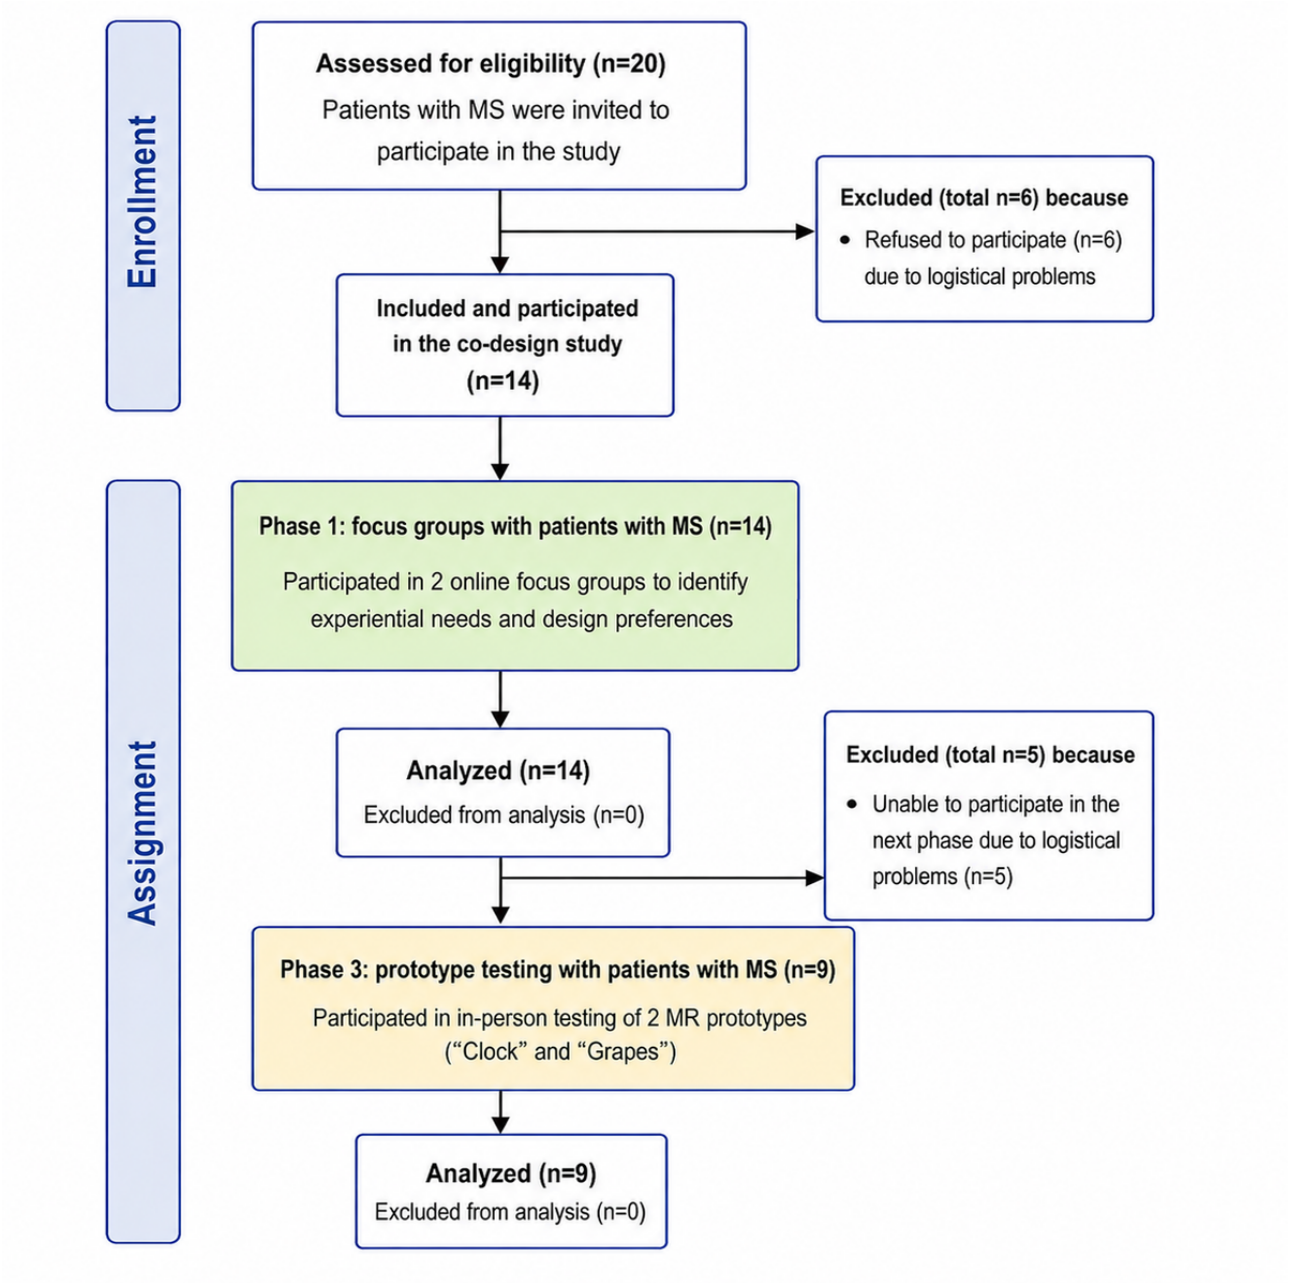
Participant Selection

People with MS were selected using purposive sampling principles [47] with the aim of including people with MS presenting different levels of disability and, therefore, potentially different needs, movement constraints, and perspectives relevant to MR balance training design. To ensure heterogeneity of experience, participants in phase 1 were intentionally recruited across a range of disability levels. Two separate online focus groups were conducted: the first included participants with higher disability levels, while the second included participants with lower disability levels.

In line with the qualitative and co-design nature of the study, no formal statistical sample size calculation was performed, and recruitment was not guided by a predefined thematic saturation threshold. Instead, participant involvement was guided by the iterative needs of the prototype development process. After each focus group, our research group pragmatically assessed whether the discussion had generated clear, recurrent, and actionable design-relevant information to inform the next co-design phase, including decisions about prototype features, safety requirements, usability issues, and technical feasibility.

People with MS were eligible if they met the following inclusion criteria: aged 18 to 75 years, diagnosis of MS, disability level lower than 6.5 as assessed using the Kurtzke Expanded Disability Status Scale (EDSS) [48], adequate digital skills, and the presence of a caregiver. Participants were excluded if they required bilateral support to walk or had a Mini-Mental State Examination (MMSE) score lower than 24, consistent with the conventional cutoff used to identify individuals with cognitive impairment [49].

