An initial application concept was formulated to address the persistent challenge of fall prevention in MS through volitional multidirectional step training. The proposed MR application implemented stepping response development using a Meta Quest 3 HMD running a Unity application presenting virtual floor-level targets arranged in a clock-face distribution. However, the task execution mechanism (foot occlusion of a virtual target) revealed a critical biomechanical limitation: patients could achieve foot-target contact while maintaining center-of-mass displacement on the stance limb, executing an isolated foot movement without genuine weight transfer. Additionally, floor-level targets required sustained downward head flexion, imposing postural burden and risk of compensatory strategies. The initial design lacked: (1) a biomechanical enforcement mechanism ensuring target achievement required valid weight transfer, and (2) ergonomic compatibility with neutral head posture and safe caregiver supervision. These unresolved problems motivated iterative refinement toward architectural modifications enforcing biomechanical validity while maintaining clinical and usability requirements.

Phase 2: Patient-Centered Initial Requirements—Focus Group With Patients With MS

Fourteen people with MS attended an online focus group. The first patient focus group elicited user-derived requirements reflecting lived experience with motor rehabilitation and technology use preferences. Qualitative analysis identified five fundamental requirements: (1) closed-loop, real-time multisensory feedback enabling action-perception and motor error correction; (2) gamification and intrinsic motivation mechanisms sustaining long-term adherence; (3) personalized progress tracking fostering self-efficacy; (4) accessible visual design accommodating diverse visual abilities; and (5) ergonomic noninvasive design minimizing burden and compatible with corrective eyewear and mobility aids.

Patients reported an overall positive attitude toward the proposed MR application, describing curiosity, interest, and perceived usefulness. One participant felt that introducing this type of technology would be "a very positive step," while others stated, "I am curious" and "I mainly see the positive aspects of the application; I am not afraid, and I do not perceive any particular risks." Only a small number of participants reported initial

XSL•FO
RenderX

apprehension, mainly related to being unfamiliar with the system or potential side effects. Participants emphasized the importance of balancing engagement with comfort and safety. Concerns were raised regarding possible nausea, sensory overload, and physical fatigue associated with headset use. For instance, one participant noted, "I might experience fatigue with the heavy headset," while another commented that "the exercises seem quite tiring." A further participant expressed concern about cybersickness, stating, "I heard that this type of application can make you feel sick, and this worries me a little."

Participants expressed different views regarding sensory complexity and environmental distractions. Some considered additional stimuli potentially distracting or destabilizing, with one participant explaining that "the environment should be without distractions; too many stimuli would be worse for me." Others, however, perceived increased sensory complexity as potentially motivating, provided that it was introduced progressively. Participants also highlighted the importance of clear multimodal feedback, expressing a preference for distinct auditory cues to signal task success or failure and for high-contrast visual elements accessible to users with visual impairments. Finally, the need for personalized training and individual performance reports was consistently mentioned as an important factor to support motivation and long-term engagement, with one participant stating that "personalized training would be perfect for me."

Phase 3: Clinical and Technical Requirements—Focus Group With Clinicians and Engineers

The interdisciplinary focus group established clinical specifications and identified technical constraints. Clinicians articulated positive design recommendations: adaptive task difficulty modulation, cognitive-motor integration through dual-task paradigms, and progressive environmental complexity scaling. As one participant noted, "increasing task difficulty would be optimal," while another emphasized that "it would be important to add extra elements to increase the difficulty." Critically, the following three design challenges were identified, requiring mitigation: (1) risk of visual overreliance potentially fostering proprioceptive underengagement and limiting functional transfer, (2) postural compensation from visual target pursuit inducing cervical burden and invalidating motor execution, and (3) safety risks requiring caregiver supervision while maintaining system accessibility.

Clinicians and engineers confirmed personalization as a major strength of the MR concept and supported adaptive modulation of task difficulty. One participant stated that they were "particularly impressed by the personalization." Suggestions focused on increasing task complexity through cognitive-motor integration and environmental challenges to better approximate real-world balance demands. Safety considerations featured prominently in the discussion, particularly regarding home-based use and the need for supervision in more impaired patients. As one participant explained, "home-based application would be more critical, and it would be useful to have a caregiver present during training." Technical concerns included the accuracy of foot contact detection, limitations of sensor-based measurements, and the potential impact of headset weight and altered visual perspective on movement behavior. Participants suggested combining visual and auditory feedback and integrating complementary measurement approaches to support more robust assessment, with one participant noting that "a global assessment/measurement would be useful."

Phase 4: Prototype Development—2 MR Prototypes

Phase 4 operationalized requirements and design challenges into 2 distinct prototypes exploring alternative solutions. The clock application prioritized ergonomic comfort through acoustic guidance, eliminating visual downward head flexion requirements. The grape application prioritized engagement through high-quality gamification (vineyard themes, realistic goal celebration and failure sounds, and ball trajectory animation). This parallel approach enabled comparative evaluation of design trade-offs.

Phase 5: Comparative Usability Evaluation—Focus Group With Patients on Prototype Demos

The third focus group conducted hands-on comparative testing. The clock application demonstrated strong usability for acoustic guidance, reducing cervical burden and head flexion requirements. The grape application excelled in gamification quality and sonification realism, generating higher engagement. However, the grape application revealed a critical limitation: continuous visual field maintenance for floor-level targets required sustained head flexion, resulting in excessive cervical discomfort and increased vestibular load—empirically validating clinicians' concerns about the risk of postural compensation. As an exploratory quantitative usability measure, the overall SUS score after hands-on testing indicated excellent perceived usability, with a median score of 95 (IQR 82.5-97.5). The SUS was administered once after the full hands-on testing session, as this phase was intended to provide a preliminary indication of the perceived usability of the overall MR training experience [50].

From the brief focus group discussion, participants reported that both MR demos were generally engaging and enjoyable, with initial apprehension related to the headset or task demands resolving quickly. Some participants described the headset experience as "really impressive" and "fascinating," highlighting the novelty and positive impact of the immersive interaction. No symptoms of nausea or cybersickness were reported. The clock application was perceived as calmer and more comfortable due to its reliance on auditory guidance, which reduced the need for downward gaze. In contrast, the grape application was described as more dynamic and engaging, with participants commenting that "the game was very beautiful" and "very fun," and appreciating the realistic and pleasant sound feedback. However, interaction with floor-level targets was associated with postural discomfort and reduced stability. One participant observed, "my posture is a bit strange," while another reported that "when looking down, I lose my balance a little." Participants therefore suggested presenting targets at a higher level to reduce head flexion. Additional observations included difficulties related to visual contrast and the use of corrective eyewear.

RenderX

Phase 6: Final MR Concept—Head Your Limits App

Phase 6 synthesized requirements and insights into the final application architecture, resolving identified tensions through integrated problem-solving. The core innovation repositioned targets from floor level to eye level (12-hour clock configuration) while shifting from foot-based occlusion to HMD position tracking. This modification simultaneously resolved multiple constraints reported in Table 1 and considered the following elements. First, ergonomic resolution: eye-level positioning enabled a neutral head posture, eliminating downward flexion burden, cervical strain, and vestibular load. Second, biomechanical validity: HMD tracking created kinematic coupling between target engagement and center-of-mass displacement onto the stepping limb, physically enforcing intended postural control. Third, proprioceptive preservation: distributed clock layout reduced visual guidance dependence on lower-limb movement, preserving proprioceptive engagement and reducing visual-dominance compensatory strategies. Fourth, caregiver proximity: HMD-based tracking permitted caregiver proximity without target occlusion, enabling physical support during execution. Fifth, gamification integration: realistic goal-celebration and crowd-disappointment sonification, with a soccer metaphor (ball-heading game), enhanced intrinsic motivation. Sixth, progress tracking: personalized end-of-session reports quantified successful contacts, distance, and balance quality, supporting self-efficacy. Seventh, cognitive-motor integration: eye-level distractors supported the training of rapid decision-making abilities.

The Head Your Limits application exemplifies unified problem-solving, in which ergonomic optimization, biomechanical validity, proprioceptive preservation, safety supervision, gamification, and progress tracking were integrated into a coherent architecture. Each modification reinforces the others: eye-level positioning enables ergonomic comfort and HMD tracking; HMD tracking enables caregiver proximity and proprioceptive preservation. The design directly addresses all clinician-identified challenges and integrates all patient-derived requirements, demonstrating how rigorous stakeholder engagement and iterative prototyping transform competing design tensions into integrated solutions aligned with therapeutic efficacy, patient experience, and clinical safety.

Table 1. Summary of stakeholder-derived requirements identified during the user-centered co-design process of the Head Your Limits application. The table summarizes key patient- and clinician-derived needs emerging across the co-design phases, their source, their translation into specific design solutions implemented in the final mixed-reality application, and the expected clinical benefit in people with MS[a].

Problem or requirement	FG[b] source	"Head Your Limits" application solution	Clinical benefit
Overreliance on visual feedback (proprioceptive loss)	Clinicians (FG2)	Neutral head posture reduces visual guidance on lower limbs; HMD[c] tracking forces center-of-mass displacement	Preserved proprioceptive integration and reduced avoidance of weight shifting on the stepping leg
Neck flexion discomfort and vestibular overload	Patients (FG3, grape app)	Eye-level targets (no downward head flexion)	Eliminated cervical burden and sustained comfort for extended sessions
Lack of gamification and engagement	Patients (FG1)	Realistic goal celebration (audio + visual) vs crowd disappointment	Enhanced intrinsic motivation and higher session adherence
Insufficient progress tracking	Patients (FG1)	Personalized end-of-session reports (targets, distance, and balance quality)	Performance awareness and self-efficacy enhancement
Safety: caregiver supervision requirement	Clinicians (FG2)	HMD-based tracking (no hand and foot occlusion) allows caregiver proximity	Supervision feasible without interference and fall risk mitigation
Biomechanically invalid motor execution	Clinicians (FG2)	Head-actuated target requires center-of-mass shift onto stepping limb	Valid gait motor learning and functional transfer to real-world
Accessibility: head flexion during visual guidance	Clinicians (FG2)	12-hour clock layout at eye level	Distributed targets reduce sustained head flexion and inclusive design
Difficulty increase: progressive scaling of environmental complexity	Clinicians (FG2)	Eye-level target distractors	Training of rapid decision-making abilities

[a]MS: multiple sclerosis.

[b]FG: focus group.

[c]HMD: head-mounted display.

The application was named Head Your Limits to reflect its underlying rehabilitative rationale. The term head refers both to the act of heading a ball and, more broadly, to the active and intentional engagement required to challenge balance control. The word *limits* alludes to the participants' limits of dynamic stability that the intervention aims to explore and expand. The name also conveys the idea that functional limitations are not solely determined by neurological impairment but are often shaped by conservative movement strategies adopted in response to fear of falling [53] and kinesiophobia [54]. In this sense, the

XSL•FO
RenderX

application is designed to encourage users to safely challenge their limits, promoting exploratory and adaptive motor behavior. This perspective aligns with contemporary approaches in neurological rehabilitation, which emphasize the guided discovery of motor abilities and strategies rather than the mere repetition of predefined movement patterns [55].

Discussion

Principal Results

This study aimed to illustrate the user-centered iterative co-design process of a home-based MR rehabilitation application for volitional stepping training in people with MS. Our results show that integrating patient, clinician, and engineering perspectives enabled the identification and translation of key design requirements into the final Head Your Limits application while addressing common tensions in rehabilitation technology development, such as ergonomic burden, biomechanical validity, sensory reliance, caregiver involvement, and user engagement.

The adopted co-design methodology can be interpreted as a concrete operationalization of the 6 ISO 9241-210 principles reported by Ortiz-Escobar et al [46] in the context of assistive technology design. First, the principle that "the design is based upon an explicit understanding of users, tasks, and environments" was addressed by exploring the rehabilitation experiences, functional limitations, perceptual needs, safety concerns, and home-use constraints of people with MS, together with the clinical and technical requirements identified by rehabilitation professionals and an engineer. Second, the principle that "users are involved throughout design and development" was reflected in the sequential involvement of people with MS during the initial online focus groups and subsequent hands-on prototype testing [54], with clinician and engineering input incorporated between these patient-centered phases. Third, the principle that "the design is driven and refined by user-centered evaluation" was operationalized by using stakeholder feedback to develop, compare, and refine the 2 MR prototypes, with the strengths and limitations of the clock and grapes demos informing subsequent design decisions. Fourth, the iterative nature of the process was ensured by documenting the outputs of each phase, sharing them within the research team, and using them to guide the next development step. Fifth, the principle that "the design addresses the whole user experience" was reflected in the fact that evaluation was not limited to task performance but also considered comfort, fatigue, sensory load, visual accessibility, motivation, perceived safety, headset ergonomics, and caregiver compatibility. Finally, the principle that "the design team includes multidisciplinary skills and perspectives" was implemented by integrating the views of people with MS, physiotherapists, a physiatrist, rehabilitation researchers, and biomedical engineers. In this sense, ISO 9241-210 did not merely provide a conceptual reference for the study but functioned as an organizing framework linking stakeholder involvement, data collection, prototype comparison, iterative refinement, and final design decisions [46].

The co-design sessions culminated in the final Head Your Limits application, an MR-based SGs. In the game, players must hit different targets generated at eye level in a clock-based spatial layout with their heads, simulating a traditional soccer task. The transition from floor-level to eye-level targets combined with HMD-based tracking emerged as a pivotal design decision that enabled biomechanically valid task execution, easier integration of visual distractors, improved safety, and enhanced experiential quality within a single interaction paradigm. Although head-mediated interaction is commonly used in commercial VR entertainment and fitness games [56], its use in rehabilitation contexts has largely focused on engagement rather than on enforcing biomechanically valid movement strategies [57]. In the present application, head-based interaction was deliberately repurposed as a therapeutic constraint to promote center-of-mass displacement during volitional stepping [58], rather than as a purely game-driven interaction mechanic.

Comparison With Prior Work

Previous studies in people with MS [20-22] have explored XR applications for gait adaptability, upper-limb rehabilitation, and personalized exergame-based gait training. Although recent studies on digital interventions for people with MS [59,60] have emphasized the value of participatory development, structured co-design approaches specifically focused on the development of MR-based SGs remain limited [22]. To the best of our knowledge, this is the first study to describe the development of an MR application for volitional step training in people with MS through a cross-sectional qualitative, user-centered co-design process. This study confirms that the participatory approach is particularly relevant for aligning technological functionalities with user needs and supporting the ecological relevance and long-term engagement of digital rehabilitation tools for people with MS [60,61].

Consistent with previous studies [62], the present findings support the inclusion of game-based elements as a relevant design components of MR-based rehabilitation applications. Specifically, participants identified game elements as important features to sustain interest and increase motivation and challenge during repeated training. They also highlighted the importance of clear visual and auditory feedback, including information on progress within the game. Progress tracking was primarily framed by participants as a motivational and self-monitoring feature, intended to support personal goal setting and self-efficacy during training. This is consistent with previous work [20-22,62] showing that feedback systems can support the training performance of people with MS and facilitate interaction with SGs. According to previous studies [20,21], another important design element that should be considered is the possibility of adapting the game based on user performance. This capacity for tailored task challenge adaptation may enable the delivery of this challenging stepping exercise even in people with MS with higher levels of disability, who represent a critical yet often overlooked target population for fall-prevention interventions [10]. Clinicians and engineers emphasized the importance of including a cognitive task during motor training. This is supported by existing evidence showing that dual-task training maximizes improvements in balance and mobility in people with MS [63] and promotes gains in both motor and cognitive outcomes [14].

XSL•FO
RenderX

Compared with existing technological solutions for volitional step training, Head Your Limits leverages the potential of MR to overcome the hardware constraints typically required to train stepping responses, such as stepping mats or exergame pads [14,16]. This flexibility is crucial to increase the number and spatial distribution of targets available to the participants, thereby enhancing both the ecological validity of the task and its individual tailoring to each participant's postural control capacity [64]. Moreover, Head Your Limits presents interaction targets at eye level rather than at foot level. This design choice emerged from the co-design process and prototype testing, where floor-level targets were associated with downward gaze, cervical discomfort, and increased visual dependence on foot placement. By moving the targets to eye level, the final application preserves the therapeutic goal of volitional multidirectional stepping while encouraging body weight transfer and the need for continuous visual monitoring of the feet. This enables the prevention of compensatory mechanisms reported in people with MS, such as inappropriate weight transfer [65] and visual dependency while moving [66].

Limitations

Some methodological limitations should be acknowledged. First, as is inherent in focus group methodology, some participants' feedback may have been influenced by novelty effects, as some were new to MR technologies. Second, given the exploratory nature of focus groups involving early-stage concepts and prototypes, the ability to anticipate long-term usability, fatigue, or safety issues may be limited. Third, focus group dynamics may have influenced participants' individual responses, thereby shaping the expression of personal experiences and needs. Furthermore, formal thematic saturation was not used as a criterion for participant recruitment or study completion. Consistent with the co-design nature of the study, participant involvement was guided by the inclusion of key stakeholder groups and the iterative needs of the development process rather than by a predefined saturation threshold. Consequently, although recurring themes emerged across focus groups, additional stakeholder input may have identified further requirements, preferences, or usability considerations relevant to the development of the mixed-reality application. Finally, the limited focus group sample size and our purposive recruitment strategy limit the representativeness and generalizability of our findings.

Conclusions

In conclusion, this study demonstrates how iterative co-design methodology can effectively guide the development of an MR rehabilitation application by translating diverse stakeholder needs into coherent and clinically meaningful design solutions.

Building on the insights gained through this co-design process, several directions for the future development of the Head Your Limits application can be identified. In particular, by leveraging the adaptive capabilities of MR-based SG, task challenge progression can be personalized to individual motor abilities by dynamically adjusting the spatial and temporal characteristics of the stepping targets. Following a baseline assessment to identify each participant's stepping limits, targets can be positioned to slightly exceed these limits, thereby promoting exploratory and adaptive stepping.

Although the present work does not evaluate clinical effectiveness, it provides a transparent and methodologically grounded account of the design process underpinning Head Your Limits, offering a replicable framework for the development of future rehabilitation technologies. Further work will be required to evaluate the usability, safety, and clinical impact of the MR application in individuals with MS, with effectiveness assessed through outcomes based on stepping performance and fall-related measures.

Acknowledgments

The authors would like to thank all people with multiple sclerosis who participated in the focus groups and prototype testing sessions for their time, insights, and contribution to the co-design of the Head Your Limits application. We also thank the multidisciplinary clinical and technical team involved in the development and testing of the mixed-reality prototypes.

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), the following tasks were delegated to GenAI tools under full human supervision: visualization, proofreading and editing, and translation. The GenAI tool used was ChatGPT 5.5 (OpenAI). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Funding

The present work was supported by #NEXTGENERATIONEU (NGEU) and funded by the Ministry of University and Research (MUR), National Recovery and Resilience Plan (NRRP), project MNESYS (PE0000006)—A Multiscale Integrated Approach to the Study of the Nervous System in Health and Disease (DN. 1553 11.10.2022). The funder had no involvement in the study design, data collection, analysis, interpretation of data, or writing of the manuscript.

Abstract

Background: Minimally invasive endodontics requires precise visualization to preserve tooth structure, often relying on indirect vision with a dental mirror—a challenging skill for dental students. Although virtual reality (VR) simulators provide immersive environments for dental training, most existing systems primarily focus on procedural simulation and haptic feedback, with limited capabilities for real-time mirror positioning and indirect visual guidance.

Objective: The aim of this study was to evaluate verbal, visual, and haptic VR-based mirror guidance for indirect vision during minimally invasive endodontic access cavity preparation.

Methods: Eligible fourth-year preclinical dental students were recruited through institutional email invitations and public announcements. A randomized controlled crossover trial was conducted with 30 participants, who completed all VR sessions in a simulation laboratory under direct investigator supervision to ensure standardized implementation of the training protocol. Participants performed simulated maxillary first molar access cavity preparations under 4 VR mirror guidance conditions—verbal guidance, visual guidance, haptic guidance, and no guidance—following a randomized 4 × 4 Latin square sequence with a 48-hour washout period between sessions. The primary outcome was outcome error score. Exploratory secondary outcomes included operating area visibility, operating area obstruction, operator posture error, task completion time, and Virtual Reality System Usability Questionnaire score. Outcomes were analyzed using linear mixed-effects models accounting for the crossover design. Estimated marginal mean differences (MDs) with 95% CIs and partial eta-squared (ηp^2) effect sizes were reported, with Bonferroni-adjusted pairwise comparisons used to account for multiple comparisons.

Results: Guidance modality significantly affected the primary outcome, outcome error score ($F_{3,84}$=20.34; P<.001; ηp^2=0.421). Compared with no guidance, outcome error scores were significantly lower with verbal (MD −0.50, 95% CI −0.76 to −0.24), visual (MD −0.68, 95% CI −0.94 to −0.42), and haptic guidance (MD −0.63, 95% CI −0.89 to −0.37; all adjusted P<.001). Guidance modality also significantly affected operating area visibility ($F_{3,84}$=12.31; P<.001; ηp^2=0.305). Compared with no guidance, visibility duration was significantly greater with verbal (MD 37.79, 95% CI 11.15-64.43 seconds; adjusted P=.001), visual (MD 59.15, 95% CI 32.51-85.79 seconds; adjusted P<.001), and haptic guidance (MD 31.52, 95% CI 4.90-58.15 seconds;

XSL•FO
RenderX

adjusted *P*=.01). No significant differences were detected for operating area obstruction, operator posture error, task completion time, or usability.

Conclusions: VR-based mirror guidance improved the outcome error score and increased operating area visibility during minimally invasive endodontic access cavity preparation. Verbal, visual, and haptic guidance resulted in fewer outcome errors and greater operating area visibility than no guidance, while no significant differences were detected in other performance measures or usability. These findings demonstrate the potential of diverse feedback modalities to provide effective guidance for indirect vision and inform future development of adaptive VR training systems using 1 or more modalities to suit learner needs.

Introduction

Background

Virtual reality (VR) has become an increasingly prominent tool in health professions education, offering immersive simulation, standardized training environments, and objective performance assessment [1]. Simulation-based education has been shown to enhance psychomotor skill acquisition, facilitate deliberate practice, and reduce reliance on variable instructor-dependent feedback [2]. By enabling repetitive, risk-free practice with integrated performance metrics, VR platforms provide opportunities to enhance technical training while supporting evidence-based educational design [3].

In dental education, VR simulators have been introduced to support psychomotor skill training. These systems allow learners to practice cavity preparation, spatial hand-eye coordination, and instrument control within a controlled digital environment. Previous studies have demonstrated that VR-based dental simulators can improve technical precision, increase learner confidence, and provide reliable performance tracking [4,5]. Recent systematic reviews and meta-analyses have further confirmed the effectiveness of VR simulation in dental education, demonstrating positive effects on knowledge acquisition, technical performance, and learner satisfaction across various disciplines [6]. The application of VR and AR technologies has also expanded into operative dentistry, endodontics, and oral and maxillofacial surgery education, reflecting their increasing role in supporting clinical skills training and competency development [7-9]. Beyond procedural replication, modern VR platforms increasingly incorporate real-time feedback mechanisms, reflecting the growing recognition that structured augmented feedback is central to effective motor skill development [10,11]. Evidence from immersive learning research further suggests that virtual environments can enhance psychomotor skill acquisition, spatial understanding, and learner engagement through realistic and interactive training experiences [12].

Minimally invasive dentistry, particularly minimally invasive endodontic access cavity preparation, requires a high level of precision and spatial awareness [13]. Contemporary endodontic philosophy emphasizes preservation of pericervical dentin and conservation of coronal tooth structure to maintain fracture resistance and long-term tooth survival [14]. However, reducing access cavity size must be carefully balanced against adequate visualization of the pulp chamber and canal orifices. Insufficient access or compromised visualization may increase the risk of missed canals, iatrogenic errors, and procedural complications [15,16]. Achieving this balance depends heavily on accurate indirect vision using a dental mirror. For novice learners, maintaining appropriate mirror orientation while simultaneously controlling bur movement presents a substantial cognitive and psychomotor challenge.

Despite the importance of indirect vision control, structured training of mirror orientation remains limited. Traditional instruction relies primarily on instructor observation and verbal correction, which may vary in timing, frequency, and specificity. While existing VR dental simulators focus largely on bur position, cavity form, and volumetric preparation metrics, few systems incorporate dedicated mirror alignment guidance as an explicit instructional component [5,17]. Given the critical role of visualization in minimally invasive access cavity preparation, the absence of structured mirror feedback represents a meaningful educational gap.