Participant or Other Data Sources



A total of 20 people with MS were initially screened for participation (Figure 1). Of these, 6 were eligible but did not participate due to logistical constraints. Therefore, 14 people with MS were enrolled in the online focus groups, including 5 individuals with an EDSS score greater than 5.5, another 5 with EDSS scores between 4 and 5.5, and 4 with EDSS scores less than 4. Of these 14 participants, 9 subsequently attended the in-person focus group, which included hands-on interaction with the prototype demonstrations. The remaining 5 participants were unable to take part in the testing phase due to logistical constraints.

The mean age of the in-person focus group was 56.2 (SD 7.0) years, with a mean EDSS score of 5.1 (SD 1.3) and a mean disease duration of 12.0 (SD 6.3) years. Six participants (66.7%) were female. Most participants required a walking aid, with 6 (66.7%) using a single cane and 3 (33.3%) walking without support. Both relapsing-remitting and progressive MS phenotypes were represented in the sample.

The clinician and engineer focus group included 3 physiotherapist researchers, 1 physiatrist researcher, and 1 biomedical engineer. All participants had expertise in MS and MS-related interventions.

Figure 1. Participant flow through the co-design study. Flow diagram showing participant recruitment, inclusion, exclusion, and progression through phase 1 focus groups and phase 3 in-person prototype testing. Twenty people with multiple sclerosis were assessed for eligibility; 14 participated in phase 1, and 9 completed phase 3. A total of 6 declined participation at enrollment, and 5 were unable to participate in phase 3 because of logistical reasons. MR: mixed reality.

Data Collection

Design and Procedure

All focus groups were conducted using a semistructured format and moderated by 2 trained researchers. Discussions followed ad hoc discussion guides while allowing flexibility to explore emerging topics raised by participants.

The 2 initial patient focus groups (taking place on the same day) and 1 interdisciplinary focus group were conducted remotely via Zoom (Zoom Communications, Inc), whereas the final patient focus group was conducted in person. The interdisciplinary focus group, involving health care professionals (n=4) and 1 engineer, was conducted using a parallel semistructured format. All focus groups conducted via Zoom were video recorded.

The third patient focus group was conducted in person and centered on hands-on testing of the MR applications. Following hands-on testing of both prototypes, participants completed the System Usability Scale (SUS) [50] as an exploratory quantitative measure of overall perceived usability of the MR experience [51]. This session also included a brief focus group discussion, which was audio recorded.

Semistructured discussion guides were developed for both the initial patient focus groups and the interdisciplinary focus group. The full outlines and guiding questions are reported in Multimedia Appendices 1-3. The focus group guides were developed through discussion within the multidisciplinary

XSL•FO
RenderX

research team, which included clinical, psychological, rehabilitation, and technological expertise. This process was intended to ensure that the guides addressed both the experiential perspectives of end users and the clinical and technical requirements relevant to the development of the MR application. The content of the guides was aligned with the ISO 9241-210 principles for human-centered design, established focus group methodology [42,43,45], and the specific objectives of each co-design phase.

Recording and Data Transformation

The findings emerging from each phase of the co-design process were systematically documented and used to inform subsequent stages. Following each focus group, the moderators produced structured summary reports synthesizing key discussion points and design-relevant considerations. These reports did not aim to provide exhaustive qualitative analyses, but rather to capture actionable insights relevant to the iterative development of the MR application. Outputs from the initial patient focus groups were first shared within our research team and subsequently discussed during the interdisciplinary focus group with experts. In this focus group, patient-derived perspectives were reviewed to support shared interpretation and prioritization of design-relevant insights. Similarly, insights emerging from the interdisciplinary focus group were summarized and communicated back to our research team and used to guide the preparation of the MR application prototypes evaluated in the subsequent patient focus group. During the final patient session, selected elements derived from earlier phases were explicitly presented to participants to support informed discussion and hands-on evaluation.

Data-Analytic Strategies: Review and Synthesis of Focus Group Material

After each session, focus group recordings and moderator notes were reviewed using a pragmatic descriptive approach. The review focused on identifying recurrent discussion points, user preferences, perceived barriers, safety and usability concerns, and design-relevant requirements that could inform subsequent prototype refinement. Particular attention was given to comments related to acceptability, comfort, feedback modalities, motivational elements, accessibility, home-based use, clinical applicability, and technical feasibility. Based on this review, the moderators prepared structured summary reports capturing the main design-relevant considerations emerging from each focus group. These reports were used to organize the focus group material into actionable co-design outputs and to document the main considerations informing iterative prototype refinement. The analytic process was therefore oriented toward the generation of practical design insights rather than toward formal thematic analysis, while ensuring transparent reporting of the data sources and procedures used to summarize and interpret the focus group material.

Methodological Integrity

Methodological integrity was supported through the iterative and multidisciplinary nature of the co-design process. The inclusion of patients with different disability levels, together with clinicians and engineers, ensured that multiple perspectives informed the development of the application. Throughout the study, stakeholder feedback was systematically documented, discussed within the multidisciplinary team, and translated into successive prototype refinements. Findings are supported by representative participant quotations and by a transparent description of how qualitative insights informed specific design decisions, thereby enhancing the credibility and practical utility of the study.

Technological Tools

Based on the results of the first 2 focus group sessions, 2 demos were developed. The first demo, namely, the clock demo, simulated a virtual clock and required users to select the correct number displayed in the environment. The target number was indicated through an artificial voice, created via ElevenLabs (Eleven Labs Inc). When the correct button was pressed, the system provided both visual feedback (the selected number turned green) and auditory feedback (Figure 2). All buttons remained visible on the floor throughout the task.