Effective psychomotor training depends not only on practice but also on well-designed augmented feedback. Motor learning theory emphasizes the importance of knowledge of performance feedback in supporting early-stage skill acquisition and refining movement patterns [18]. At the same time, Cognitive Load Theory posits that instructional support must be carefully calibrated to minimize extraneous cognitive load and optimize working memory resources during complex tasks [19]. Multimedia Learning Theory further suggests that feedback modalities should be integrated coherently to avoid competing sensory demands [20]. Therefore, the integration of structured, multimodal mirror guidance within VR environments represents a promising but underexplored strategy for enhancing indirect vision training in minimally invasive dentistry.

To address this need, a mirror positioning guidance module has been developed as an extension of the previously validated VR-based dental training platform [17]. The current iteration integrates 3 real-time feedback modalities—verbal, visual, and haptic—to support learners in maintaining appropriate mirror orientation during minimally invasive operation. The educational impact of different feedback modalities for VR-based mirror

XSL•FO
RenderX

guidance has not been systematically investigated. Understanding how verbal, visual, and haptic feedback influence mirror orientation performance and learner experience is essential for evidence-based design of VR-supported preclinical dental education.

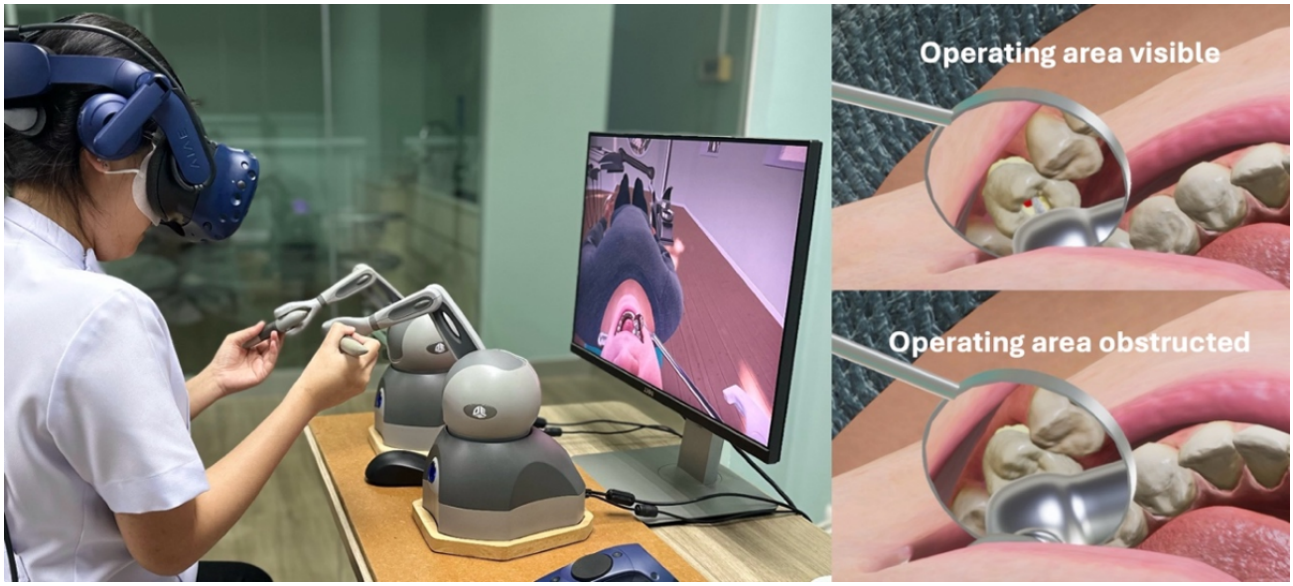
Study Objectives

The aim of this study was to evaluate verbal, visual, and haptic VR-based mirror guidance for indirect vision during minimally invasive endodontic access cavity preparation. The primary outcome was outcome error score, while operating area visibility, operating area obstruction, operator posture error, task completion time, and usability were evaluated as exploratory secondary outcomes. We hypothesized that the different VR-based mirror guidance modalities would produce different effects on indirect vision performance, with guided conditions expected to reduce outcome error score compared with the no-guidance control condition.

Methods

Ethical Considerations

This study was approved by the Human Research Ethics Committee of Thammasat University (approval number COA No. 003/2569) on January 22, 2026. The study was conducted in accordance with the ethical principles of the Declaration of Helsinki. The trial was prospectively registered with the Thai Clinical Trials Registry (TCTR20260126008) on January 26, 2026, before enrollment of the first participant on July 25, 2026. All participants provided written informed consent before participation. Participation was voluntary, and participants were informed of their right to withdraw from the study at any time without academic consequences. Participant data were anonymized before analysis and securely stored to ensure confidentiality. No personally identifiable information or identifiable participant images are included in this manuscript. Participants received financial compensation of 50 Thai baht (THB; approximately US $1.50) for each experimental session, consistent with the institutional rate for student research assistants. As each participant completed 4 experimental sessions, the total compensation was 200 THB (approximately US $6) per participant. The study was designed, conducted, and reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2025 statement and the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health) guidelines [21,22]. The CONSORT checklist and the trial protocol are available in Multimedia Appendices 1 and 2.



Overview

A randomized crossover trial was conducted to evaluate the effectiveness and usability of different VR-based mirror guidance modalities for improving indirect vision during minimally invasive endodontic access cavity preparation.

VR-Based Mirror Guidance

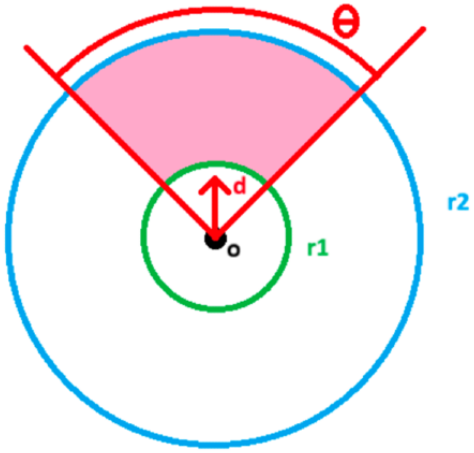
The VR dental simulator was developed using Unreal Engine (UE) 4.27.2. Stereo visualization was provided through an HTC Vive Pro Eye head-mounted display (resolution 2880 × 1600) integrated with eye-tracking sensors using the SteamVR and SRanipal Unreal plugins. A virtual dental handpiece and mouth mirror were manipulated using 2 Geomagic Touch haptic devices (3D Systems), providing 6 degrees of freedom and force feedback to simulate tactile interaction with the virtual tooth. Realistic drilling sounds and visual rendering were incorporated to enhance immersion (Figure 1). The source code for the VR-based mirror guidance system and demonstration materials, including screenshots and video recordings, are provided in Multimedia Appendices 3 and 4.

Figure 1. Virtual reality (VR) dental simulator and examples of operating area visibility assessment during minimally invasive endodontic access cavity preparation using indirect vision. The simulator used in this randomized controlled crossover trial allowed fourth-year preclinical dental students to manipulate a virtual dental handpiece and mirror using a head-mounted display and haptic devices. Representative images demonstrate conditions in which the operative field (including the bur tip and the occlusal cutting area) was either visible or obstructed during access cavity preparation.

XSL•FO
RenderX

A virtual patient model was created using the MetaHuman framework and integrated into the UE environment. The left maxillary first molar (tooth 26) was replaced with a custom tooth model reconstructed from microcomputed tomography (micro-CT) scans of human teeth to provide anatomically realistic internal structures. The model was implemented using UE's Procedural Mesh Component and dynamically rendered using a metaballs-based surface reconstruction approach. Haptic interactions during drilling were simulated using a sphere-packing representation of enamel, dentin, and pulp tissues, with force and friction parameters calibrated in consultation with an expert dentist.

Mirror Correction Algorithm



Overview

The mirror correction algorithm was developed to detect suboptimal mirror positioning and automatically trigger appropriate VR guidance. All mirror guidance modalities (verbal, visual, and haptic) were designed to assist the user in adjusting the dental mirror so that the tooth remained visible when the dental handpiece contacted the tooth. The guidance system operated under 3 conditions that determined when corrective feedback was applied.

Condition A: Mirror Position Outside the Optimal Area

Guidance was triggered when the mirror position was outside a predefined optimal region where the mirror was expected to be positioned. As illustrated in Figure 2, the optimal region was defined as a conical space characterized by 5 parameters: origin point (o), inner radius (r_1), outer radius (r_2), cone direction (d), and cone angle (θ).

Figure 2. Visualization of the mirror correction algorithm used in the virtual reality–based mirror guidance system for indirect vision training during minimally invasive endodontic access cavity preparation. The optimal mirror positioning region is modeled as a conical space defined by the origin point (o), inner radius (r1), outer radius (r2), cone direction (d), and cone angle (θ). Mirror positions located within this predefined region were considered acceptable for achieving appropriate reflection of the operating area during the randomized controlled crossover trial.

To determine whether the mirror was within the optimal region, the following procedure was applied:

- Let p represent the mirror position in 3D space.
- Compute the unit vector d_p from o to p.
- Calculate the angle (θ_p between d and d_p.

If $\theta_p < \theta/2$ and the distance between p and o lies between r_1 and r_2, the mirror is considered inside the optimal region.

Condition B: Incorrect Mirror Orientation

When the mirror was positioned within the optimal region but oriented incorrectly, the reflected image did not allow the tooth to be seen by the user. Mirror orientation was evaluated based on the user's head and eye positions and the mirror's reflection geometry.

The following variables were used: user head position (p_h), left eye position (p_{le}), right eye position (p_{re}), mirror position (p_m), mirror normal (n_m), tooth position (p_t), and a base angular threshold (θ_{th}).

The orientation algorithm consisted of the following steps:

- Compute the distance (d) between p_t and p_m.
- Adjust the angular threshold (θ'_{th} based on d, such that the allowable angle decreases as the mirror-tooth distance increases.
- Calculate the reflection vector (r) using the tooth position (p_t) as the source and the mirror position (p_m) and normal (n_m) as the reflection parameters.
- Compute normalized target vectors from the mirror to the head (t_h), left eye (t_{le}), and right eye (t_{re}).
- Calculate the angle between r and each target vector.
- If the smallest angle exceeded θ'_{th}, the tooth was considered not visible in the mirror.

Condition C: Operating Area Obstructed by the Handpiece

Even when the mirror was correctly positioned and oriented, the operating area could still be obstructed by the dental handpiece. To detect occlusion, the following variables were considered: tooth tip position (p_t), handpiece head position (p_b), handpiece head radius (r_b), and mirror position (p_m).

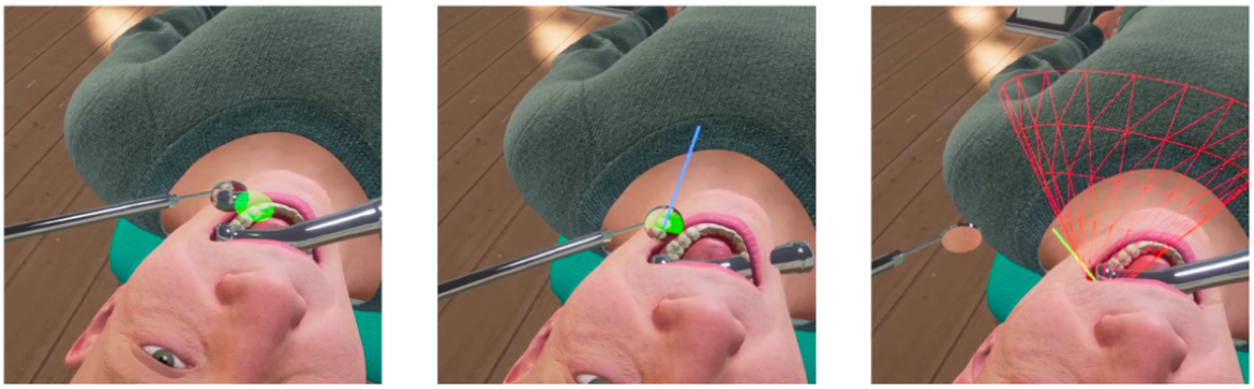
XSL•FO
RenderX

The occlusion detection algorithm was implemented as follows:

- Construct a line (l) from the tooth tip (p_t) to the mirror (p_m).
- Compute the distance (d_{lb}) between the handpiece head (p_b) and the closest point on line (l).
- If $d_{lb} > r_b$, the view was unobstructed; otherwise, the view was considered obstructed.

When occlusion occurred, a suggested mirror position (p'_m) was computed by identifying tangent lines between the tooth tip and the handpiece head. The suggested mirror position was selected along the tangent line that produced the smallest angular deviation from the original viewing line while maintaining the same distance from the tooth.

Verbal Guidance



Verbal guidance was implemented to notify users when mirror adjustment was required during indirect vision tasks. The system assumed that dental students were familiar with basic mirror manipulation and therefore provided brief corrective prompts rather than detailed instructions. When the mirror correction algorithm detected one of the predefined conditions described in the previous section, prerecorded audio cues were triggered as follows:

- Condition A: “move mirror to the mouth.”
- Condition B: “adjust mirror.”
- Condition C: “tool tip is not visible.”

Visual Guidance

The visual guidance system incorporated multiple visual cues, including a ghost mirror, a reflection line, and a cone visualization, each activated according to specific mirror positioning conditions (Figure 3). These components were designed to provide spatial information to assist learners in achieving appropriate mirror alignment and indirect visualization. The ghost mirror represented the ideal mirror position and orientation required for proper indirect visualization of the tooth. When displayed, users were instructed to align the real mirror with the ghost mirror. The ghost mirror orientation was computed based on reflection geometry such that the tooth location would appear in the mirror when viewed by the user. The opacity of the ghost mirror was dynamically adjusted according to positional and angular differences between the real mirror and the ideal mirror position, providing continuous visual feedback during alignment. Similar ghost tool visualization has previously been used to support medical skills training [23].

Figure 3. Visual guidance components of the virtual reality–based mirror guidance system. (A) Ghost mirror indicating the ideal mirror position and orientation to achieve indirect visualization. (B) Reflection line representing the reflection vector from the tooth surface to facilitate fine adjustment of mirror orientation. (C) Cone visualization indicating the predefined optimal spatial region for mirror placement during minimally invasive endodontic access cavity preparation.

To assist with fine adjustment of mirror orientation, a reflection line was also displayed. The reflection line represented the reflection vector of the tooth on the mirror surface. When the mirror was oriented correctly, this line pointed toward the user’s head position, indicating that the tooth would be visible in the mirror. The opacity of the reflection line decreased as the reflection vector approached the user’s head, minimizing visual distraction once the correct orientation was achieved.

Finally, when the mirror position moved outside the predefined optimal region, a cone visualization was displayed. This cone indicated the acceptable spatial region for mirror placement and guided the user to reposition the mirror back into the optimal area. Based on the mirror correction conditions described in the previous section, visual guidance was applied as follows:

- Condition A: the cone visualization was displayed to guide the mirror back into the optimal region.
- Condition B: the ghost mirror and reflection line were displayed at the current mirror position to assist with orientation correction.
- Condition C: the ghost mirror was displayed at the suggested mirror position calculated by the algorithm to help restore visibility of the operating area.

Haptic Guidance

The haptic guidance strategy integrated corrective force feedback with haptic disturbance to enhance user awareness of inappropriate mirror positioning. Feedback was applied according to the mirror correction conditions described previously.

XSL•FO
RenderX

- Condition A: when the mirror was located outside the optimal region, a direct haptic force was applied to the mirror device, directing the user's hand toward the optimal area.
- Condition B: when the mirror was positioned within the optimal region but incorrectly oriented, the system referenced the most recent mirror position at which the tooth was successfully visible. Let this position be p, and the current mirror position be p_m.
- If the distance between p and p_m exceeded a predefined threshold (d_{th}, a corrective force was applied to guide the mirror from p_m toward p.
- If the distance between p and p_m was below the threshold but the angular difference exceeded an orientation threshold (θ_{th}), haptic noise was applied to the device to indicate that the mirror orientation should be adjusted. Haptic noise has previously been shown to support motor skill learning [24].
- Condition C: when the operating area was obstructed by the handpiece, a corrective force was applied to guide the mirror from its current position toward the suggested mirror position calculated by the algorithm.

Patient and Public Involvement

Patients and members of the public were not involved in the design, conduct, reporting, or dissemination planning of this trial. The study involved fourth-year preclinical dental students as participants and evaluated a VR-based educational intervention.

Trial Design

This study was conducted as a randomized 4 × 4 Latin square crossover trial to evaluate the effectiveness and usability of different VR-based mirror guidance modalities, including verbal, visual, and haptic guidance, for improving indirect vision during minimally invasive endodontic access cavity preparation.

Changes to Trial Protocol

The study protocol was amended to increase the approved sample size, with the amendment approved on July 17, 2026. No changes were made to the study outcomes or intervention protocol.

Trial Setting

The trial was conducted in the VR simulation laboratory at the Faculty of Dentistry, Thammasat University, Thailand.

Eligibility Criteria

Fourth-year preclinical dental students who had successfully completed the preclinical endodontics course were eligible to participate. Students with prior experience using a dental VR simulator were excluded.

No additional eligibility criteria were specified for the study site because the trial was conducted at a single simulation laboratory. No eligibility criteria were specified for intervention providers because the assigned guidance was delivered automatically by the VR system. The supervising investigator provided standardized orientation and technical support but did not provide instructional guidance or performance feedback during the experimental tasks.

Intervention and Comparator

Overview

The intervention consisted of real-time VR-based guidance for dental mirror positioning during minimally invasive endodontic access cavity preparation. It was delivered through a VR dental simulation system incorporating a head-mounted display, 2 haptic devices, and real-time performance monitoring.

Core Components and Mode of Delivery

The intervention comprised 3 active guidance conditions—verbal, visual, and haptic guidance—and a no-guidance control condition. All guidance was delivered automatically by the VR system during task performance. A mirror positioning correction algorithm continuously monitored the position and orientation of the virtual dental mirror during access cavity preparation. When suboptimal mirror positioning resulted in reduced visibility of the operating area, the system automatically provided real-time guidance to assist the participant in adjusting the mirror to restore appropriate indirect visualization. Verbal guidance provided auditory instructions, visual guidance displayed directional cues within the VR environment, and haptic guidance delivered force-based directional cues through the haptic device controlling the dental mirror. In the no-guidance condition, participants performed the same task using the same VR system without these corrective guidance cues. Guidance in the 3 active conditions was delivered synchronously and was automatically triggered according to the participant's real-time mirror positioning performance. No instructor-delivered mirror positioning feedback, external communication, web-based interaction, or adaptive educational content beyond the mirror correction algorithm was incorporated.

Setting, Equipment, and Intervention Provider

All sessions were conducted individually in a supervised simulation laboratory at Thammasat University Faculty of Dentistry. The VR simulator incorporated a head-mounted display and 2 Geomagic Touch haptic devices, which provided 6-degree-of-freedom positional sensing and 3-degree-of-freedom force feedback for manipulation of the virtual dental handpiece and dental mirror. Before participant enrollment, the VR simulator and mirror guidance modules underwent technical testing to ensure stable system performance, accurate delivery of verbal, visual, and haptic guidance, and reliable recording of performance data. The virtual training environment, instrument settings, and guidance parameters were standardized and remained unchanged throughout the study. Participants did not require personal devices, internet access, or payment to use the system.

The VR system itself delivered the assigned guidance automatically. Before the first experimental session, an investigator provided each participant with standardized face-to-face orientation and instructions on operation of the VR simulator and study procedures. During experimental sessions, an investigator was present to supervise protocol implementation

XSL•FO
RenderX

and provide technical support only; no additional instructional coaching, mirror positioning guidance, or performance feedback was provided by the investigator.

Exposure and Schedule

Each participant performed a minimally invasive endodontic access cavity preparation on tooth 26 (maxillary left first molar) under all 4 guidance conditions. The order of conditions was determined by the randomized crossover sequence. There was no fixed duration for an experimental session; participants continued the task until access cavity preparation was completed. Consecutive sessions were separated by a 48-hour interval to minimize immediate carryover effects, including fatigue and short-term adaptation to the preceding guidance condition; however, this interval was not intended to eliminate longer-term motor learning or skill acquisition associated with repeated task performance [25]. Participants requiring visual correction were instructed to wear their habitual eyeglasses or contact lenses during all VR sessions to ensure that tasks were performed under their normal corrected visual conditions.

Intervention Standardization and Fidelity

The same VR hardware, virtual environment, task, instrument settings, and guidance parameters were used throughout the study. Implementation fidelity was maintained through automated delivery of the assigned guidance condition and direct investigator supervision of each session. Performance data were automatically recorded by the VR system at the end of each session. After completing each guidance condition, participants completed the Virtual Reality System Usability Questionnaire (VRSUQ) [26].

Outcomes

The primary outcome was the outcome error score. Secondary outcomes included the duration of operating area visibility, operating area obstruction, operator posture error, task completion time, and usability score, and were interpreted as exploratory measures of procedural performance and user experience. All quantitative performance outcomes, including outcome error score, operating area visibility, operating area obstruction, operator posture error, and task completion time, were automatically recorded and calculated by the VR simulator using predefined algorithms, thereby eliminating the need for human outcome assessment.

The outcome error score (0-15) was automatically generated using a previously validated computational assessment system [17]. The algorithm compared the final virtual access cavity with an expert-defined ideal drilling pattern of the pulp chamber walls and floor. Similarity was quantified using the F_1-score and converted into a standardized clinical error scale using a supervised learning model. Previous validation demonstrated excellent agreement between automated scores and expert evaluation (Cohen κ=0.87; intraclass correlation coefficient [ICC]=0.98).

The duration of operating area visibility (seconds) was defined as the cumulative time during which the bur tip and the occlusal region of the tooth being actively prepared were visible to the operator through the dental mirror during cutting. The VR simulator continuously assessed this condition at every rendering frame using a geometric reflection-based algorithm. A vector projected from the target tooth surface toward the mirror was reflected according to the mirror orientation and compared with vectors directed from the mirror toward the left eye, right eye, and cyclops eye positions. When the minimum angular difference exceeded a predefined threshold, the target area was considered not visible through the mirror.

The duration of operator posture error was defined as the cumulative time during which the operator's head position or orientation deviated beyond predefined thresholds from an individually calibrated reference posture. Before each session, participants established their preferred ergonomic head position and orientation, which were used as the reference for continuous posture monitoring.

The usability of the VR system was assessed using the VRSUQ [26], a validated VR-specific instrument developed to comprehensively evaluate perceived usability in immersive virtual environments. Unlike general usability scales such as the System Usability Scale (SUS) [27], which are designed for broad application across conventional systems, the VRSUQ specifically captures VR-related dimensions, including interaction, feedback, and user experience within 3D environments. The questionnaire was developed through literature review and expert input, and its construct validity was established using exploratory and confirmatory factor analyses across multiple VR systems. Responses were rated on a 5-point Likert scale and converted to a composite usability score ranging from 0 to 100, with higher scores indicating better usability.

Additional participant feedback was collected through an optional open-ended written comment following completion of the VRSUQ. The purpose of this feedback was to capture participants' subjective impressions and suggestions regarding the different guidance modalities. Comments were reviewed by the research team and descriptively summarized to identify common observations related to usability, clarity of feedback, and perceived challenges. Given the exploratory nature and limited depth of these brief written comments, no formal qualitative coding, thematic analysis, or interrater reliability assessment was performed.

Harms

Potential harms were defined as physical discomfort, disorientation, dizziness or motion sickness, mental burden such as tension or frustration, or other VR-related adverse effects experienced during or immediately after the simulation. Harms were assessed through direct observation by the supervising investigator, participant reporting, and prespecified items in the VRSUQ, which all participants completed after each VR session. Specifically, the VRSUQ included items assessing dizziness or motion sickness and mental burden such as tension or frustration during VR use. Participants were also instructed to report any symptoms immediately during or after each simulation session.