The second demo, named grapes (Figure 3), required players to interact with a bunch of grapes that appeared at randomly selected clock-face positions in the environment, one at a time. Each time a bunch appeared, the player was required to press it (selection is performed by stepping onto the desired floor button; contact is detected via collision logic and confirmed by visual and auditory feedback). Upon interaction, the system provided visual and auditory feedback, represented by the visual explosion of the grape bunch accompanied by a sound effect.

Both demos were developed in Unity (version 2022.3.45f1) and deployed for Meta Quest 3/3S. The applications were kept deliberately basic in order to facilitate a clearer, more focused, and more reliable co-design evaluation process. The head-mounted display (HMD) was selected based on device characteristics associated with improved comfort and usability in immersive applications, including high resolution, low latency, and relatively low weight, which have been reported among the hardware-related factors influencing cybersickness [52]. A key technological challenge concerned the detection of foot movements without relying on external sensors beyond the MR headset. A key limitation of current MR systems is their use of inside-out tracking architectures, which are mainly focused on head pose estimation and, in some cases, hand or controller tracking. On the other hand, using external sensors limits the feasibility of all-in-one solutions suitable for all rehabilitation settings. To address this issue, 2 different approaches were explored. In the first application (clock demo), the default Meta Blocks tools were used to define the player, track their position within the mixed environment, and manage collisions with the virtual clock elements. In the second demo (grapes demo), player interaction with the grape bunches was instead detected through the occlusion system, enabling collision-based interaction directly within the MR space. Specifically, foot-target interaction was inferred by combining Meta's environment depth-based occlusion rendering with custom collision detection logic implemented in C#. A volumetric probe was defined above each target and periodically queried using the MR Utility Kit Environment Raycast Manager to detect the presence of real-world geometry within the target

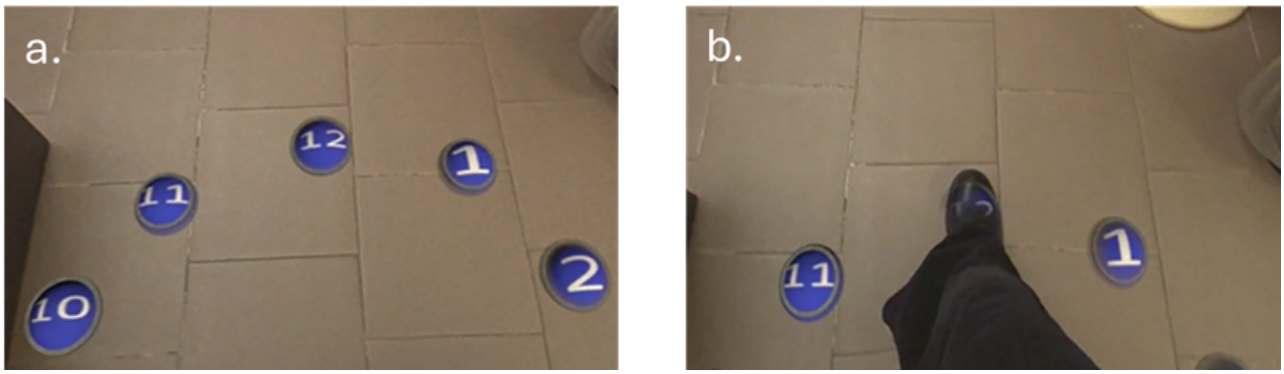
space. To reduce false positives due to depth noise, a temporal threshold was applied before confirming a valid interaction event, which then triggered spatialized audio and visual feedback.

Figure 2. Clock demo. The figure illustrates the clock prototype developed as part of the user-centered co-design process. (A) Participants wearing a Meta Quest 3 (Meta Platforms, Inc) head-mounted display were prompted by an auditory cue to step on a specific number positioned within a virtual clock layout to promote multidirectional stepping and weight shifting. (B) Successful task completion triggered visual and auditory feedback to reinforce performance and engagement.



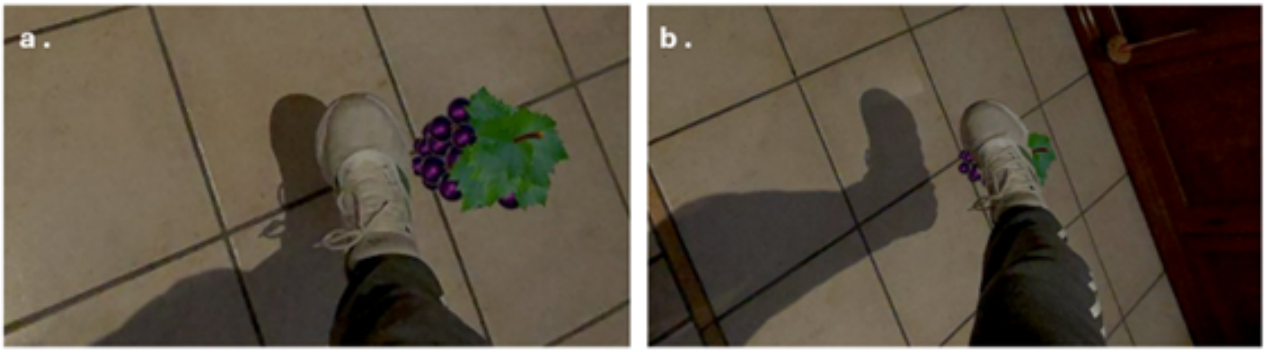


Figure 3. Grapes mixed reality (MR) demo. The figure illustrates the grapes MR prototype developed as part of the user-centered co-design process. (A) The virtual grape bunch appears on the floor in an unpredictable position as a stepping target to promote multidirectional stepping and lower-limb weight shifting within the MR environment. (B) Interaction is triggered when the user's foot overlaps the target area, progressively occluding the virtual object through depth-based occlusion, and is confirmed through visual and auditory feedback.