Sample Size

The sample size was calculated a priori using G*Power (version 3.1.9.7) for a repeated-measures crossover design. The calculation was based on the primary outcome, outcome error

XSL•FO
RenderX

score. Secondary performance outcomes were considered exploratory and were not included in the a priori sample size estimation. Assuming a medium effect size (Cohen *f*=0.25), an α level of .05, a power of 90%, and an assumed correlation among repeated measures of 0.60, a minimum sample size of 25 participants was required. This approach was consistent with a previous VR-based dental education study involving similar learner populations and performance-based outcomes, although that study did not specifically evaluate mirror guidance [28]. To account for potential participant withdrawal or incomplete datasets, 30 participants were recruited. No interim analyses were planned or conducted, and no stopping guidelines were specified.

Randomization

Sequence Generation

Participants were randomly assigned to 1 of 4 intervention sequences according to a balanced 4 × 4 Latin square crossover design. The random allocation sequence was generated by an independent statistician who was not involved in the study design or participant recruitment. Restricted randomization using the balanced Latin square design ensured that each participant completed all 4 intervention conditions (verbal guidance, visual guidance, haptic guidance, and no guidance) in a predefined sequence, with each condition appearing once in each study period across the 4 predefined sequences to control for potential order effects.

Allocation Concealment Mechanism

Allocation concealment was achieved using sequentially numbered, sealed, opaque envelopes containing the randomized intervention sequences. The envelopes were opened only after participant enrollment to maintain concealment of sequence allocation.

Implementation

Participants were enrolled by the research team, who did not have access to the random allocation sequence before enrollment. After enrollment, intervention sequences were assigned by the research team according to the sequentially numbered, sealed, opaque envelopes. The allocation sequence remained concealed until the corresponding envelope was opened after enrollment.

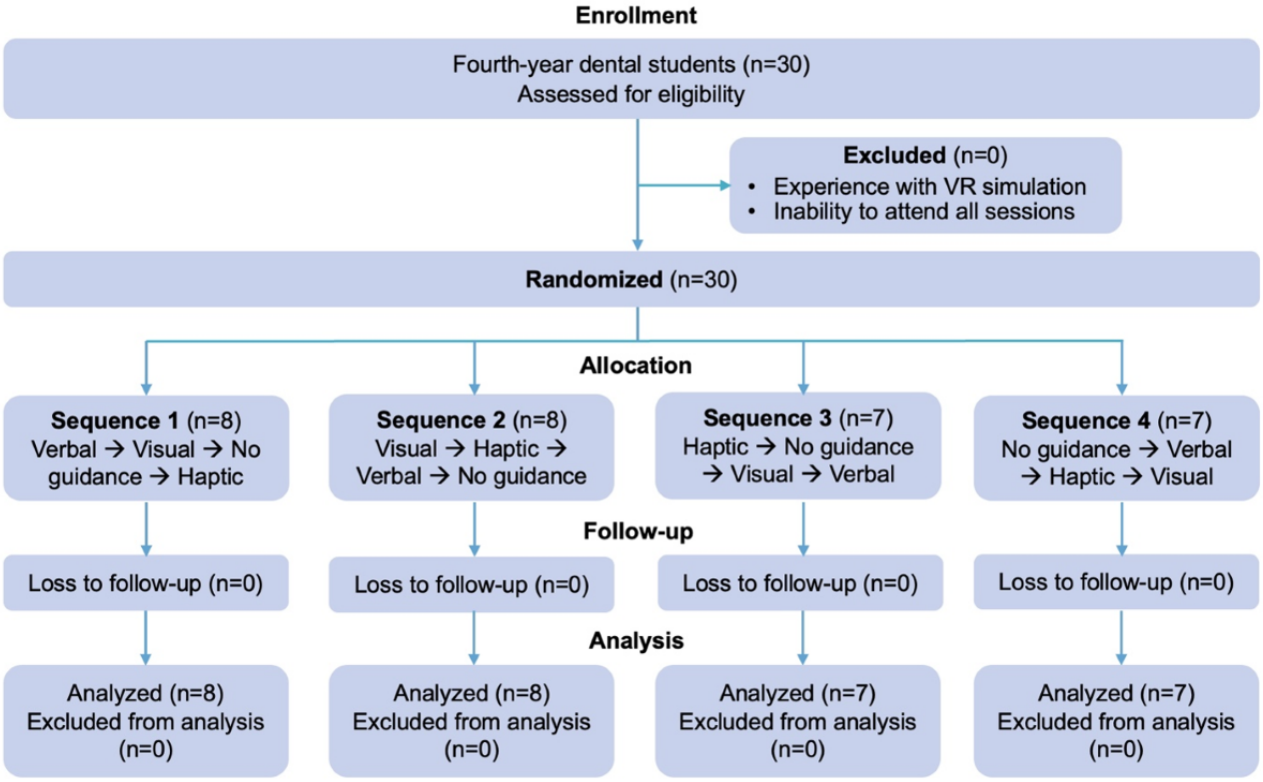
Blinding

Participant blinding was not feasible because the 4 VR mirror guidance conditions (verbal, visual, haptic, and no guidance) were inherently distinguishable during the intervention. Investigators supervising the VR sessions were also aware of the assigned guidance conditions. Participants were not informed that any specific guidance modality was considered the intervention of primary interest or that the no-guidance condition served as the comparator. Performance outcomes were automatically recorded by the VR simulator, reducing the potential for assessor-related bias. Statistical analyses were performed by an independent statistician who was not involved in the study design and was blinded to the intervention labels.

Statistical Methods

Statistical analyses were performed using IBM SPSS Statistics (IBM Corp). A linear mixed-effects model was used to evaluate the effects of VR guidance condition (verbal, visual, haptic, and no guidance) on performance and usability outcomes within the 4 × 4 Latin square crossover design. The model included fixed effects for treatment (guidance condition), period, and sequence, with participants treated as a random effect to account for repeated measurements within individuals. A compound symmetry covariance structure was applied to model the correlation among repeated observations from the same participant.

Because the study was designed with a single predefined primary outcome, the significance threshold was set at α=.05 for the primary analysis. Secondary outcomes were considered exploratory, and no formal adjustment for multiplicity was applied across secondary outcomes. Model assumptions were assessed through residual diagnostics, including visual inspection of residual plots and evaluation of residual normality using the Shapiro-Wilk test. Treatment effects are reported as *F* statistics, *P* values, and partial eta-squared (ηp^2) effect sizes calculated from the corresponding *F* statistics and degrees of freedom. Estimated marginal mean differences (MDs) with 95% CIs and ηp^2 effect sizes were reported, with Bonferroni-adjusted pairwise comparisons used to account for multiple comparisons. A *P* value of <.05 was considered statistically significant.



Results

Participant Flow

Thirty fourth-year preclinical dental students were assessed for eligibility. No students met the exclusion criterion of prior experience with a dental virtual reality simulator. All 30 eligible students provided written informed consent and were enrolled in the study (Figure 4). Participants were randomly assigned to 1 of 4 intervention sequences according to a balanced 4 × 4 Latin square design and completed all 4 experimental conditions (verbal guidance, visual guidance, haptic guidance, and no guidance) across 4 sessions separated by 48-hour washout intervals. All randomized participants completed the study, with no protocol deviations, intervention discontinuations, missing outcome data, or losses to follow-up. All 30 randomized participants were included in the final analysis.

XSL•FO
RenderX

Figure 4. CONSORT (Consolidated Standards of Reporting Trials) flow diagram showing participant progression through the randomized controlled crossover study. Thirty fourth-year dental students were assessed for eligibility and enrolled. Participants were randomized to 1 of 4 sequences in a 4 × 4 Latin square crossover design and completed all 4 virtual reality (VR) mirror guidance conditions (verbal, visual, haptic, and no guidance). No participants withdrew, and data from all 30 participants were included in the final analysis.

Recruitment

Participants were recruited through email invitations and public announcements from July 18 to 23, 2026. Participation was voluntary, and students were free to decline participation without any academic consequences. Outcome and harms assessments were conducted during the experimental sessions from July 25, 2026, to September 4, 2026, with harms assessed during and immediately after each session. The trial ended as planned after all enrolled participants had completed the prespecified study procedures; it was not stopped early.

Intervention and Comparator Delivery

All guidance conditions and the no-guidance comparator were delivered as intended by the VR system, with no deviations from the assigned conditions. The supervising investigator provided standardized orientation and technical support but did not provide additional instructional guidance or performance feedback during the experimental tasks. No concomitant training or other educational interventions related to indirect vision or VR mirror guidance were provided during the trial.

Baseline Data

Thirty participants completed the study (female: n=21, 70%; male: n=9, 30%). The mean age was 22.7 (SD 1.62; range 21-26) years. Twenty-five (83.33%) participants reported myopia and performed the VR sessions using their habitual visual correction (eyeglasses or contact lenses) while wearing the head-mounted display, whereas 5 (16.67%) participants reported normal vision. All participants were right-handed. All participants completed the 4 guidance conditions according to the assigned Latin square sequence (Table 1).

Table 1. Baseline characteristics of fourth-year preclinical dental students enrolled in a randomized controlled crossover trial evaluating virtual reality–based mirror guidance for indirect vision training during minimally invasive endodontic access cavity preparation (n=30).

Characteristic	Value
Age (years), mean (SD)	22.7 (1.62)
Female, n (%)	21 (70)
Male, n (%)	9 (30)
Myopia, n (%)	25 (83.33)
Normal vision, n (%)	5 (16.67)
Right-handed, n (%)	30 (100)

Numbers Analyzed, Outcomes, and Estimation

All 30 randomized participants were included in the analysis of each outcome, with no missing outcome data. Linear mixed-effects analysis demonstrated a significant effect of guidance modality on the primary outcome, outcome error score ($F_{3,84}$=20.34; P<.001; ηp^2=0.421). Mean outcome error scores were 2.57 (SD 0.52) for verbal guidance, 2.39 (SD 0.31) for visual guidance, 2.44 (SD 0.38) for haptic guidance, and 3.07 (SD 0.30) for no guidance. Bonferroni-adjusted pairwise comparisons showed significantly lower outcome error scores for verbal (MD −0.50, 95% CI −0.761 to −0.235; adjusted P<.001), visual (MD −0.68, 95% CI −0.944 to −0.417; adjusted P<.001), and haptic guidance (MD −0.63, 95% CI −0.892 to −0.365; adjusted P<.001) compared with no guidance.

Guidance modality also had a significant effect on the duration of operating area visibility ($F_{3,84}$=12.31; P<.001; ηp^2=0.305). Mean visibility durations were 131.12 (SD 54.29) seconds for verbal guidance, 152.38 (SD 33.68) seconds for visual guidance, 124.79 (SD 46.35) seconds for haptic guidance, and 93.36 (SD 33.98) seconds for no guidance. Bonferroni-adjusted comparisons showed significantly longer durations of operating area visibility with verbal guidance (MD 37.79, 95% CI 11.15-64.43 seconds; adjusted P=.001), visual guidance (MD 59.15, 95% CI 32.51-85.79 seconds; adjusted P<.001), and haptic guidance (MD 31.52, 95% CI 4.90-58.15 seconds; adjusted P=.01) compared with no guidance.

No statistically significant treatment effects were detected for operating area obstruction ($F_{3,84}$=1.94; P=.13; ηp^2=0.065), operator posture error ($F_{3,84}$=0.93; P=.43; ηp^2=0.032), task completion time ($F_{3,84}$=1.73; P=.17; ηp^2=0.058), or usability score ($F_{3,84}$=0.72; P=.54; ηp^2=0.025). Descriptively, operating area obstruction was lowest with verbal guidance (54.92, SD 45.39 seconds) and highest with no guidance (72.96, SD 44.02 seconds). Haptic guidance had the lowest mean duration of operator posture error (1.54, SD 1.04 seconds), while task completion time was shortest with haptic guidance (212.47, SD 56.43 seconds). Usability scores were high and similar across all conditions, ranging from 83.48 (SD 8.99) with verbal guidance to 85.37 (SD 8.23) with visual guidance.

No significant period effects were detected for outcome error score (P=.62), operating area visibility (P=.78), operating area obstruction (P=.38), operator posture error (P=.64), task completion time (P=.79), or usability score (P=.19). Similarly, no significant sequence effects were identified for any outcome (all P>.05), indicating no evidence of systematic period or sequence effects in the crossover design (Table 2).

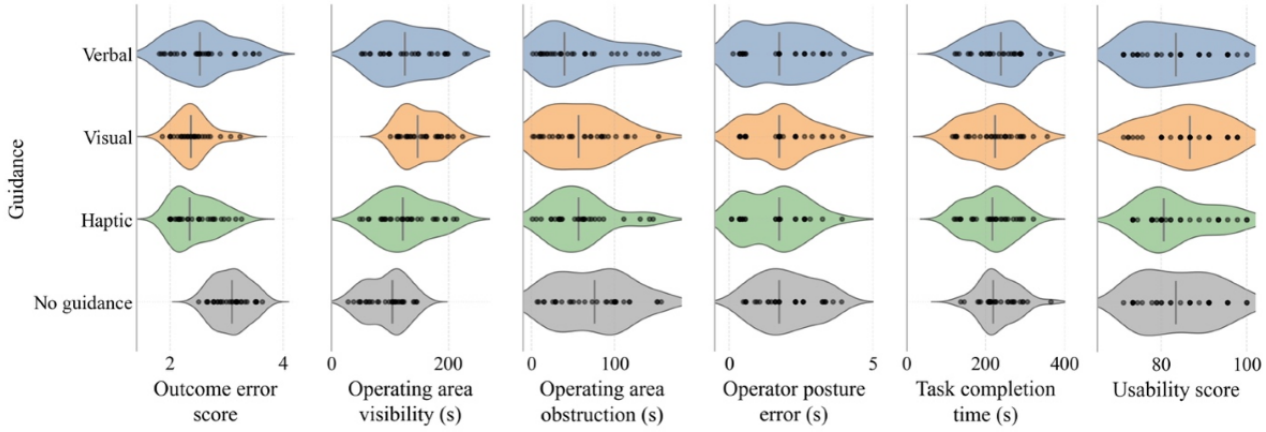

Figure 5 illustrates the distribution of performance and usability outcomes across the 4 guidance conditions.

Table 2. Performance and usability outcomes across 4 virtual reality mirror guidance conditions (verbal, visual, haptic, and no guidance) in a randomized controlled crossover trial of indirect vision training for minimally invasive endodontic access cavity preparation among fourth-year preclinical dental students (n=30). F test values correspond to the fixed effect of guidance modality from the linear mixed-effects models accounting for the 4 × 4 Latin square crossover design.

Outcome	Verbal, mean (SD)	Visual, mean (SD)	Haptic, mean (SD)	No guidance, mean (SD)	*F* test (*df*)	Treatment *P* value	Period *P* value	Sequence *P* value	Effect size, ηp2
Outcome error score (0-15)	2.57 (0.52)	2.39 (0.31)	2.44 (0.38)	3.07 (0.30)	20.34 (3, 84)	<.001	.62	.64	0.421
Duration of operating area visibility (seconds)	131.12 (54.29)	152.38 (33.68)	124.79 (46.35)	93.36 (33.98)	12.31 (3, 84)	<.001	.78	.22	0.305
Duration of operating area obstruction (seconds)	54.92 (45.39)	59.07 (39.84)	57.46 (37.21)	72.96 (44.02)	1.94 (3, 84)	.13	.38	.80	0.065

Figure 5. Distribution of performance and usability outcomes across 4 virtual reality mirror guidance conditions (verbal guidance, visual guidance, haptic guidance, and no guidance) in a randomized controlled crossover trial of indirect vision training for minimally invasive endodontic access cavity preparation among fourth-year preclinical dental students. Violin plots display the distribution density of individual participant values for outcome error score, operating area visibility, operating area obstruction, operator posture error, task completion time, and usability score.

Harms

No important harms or unintended effects were detected during any of the 4 VR mirror guidance conditions. No participants reported physical discomfort, disorientation, motion sickness, or other adverse reactions related to the VR simulation. No unintended positive or negative effects that influenced study participation or outcomes were identified.

Ancillary analyses

The VRSUQ demonstrated good internal consistency in the present study (Cronbach α=0.854), supporting the reliability of the usability measurements obtained from the participants. Table 3 presents the mean VRSUQ scores across the 4 guidance conditions. Overall, participants reported positive usability perceptions for all conditions, with mean item scores generally above 3.75 on the 5-point scale.

Table 3. VRSUQ[a] scores across 4 VR[b] mirror guidance conditions (verbal, visual, haptic, and no guidance) in a randomized controlled crossover trial of indirect vision training for minimally invasive endodontic access cavity preparation among fourth-year preclinical dental students (n=30). Responses were rated on a 5-point Likert scale (1=strongly disagree; 5=strongly agree).

Item	Description	Verbal, mean (SD)	Visual, mean (SD)	Haptic, mean (SD)	No guidance, mean (SD)
1	System responded well to user manipulations without delays	4.40 (0.61)	4.40 (0.55)	4.35 (0.59)	4.40 (0.62)
2	VR system provided clear feedback on manipulations	4.45 (0.59)	4.60 (0.54)	4.40 (0.61)	4.45 (0.64)
3[c]	I kept making errors while using the VR system	4.50 (0.57)	4.70 (0.49)	4.45 (0.56)	4.50 (0.60)
4	Information presented in the virtual environment was easy to understand	3.85 (0.58)	3.85 (0.64)	3.95 (0.51)	4.00 (0.69)
5	The system was user-friendly and easy to learn	4.00 (0.68)	3.90 (0.58)	4.00 (0.63)	4.10 (0.72)
6	It was easy to correct errors during VR use	4.45 (0.56)	4.60 (0.48)	4.50 (0.55)	4.40 (0.61)
7	I enjoyed the virtual reality experience	4.40 (0.59)	4.60 (0.51)	4.60 (0.58)	4.40 (0.63)
8[c]	I experienced dizziness or motion sickness during VR use	4.50 (0.55)	4.60 (0.47)	4.50 (0.54)	4.60 (0.59)
9[c]	I experienced mental burden such as tension or frustration during VR use	4.50 (0.57)	4.50 (0.50)	4.45 (0.57)	4.50 (0.60)
Total	Overall usability score (1-100)	83.48 (8.99)	85.37 (8.23)	83.74 (8.30)	84.11 (8.78)

[a]VRSUQ: Virtual Reality System Usability Questionnaire.

[b]VR: virtual reality.

[c]Items were reverse-coded according to the questionnaire developer [27] so that higher scores consistently indicated more positive usability. The composite usability score (0-100) was calculated as: (mean item score − 1)/4 × 100.

Participants were invited to provide additional comments following completion of the usability questionnaire. These comments were reviewed and summarized descriptively to identify recurring perceptions regarding each guidance modality. Several common observations were identified regarding the perceived advantages, challenges, and areas for improvement of each feedback strategy. Verbal guidance was generally perceived as supportive and reassuring, with participants noting

XSL•FO
RenderX

that it resembled continuous instructor supervision. The auditory reminders that the bur was not visible were described as helpful for maintaining awareness of the operative field, although some participants reported uncertainty regarding the required level of visibility. For visual guidance, some participants reported that the combination of multiple visual elements (eg, ghost mirror, reflection line, and cone visualization) was complex and occasionally confusing. For haptic guidance, some participants noted that although corrective forces were perceived, the direction of the required mirror adjustment was not always clear. Overall, the qualitative feedback aligns with the usability findings and highlights areas for refinement, particularly for visual and haptic guidance modalities.

Discussion

Principal Findings

This randomized controlled crossover trial evaluated the effectiveness and usability of different VR-based mirror guidance modalities, including verbal, visual, and haptic guidance, for improving indirect vision during minimally invasive endodontic access cavity preparation. All 3 guidance modalities significantly reduced outcome error scores compared with no guidance. Verbal, visual, and haptic guidance also significantly increased operating area visibility. In contrast, operating area obstruction, operator posture error, task completion time, and usability did not differ significantly among conditions. Together, these findings suggest that real-time mirror guidance can improve key aspects of indirect vision performance without compromising task efficiency or perceived usability, supporting its integration into VR-based dental training [29,30].

Comparison With Prior Work

Recent work by Samuel et al [23] on visuo-haptic guidance for dental nerve block training provides an important reference point for the design of multimodal feedback in immersive dental simulation. Their system integrates stepwise visual guidance with haptic feedback to support procedural learning, using a gated progression approach in which learners must align a virtual syringe with predefined spatial targets before advancing through the task. In contrast, the present study addresses a different but equally critical challenge in dental education—real-time mirror positioning for indirect vision, which is inherently continuous, dynamic, and less amenable to discrete stepwise guidance. Rather than guiding learners through predefined procedural stages, our visual guidance system supports ongoing spatial alignment between the mirror, operator viewpoint, and operative field. This distinction is important: while prior systems emphasize procedural correctness, our approach targets perceptual-motor coordination under indirect visualization conditions [17].

Differences in task structure may explain the contrasting usability findings. The gated, sequential guidance of Samuel et al [23] may reduce extraneous cognitive load by limiting concurrent visual information, whereas multiple visual elements in the present study may have increased processing demands during mirror interpretation and fine motor control [12,19]. Consistent with Cognitive Load Theory [19], participant feedback identified visual complexity as a source of confusion despite improved operating area visibility; however, cognitive load was not directly measured. Thus, stepwise guidance may suit sequential procedures [23], whereas simplified or adaptive guidance may be more appropriate for continuous perceptual-motor tasks such as indirect vision [12,19]. Future systems could dynamically adjust visual cues according to task phase or learner proficiency.

For haptic guidance, some participants noted that although corrective forces were perceived, the direction of the required mirror adjustment was not always clear. This limitation may be attributable to the characteristics of the haptic interface used in this study. The dental virtual handpiece and mirror were controlled using a Geomagic Touch device, which provides 6 degrees of freedom positional input but only 3 degrees of freedom force output. While users can manipulate the mirror in both translation and rotation, the system can deliver force feedback only in translational directions and cannot provide rotational torque cues. From a motor learning perspective, ambiguous or incomplete feedback may impair accurate error attribution and hinder efficient motor adaptation [18]. The use of a fully actuated 6 degrees of freedom haptic device capable of delivering both force and torque feedback may therefore improve spatial specificity and instructional effectiveness [31].

Lee and Choi [24] demonstrated that haptic disturbance can enhance motor learning by promoting active error correction, whereas the present system primarily used assistive corrective forces. Controlled perturbation or progressive fading of guidance may therefore promote active learning and skill retention [18,24]. Participants also reported surprise when haptic correction was activated, suggesting that abrupt feedback may disrupt ongoing motor execution. Coordinated multimodal feedback may facilitate skill acquisition when sensory channels provide complementary information [18,20,23,24]. Although these mechanisms were not directly evaluated, anticipatory verbal cues before haptic activation may facilitate sensorimotor integration and, consistent with Multimedia Learning Theory [20], support cognitive processing and motor learning.

The challenges associated with indirect vision are not unique to dentistry. Similar visuomotor demands are encountered in laparoscopic and microsurgical procedures, where surgeons must interpret indirect visual information and translate it into precise instrument movements [32-34]. Recent advances in these fields have highlighted the importance of augmented visual feedback to improve spatial orientation and facilitate skill acquisition. For example, Feng et al [32] demonstrated that a virtual pointer for gaze guidance during laparoscopic surgery improved users' ability to maintain visual attention on relevant anatomical targets and enhanced task efficiency. Similarly, Gao et al [33] developed an intraoperative laparoscopic photoacoustic image guidance system integrated with the da Vinci surgical platform to provide additional real-time visual information that supports more accurate localization of anatomical structures. In microsurgical ophthalmic training, Akimoto et al [34] showed that recording and sharing the direct microscopic view of experienced surgeons provided trainees with improved visual references and enhanced understanding of microsurgical maneuvers. Although these technologies differ from the present VR mirror guidance system, they collectively support the

XSL•FO
RenderX

concept that supplementary visual information can reduce the challenges associated with indirect visualization and facilitate the development of complex visuomotor skills [32-34]. The present findings extend this concept to dental education, supporting real-time VR guidance for indirect vision and the adaptation of guidance strategies from image-dependent surgical disciplines to psychomotor dental training.

Strengths and Limitations

The significant improvements in both outcome error scores and operating area visibility suggest that VR-based mirror guidance can enhance procedural accuracy and maintenance of the operative field, while the absence of significant differences in other performance measures indicates that these benefits did not compromise task efficiency or usability. Participant feedback provided complementary insights into the usability, interpretability, and perceived demands of each guidance modality. By building upon an established and validated VR simulation platform and introducing targeted feedback enhancements, the present study isolates the pedagogical contribution of multimodal mirror guidance, minimizing potential confounding effects related to system novelty. The integration of quantitative performance data with qualitative user feedback therefore strengthens both the ecological validity and the practical relevance of the findings for the design of VR-based dental training systems.

Several limitations should be considered. First, participants were fourth-year dental students from a single institution, limiting generalizability. Although adequately powered for the primary outcome, confidence intervals indicate some uncertainty in effect magnitude, and smaller differences in exploratory secondary outcomes may have remained undetected. As no multiplicity adjustment was applied across the exploratory secondary outcomes, nonsignificant findings should not be interpreted as evidence of equivalence. Replication in larger, independent, and more diverse learner populations is warranted. Second, corrected visual acuity and refractive error were not formally assessed, precluding evaluation of their potential influence on VR performance. Third, although the Latin square design balanced condition order and no period or sequence effects were detected, repeated use of the same virtual tooth may have introduced anatomical familiarity or task-specific learning. Fourth, the standardized simulated environment cannot fully reproduce clinical complexity; therefore, the findings reflect short-term training performance rather than clinical effectiveness or direct translation to patient care [8,29,30]. In addition, the haptic system provided 3 degrees of freedom force feedback without rotational torque, potentially limiting haptic guidance for mirror orientation [31]. Further clinical validation is warranted. Fifth, each guidance modality incorporated multiple feedback components, preventing determination of the contribution of individual elements. Sixth, although the VRSUQ showed good internal consistency, further validation in dental VR contexts is warranted [26]. Finally, participant comments were obtained through brief open-ended responses rather than structured qualitative interviews and should therefore be considered exploratory. As the study involved preclinical students in a standardized simulated environment, the findings reflect short-term training performance rather than clinical effectiveness, and further clinical validation is needed.

Future Directions

Future research should include larger, independent, and more diverse cohorts and longitudinal designs to evaluate skill retention, transfer, and clinical performance. Factorial or component-ablation studies could clarify the contribution of individual feedback elements. Fully actuated 6 degrees of freedom haptic devices providing force and torque feedback may improve haptic guidance, while simplified, adaptive, or user-specific visual cues may balance performance benefits with usability. Hybrid strategies combining modalities sequentially or adaptively, including progressive fading of assistance, also warrant investigation.

Conclusions

VR-based mirror guidance improved the outcome error score and increased operating area visibility during minimally invasive endodontic access cavity preparation. Verbal, visual, and haptic guidance resulted in fewer outcome errors and greater operating area visibility than no guidance, while no significant differences were detected in other performance measures or usability. These findings demonstrate the potential of diverse feedback modalities to provide effective guidance for indirect vision and inform future development of adaptive VR training systems using one or more modalities to suit learner needs.

Acknowledgments

The authors thank all the dental students from the Faculty of Dentistry at Thammasat University who participated in this study. The authors declare the use of generative (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), GenAI use was limited to proofreading and language editing under full human supervision. The tool used was ChatGPT-5.5 (OpenAI). Responsibility for the final manuscript lies entirely with the authors, and generative AI tools are not listed as authors or responsible for the final outcomes.

Funding

This research was supported by the Faculty of Dentistry, Thammasat University Research Fund (grant number 9/2569). Haddawy was partially supported by a fellowship from the Hansewissenschaftskolleg Institute for Advanced Study. The funding source had no role in the study design, data collection, data analysis, interpretation of findings, manuscript preparation, or the decision to submit the manuscript for publication.

Abstract

Background: Assessing medication literacy in children is essential for evaluating school-based health education, yet traditional measurement tools often fail to engage children, compromising data quality. Gamified assessments offer an alternative, but their psychometric properties, comparability to conventional formats, and responsiveness to intervention effects require systematic evaluation.

Objective: This study developed and evaluated a gamified assessment tool for measuring medication literacy across 4 domains (knowledge, attitude, perceived behavioral control, and behavioral intention) in elementary school children through 3 sequential phases: psychometric validation, methodological comparison with a paper-based questionnaire, and application to interventions.

Methods: Three independent cohorts were recruited from a single elementary school in Nanjing, China, using cluster random sampling of intact classes (grades 4-6). We adapted the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) framework. Phase 1 (40/81, 49.4% female) includes content validity via 2 rounds of expert review, construct validity using Rasch analysis, and 1-month test-retest reliability. Phase 2 (42/85, 49.4% female) includes a randomized crossover design (10-minute washout), equivalence assessed with an intraclass correlation coefficient (ICC), Bland-Altman analysis, decision consistency, and superiority using the chi-square test (data quality) and 2-tailed independent *t* tests (enjoyment and preference on 5-point Likert scales). Phase 3 (41/85, 48.2% female) includes a single-group pre-post design, with responsiveness evaluated using generalized linear mixed models (GLMMs) with random intercepts. Analyses used R software with an α of .05.

Results: Phase 1 had perfect content validity (scale-level content validity index/average [S-CVI/Ave]=1.00), and the Rasch analysis supported unidimensionality (eigenvalues 2.14-2.25, ratios 0.34-0.40) and item fit (mean infit/outfit mean-square [MNSQ] 0.83-1.23). The test-retest ICCs were 0.76 to 0.92 (95% CI 0.64-0.95). Phase 2 equivalence was confirmed (ICC 0.94-0.99, 95% CI 0.90-0.99; κ=0.87-0.97). Validity rates were 100% (42/42, 95% CI 91.6%-100%) for gamified vs 90.7% (39/43, 95% CI 77.4%-96.9%) for paper (*P*=.13). The gamified tool yielded higher enjoyment (mean 4.26, SD 0.94 vs mean 2.46, SD 0.85; Cohen *d*=2.00, 95% CI 1.46-2.55; *P*<.001) and preference (mean 4.29, SD 0.83 vs mean 2.82, SD 0.97; Cohen *d*=1.62, 95% CI 1.11-2.13; *P*<.001). Phase 3 GLMMs showed time effects for attitude (β=1.74, 95% CI 1.25-2.22; *P*<.001), perceived behavioral control (β=2.86, 95% CI 2.18-3.53; *P*<.001), behavioral intention (β=2.33, 95% CI 1.51-3.15; *P*<.001), and knowledge (incidence rate ratio [IRR]=1.52, 95% CI 1.22-1.89; *P*<.001); time × class interactions were nonsignificant (all *P*≥.19), indicating consistent changes across classes. Effect sizes were moderate to large (Cohen *d*=0.70-1.53, 95% CI 0.36-1.97).

Conclusions: This study develops and validates a gamified assessment tool for children's medication literacy across 3 independent phases, including a randomized crossover comparison with a paper-based format. Unlike child health measures relying on adult proxy reports or adapted adult scales, our child-centered tool was directly validated with students and designed to enhance engagement. The psychometrically sound tool achieves measurement equivalence while offering a pediatric health-promotion outcome measure. The tool can support school-based medication literacy programs and advance health equity by detecting consistent improvements across diverse classrooms.

Introduction

The “Healthy China” initiative and related national policies [1-3] emphasize the critical role of individuals as the primary agents of their own health, advocating for the public to adopt appropriate health perspectives and enhance health literacy, which is defined as the ability to access, understand, appraise, and use information and services in ways that promote and maintain good health and well-being [4], a key determinant of health equity as recognized by the World Health Organization [5]. However, current health literacy research, including associations with medication adherence, self-medication behavior, and other health-related outcomes, has predominantly focused on adult populations [6-13], while largely overlooking children and adolescents as active participants in their own health development [14]. Even studies related to child health often target adult caregivers rather than children themselves [15-20].

A fundamental challenge in advancing child health literacy research is the scarcity of valid and engaging assessment tools tailored to children’s cognitive and developmental levels [14,21]. Existing tools, often adapted from adult questionnaires that typically assess functional skills such as reading prescription labels, understanding medication instructions, and calculating dosages [22], fail to fully engage children and may be susceptible to inattention and social desirability biases, thereby limiting the accurate assessment of intervention impacts and the understanding of children’s health competencies [23].

This gap is especially pressing given that schools are widely recognized as crucial settings for fostering health literacy in children [5,24-27], and there is growing policy emphasis on integrating health care professionals into school-based health initiatives for children [1,3]. Without child-centered measurement tools, however, the effectiveness of these efforts cannot be accurately evaluated. In this context, gamified assessment emerges as a methodological solution to the limitations of traditional tools [28]. By incorporating game elements, it aims to reduce assessment biases and enhance participant motivation [29-31], thereby potentially improving the validity and reliability of data collected from children.

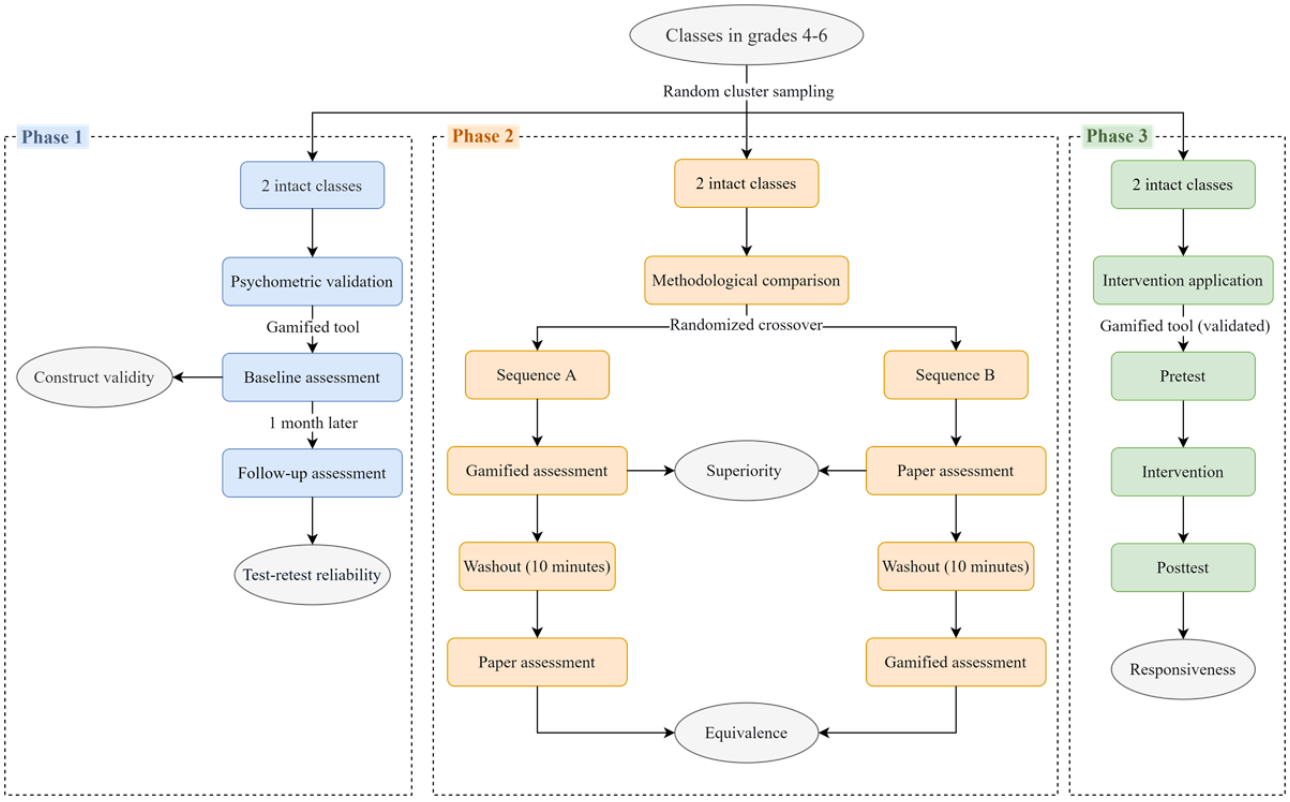
While the knowledge-attitude-practice (KAP) model offers a basic pathway from knowledge to behavior, its application in children is limited by their dependent health behaviors and the strong influence of caregivers. Merely improving knowledge and attitudes may not sufficiently enhance behavioral autonomy, and tracking actual behavior change remains challenging. In contrast, the theory of planned behavior (TPB) emphasizes behavioral intention—shaped by attitudes, subjective norms, and perceived behavioral control (PBC)—as a direct predictor of behavior. Subjective norms are inherently present in the school setting, arising from teacher expectations and peer behavior [32]. Because these norms are relatively stable over the short study period and are not directly targeted by the intervention, we did not include them as measured variables in our assessment tool. Instead, we focused on the modifiable individual-level components of the TPB (attitudes, PBC, and behavioral intention) in our assessment tool. Enhancing PBC can strengthen children’s autonomy. Moreover, behavioral intention can be assessed through contextualized scenarios, making the evaluation of health behavior change more feasible. The tool, which integrates the KAP framework with the key TPB components—knowledge, attitudes, PBC, and behavioral intention—translates these constructs into engaging game mechanics to enhance children’s engagement and support the evaluation of intervention outcomes.

Within child health literacy, one critical dimension warrants focused attention: medication literacy—a foundational health skill encompassing the knowledge, skills, and confidence required for the safe and appropriate use of medications [33]. Pharmacotherapy is the most common intervention for childhood illnesses, yet medication poisoning consistently ranks as a leading cause of pediatric poisoning [17]. This underscores the need to equip children with medication literacy—a competency that remains largely overlooked, and for which developmentally appropriate assessment tools are virtually absent.

Therefore, to address this methodological gap, this study aimed to develop and preliminarily validate a novel, theory-informed gamified assessment tool for measuring medication literacy in school-aged children, and to evaluate its psychometric properties, methodological performance, and responsiveness, thereby providing an effective means to evaluate future child-focused health promotion initiatives.

Methods

Ethical Considerations



The study protocol was approved by the Medical Ethics Committee of the Children’s Hospital Affiliated with Nanjing Medical University (approval number 202505033-1). Administrative permission was obtained from the participating school prior to study initiation. Informed consent was obtained from all parents or legal guardians. Child assent was also secured verbally from each participant immediately before activities. To protect privacy and adhere to data minimization principles, only essential nonidentifiable variables were retained for analysis: gender, class, and grade. Student IDs were temporarily used solely to match paired responses across the 3 phases and were permanently deleted upon completion of matching, replaced with anonymized participant codes. All analyses were conducted using this deidentified dataset. No compensation was provided to participants or their families for taking part in the study. The manuscript and supplementary materials contain no images that could identify individual participants. All game screenshots are generic and do not include any personal information.

RenderX

Conditions and Design

This methodological study comprised 3 independent, sequential phases (Figure 1) to develop, validate, and demonstrate the application of a novel gamified assessment tool for child medication literacy.

Figure 1. Study design overview of the 3 independent phases: psychometric validation (phase 1), methodological comparison (randomized crossover, phase 2), and intervention application (pre-post design, phase 3) in elementary school children (grades 4-6) in Nanjing, China (2025). Phase 1 establishes psychometric properties using the gamified tool. Phase 2 uses a randomized crossover design to compare the gamified tool with a traditional paper-based questionnaire. Phase 3 applies the validated tool in a longitudinal intervention study.

Phase 1 aimed to establish the tool's psychometric properties using an independent sample, without any prior intervention, including content validity through a 2-round expert review, construct validity via Rasch analysis, and test-retest reliability with a 1-month interval.

Phase 2 used a randomized crossover design with a separate sample, also without any prior intervention, to methodologically compare the new tool against a traditional paper-based questionnaire, testing its equivalence and superiority (data quality and participant experience). Participants were randomly allocated to 1 of 2 administration sequences and completed 2 assessments: sequence A (gamified → paper-based) and sequence B (paper-based → gamified), with a 10-minute washout period between sessions, which corresponded to the regular break between 2 class sessions, chosen to minimize disruption to the school schedule while providing a brief period to reduce short-term memory of responses.

Phase 3 applied the validated tool in a longitudinal, independent pre-post study with a sample distinct from those in prior phases to assess its practical responsiveness (generalized linear mixed models [GLMMs]) in detecting changes following a school-based medication literacy intervention. We implemented a compact pre-post assessment using the validated gamified tool, with participants completing the assessment immediately before and after the intervention, to maximize sensitivity to change while minimizing confounding. The intervention was designed as a single 40-minute in-person session, which included a 20-minute interactive educational component delivered by trained pharmacists, with the remaining time used for the pretest and posttest. To ensure age-appropriateness, we adapted core components from the *Chinese Citizens' Health Literacy—Basic Knowledge and Skills* (2024), focusing on medication literacy relevant to general child health rather than adult-centric topics. The selected components centered on three core principles: (1) distinguishing dietary supplements from medicines, (2) rational medication use principles, and (3) science-based and rational health care practices. To translate these principles into an engaging format, interactive educational material titled "The Great Journey of a Little Medicine" was created, which adopts a first-person narrative from the perspective of a medicine describing its metabolic journey. The storyline translates these principles into four specific educational objectives: (1) dietary supplements are not medicine substitutes, (2) preference for oral over infusion, (3) no unilateral discontinuation for side effects, and (4) no alarm for drug-induced urine discoloration. To ensure consistency, the session was delivered in a standardized manner by the same trained pharmacist, following a three-part format: (1) engaging storytelling centered on the narrative, enhanced with animated demonstrations, (2) explicit emphasis on core medication literacy points, and (3) interactive question-and-answer and experience-sharing to facilitate

XSL•FO
RenderX

immediate application, clarify concepts, and promote personal engagement.

This phased, independent-sample design ensured that psychometric properties and methodological advantages were established prior to and uncontaminated by intervention effects, aligning with best practices for novel measurement tool validation.

Inclusion and Exclusion

The study included elementary school students in grades 4 to 6. Students present on the scheduled assessment days with parental consent and child assent were included; no additional exclusion criteria were applied.

Participant Characteristics

Participants in psychometric validation were recruited from 2 classes in grades 4 and 6. The total sample for this phase consisted of 81 students (40/81, 49.4% female). Methodological comparison involved a separate cohort from 2 classes in grades 5 and 6. A total of 85 students (42/85, 49.4% female) participated in the randomized crossover study. Intervention application recruited a third independent cohort from 2 classes in grades 5 and 6, comprising 85 students (41/85, 48.2% female).

Sampling Procedures

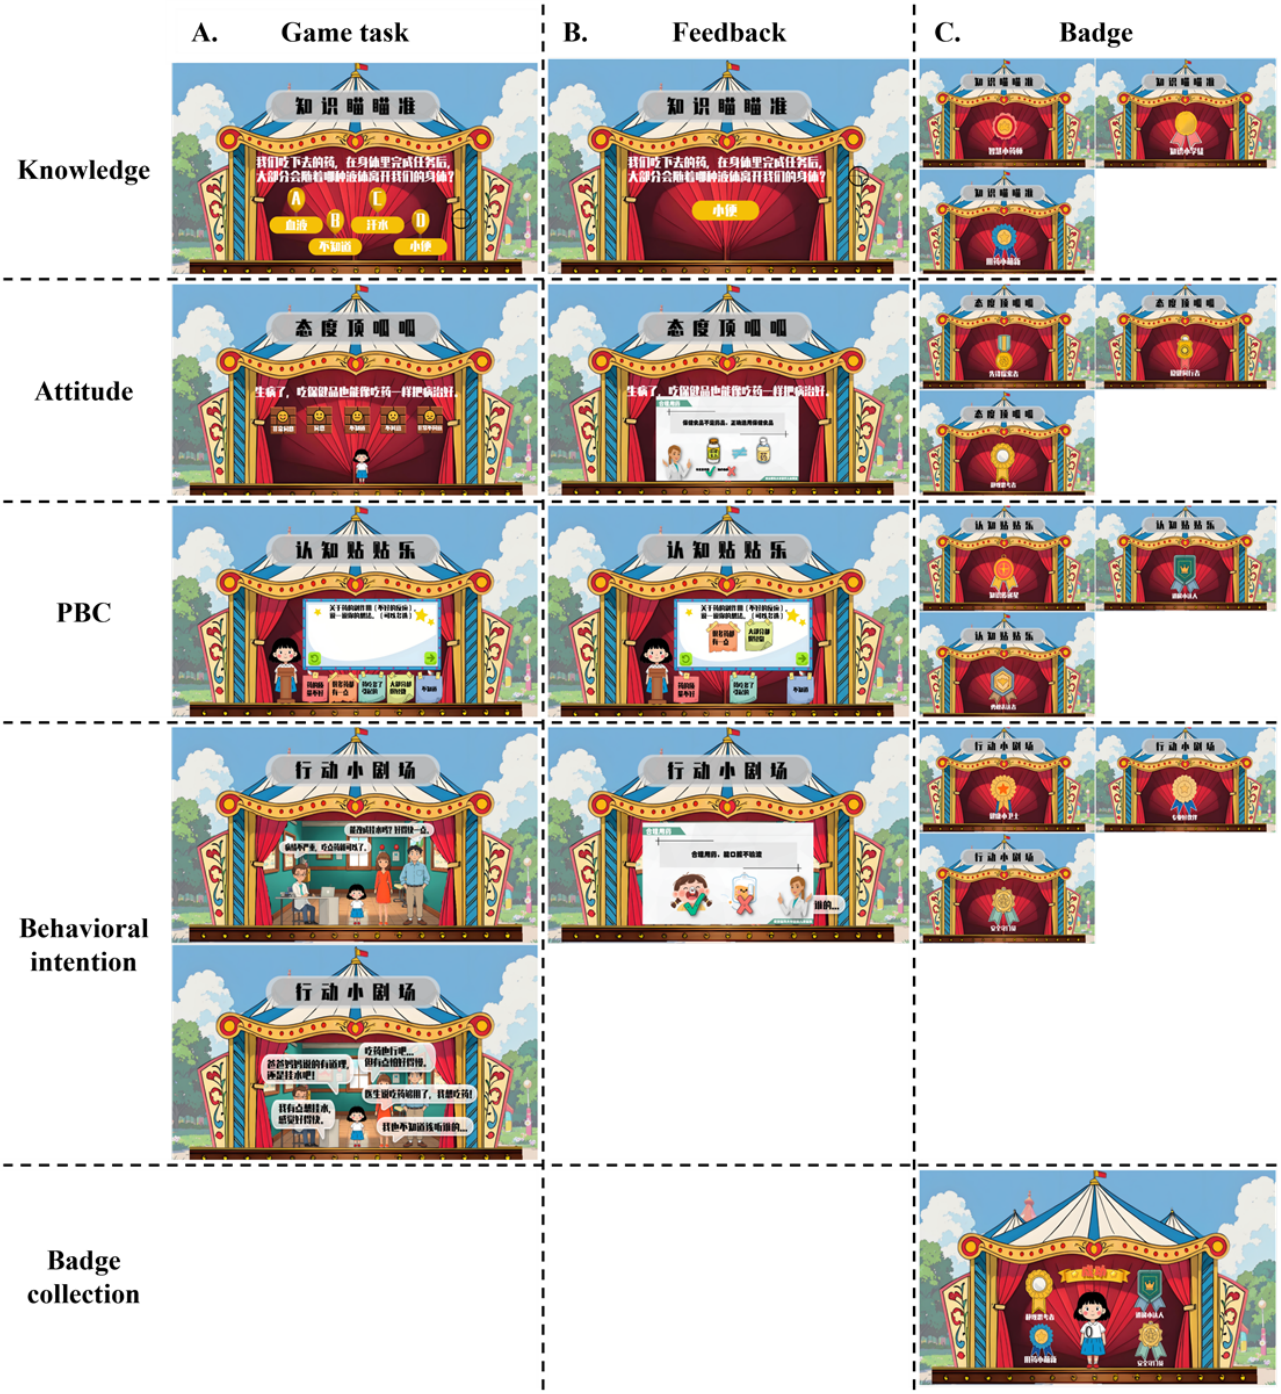
The study was conducted in a single public elementary school in Nanjing, China. Data collection for the 3 phases took place between September and December 2025. Using cluster random sampling, distinct intact classes from grades 4 to 6 were randomly selected as separate, nonoverlapping cohorts for each phase. The overall study targeted grades 4 to 6, as children in these grades (approximate age 9-12 years) have the cognitive and literacy skills needed to understand medication-related concepts and complete the gamified assessment independently. This choice was supported by the elementary school teachers who participated in our content validity review. We used grade level rather than chronological age because age within the same grade is inconsistent (birthdays occur at different times, and some families use the traditional Chinese nominal age system). In contrast, grade provides a relatively uniform educational background, allowing students to be reasonably treated as a single group for analysis.