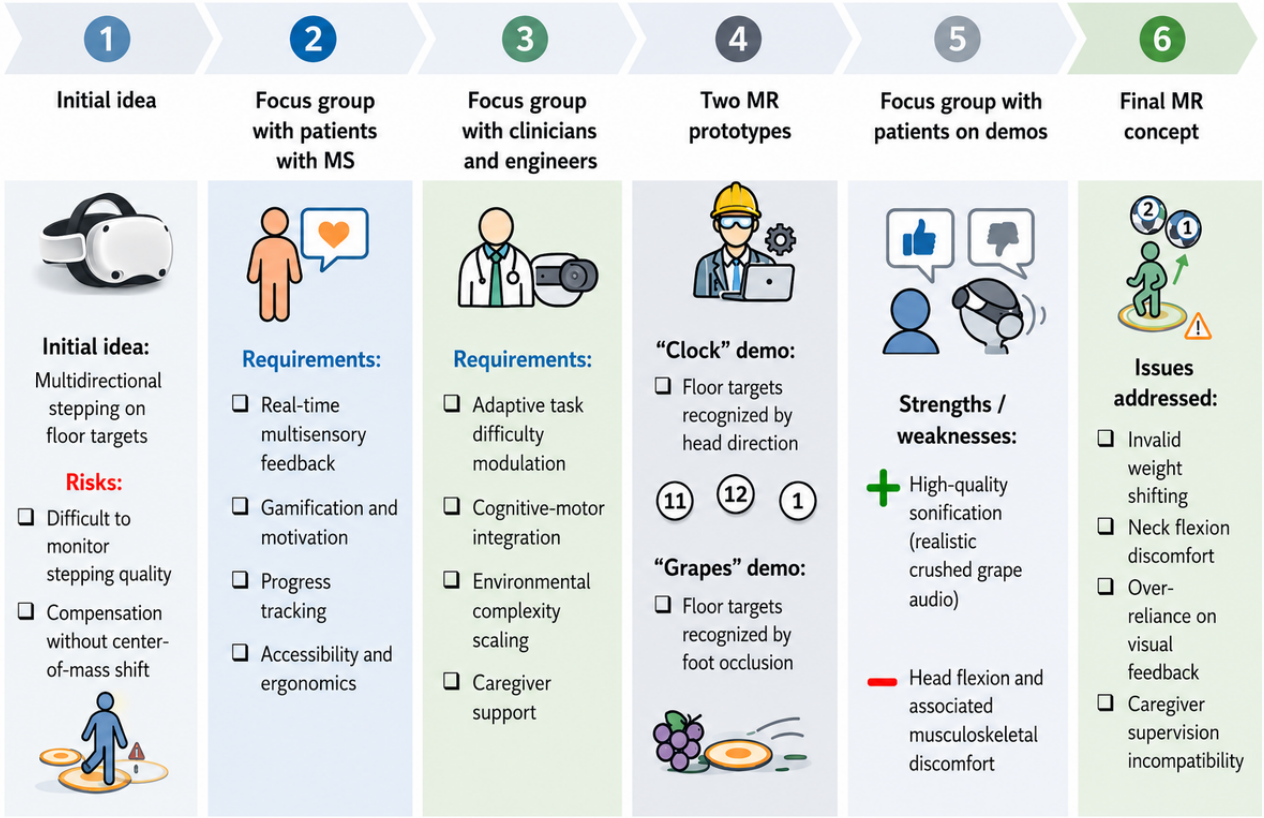
Ethical Considerations

The study was approved by the Ethics Committee Area Vasta Emilia Centro (AVEC; approval number 422/2025/Disp/AOUFe) and registered at ClinicalTrials.gov (NCT07058896). All procedures were conducted in accordance with the Declaration of Helsinki and institutional ethical standards. Written informed consent was obtained from all participants before participation in the study. Participants provided consent for participation in the focus groups and prototype testing, as well as for audio/video recording and the anonymous use of collected data for research purposes. Participation was voluntary, and participants were informed that they could decline to answer any question or withdraw from the study at any time without consequences for their clinical care or relationship with the rehabilitation team. To ensure privacy and confidentiality, all collected data were pseudonymized prior to analysis and handled in accordance with the General Data Protection Regulation (GDPR; Regulation [EU] 2016/679). Audio and video recordings were used exclusively for transcription and analysis purposes and were deleted after completion of the analytic process. No personally identifiable information is reported in this manuscript. Participants did not receive financial compensation for participation in the study. No identifiable participant information or recognizable facial images are included in the manuscript figures or supplementary materials.



Results

Overview

The final application represents the culmination of a rigorous, user-centered iterative design process spanning 6 sequential phases (Figure 4), integrating qualitative input from distinct focus groups. Each phase informed subsequent iterations, enabling systematic resolution of identified limitations through targeted architectural modifications in adherence to ISO 9241-210 principles for human-centered design.

Figure 4. Co-design process of a mixed-reality (MR) balance-training application for people with multiple sclerosis (MS). The figure illustrates the iterative co-design and prototyping pathway used to develop the Head Your Limits MR application. The process comprised six sequential steps: (1) initial development of a rehabilitation concept based on multidirectional stepping on floor targets, highlighting key risks (difficulty in monitoring stepping quality and compensation without center-of-mass shift); (2) an online focus group with people with MS to elicit requirements related to real-time multisensory feedback, gamification and motivation, progress tracking, and accessibility/ergonomics; (3) an online focus group with clinicians and extended reality (XR) engineers to define requirements including adaptive task difficulty modulation, cognitive-motor integration, environmental complexity scaling, and caregiver support; (4) development of 2 MR prototypes ("clock" demo based on head-direction recognition and "grapes" demo based on foot-occlusion recognition); (5) in-person focus group with people with MS to discuss strengths and weaknesses of both demos (eg, high-quality sonification vs discomfort related to head flexion); and (6) final MR concept, addressing key issues (invalid weight shifting, neck flexion discomfort, over-reliance on visual feedback, and caregiver supervision incompatibility). Across all steps, subject, task, and environmental constraints were iteratively refined while the core motor skill—multidirectional stepping—remained unchanged.

Phase 1: Conceptualization—Initial Idea