Sample Size, Power, and Precision

The sample size was determined based on the practical capacity of the health care professional team and the feasibility of implementation within the school's routine. Given a maximum class size of 40 to 45 students, and to match the health care professionals' workload, minimize disruption to normal school schedules, and align with available devices, we planned to recruit 2 intact classes for each phase of the study. This provided sufficient participants for each phase while allowing for occasional absences. Because of the pilot and methodological nature of the study, formal a priori power calculations were not performed. Instead, sample size adequacy was assessed against methodological literature. For Rasch analysis, simulation studies have shown that item calibration remains stable even with small samples (n≤50) [34]; our phase 1 sample (n=81) exceeds this threshold, supporting reliable parameter estimation. For the GLMMs with clustered data, methodological research indicates that GLMMs remain a consistent analytical approach when the number of clusters is small [35], and using appropriate small-sample corrections can control type I error rates [36]. In our study, the within-class sample size (n=40-45 per class) together with the Satterthwaite approximation (default in the *lmerTest* package, detailed in the Analytic Strategy section) supports the reliability of the GLMM results.

Instrumentation

We developed a novel gamified digital assessment, which was structured around the integrated KAP-TPB framework and comprised 4 core dimensions: knowledge, attitudes, PBC, and behavioral intention. Detailed descriptions of the scoring rules and measurement procedures are provided in the Measures and Covariates section.



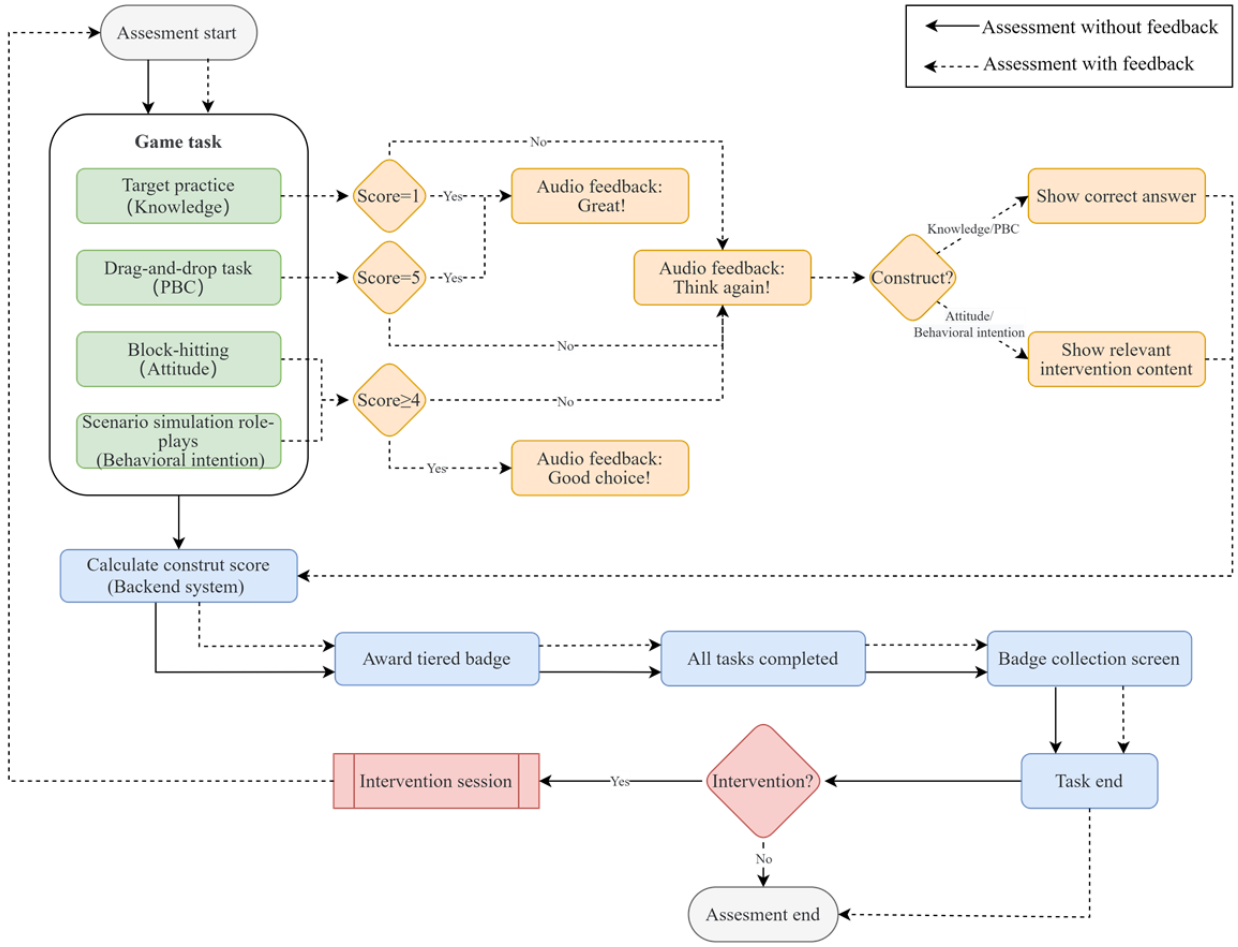
Measures and Covariates

The game content was directly derived from the key learning objectives of the planned medication literacy intervention. Although our assessment employed gamified interactions rather than traditional paper-based items, we adapted the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) framework [37] to report on user recruitment, engagement metrics, and data completeness, as these principles remain applicable to digital survey modalities.

To reduce abstraction and enhance measurability, we designed the game to generate contextualized, ordered responses rather than rely on abstract self-report. Each dimension was operationalized through a distinct game mechanic (Figure 2): knowledge was assessed via a 5-item "target practice" game where children selected answers by clicking on targets. Each item had 1 correct option; an "I do not know" choice was included to minimize guessing. Responses were scored 1 (correct) or 0 (incorrect/I do not know). Attitude was measured using a 4-item "block-hitting" game. Children jumped a character to hit blocks corresponding to their agreement with statements on a 5-point Likert scale (1=strongly disagree to 5=strongly agree), with both positively and negatively worded items. PBC was evaluated through a 4-item "speech preparation" drag-and-drop task. For each topic, children selected from 2 correct arguments (+1 each), 2 incorrect arguments (–1 each), and an "I do not know" option (0). The total score (–2 to 2) was then mapped onto a 5-point Likert scale. Behavioral intention was gauged via 4 interactive "scenario simulation" role plays. Children faced medication-related dilemmas in a continuous storyline that provides a realistic and coherent decision-making context and chose among 5 predefined behavioral responses, each prescored 1 to 5 based on theoretical alignment with rational medication literacy.

XSL•FO
RenderX

Figure 2. Interface of the gamified medication literacy assessment tool used in all phases among elementary school children (grades 4-6) in Nanjing, China (2025). The figure illustrates the 3 core components of the gamified assessment for each dimension: (A) the game task interface, (B) the feedback screen following task completion, and (C) the badge awarded based on performance. Rows 1 to 4 correspond to the 4 assessed dimensions: knowledge, attitude, perceived behavioral control (PBC), and behavioral intention. The final row displays the badge collection screen, where all earned badges are aggregated upon completion of all tasks. The interface is presented in Chinese, the language of instruction for participants. Table S1 in Multimedia Appendix 1 provides English translations of all texts shown here, along with item-level justifications and educational objectives, and badge English translations and design rationale are provided in Table S2 in Multimedia Appendix 1.



To mitigate testing anxiety and reduce social desirability bias, we replaced traditional numerical scores with a performance-based digital badge system. Participants earned a unique badge upon completing each game dimension. Crucially, badges were not titled with explicit performance tiers (eg, no "gold" or "silver") to minimize peer comparison. The complete badge system, including score ranges and design rationale, is presented in Table S2 in Multimedia Appendix 1. All badges were aggregated and displayed on a final "badge collection" screen (Figure 2). This approach was designed to elicit more authentic, low-pressure assessments of children's knowledge, attitudes, PBC, and behavioral intention.

To transform the assessment into a learning-reinforcement tool, we provided immediate corrective feedback in the posttest of intervention application to capitalize on the "teachable moment." This feedback differed by dimension (Figure 2). For knowledge and PBC, a perfect score triggered an audio cue ("great") and

XSL•FO
RenderX

unlocked the next level. An imperfect score prompted "think again," followed by display of the correct answers. For attitude and behavioral intention, a score ≥4 (on a 5-point scale) elicited positive audio feedback ("good choice"); a lower score triggered "think again," followed by a review of key intervention content. No feedback was provided during the psychometric validation, methodological comparison, and baseline pretest of intervention application to ensure measurement purity. Of note, the feedback mechanism did not influence scoring, as scores were calculated prior to feedback delivery. The workflow of this gamified assessment and feedback system is illustrated in Figure 3.

Figure 3. Operational workflow of the gamified assessment and feedback system, including game tasks, real-time audio feedback, badge awarding, and final badge collection (all phases, grades 4-6, Nanjing, China, 2025). Participants progress through 4 game tasks corresponding to the assessed dimensions (knowledge, attitude, perceived behavioral control (PBC), and behavioral intention). Solid arrows indicate the flow without feedback (phase 1, phase 2, and pretest of phase 3); dashed arrows indicate the flow with immediate corrective feedback, which was provided only during the posttest of phase 3: positive feedback for correct or high-scoring responses and corrective prompts, correct answers (knowledge and PBC) or relevant intervention content (attitude and behavioral intention) for incorrect or low-scoring responses. Upon task completion, the construct score is calculated in the backend, and a tiered badge is awarded. The final screen displays all earned badges before the assessment concludes. After all tasks are finished, participants either proceed to the intervention session (pretest of phase 3) or end the assessment (phase 1, phase 2, and posttest of phase 3).

Data quality was operationalized as the overall validity of each completed assessment, coded as a binary outcome (valid=1, invalid=0) based on predefined criteria.

In the methodological comparison study, participant experience (enjoyment and preference) was evaluated through self-reported ratings via a 5-point Likert scale.

In the longitudinal pre-post intervention study, the independent variable was time, reflecting the measurement occasion relative to the intervention (pretest vs posttest). The dependent variables were the scores of the 4 dimensions from the gamified tool. Covariates included in the analyses were class and gender.

Data Collection

Data were collected through 2 primary modes: the gamified assessment automatically recorded responses on the devices, while the paper-based questionnaire was completed manually.

Data for phase 1 were collected at baseline and again at a 1-month follow-up. Data for phase 2 were collected using both the gamified and paper-based formats according to participants' assigned sequences. Participant experience measures were collected immediately after this first assessment. Data for phase 3 were collected immediately before and after the intervention. Participants completed a 10-minute baseline pretest (T0), followed by the intervention session, and then a 10-minute posttest (T1) with the immediate feedback mechanism.

XSL•FO
RenderX

Initial data entry and basic cleaning were performed in Microsoft Excel 2024. At this stage, all negatively worded items were reverse-coded to ensure uniform scoring direction across the tool.

Quality of Measurements

No formal training or reliability assessment was conducted for data collectors, as the gamified tool was fully automated and the paper-based questionnaire was administered following a standardized protocol. Repeated observations were not used.

Masking

No masking was performed because the gamified and paper-based formats were visually distinct and the intervention was delivered in an open classroom setting.

Psychometrics

A systematic 2-round expert review was conducted to establish the content validity of the gamified tool, ensuring relevance, clarity, and age-appropriateness for elementary school students. An initial review by 5 senior pharmacists (2 chief pharmacists and 3 associate chief pharmacists; all holding master's degrees, with >10 years of experience, and representing pharmacy administration, clinical pharmacy, and outpatient pharmacy services within a tertiary children's hospital) focused on medical accuracy and relevance, ensuring item clarity for subsequent reviewers. A subsequent review by 5 experienced elementary school teachers (>10 years of teaching) then evaluated child-appropriateness, with a focus on the comprehensibility of language and the realism of scenarios for the target age group. In both rounds, experts rated each item on a 4-point Likert scale (1=irrelevant, unclear, or inappropriate; 4=highly relevant, very clear, or very appropriate). The item-level content validity index (I-CVI) and the scale-level content validity index/average (S-CVI/Ave) were calculated. Given that each panel comprised 5 experts, an I-CVI of 1.00 (unanimous agreement) was required for item retention, resulting in the overall S-CVI/Ave also having to reach the maximum value of 1.00.

We examined the internal structure and measurement properties of the gamified tool by assessing construct validity using Rasch analysis. Item fit was assessed by examining the weighted (infit) and unweighted (outfit) mean-square (MNSQ) statistics for each item, with values between 0.5 and 1.5 considered indicative of acceptable model conformity. The essential unidimensionality of each scale was tested through a principal component analysis of the standardized residuals; support for unidimensionality required the eigenvalue of the first residual component to be below 3.0, coupled with a ratio of the second to first eigenvalue of less than 0.5. The discrimination power of each item was assessed via its point-measure correlation, where a value greater than 0.30 was taken to confirm the item's positive alignment with the intended latent construct. Finally, the precision and reliability of each dimension's measure were evaluated using the person separation reliability coefficient. A coefficient exceeding 0.70 was deemed acceptable, indicating that the tool possessed adequate power to distinguish between participants of different ability levels within the sample.

To evaluate test-retest reliability, we quantified the degree of absolute agreement between the 2 time points for each dimension by calculating the intraclass correlation coefficient (ICC). An ICC value of ≥0.70 was considered the threshold for acceptable temporal stability. Then, we complemented this by examining systematic score drift through 2-tailed paired *t* tests for each dimension. A nonsignificant result ($P>.05$) would indicate no meaningful average change in scores over the 1-month period, further supporting the stability of the measurement.

Data Diagnostics

To ensure data integrity, clear validity criteria were applied to all collected questionnaires. For the paper-based questionnaire, manual completeness checks were performed, and any questionnaire with blank items was excluded. For the gamified assessment, the design enforced completion of each item before proceeding, eliminating data missingness at the item level. All responses from both formats were screened for patterned or nondifferentiated responding, which also led to exclusion. For pre-post comparisons, only participants with a complete pair of responses were considered.

Missing data were handled using complete-case analysis (listwise deletion). We also evaluated individual person-response validity by flagging participants whose infit or outfit statistics fell outside the 0.5 to 1.5 range, suggesting potential aberrant response patterns. When the estimated class-level variance was 0 (resulting in a singular fit), the ICC was set to 0.00. Model diagnostics were examined for linear models.

No additional statistical outliers were defined or excluded beyond the prespecified validity criteria. No formal distributional tests were performed as the planned analyses (GLMMs) are robust to moderate deviations from normality; residual diagnostics were examined for linear models. No additional data transformations were applied beyond those described in the Data Collection section.

Analytic Strategy

All statistical analyses were conducted using R software (version 4.5.2; R Core Team) with packages *dplyr* (version 1.1.4), *tidyr* (version 1.3.1), and *ggplot2* (version 4.0.1) for data cleaning, transformation, and visualization, and dedicated packages for specific analyses as detailed below. All statistical tests were 2-sided with a significance level of $\alpha=.05$.

In phase 1, construct validity analyses were conducted on the baseline data within the Rasch measurement framework. Given the different response formats across dimensions, we applied the dichotomous Rasch model to the binary-scored knowledge items and the partial credit model to the polytomous items measuring attitude, PBC, and behavioral intention. All models were estimated via the marginal maximum likelihood method, using robust convergence criteria (maximum iterations=1000, increment factor=1.05) using the *TAM* package (version 4.3-25), complemented by the *psych* package (version 2.5.6). Regarding item performance, we calibrated item difficulty/location parameters and their standard errors. Test-retest reliability was quantified by comparing data from the 2 time points using a 2-way mixed-effects model for absolute agreement (ICC 3-1)

XSL•FO
RenderX

via the *psych* package (version 2.5.6). Paired *t* tests (base R) were used to examine systematic score drift over the 1-month interval.

In phase 2, measurement equivalence was evaluated through a multimethod approach using data from both assessment sessions. To ensure the validity of pooling data from the crossover design, we tested for order effects using a 2 × 2 mixed-design ANOVA (base R), with sequence (A or B) as the between-subjects factor and modality (gamified or paper) as the within-subjects factor. A nonsignificant sequence × modality interaction (P>.05) was taken to indicate the absence of a meaningful order effect, permitting data pooling. With order effects assessed, absolute agreement between the 2 modalities was quantified using ICC(3,1). We used paired *t* tests to examine systematic mean differences, with Cohen *d* (*effsize* package, version 0.8.1) quantifying the effect size. Concurrently, Bland-Altman analysis (*BlandAltmanLeh* package, version 0.3.1) was applied to visualize individual-level differences, estimate mean bias, and calculate 95% limits of agreement. Finally, to assess the consistency of categorical decisions made from the 2 tools, scores for each dimension were dichotomized into "high" and "low" groups based on the median. We then computed both Cohen κ coefficient (*irr* package, version 0.84.1) and simple percentage agreement to evaluate the classification consistency between modalities. To ensure a fair comparison of initial exposure and minimize carryover effects in the crossover design, the superiority analysis used only the data from the first assessment session (gamified assessment from sequence A; paper-based assessment from sequence B). We compared the proportion of valid responses between the 2 modalities using a chi-square test (base R) and calculated the validity rate with its 95% CI for each. Participant experience was compared using independent-samples *t* tests (base R) with Cohen *d* as the effect size.

In phase 3, baseline comparability was assessed using only the pretest data. We used 1-way ANOVA (base R) to compare class-level baseline scores for all 4 dimensions: knowledge (percentage correct, 0%-100%), attitude, PBC, and behavioral intention (each a Likert sum score ranging from 4 to 20). To quantify between-class clustering at baseline, we estimated the ICC(1) for each dimension using a 1-way random-effects model with a random intercept for class (*lme4* package, version 1.1-38) and extracted the ICC (*performance* package, version 0.15.3). Responsiveness was evaluated using GLMMs on paired pre-post test data using the *lme4* (version 1.1-38), *lmerTest* (version 3.2-0), and *emmeans* (version 2.0.1) packages. Considering the distinct measurement scales, different model families were specified: a Poisson mixed model with a log link for the count-type knowledge score, and linear mixed models for the continuous attitude, PBC, and behavioral intention scores. Each model included time (T0/T1), class, gender, and the class × time interaction as fixed effects, and incorporated a random intercept per participant to account for repeated measurements. The class × time interaction was tested using likelihood-ratio tests (Poisson model) or *F* tests (linear models). If the interaction was significant, simple-effects analyses with Tukey-adjusted *P* values were performed to clarify differential change across classes. To quantify the magnitude of within-class change, the effect size was estimated as Cohen *d* for paired data, derived from the model-estimated marginal means and pooled SD.

Results

Sample Characteristics

The flowchart of participant enrollment is detailed in Figure 4. In phase 1, the full sample (n=81) provided data for the assessment of construct validity. For test-retest reliability analysis, 77 of the original 81 participants (39/77, 50.6% female) completed both assessments. Four participants were excluded due to nonresponse at the second time point (1-month follow-up), resulting in 4 missing data points (4/81, 4.9%). In phase 2, all 85 participants provided data for the analysis of methodological superiority, which used first-assessment data only. For the sequence effects and equivalence analyses, after confirming no significant order effect, data from participants with valid responses at both time points were pooled across sequences, yielding a final analytic sample of 76 paired observations (39/76, 51.3% female). Nine participants were excluded because at least 1 of their 2 assessments was invalid (9/85, 10.6%). In phase 3, the entire sample with complete preintervention and postintervention data was used in the longitudinal GLMM analysis to assess the tool's responsiveness. Detailed sample sizes for each analysis are presented in Table 1.

XSL•FO
RenderX

Figure 4. Participant flow diagram for the 3 study phases (psychometric validation, methodological comparison, and intervention application) among elementary school children (grades 4-6) in Nanjing, China (2025). Numbers indicate participants assessed for eligibility (n=258), excluded due to absence (n=7), allocated to each phase (phase 1: n=81, phase 2: n=85, and phase 3: n=85), and subsequently included in the analyses. Attrition (loss to follow-up, n=4 in test-retest reliability in phase 1) and exclusions from analysis (superiority analysis in phase 2: n=4 due to invalid questionnaires; sequence effect and equivalence analysis in phase 2: n=9 due to invalid questionnaires) are explicitly indicated.

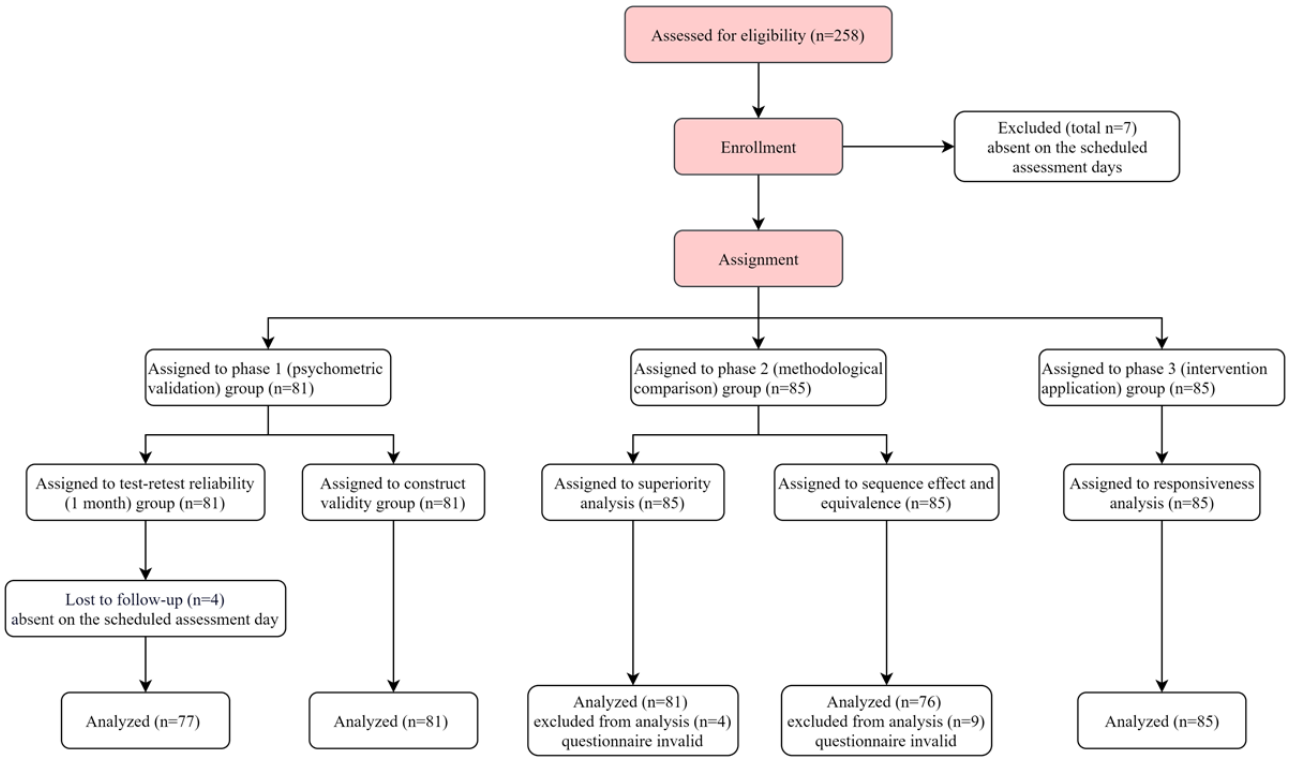


Table 1. Sample characteristics and analytic sample sizes by study phase for elementary school children (grades 4-6) in Nanjing, China (2025).

Phase (classes; grades) and analysis	Female, n/N (%)
Psychometric validation (2; 4 and 6)	40/81 (49.4)
Construct validity	40/81 (49.4)
Test-retest reliability	39/77 (50.6)
Methodological comparison (2; 5 and 6)	42/85 (49.4)
Sequence effect	39/76 (51.3)
Equivalence	39/76 (51.3)
Superiority	42/85 (49.4)
Intervention application (2; 5 and 6)	41/85 (48.2)
Responsiveness	41/85 (48.2)

Phase 1: Psychometric Validation

Content Validity

In the first-round expert review (pharmacy experts), 15 of 18 initial items directly achieved an I-CVI of 1.00. One item was deleted due to low relevance (I-CVI=0.20), and 2 items were revised based on clarity feedback and subsequently reached consensus (I-CVI=1.00). In the second round (teacher experts), 11 of the 17 revised items directly achieved an I-CVI of 1.00 for age-appropriateness; the remaining 6 items were modified per expert suggestions and then also achieved unanimous approval. Consequently, all retained items attained an I-CVI of 1.00, resulting in an S-CVI/Ave of 1.00. The content validity indices are summarized in Table 2. These results indicate fine content relevance, clarity, and age-appropriateness of the gamified assessment tool.

XSL•FO
RenderX

Table 2. Psychometric properties (content validity, item fit, unidimensionality, person separation reliability, and 1-month test-retest reliability) of the gamified medication literacy tool in a validation sample (phase 1, n=81, grades 4 and 6, Nanjing, China, 2025).

Domain	Content validity (I-CVI[a]); item fit (mean infit MNSQ[b])	Unidimensionality[c] (residual eigenvalue/ratio)	Person separation reliability[d]	Test-retest reliability, ICC[e] (95% CI)
Knowledge	1.00; 1.01	2.25/0.40	0.69	0.76 (0.64-0.84)
Attitude	1.00; 1.07	2.14/0.34	0.72	0.92 (0.88-0.95)
Perceived behavioral control	1.00; 1.04	2.19/0.34	0.71	0.86 (0.79-0.91)
Behavioral Intention	1.00; 1.04	2.21/0.38	0.74	0.86 (0.79-0.91)

[a]I-CVI: item-level content validity index (unanimous agreement among 5 experts per panel; I-CVI=1; scale-level content validity index/average [S-CVI/Ave]=1.00).

[b]MNSQ: mean-square statistic (item fit was considered acceptable if infit MNSQ was between 0.5 and 1.5).

[c]Unidimensionality criteria: residual eigenvalue (first residual component eigenvalue) <3.0 and ratio of the second to first eigenvalue <0.5.

[d]Person separation reliability ≥0.70.

[e]ICC: intraclass correlation coefficient. ICC(3,1) was calculated over a 1-month interval using a 2-way mixed-effects model with absolute agreement; ICC≥0.70 was considered acceptable).

Construct Validity

Mean infit MNSQ values were between 1.01 and 1.07, and mean outfit MNSQ values were between 0.83 and 1.23. Individual infit and outfit MNSQ values for all 17 items were predominantly within 0.5 to 1.5. All item-level and person-level values were within the acceptable range, indicating adequate model-data fit and no aberrant response patterns. The eigenvalue of the first residual component ranged from 2.14 to 2.25 (all <3.0), and the unidimensionality ratio ranged from 0.34 to 0.40 (all <0.5), supporting the essential unidimensionality of each dimension. Item difficulty parameters spanned from –2.07 to 1.59 logits for knowledge, from –0.81 to 0.44 for attitude, from 0.40 to 0.87 for PBC, and from –0.66 to 0.27 for behavioral intention. Point-measure correlations ranged from 0.67 to 0.73, exceeding the 0.30 criterion and confirming satisfactory item discrimination. Person separation reliability ranged from 0.69 to 0.74, approaching or exceeding the acceptable threshold of 0.70 for group-level comparisons. The Rasch-based model fit statistics, unidimensionality indices, and reliability estimates for each domain are presented in Table 2. Collectively, these findings support the structural validity of the gamified assessment tool.

Test-Retest Reliability

Across the 4 dimensions, ICC(3,1) values ranged from 0.76 to 0.92, all exceeding the prespecified criterion of 0.70 and indicating good to excellent temporal stability. The narrow 95% CIs indicate precise estimates of temporal stability (Table 2). No statistically significant mean differences were observed between time point 1 and time point 2 (knowledge: P=.41; attitude: P=.09; PBC: P=.39; behavioral intention: P=.71), suggesting no systematic score drift over the 1-month interval.

Phase 2: Methodological Comparison

Equivalence Analysis

The 2 × 2 mixed-design ANOVA found no significant sequence (A or B) × modality (gamified or paper) interaction for any dimension (all P>.05, detailed in Table 3), indicating the absence of a meaningful order effect. This finding also confirms that the 10-minute washout period was sufficient to avoid systematic recall bias. Therefore, data from both administration sequences were pooled for subsequent equivalence analyses. The results of the multimethod equivalence analysis are presented in Table 3. For all 4 dimensions, ICC(3,1) values ranged from 0.94 to 0.99, with narrow 95% CIs indicating precise estimates. Paired t tests revealed no statistically significant mean score differences (all P>.05), with associated Cohen d values from –0.017 to 0.047 and narrow 95% CIs indicating high precision. Bland-Altman analyses showed mean bias values close to 0, with 95% limits of agreement ranging from ±0.16 to ±0.63 logit; the 95% CIs for the mean biases were also narrow, indicating high precision. These negligible biases and narrow limits of agreement are visually summarized in the Bland-Altman plots presented in Figure 5. Cohen κ coefficients ranged from 0.87 to 0.97, and percentage agreement from 93.4% to 98.7%. These convergent findings across multiple indices support the measurement equivalence of the 2 modalities, indicating that the gamified tool produces scores comparable to the paper-based format.

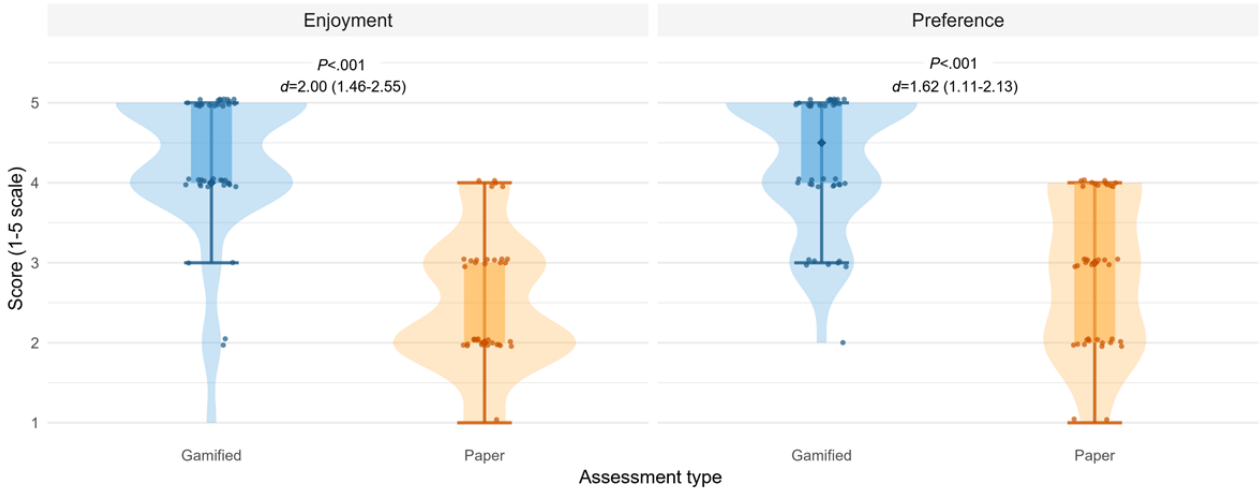
Superiority Analysis

The results of the superiority analysis are summarized in Table 4. Figure 6 provides an integrated overview of the comparisons in terms of experience (enjoyment and preference). Overall tool validity did not differ significantly between modes (χ^2_1=2.3; *P*=.13), with rates of 100% (42/42) for the gamified and 90.7% (39/43) for the paper-based assessment. The wide overlap of these 95% CIs is consistent with the nonsignificant chi-square test. In contrast, the gamified tool yielded substantially higher scores for both enjoyment and preference, with all corresponding *t* tests being highly significant (*P*<.001). The narrow 95% CIs confirm the precision of these estimates. These results demonstrate that while the gamified tool achieves measurement parity, it offers a clear advantage in user experience.

Table 4. Methodological superiority of gamified vs paper-based medication literacy assessment: data quality and participant experience (enjoyment and preference) in the first assessment of a crossover study (phase 2, n=85, grades 5 and 6, Nanjing, China, 2025).

Comparison metric	Gamified tool	Paper-based questionnaire	Test statistic, chi-square (*df*) or *t* test (*df*)	*P* value	Cohen *d* (95% CI)
Data quality[a]					
Valid response rate, n/N (%); 95% CI	42/42 (100); 91.6%-100%	39/43 (90.7); 77.4%-96.9%	2.29 (1)[b]	.13	—[c]
Participant experience[d]					
Enjoyment, mean (SD)	4.26 (0.94)	2.46 (0.85)	9.01 (79)[e]	<.001	2.00 (1.46-2.55)
Preference, mean (SD)	4.29 (0.83)	2.82 (0.97)	7.30 (79)[e]	<.001	1.62 (1.11-2.13)

[a]Data quality was assessed based on predefined completion criteria.



[b]Indicates a chi-square statistic.

[c]Not applicable.

[d]Participant experience was rated on a 5-point Likert scale immediately after the first assessment. Independent-samples *t* tests were used to compare experience between groups.

[e]Indicates a *t* test statistic.

Figure 6. Distribution of enjoyment and preference scores by assessment format (violin plot) among elementary school children (grades 5 and 6) in Nanjing, China (2025). Mean scores for enjoyment and preference. Error bars represent 95% CIs.

Phase 3: Intervention Application

Descriptive Statistics

The intervention cohort was from 2 intact classes (A and B), each representing a distinct grade level (grades 6 and 5, respectively). Class-level comparisons revealed a significant baseline difference for knowledge (*P*=.007), with class A (grade 6) scoring higher than class B (grade 5). In contrast, no significant between-class differences were observed at baseline for attitude (*P*=.65), PBC (*P*=.43), or behavioral intention (*P*=.49). ICC(1) for knowledge was 0.14 (95% CI 0.00-0.53), indicating low clustering. For attitude, PBC, and behavioral intention, the ICC(1) estimates were 0.00 (95% CI 0.00-0.18, 95% CI 0.00-0.14, and 95% CI 0.00-0.16, respectively), indicating negligible clustering.

Responsiveness Analysis

The GLMM results are presented in Table 5. All 95% CIs for the time effects (β and incidence rate ratio [IRR]) exclude the null value, indicating precise and reliable estimates of pre-post change. The Poisson mixed model for knowledge also showed

XSL•FO
RenderX

a significant improvement (*P*<.001). For the continuous outcomes (attitude, PBC, and behavioral intention), linear mixed models revealed significant main effects of time (all *P*<.001). The time × class interaction effects were nonsignificant across all dimensions (all *P*≥.19), indicating consistent pre-post changes across classes.

Table 5. GLMM[a] results for intervention responsiveness of the gamified medication literacy tool in a pre-post design (phase 3, n=85, grades 5 and 6, Nanjing, China, 2025).

Domain (model) and fixed effect	β[b] (95% CI) or IRR[c] (95% CI)	*z* score, chi-square (*df*), *t* test (*df*), or *F* test (*df*)	*P* value
Knowledge (Poisson)			
Time (posttest vs pretest)	1.52 (1.22-1.89)	3.72[d]	<.001
Time × class	—	0.38 (1)[e]	.54
Attitude (linear)			
Time (posttest vs pretest)	1.74 (1.25-2.22)	7.04 (83)[f]	<.001
Time × class	—	0.00 (1, 83)[g]	.99
Perceived behavioral control (linear)			
Time (posttest vs pretest)	2.86 (2.18-3.53)	8.30 (83)[f]	<.001
Time × Class	—	0.03 (1, 83)[g]	.85
Behavioral intention (linear)			
Time (posttest vs pretest)	2.33 (1.51-3.15)	5.59 (83)[f]	<.001
Time × class	—	1.74 (1, 83)[g]	.19

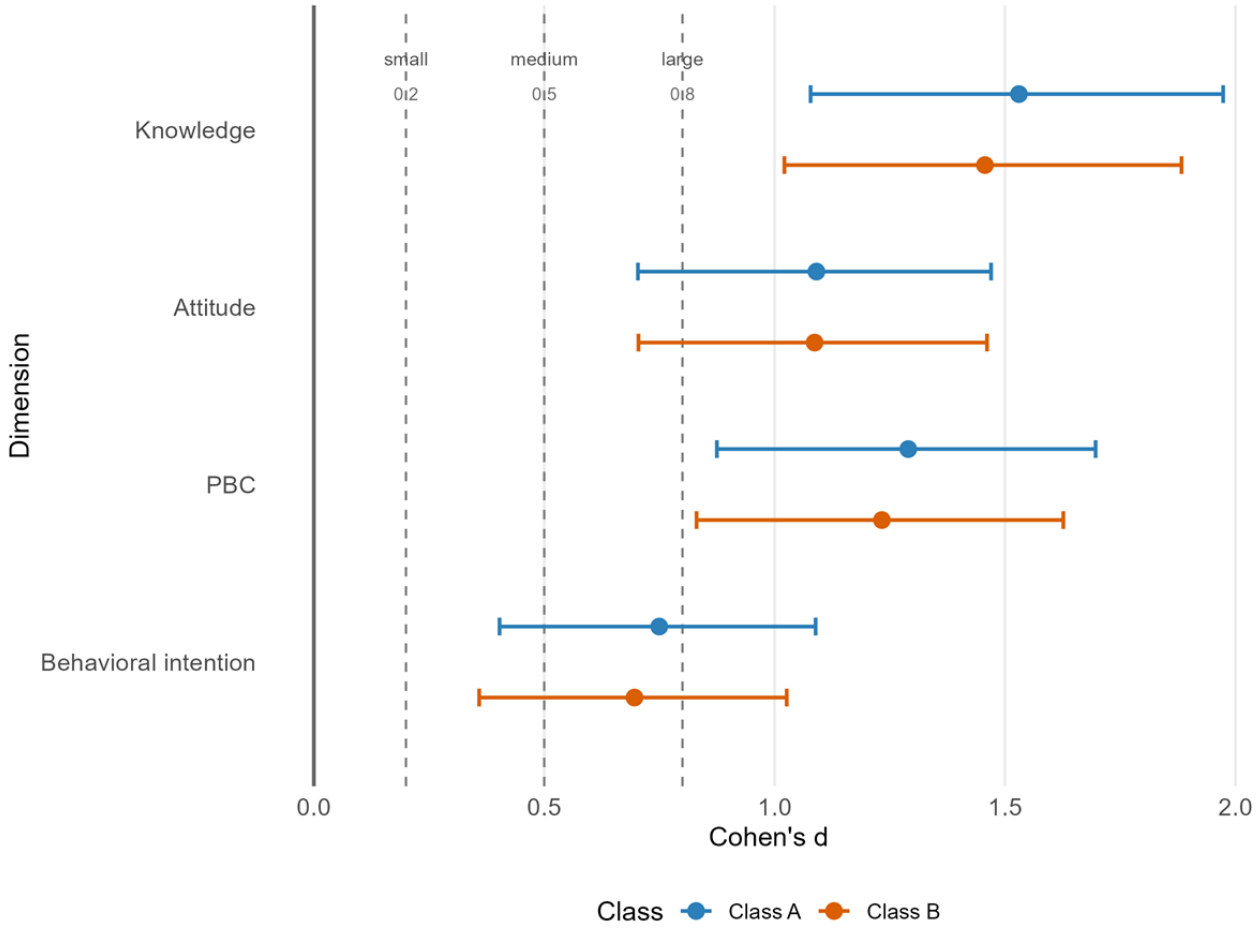
[a]GLMM: generalized linear mixed model.

[b]Unstandardized coefficient (linear models).

[c]IRR: incidence rate ratio (Poisson model). All models included random intercepts for class and individual (ID). For the count outcome (knowledge), the interaction *P* value was obtained from a likelihood ratio test (chi-square test); for continuous outcomes, the time × class interaction was tested using an *F* test.

[d]Indicates a *z* score statistic.

[e]Indicates a chi-square statistic.



[f]Indicates a *t* test statistic.

[g]Indicates an *F* test statistic.

The within-class effect sizes (Cohen *d*; Figure 7) with 95% CIs were as follows: for knowledge, class A was 1.53 (95% CI 1.08-1.97) and class B was 1.46 (95% CI 1.02-1.88); for attitude, both classes were 1.09 (95% CI 0.70-1.47 for class A, 95% CI 0.70-1.46 for class B); for PBC, class A was 1.29 (95% CI 0.87-1.70) and class B was 1.23 (95% CI 0.83-1.63); and for behavioral intention, class A was 0.75 (95% CI 0.40-1.09) and class B was 0.70 (95% CI 0.36-1.03). All 95% CIs were relatively narrow and did not include 0, indicating precise and statistically significant changes from pretest to posttest. Figure 7 presents these effect sizes graphically.

XSL•FO
RenderX

Figure 7. Forest plot of within-class effect sizes (Cohen d) for the 4 medication literacy dimensions (knowledge, attitude, perceived behavioral control [PBC], and behavioral intention) by class (class A and class B) in a pre-post intervention study (phase 3, n=85, grades 5 and 6, Nanjing, China, 2025). Cohen d was calculated using paired t tests (preintervention vs postintervention). Each solid point represents the point estimate for one class in a given dimension; error bars show the 95% CI. The vertical dashed lines at d=0.2, d=0.5, and d=0.8 indicate small, medium, and large effect size benchmarks, respectively.

Discussion

Principal Results

The primary objective of this study was to develop and validate a gamified assessment tool for measuring medication literacy in elementary school children, to compare it with a traditional paper-based format, and to evaluate its responsiveness to an educational intervention. The results across the 3 phases collectively show that the tool has adequate psychometric properties, is measurement-equivalent to the paper-based questionnaire, is preferred by children, and can detect changes associated with the intervention consistently across classrooms. The psychometric validation results indicate that the newly developed gamified assessment tool demonstrates adequate psychometric properties for research use with elementary school students. The perfect content validity indices confirm that the gamified content is not only theoretically sound but also contextually appropriate and comprehensible for elementary school students [38]. Rasch analysis supported the structural validity of the 4 hypothesized constructs within the gamified format. The essential unidimensionality and acceptable item fit of all dimensions indicate that children's interactions with the game-like interface produced response data consistent with the underlying measurement models [39,40]. The point-measure correlations exceeding the criterion further verify that each item effectively discriminated along its intended latent trait [40]. The person separation reliability coefficients of attitude, PBC, and behavioral intention were in the acceptable range for group-level analysis [40]. The slightly lower value for knowledge is not surprising, given that binary items typically yield lower person separation reliability than polytomous items with a comparable number of items [41]. Overall, the tool provides reasonable precision for distinguishing between cohorts with different ability levels across all dimensions. These Rasch-based findings are consistent with the methodological approach used in the validation of other child-focused assessment tools [42], supporting the appropriateness of this framework for pediatric samples. The test-retest results showed strong temporal stability, indicating that the engaging format did not introduce response instability or significant practice effects upon readministration [43]. In summary, phase 1 establishes that the methodological innovation of gamification can yield measurements that meet rigorous psychometric standards, providing a reliable and valid means to assess the target constructs. This lays the foundation for its subsequent comparison against traditional methods in phase 2 and its application in evaluating intervention effects in phase 3.

XSL•FO
RenderX

Turning to the methodological comparison, the results indicate that the 2 modalities produce effectively equivalent measurements, while the gamified version addresses a key limitation of traditional paper-based questionnaires by significantly enhancing participant engagement. The equivalence analysis confirmed that the 2 formats measure the same constructs [44]. After establishing the absence of order effects, pooled data revealed high ICCs across all dimensions [45]. This was consistent with other metrics: no systematic mean differences were detected, Bland-Altman plots showed minimal bias [46], and decision consistency was high [47]. These convergent results across multiple indices support measurement equivalence, satisfying a fundamental prerequisite for considering the gamified tool a valid alternative to the paper-based format [44]. Where the tools meaningfully diverge is in the participant experience—the core value proposition of this methodological innovation. While both yielded data of comparable quality—reflected in the high and nonsignificantly different validity rates—this surface-level equivalence in completion likely reflects the strong subjective norms of the school setting [32], which can ensure task compliance even for less engaging formats. The gamified tool, in contrast, was rated substantially higher in both enjoyment and preference, consistent with previous reports that gamified assessments are more engaging for children [27]. This shift proactively addresses a core challenge to the validity of child self-report data [23]. It moves beyond reliance on external compliance by transforming the assessment into a more motivationally compatible activity—a transformation that fosters greater willingness to engage and reduces inattentive responding [48]. In conclusion, this comparative phase demonstrates that the gamified tool successfully bridges a common gap in assessment methodology. It achieves measurement equivalence with the paper-based format while simultaneously enhancing the engagement necessary for high-quality data collection from children. This achievement validates it as a methodologically robust instrument appropriate for the target population, well-suited for application in the subsequent intervention study.

In terms of intervention responsiveness, the gamified assessment tool demonstrated satisfactory responsiveness [49], detecting significant changes across all 4 medication literacy domains following a targeted educational intervention. The moderate to large effect sizes indicated that the tool captured substantial changes across the 4 domains [50]. Notably, the pre-post changes were consistent across classrooms for all dimensions, despite a significant baseline difference in knowledge scores. This finding carries practical importance: students with lower baseline knowledge showed comparable improvements to those with higher baseline scores. This pattern aligns with recent evidence that game-based interventions can improve outcomes equitably regardless of baseline disparities [51]. More broadly, school-based health literacy interventions have been recognized as a promising strategy for reducing health inequalities [52]. The tool's ability to detect uniform changes across classrooms may be useful for evaluating health education initiatives in diverse settings [53,54]. Taken together, these results confirm that the tool is capable of capturing meaningful pre-post changes in children's medication literacy, supporting its utility as an outcome measure for school-based health promotion initiatives.

Limitations

Several limitations should be acknowledged. The intervention used a single-group pre-post design without a control condition. While the primary aim was to evaluate the tool's responsiveness rather than intervention efficacy, the absence of a comparison group limits causal inference regarding the observed changes. Therefore, our results should be interpreted as evidence that the tool can detect changes associated with the intervention, not as proof that the intervention caused those changes. Moreover, the immediate posttest administration may have introduced short-term recall effects, potentially overestimating immediate improvements relative to long-term retention. This study did not examine whether the observed changes were sustained over time, leaving the question of their long-term sustainability unanswered. Future studies should consider incorporating a control arm and longer-term follow-up assessments to strengthen causal conclusions and evaluate the durability of the measured changes.

All 3 phases recruited independent samples from a single elementary school—a decision driven by practical considerations of conducting research in real-world school settings, though it may constrain generalizability to other educational environments or age groups. Replicating these findings across multiple schools with diverse demographics would help establish the tool's broader applicability. The sample sizes are acceptable but modest; the Rasch sample approaches the lower bound for stable calibration, and the small number of classes (2 per phase) limits the precision of random-effect estimates. While the absence of significant order effects indicates that the 10-minute washout period was adequate for this study, longer intervals (eg, 24 hours) could be considered in future crossover designs to further eliminate any potential recall of responses. Although the missing data proportion was low (4/81, 4.9% in phase 1, none in phase 3) and the exclusions in phase 2 (9/85, 10.6%) were based on questionnaire validity, complete-case analysis may introduce some bias. We allocated 10 minutes for each assessment session based on pilot estimates, but individual completion times were not systematically recorded. Future studies should collect such feasibility data to better inform practical implementation in school settings.

Conclusions

We conclude that a gamified assessment tool can be both psychometrically rigorous, engaging for elementary school children, and responsive to detecting intervention-associated changes. This study demonstrates the use of a fully gamified format to target children's medication literacy, directly compares it against a paper-based questionnaire using a randomized crossover design, and shows consistent pre-post changes across classrooms with different baseline knowledge levels. Unlike many existing child health measures that rely on adult proxy reports or adapted adult scales, our tool is child-centered, directly validated with students, and designed to enhance engagement. Beyond providing an effective alternative to traditional paper-based questionnaires, the tool may offer a practical solution for evaluating school-based medication literacy programs. The ability to detect uniform changes across classrooms points to its potential to support health equity. We

XSL•FO
RenderX

suggest that as digital health interventions become more common in schools, validated gamified assessments like this one may provide practical outcome measures for evaluating their effects. Future research should extend this tool to other health domains and test its utility in longitudinal, multisite studies, ideally with larger samples (eg, ≥150 participants) and more clusters (eg, ≥4 schools) to improve generalizability.

Acknowledgments

The authors would like to thank the students, parents or legal guardians of students, teachers, and school administrators for their participation and support throughout this study. We are grateful to the pharmacy experts and elementary school teachers who contributed to the content validation process.

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), proofreading and editing were delegated to GenAI tools under full human supervision. The GenAI tool used was DeepSeek-V3 (DeepSeek). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Unicompartmental knee arthroplasty (UKA) requires precise intraoperative coordination from operating room nurses. Conventional teaching may be insufficient for junior nurses learning complex UKA surgical cooperation, particularly regarding self-efficacy and cognitive demands. Serious games have emerged as a promising educational tool for nursing training.

Objective: This study evaluated whether adding a WeChat-based serious game to conventional UKA training was associated with improved theoretical knowledge, self-efficacy, preoperative preparation, intraoperative performance, and perceived cognitive load among junior operating room nurses.

Methods: This quasi-historical controlled study compared 2 sequential, noncontemporaneous cohorts of newly recruited junior operating room nurses from a tertiary hospital in Xuzhou, China. Nurses recruited in 2023 were assigned to the conventional training group (n=21, 50%), whereas nurses recruited in 2024 were assigned to the serious game–assisted training group (n=21, 50%). Both groups received the same UKA curriculum, including theoretical teaching and supervised intraoperative practice, while the intervention group additionally used a mobile serious game. Outcomes included theoretical test scores, General Self-Efficacy Scale scores, National Aeronautics and Space Administration Task Load Index (NASA-TLX) cognitive load scores, and assessments of preoperative preparation and intraoperative performance.

Results: Data from all 42 eligible participants were included. Compared with conventional training, serious game–assisted training was associated with higher theoretical knowledge scores (mean 96.86, SD 3.09 vs mean 92.38, SD 4.32; *P*<.001; Cohen *d*=1.19), preoperative preparedness (mean 4.19, SD 0.33 vs mean 3.49, SD 0.29; *P*<.001; Cohen *d*=2.27), intraoperative performance (mean 4.00, SD 0.30 vs mean 3.41, SD 0.28; *P*<.001; Cohen *d*=2.03), and overall preparedness and performance (mean 4.10, SD 0.23 vs mean 3.45, SD 0.20; *P*<.001; Cohen *d*=3.02). Self-efficacy was higher in the unadjusted analysis (mean 34.05, SD 2.87 vs mean 31.57, SD 3.43; *P*=.02; Cohen *d*=0.78), but this difference was attenuated after adjustment for age and education (adjusted mean difference 2.45, 95% CI −0.26 to 5.15; *P*=.08). The serious game–assisted group also reported higher NASA-TLX total cognitive load (mean 65.44, SD 12.00 vs mean 58.21, SD 6.05; *P*=.02; Cohen *d*=0.76).

Conclusions: Serious game–assisted training was associated with better theoretical knowledge and procedural performance but higher perceived cognitive load among junior operating room nurses learning UKA coordination. The adjusted self-efficacy result, as well as the overall findings, should be interpreted cautiously rather than as definitive causal evidence because the study used a quasi-historical design without a contemporaneous control group.

Introduction

Background and Rationale

Instrument nurse cooperation ability is one of the core competencies required for operating room nurses. In the unique environment of the operating room, efficient collaboration with surgeons and other professionals is key to ensuring the smooth progress of surgery [1,2]. Unicompartmental knee arthroplasty (UKA), as a precise surgical procedure for unicompartmental knee disease, offers advantages over total knee arthroplasty,

XSL•FO
RenderX

such as less trauma, a shorter recovery period, and better preservation of proprioception and joint function [3]. However, it places stringent demands on the coordination ability of instrument nurses.

Self-efficacy refers to nurses' belief in their ability to achieve goals and successfully handle difficulties encountered in the process, reflecting their confidence in achieving objectives [4], which may affect their psychological perception, mentality, and behavior [5]. Cognitive load refers to the total mental effort expended in working memory, consisting of intrinsic load (complexity of the task), extraneous load (processes not directly contributing to learning), and germane load (schema construction during learning) [6]. Cognitive work in nursing refers to organization, sequencing, and decision-making in practice, which constitute a nurse's cognitive load.

Junior nurses commonly face dual challenges in learning UKA surgical coordination. On one hand, they may have limited familiarity with procedural steps, operative anatomy, and intraoperative decision-making, which may reduce confidence and perceived self-efficacy [7,8]. On the other hand, UKA procedures are time-sensitive and technically demanding, requiring rapid instrument switching, sustained attention, and multitask coordination within a limited time frame, which may increase cognitive load and affect procedural performance 8. In this study, these challenges were operationalized through broader educational outcomes, including self-efficacy, perceived cognitive load, and observer-rated preoperative preparation and intraoperative performance, rather than through direct measurement of specific technical subskills.

Currently, clinical nursing training mainly relies on traditional methods such as theoretical lectures and operational demonstrations. However, the separation of theory and practice makes it difficult for nurses to apply what they have learned, resulting in poor learning outcomes. Furthermore, junior nurses' lack of confidence in performing surgical cooperation tasks and the high cognitive load generated when learning complex UKA procedures further restrict training effectiveness. The one-way teaching model in traditional training tends to increase cognitive fatigue, weaken initiative, and form a vicious cycle of "low self-efficacy–high cognitive load." The lack of personalized training cannot meet different nurses' needs, and the underdeveloped feedback and evaluation system hinders understanding of individual progress. Therefore, introducing diverse teaching methods closely integrated with clinical practice is urgently needed to effectively improve junior nurses' surgical cooperation skills.

In recent years, innovative teaching methods have attracted increasing attention in nursing education. Among them, virtual clinical simulation provides an immersive learning environment, allowing students to practice nursing skills in a safe, controlled setting and simulating complex real-world clinical scenarios [9], thus compensating for the shortcomings of traditional teaching. Serious games—interactive computer applications designed to deliver specific learning objectives—serve as virtual simulation teaching tools. Through realistic simulated environments and risk-free error consequences, learners acquire key skills such as problem analysis, problem-solving, and teamwork through role-playing, thereby enhancing motivation, engagement, and experiential learning [10]. Mitchell et al [11] explored the impact of serious games on nursing students' knowledge and behavior regarding influenza vaccination, confirming the potential value of serious games in nursing practice and behavior change. Aloweni et al [12] further demonstrated that serious games not only have substantial educational potential but also effectively enhance nurses' professional knowledge and skills.

Study Aim

Therefore, the aim of this study was to evaluate whether adding a WeChat-based serious game to conventional UKA training for junior operating room nurses was associated with improved theoretical knowledge, self-efficacy, preoperative preparation, and intraoperative performance, and with differences in perceived cognitive load compared with conventional training alone. Given the quasi-historical design, the findings were interpreted cautiously because temporal changes in the clinical setting could not be fully controlled.

Methods

Study Design

This study was a completed single-center quasi-historical controlled educational study that compared 2 sequential cohorts of junior operating room nurses involved in UKA coordination. In this context, "quasi-historical" indicates that the comparison was made between 2 sequential cohorts recruited in different calendar years rather than between concurrently allocated groups. The analysis was based on deidentified training and assessment data from 2 consecutive nurse entry cohorts at Xuzhou Central Hospital: nurses recruited in 2023 received conventional training, whereas nurses recruited in 2024 received serious game–assisted training. To strengthen internal validity in this quasi-historical comparison, we applied identical eligibility criteria, used the same clinical teaching team, and maintained the same training schedule, curriculum content, and assessment standards across both cohorts. All trainees received the same UKA curriculum, supervised intraoperative mentoring (12 assisted UKA cases), and standardized evaluations using the same scoring rubrics. However, because the comparison relied on a historical control design rather than contemporaneous allocation, temporal confounding cannot be fully excluded. Year-to-year differences in staffing, workflow, case exposure, teaching context, or other unmeasured environmental factors may have contributed to the observed between-group differences. Therefore, baseline characteristics were compared between groups, and sensitivity analyses adjusting for age and education were performed.

Ethical Considerations

Ethics approval for the research use and analysis of deidentified training and assessment data was obtained from the Xuzhou Central Hospital Biomedical Research Ethics Review Committee on February 26, 2025 (XZXY-LJ-20250226 - 032). The study was conducted in accordance with the Declaration of Helsinki and institutional requirements for medical research involving human participants. Written informed consent was obtained

XSL•FO
RenderX

from all participants before the research use and analysis of their training and assessment data. All data were deidentified before analysis, and no personally identifiable information was reported in this manuscript or the supplementary materials. Participants received no compensation for inclusion in this analysis.

Trial Registration

This study was not prospectively registered because it was a quasi-historical controlled educational study rather than a randomized controlled trial. The study protocol, eligibility criteria, training procedures, and outcome assessments were defined before data collection and were implemented consistently across the 2 cohorts.

Participants

A total of 42 newly recruited junior operating room nurses from Xuzhou Central Hospital were included in the study. The 2023 entry cohort comprised 21 (50%) nurses and served as the traditional training group, whereas the 2024 entry cohort comprised 21 (50%) nurses and served as the serious game–assisted training group. Baseline characteristics were descriptively summarized for the 2 groups.

The inclusion criteria included being newly recruited nurses; having no prior operating room work experience before employment; participating in theoretical training, skills training, and operative cooperation practice related to UKA; and being informed and willing to participate in the study.

The exclusion criteria included being unable to participate in orthopedic surgery cooperation due to pregnancy or other special reasons; being on sick leave, maternity leave, or not continuously employed during the study period; or missing more than 3 training sessions for any reason during the study period.

Instruments

Baseline Sociodemographic and Occupational Characteristics

Baseline sociodemographic and occupational characteristics were extracted from deidentified training and personnel records and included sex, age, educational background, marital status, and professional title. These variables were summarized descriptively.

Outcome Measures

Theoretical Performance, Cognitive Load, and Self-Efficacy

Because the study focused on overall educational and procedural performance, outcomes were assessed using self-efficacy, cognitive load, and observer-rated preparation and intraoperative performance rather than direct task-specific measures, such as instrument transfer accuracy or anatomic identification.

A self-designed theoretical knowledge questionnaire was used, with a total score of 100 and a passing score of 80. The full text of the self-designed theoretical knowledge questionnaire is provided in Multimedia Appendix 1.

Cognitive load was assessed using the National Aeronautics and Space Administration Task Load Index (NASA-TLX) developed by Hart and Staveland [13]. The instrument includes 6 dimensions, each represented by 1 rating item: mental demand, physical demand, temporal demand, performance, effort, and frustration. Each dimension was rated on a scale from 0 to 20, with higher scores indicating greater perceived task load for that dimension. In accordance with the scoring approach used in the Chinese version reported by Liang et al [14], the overall NASA-TLX score was calculated as a weighted composite score ($TLX=\sum[\rho i \times ri]$), with a total range of 0 to 100. Higher total scores indicate greater perceived cognitive load. The Chinese version has shown acceptable reliability, with a split-half reliability of 0.808 and a Cronbach α of 0.758 [14].

Self-efficacy was assessed using the General Self-Efficacy Scale (GSES), which contains 10 items scored from 1 to 4, yielding a total score of 10 to 40. Higher scores indicate higher self-efficacy [15].

Preoperative Preparation and Intraoperative Performance

These assessment items were directly adopted from the questionnaire reported by Zhao and Cong [1] and were used without modification. Senior nurses completed the ratings after the operation using a 5-point Likert scale (1=strongly disagree; 5=strongly agree).

Feedback on Training Methods

The posttraining feedback questionnaire was directly adopted from the instrument reported by Zhao and Cong [1] and was used without modification. The questionnaire consists of 10 items rated on a 5-point Likert scale and was completed by junior nurses after training in both groups. In the primary analysis, these items were used as posttraining feedback measures for between-group comparison. Details of the serious game design, interface, gameplay workflow, and representative screenshots are provided in Multimedia Appendix 2.

Training Programs

The control group received traditional teaching consisting of two stages: (1) 2 weeks of theoretical study (PowerPoint lectures and on-site simulation) and (2) 4 weeks of intraoperative one-on-one mentoring, with each nurse completing 12 UKA cooperation sessions under supervision.

In the game teaching group, a mobile game (“Joint Replacement Master”) was introduced in addition to the traditional teaching methods. After the first stage, nurses were instructed in the operation of the game. During the second stage, nurses played the game 3 times before surgery each day to reinforce their understanding of UKA steps.

The game, inspired by WeChat’s “3D Puzzle,” features 29 levels corresponding to UKA steps. Instruments are integrated into a “tool library.” Realistic videos simulate the surgical environment. Each level provides step prompts; correct instrument selection progresses the game, whereas errors prompt immediate feedback and require a retry. The game includes a story format, badge rewards, background music, and a ranking system to enhance engagement and competition.

XSL•FO
RenderX

Details of the serious game design, interface, gameplay workflow, and representative screenshots are provided in Multimedia Appendix 2.

Statistical Analysis

Descriptive statistics (frequency, mean, SD, and range) were calculated. Differences between groups were analyzed using 2-tailed independent-sample *t* tests for continuous variables, chi-square tests for categorical variables, and Mann-Whitney *U* tests for ordinal variables. Statistical significance was set at $P<.05$. All analyses were performed using SPSS (version 27.0; IBM Corp).

In addition to *P* values, measures of practical importance were reported for key between-group comparisons, including mean differences (MDs) with 95% CIs, Cohen *d*, and eta-squared, to facilitate interpretation of the magnitude of the observed effects. Test statistics and degrees of freedom were reported where appropriate.

As a robustness check, we fitted analyses. of covariance and linear regression models with the posttraining outcome as the dependent variable and group (game vs traditional) as the primary predictor, adjusting for age (continuous) and education level (categorical). Given the small sample size, HC3 robust SEs were used to estimate adjusted MDs (β for group) with 95% CIs.

Results

Participant Cohorts and Analytical Sample

This manuscript reports a completed analysis of 2 sequential cohorts of newly recruited junior operating room nurses at Xuzhou Central Hospital. The traditional training cohort was recruited in 2023 (n=21), and the serious game–assisted training cohort was recruited in 2024 (n=21). Complete training and outcome assessment data were available for all 42 eligible participants, and the final statistical analyses were completed before manuscript submission. Because the study compared noncontemporaneous cohorts recruited in 2023 and 2024, all between-group findings should be interpreted with awareness of potential temporal confounding.

Baseline Sociodemographic and Occupational Characteristics

Table 1 presents the baseline sociodemographic and occupational characteristics of the 2 cohorts. Overall, the distributions of sex, age, educational background, marital status, and professional title were broadly similar between the conventional training and serious game–assisted training groups.

Table . Sociodemographic and occupational characteristics of the 2 groups of nurses (N=42)[a].

Characteristics	Conventional training group (n=21)	Serious game–assisted training group (n=21)
Sex, n (%)		
Male	6 (29)	9 (43)
Female	15 (71)	12 (57)
Age (y), mean (SD)	22.52 (1.75)	22.38 (2.33)
Educational background, n (%)		
Junior college	9 (43)	6 (29)
Undergraduate student	12 (57)	11 (52)
Graduate student	0 (0)	4 (19)
Marital status, n (%)		
Unmarried	21 (100)	21 (100)
Married	0 (0)	0 (0)
Professional title, n (%)		
Nurse	20 (95)	17 (81)
Nurse practitioner	1 (5)	4 (19)

[a]Percentages are shown without decimal places because the group sample sizes were less than 100. Baseline characteristics are presented descriptively; no baseline significance testing was performed.

Theoretical Performance, Cognitive Load, and Self-Efficacy

Table 2 summarizes between-group comparisons with effect sizes. After training, the serious game–assisted training group had higher theoretical performance scores than the conventional training group (mean 96.86, SD 3.09 vs mean 92.38, SD 4.08; $t_{40}=4.009$; $P<.001$). The between-group difference in theoretical performance also showed a large effect size (Cohen $d=1.24$; $\eta^2=0.287$).

[a]Mean differences were calculated as serious game–assisted training minus conventional training.

[b]NASA-TLX: National Aeronautics and Space Administration Task Load Index.

For cognitive load (NASA-TLX), the game group reported higher total scores (mean 65.44, SD 12.00 vs mean 58.21, SD 6.05; t_{40}=2.465; *P*=.02), indicating higher perceived workload. Specifically, the game group reported higher mental demand (mean 15.45, SD 9.74 vs mean 10.13, SD 4.75; t_{40}=2.252; *P*=.03) and temporal demand (mean 13.71, SD 8.45 vs mean 8.72, SD 6.89; t_{40}=2.096; *P*=.04). No between-group differences were observed in physical demand (*P*=.71), frustration (*P*=.77), effort (*P*=.30), or performance (*P*=.57).

After adjusting for age and education (analysis of covariance and linear regression with HC3 robust SEs), the between-group differences remained consistent for theoretical performance (adjusted MD 3.94, 95% CI 1.04-6.83; *P*=.008) and NASA-TLX total scores (adjusted MD 6.97, 95% CI 0.17-13.78; *P*=.045).

Preparation and Intraoperative Performance

As shown in Table 3, the serious game–assisted group generally scored higher than the conventional training group on the preoperative preparedness and intraoperative performance items. The average score for preoperative preparation was significantly higher in the game group (mean 4.19, SD 0.33 vs mean 3.49, SD 0.29; *P*<.001), as was intraoperative performance (mean 4.00, SD 0.30 vs mean 3.41, SD 0.28; *P*<.001), and the overall average score (mean 4.10, SD 0.23 vs mean 3.45, SD 0.20; *P*<.001).

Table . Preparedness and performance feedback statement mean scores.

Feedback questionnaire statement	Serious game–assisted training group (n=21), mean (SD)	Conventional training group (n=21), mean (SD)	Mean difference[a] (95% CI)	Cohen *d* (95% CI)	η^2	*P* value
Preoperative preparedness						
I felt that the nurse checked the surgical instruments before starting the procedure	4.14 (0.48)	3.57 (0.51)	0.57 (0.26-0.88)	1.16 (0.50-1.81)	0.261	<.001
The nurse knew and understood the relevant anatomy	4.14 (0.57)	3.43 (0.68)	0.71 (0.32-1.11)	1.14 (0.48-1.79)	0.254	<.001
The nurse knew the operation procedure steps	4.24 (0.54)	3.52 (0.60)	0.71(0.36-1.07)	1.25 (0.58-1.91)	0.291	<.001
The nurse was well aware of the operation procedure specific details that could have affected or changed the procedural steps or decisions	4.24 (0.54)	3.29 (0.56)	0.95 (0.61-1.30)	1.73 (1.01-2.44)	0.441	<.001
Overall, the nurse was well prepared for the operation procedure	4.19 (0.51)	3.62 (0.74)	0.57 (0.17-0.97)	0.90 (0.26-1.53)	0.175	.006
Preoperative preparedness score	4.19 (0.33)	3.49 (0.29)	0.70 (0.51-0.90)	2.27 (1.48-3.05)	0.576	<.001
Intraoperative performance						
The nurse's performance was not affected by stress or anxiety	4.10 (0.44)	3.33 (0.58)	0.76 (0.44-1.08)	1.49 (0.79-2.17)	0.368	<.001
The nurse was insightful and understood the surgeon's directions	4.00 (0.63)	3.43 (0.60)	0.57 (0.19-0.96)	0.93 (0.29-1.56)	0.185	.005
The nurse had a better grasp of key procedure steps	3.95 (0.59)	3.43 (0.75)	0.52 (0.10-0.94)	0.78 (0.15-1.40)	0.137	.02
The nurse delivered the right tool according to the procedure	4.05 (0.67)	3.43 (0.51)	0.62 (0.25-0.99)	1.04 (0.39-1.68)	0.222	.002
The nurse was a good assistant to the operation	3.90 (0.54)	3.43 (0.75)	0.48 (0.07-0.88)	0.73 (0.10-1.35)	0.123	.02
Intraoperative performance score	4.00 (0.30)	3.41 (0.28)	0.59 (0.42-0.78)	2.03 (1.27-2.77)	0.519	<.001
Overall preparedness and performance score	4.10 (0.23)	3.45 (0.20)	0.65 (0.51-0.78)	3.02 (2.11-3.90)	0.705	<.001

[a]Mean differences were calculated as serious game–assisted training minus conventional training.

Adjusted analyses also supported higher preoperative preparedness (adjusted MD 0.65, 95% CI 0.42-0.89; *P*<.001), intraoperative performance (adjusted MD 0.61, 95% CI 0.38-0.83; *P*<.001), and overall performance (adjusted MD

XSL•FO
RenderX

0.63, 95% CI 0.47-0.79; *P*<.001) in the game group; the adjusted between-group difference in self-efficacy was attenuated (adjusted MD 2.45, 95% CI –0.26 to 5.15; *P*=.08).

Feedback on Training Methods

According to Table 4, the game group scored higher on most feedback questionnaire items. Overall satisfaction with the training method was significantly higher in the game group (mean 4.06, SD 0.17 vs mean 3.44, SD 0.20; *P*<.001). The game group also rated the method as better designed (*P*<.001), more conducive to achieving learning objectives (*P*<.001), more helpful for skill improvement (*P*=.03), more interesting (*P*<.001), and more likely to enhance judgment (*P*=.02) and satisfaction (*P*<.001). However, there was no significant difference between groups in confidence improvement (*P*=.16).

Table . Posttraining feedback questionnaire scores for the 2 training methods.

Item	Serious game–assisted training group (n=21), mean (SD)	Conventional training group (n=21), mean (SD)	Mean difference[a], 95% CI	Cohen *d* (95% CI)	η^2	*P* value
Training method was well designed	4.19 (0.51)	3.29 (0.64)	0.90 (0.54 to 1.27)	1.56 (0.85 to 2.24)	0.389	<.001
Training method achieved our learning goals	4.10 (0.54)	3.14 (0.65)	0.95 (0.58 to 1.33)	1.59 (0.88 to 2.28)	0.398	<.001
Teaching method made me confident	3.81 (0.51)	3.52 (0.75)	0.29 (–0.11 to 0.69)	0.45 (–0.17 to 1.06)	0.049	.16
Training method was useful to improve operation nursing skills	3.90 (0.62)	3.48 (0.60)	0.43 (0.05 to 0.81)	0.70 (0.07 to 1.32)	0.114	.03
Training method stimulated my interest	4.14 (0.65)	3.38 (0.59)	0.76 (0.37 to 1.15)	1.22 (0.56 to 1.88)	0.282	<.001
Training method was effective	4.00 (0.55)	3.52 (0.51)	0.48 (0.15 to 0.81)	0.90 (0.26 to 1.53)	0.175	.006
I accomplished complete understanding of the operation procedure	3.90 (0.62)	3.24 (0.54)	0.67 (0.30 to 1.03)	1.14 (0.48 to 1.79)	0.255	<.001
I developed individual judgment	4.10 (0.62)	3.62 (0.67)	0.48 (0.07 to 0.88)	0.74 (0.11 to 1.36)	0.124	.02
I would like to repeat the experience	4.14 (0.48)	3.52 (0.51)	0.62 (0.31 to 0.93)	1.25 (0.58 to 1.91)	0.291	<.001
The overall satisfaction of nurses with the method	4.29 (0.46)	3.67 (0.48)	0.62 (0.32 to 0.91)	1.31 (0.63 to 1.97)	0.310	<.001
Total score	4.06 (0.17)	3.44 (0.20)	0.62 (0.50 to 0.73)	3.38 (2.42 to 4.33)	0.750	<.001

[a]Mean differences were calculated as serious game–assisted training minus conventional training.

Discussion

Principal Findings

This study found that, compared with conventional training alone, serious game–assisted training was associated with higher theoretical knowledge scores, better preoperative preparation, and better intraoperative performance among junior operating room nurses involved in UKA coordination. The serious game–assisted group also showed higher self-efficacy in unadjusted analyses, although this between-group difference was attenuated after adjustment for age and education. In addition, participants in the serious game–assisted group reported higher overall cognitive load, particularly in the domains of mental demand and temporal demand. Taken together, these findings suggest that serious game–assisted training may be a useful adjunct to conventional teaching for improving learning and procedural performance in this setting, while also increasing perceived cognitive demands.

Importantly, the interpretation was strengthened by reporting practical significance indices in addition to *P* values. The effect sizes indicated large differences for theoretical performance (Cohen *d*=1.24), preoperative preparedness (Cohen *d*=2.27), intraoperative performance (Cohen *d*=2.03), and overall preparedness and performance (Cohen *d*=3.02), and a moderate-to-large difference for NASA-TLX total cognitive load (Cohen *d*=0.76). These findings suggest that the observed differences were not only statistically detectable but also meaningful in educational practice. In contrast, the interpretation

XSL•FO
RenderX

of self-efficacy remained cautious because the adjusted analysis attenuated this difference.

Comparison With Prior Work

Practical training is a cornerstone of nursing education, yet the transition from student to professional operating room nurse often requires substantial time, repeated exposure, and progressive familiarity with complex procedural tasks [16]. In recent years, game-based and simulation-based educational approaches have received increasing attention as potential tools to enhance procedural learning and learner engagement. A meta-analysis suggested that serious games may improve learner interaction, motivation, and educational outcomes in nursing education [17].

A 2024 systematic review and meta-analysis of randomized controlled trials reported that digital serious games were associated with improvements in nursing students' knowledge, performance, and confidence, although heterogeneity and limited long-term follow-up required cautious interpretation [18]. Similarly, a 2024 randomized wait-list controlled trial found that a serious smartphone game improved theoretical knowledge in adult basic life support among nursing students, although improvement in practical skills was less consistent [19]. A 2025 systematic review also summarized that serious games in nursing education have been used to enhance knowledge, clinical decision-making, practical skills, teamwork, and learner engagement [20]. Similarly, previous studies have reported that game-based mobile apps were associated with improved knowledge and skills in areas such as extracorporeal membrane oxygenation pipeline preflushing and venous blood specimen collection [21,22]. Our findings are broadly consistent with this emerging literature and extend it to the context of UKA nursing coordination, where rapid instrument switching, familiarity with procedural steps, and efficient teamwork are especially important.

The better preoperative preparation and intraoperative performance observed in the serious game–assisted group may reflect the value of repeated, structured, stepwise practice in reinforcing procedural memory and improving familiarity with key steps of UKA coordination. In the current intervention, the level-based design of the game corresponded to actual procedural steps, and immediate feedback was provided after incorrect choices. Such features may help learners consolidate task sequences, identify weak points, and rehearse decision-making in a low-risk environment before entering the operating room. In this sense, the intervention may have supported transfer from cognitive rehearsal to procedural performance, which is particularly relevant for junior nurses who are still developing confidence and workflow fluency.

Interpretation of Cognitive Load Findings

At the same time, the higher cognitive load reported in the serious game–assisted group should be interpreted cautiously. The increase was mainly observed in mental demand and temporal demand rather than in frustration, physical demand, or effort. One possible explanation is that the serious game required learners to process procedural cues actively, make rapid judgments, and respond to task demands in a more concentrated way than conventional learning alone. This pattern may indicate greater task engagement and attentional investment during training. However, this study design did not allow us to determine whether the increased cognitive load represented a beneficial challenge, a temporary burden, or some combination of both.

From the perspective of cognitive load theory, structured repetition, immediate feedback, and staged progression may support schema construction in complex learning tasks [23,24]. However, without longitudinal measurement, it would be inappropriate to conclude that the increased cognitive load observed here was necessarily adaptive or transient. Our findings therefore suggest that serious game–assisted teaching may involve a trade-off: better knowledge and performance may occur alongside greater perceived cognitive demands during training. Future studies should examine how this pattern evolves over time, whether cognitive load decreases with repeated exposure, and whether optimal game difficulty can be calibrated to balance challenge and usability.

Self-Efficacy and Learner Experience

The serious game–assisted group showed higher self-efficacy in unadjusted analyses, but this difference was attenuated after adjustment for age and education (adjusted MD 2.45, 95% CI –0.26 to 5.15; P=.08). This finding suggests that the intervention may have had a positive association with perceived confidence, but the strength and independence of this effect remain uncertain. It is possible that repeated game-based rehearsal and greater familiarity with the operative sequence contributed to this pattern. However, given the adjusted analysis, this interpretation should remain cautious.

Feedback data nevertheless indicated that participants in the serious game–assisted group generally rated the training method more favorably than those in the conventional group. They reported higher satisfaction and stronger perceptions that the method was interesting, helpful, and well designed. This is consistent with the broader literature suggesting that interactive and gamified educational methods may enhance learner acceptance and engagement [17,21,22]. In this study, these favorable perceptions are important because they may support adherence to training and willingness to repeat practice. Future studies may incorporate objective back-end use data, such as the number of sessions, completion time, and error patterns, to better understand how serious game use relates to learning outcomes.

Practical Implications

These findings have practical implications for perioperative nurse training. UKA coordination requires not only declarative knowledge but also procedural sequencing, timely instrument selection, and coordinated interaction with the surgeon. These are difficult competencies to develop through didactic teaching alone. A mobile serious game may offer a feasible supplementary format for repeated preclinical rehearsal, especially when opportunities for direct exposure are limited or when junior nurses are at an early stage of skill acquisition.

The intervention used in this study was delivered through a WeChat-based platform, which may also increase accessibility

XSL•FO
RenderX

and ease of implementation in routine clinical education settings. From an operational perspective, such tools may be particularly useful for fragmented learning, reinforcement of procedural steps, and standardization of teaching content across trainees. However, their use should complement rather than replace direct supervision, clinical mentoring, and real-world operative experience.

Limitations

Several limitations should be acknowledged. First, this study used a quasi-historical controlled design based on sequential cohorts recruited in 2023 and 2024 rather than contemporaneous allocation. Although we used the same eligibility criteria, teaching team, curriculum framework, training duration, and assessment standards across the 2 cohorts, residual temporal confounding cannot be excluded. Year-to-year changes in the clinical setting, such as differences in staffing patterns, case exposure, workflow organization, informal teaching environment, or broader departmental changes, may have influenced learning opportunities and performance independently of the intervention itself. Therefore, the observed between-group differences should be interpreted cautiously and should not be taken as definitive evidence that the intervention alone caused the observed effects.

Second, the study was conducted at a single center with a relatively small sample size, which limits statistical power and generalizability. Third, outcomes were assessed immediately after training, and long-term retention, skill transfer, and sustainability of benefit were not evaluated. Fourth, several outcomes relied on observer-based assessments completed by senior nurses. Although direct observation of performance is a strength of the study, we did not collect or report sufficiently detailed information on the observers, including the number of evaluators involved, whether the same evaluators assessed both groups, or whether formal observer training and calibration procedures were implemented. Interrater reliability was also not formally assessed. As a result, detection bias and variability in scoring cannot be fully excluded. In addition, although the feedback and performance assessment questionnaires were adopted from a previously published source and used without modification, we did not perform additional psychometric testing, such as internal consistency or interrater reliability analysis, in the current sample.

Fifth, although the introduction highlights clinically relevant challenges, such as instrument transfer accuracy, understanding of operative anatomy, and response to intraoperative events, these specific competencies were not directly measured using objective task-based assessments. Instead, the study evaluated broader outcomes, including self-efficacy, perceived cognitive load, and observer-rated preparation and performance. Therefore, the findings should be interpreted as reflecting overall educational and procedural performance rather than direct evidence of improvement in specific technical subskills.

Finally, although the serious game platform is technically capable of exporting objective use data, such back-end logs were not available in this dataset. As a result, engagement was evaluated using questionnaire-derived proxy measures rather than direct behavioral metrics.

Conclusions

Serious game–assisted teaching was associated with better theoretical performance, preoperative preparation, and intraoperative performance among junior operating room nurses learning UKA coordination, while also being associated with higher perceived cognitive load. These findings support the potential value of serious games as a supplementary educational strategy in perioperative nursing training.

However, because of the quasi-historical design and absence of a contemporaneous control group, the results should be interpreted cautiously and not as definitive causal evidence. Larger, prospective, multicenter studies with objective use metrics and longitudinal follow-up are needed to better establish the effectiveness, mechanisms, and sustainability of serious game–based training in surgical nursing education.

Abstract

Background: Interprofessional education (IPE) is essential for developing teamwork and communication skills in health care training. Building interprofessional competency involves acquiring knowledge, cultivating readiness to engage in teamwork, and fostering effective collaboration. However, challenges include geographical barriers and faculty resistance that can hinder progress. Innovative solutions to enhance engagement and collaboration include serious games played using immersive virtual reality (IVR) and web-based platforms. Despite their potential, research comparing the effectiveness of these approaches for IPE remains limited.

Objective: This study aimed to identify effective implementation methods by evaluating the impact of IVR and web-based serious games on health care students' interprofessional competencies and learning experiences.

Methods: A multimethod approach was used to evaluate students' pre- and postlearning outcomes and experiences. Nursing and physiotherapy students were randomly assigned to either the IVR group or web-based group. The Readiness for Interprofessional Learning Scale (RIPLS), Brief Sense of Community Scale (BSCS), and Intrinsic Motivation Inventory (IMI) were used to measure learning experiences. Learning outcomes were examined through multiple-choice questions (MCQs). After the outcome assessments, groups switched modalities to allow all students to experience both learning approaches. Four focus groups (n=34) provided qualitative insights into learning experiences.

Results: The study included 271 students (IVR group: 125; web-based group: 146). Both groups showed significant improvements in community building (BSCS; IVR: r=−0.29, 95% CI 0.06-0.31; P=.001; web-based: r=−0.27, 95% CI 0.07-0.31; P=.001). The IVR group showed improvements in only the pressure/tension subscale of the IMI (r=−0.45, 95% CI −0.05 to −0.25; P<.001), while the web-based group showed improvements across all IMI subscales, including interest/enjoyment (r=−0.17, 95% CI 0.00-0.30; P=.043), perceived competence (r=−0.19, 95% CI 0.00-0.50; P=.02), and pressure/tension (r=−0.46, 95% CI −0.75 to −0.50; P<.001). Both groups showed significant improvements in knowledge-checking MCQ scores (IVR: r=−0.64, 95% CI 2.00-3.00; P<.001; web-based: r=−0.80, 95% CI 4.50-6.00; P<.001), with the web-based group outperforming the IVR group (r=−0.34, 95% CI −3.00 to −2.00; P<.001). RIPLS scores showed no significant difference in both groups, suggesting that greater exposure is required to enhance IPE readiness. A qualitative analysis revealed 6 themes: valuing collaboration opportunities, fostering trust and shared learning, promoting engagement and authenticity, enhancing knowledge retention, balancing innovation with practicality, and improving realism and inclusivity. No adverse events were noted.

Conclusions: To our knowledge, this is the first study to compare the effects of 2 different modalities (IVR and web-based approaches) on a technology-enabled IPE program. These findings highlight the practical potential of both approaches in supporting IPE. The web-based approach's superior performance in enhancing learning outcomes and motivation suggests that its flexible format better accommodates diverse learning preferences. These findings support technology-enhanced IPE, offering educators scalable, evidence-based strategies to develop collaborative, patient-centered professionals who are equipped for real-world practice.

KEYWORDS

interprofessional education; virtual reality; undergraduate health care education; serious games; health care students; randomized controlled trial; educational technology

Introduction

Background and Rationale

Interprofessional education (IPE) is increasingly recognized as a vital component of health care education owing to its ability to bridge disciplinary divides and cultivate in participants the essential collaborative competencies necessary to address complex patient care challenges [1,2]. By fostering teamwork, communication, and mutual role understanding among individuals in diverse health care disciplines, IPE addresses gaps traditionally reinforced by siloed curricula [1,3]. Empirical evidence has consistently demonstrated that early exposure to IPE enhances undergraduate health care students' teamwork abilities, communication skills, and readiness for collaborative practice [4,5]. Conversely, the absence of IPE can limit students' interprofessional skills, potentially leading to poorer health outcomes for patients in the future [6]. However, despite its proven benefits, IPE implementation faces persistent systemic barriers [7,8].

Geographical and institutional barriers often limit meaningful interaction among individuals in different health care disciplines, as many educational programs are housed in separate departments or institutions [9]. This separation fosters professional silos, hindering students' ability to develop effective cross-disciplinary communication and collaboration skills. Furthermore, faculty's resistance to change, particularly among those accustomed to traditional, discipline-centered teaching methods, presents an additional challenge [10,11]. Compounding these issues is the frequent absence of established frameworks or guidelines for IPE integration into existing curricula. Without systematic implementation, IPE initiatives risk being reduced to superficial additions rather than becoming foundational components of health care education [6,12]

To enhance learning outcomes in IPE, several strategies have been implemented. A systematic review revealed that the most commonly used teaching and learning methods in universities to implement IPE were problem-based learning, case-based learning, and team-based learning [13]. In addition, simulation-based learning, e-learning, and serious games have been recognized as effective methods for cultivating IPE competencies [13-16]. Technology enables flexible learning options offered by IPE and can accommodate many schedules and geographical distances. This accessibility allows students from many fields to engage in group learning projects independent of physical limitations [17].

Technology-Enabled IPE: Serious Games as a Solution

Serious games are defined as interactive digital tools designed to merge gameplay with measurable learning outcomes. They have emerged as a promising solution to IPE implementation challenges [18]. These games can be delivered through 2 distinct modalities, namely immersive virtual reality (IVR) and web-based platforms.

Incorporating IVR into IPE can provide students with repeatable experiential learning opportunities within and across disciplines. It provides high-fidelity clinical simulations that enhance experiential learning through realistic scenarios, emotional presence, and embodied cognition [19]. IVR's unique capacity for perspective-taking and risk-free practice makes it particularly valuable for empathy development and high-stakes skills training [20]. IVR can overcome organizational barriers, such as a lack of time, limited skilled professional instructors, and a lack of space [21,22], as all of the scenarios are predesigned and set in an IVR environment.

Web-based platforms emphasize accessibility, flexibility, and scalability, enabling asynchronous collaboration and real-time performance tracking for geographically dispersed learners. Their strength lies in creating interactive digital spaces that support interprofessional interaction without temporal or spatial constraints [23]. This allows students to engage in activities at their convenience from home, offering multiple opportunities for practice. Additionally, it overcomes geographical and institutional challenges, such as limited space and resources [23].

Both modalities share the core benefits of serious games, which improve engagement, knowledge retention, and collaborative skills [24]. IVR-based serious games offer unique advantages in creating authentic health care team dynamics through immersive simulations [25]. Studies indicate that these environments significantly enhance collaborative problem-solving and interprofessional learning experiences [26]. The technology's unparalleled capacity for experiential immersion accelerates the development of competency in complex interpersonal skills by fostering teamwork and enhancing knowledge acquisition [19].

Meanwhile, studies have consistently demonstrated that interdisciplinary collaboration facilitated by web-based serious games enables students to consolidate and apply knowledge more effectively, fostering collaborative behaviors that enhance clinical decision-making skills [27,28]. The inherent accessibility and lower infrastructure requirements of these arrangements make them particularly suitable for resource-constrained settings [23].

Despite these established benefits, no studies have directly compared how these delivery modalities (IVR vs web-based learning) influence IPE outcomes. This gap leaves educators without the evidence necessary to choose between high-immersion (but resource-intensive) IVR and scalable (but less immersive) web-based platforms.

In addition, the successful implementation of technology-mediated IPE hinges on 2 critical factors: sustained

XSL•FO
RenderX

student engagement and meaningful interpersonal connections [29]. These elements are particularly vulnerable in digital learning environments, where the lack of physical proximity may compromise the development of interdisciplinary relationships. This challenge is especially pronounced in web-based platforms, which must overcome the inherent limitations of asynchronous interaction to foster authentic collaboration [30]. Conversely, IVR offers unique advantages in this regard, with its capacity to generate emotional presence and embodied learning experiences that may strengthen interprofessional bonds [20].

This study addresses these considerations through a comprehensive comparison of 2 technological approaches. We explore how experiential learning, utilizing IVR and web-based platforms, differentially influences both concrete learning outcomes and essential experiential factors. Specifically, the investigation evaluates their relative effectiveness in developing interprofessional competencies (teamwork and knowledge acquisition) while simultaneously cultivating the motivation (interest and competence) that predicts ongoing engagement with IPE collaboration [31] and the community-building aspects (membership and emotional ties) that ensure long-term engagement with collaborative practice [32].

Objectives

This study compared IVR with web-based serious games for developing health care students' (1) interprofessional competencies (teamwork readiness and knowledge acquisition) and (2) learning experiences (motivation and community perception), with the aim of identifying the optimal modality for IPE implementation. The investigation specifically assessed how each approach differentially impacts competency development, intrinsic engagement (interest and perceived competence), and community formation (membership, support, and connection), providing evidence for technology-enhanced IPE strategies.

Methods

Patient and Public Involvement

Since this study aimed to compare the effectiveness of IVR and game-based learning in IPE among health care students and was conducted in a local university, there was no patient or public involvement.

Trial Design

This study used a multimethod design, which incorporated pre/postlearning approaches to measure competency gains, knowledge-checking games to evaluate the application of skills, and focus group interviews to capture qualitative experiential differences between the 2 delivery modalities. This comprehensive approach enabled a robust comparative analysis of the educational effectiveness of the 2 modalities, addressing a critical gap in understanding how technological immersion levels impact IPE outcomes [33]. This study has been reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2025 checklist (Checklist 1) and CONSORT-EHEALTH checklist for randomized controlled trials (Checklist 2) [34,35]. In line with these guidelines, the study was retrospectively registered at ClinicalTrials.gov on February 27, 2026 (NCT07474701). This was an educational randomized study conducted among undergraduate health care students, with outcomes focused on training-related measures that included knowledge, attitudes, skills, and learning outcomes rather than patient health outcomes. Given the low-risk, nonclinical nature of the study and outcomes, the trial was not prospectively registered.

Trial Setting and Eligibility Criteria

This study was conducted at a government-funded university that offers undergraduate nursing and physiotherapy programs. Convenience sampling was used to recruit undergraduate health care students from the 2024/25 cohort. The participant pool consisted of 215 third-year nursing students enrolled in a gerontological nursing course and 68 third- and fourth-year physiotherapy students attending preclinical training workshops.

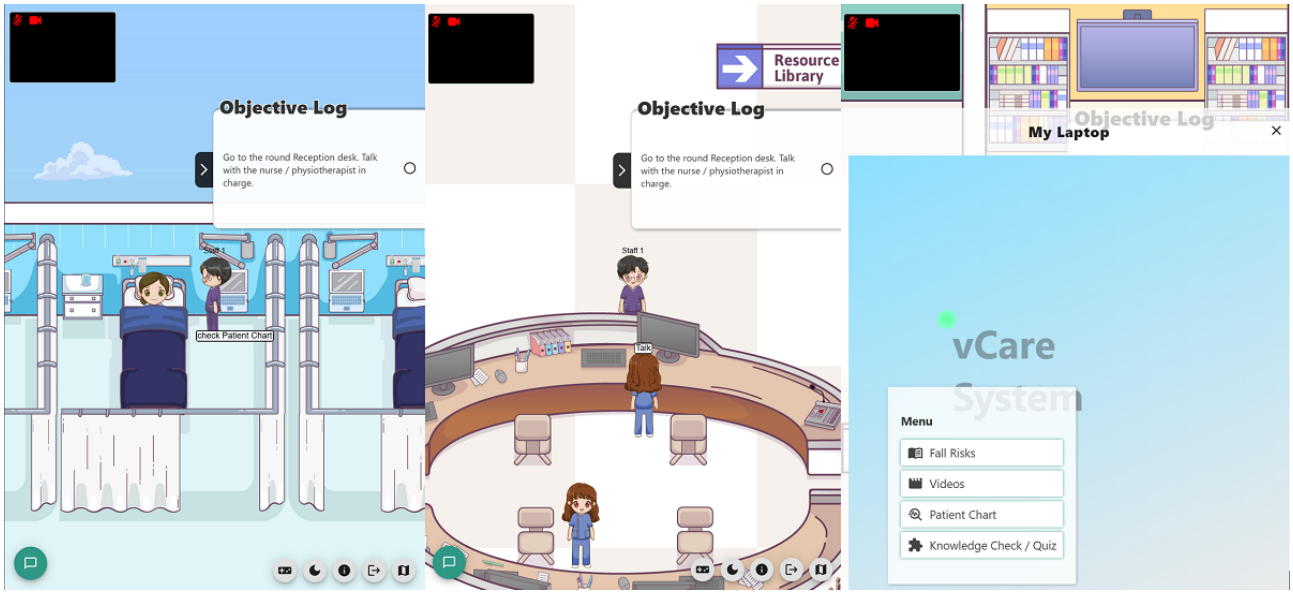
All eligible students were invited to complete surveys about their learning experiences as part of the course evaluation. However, only students who provided consent were included in the study analysis and reporting. Students were organized into 34 interprofessional groups, each comprising 7 - 8 nursing students and 1 - 2 physiotherapy students, and they were randomly allocated to IVR training (17 IPE groups) or web-based serious gaming (17 IPE groups). Details of the randomization procedure are provided in the Randomization section.

Participation in focus groups was optional. After completion of the IPE learning activities, 4 face-to-face focus group discussions were conducted, with each session lasting an average of approximately 60 minutes. Representatives from the 34 groups were invited to participate in the focus group (34 students; 22 nursing students and 12 physiotherapy students).

Ethical Considerations

Ethical approval was obtained from the Human Subjects Ethics Review Committee of the university (HSEARS20240827002). While participation in the IPE tutorials was mandatory for nursing and physiotherapy students, involvement in the research study was strictly voluntary. Students were explicitly assured that their decision to participate would not affect their academic standing, course grades, or access to learning opportunities. No monetary or nonmonetary compensation, course credits, or other incentives were provided for participation in the research study. Written informed consent was obtained from all study participants, and stringent confidentiality measures were implemented, including deidentification of all data prior to analysis. Access to raw data was restricted to only 3 nursing faculty members (JYWL, PPKK, and SW), the physiotherapy lecturer (CKHW), and the project research assistant (RWYW) to protect participant privacy while enabling necessary educational assessments. This clear separation between required learning components and optional research participation was maintained throughout the study period, with all students receiving equal access to learning experiences regardless of their research participation status. In addition, no individual participants in this study can be identified from the images included in the manuscript or supplementary materials.

XSL•FO
RenderX



Intervention and Comparator: IPE Program Design

The IPE learning activities were strategically implemented during weeks 7 - 8 of the 13-week semester to ensure that the students would have acquired foundational knowledge before engaging in collaborative competency development. The research team designed a unified serious game flow that simulated the care trajectory of an older adult recovering from a fall-induced hip fracture, with the following three IPE-focused levels: (1) interprofessional care transition (acute to rehabilitation), (2) interprofessional team dynamics (rehabilitation ward), (3) interprofessional discharge coordination (community reintegration). This identical clinical scenario was delivered through both modalities—IVR (Figure 1) and web-based platform (Figure 2)—maintaining consistency in learning objectives across conditions. The web-based platform had different user interface panels for the PC and mobile displays, with a website URL that made both the PC and mobile platforms user-friendly. The 2 formats differed only in their technological delivery and gamification elements, with content that did not require hands-on practice (Table 1).

Figure 1. Interface screenshots of the immersive virtual reality platform, including (A) the overall virtual environment settings, (B) patient information with case details, (C) knowledge-checking questions, and (D) a discussion panel from the first-person view of a nurse.

Figure 2. Interface screenshots of the web-based platform, including the overall environment settings (left and middle) and the resource hub with knowledge-checking questions and self-learning materials (right).

Table . Overview of the learning objectives and activities of interprofessional education–focused levels and comparisons of gamification elements between IVR[a] and web-based platforms.

Variable	Interprofessional care transition (acute to rehabilitation)	Interprofessional team dynamics (rehabilitation ward)	Interprofessional discharge coordination (community reintegration)
Learning objective	Develop shared decision-making skills for transitional care planning.	Practice role clarity and communication in fracture rehabilitation.	Refine patient-centered discharge strategies.
Learning activities	Nursing and physiotherapy students collaborate on (1) transferring documentation and medication reconciliation, (2) setting shared rehabilitation goals, and (3) addressing potential complications (eg, delirium risk [nursing focus] and early mobilization [physiotherapy focus]).	Students coordinate daily routines to resolve real-world interdisciplinary challenges (eg, balancing wound care schedules [nursing] with mobility exercises [physiotherapy]) and practice communication and teamwork to ensure patient-centered care.	Interprofessional teams work together to (1) develop comprehensive discharge plans, (2) address medication management (nursing) and home mobility adaptations (physiotherapy), and (3) apply structured negotiation for patient transition to home care.
Gamification elements of the IVR platform	—[b]	Real-time verbal discussions within a virtual ward, with all audio interactions automatically recorded for teaching and review purposes.	—
Gamification elements of the web-based platform	—	Separated real-time discussion rooms using text or video chat on the platform for group discussions, with all sessions recorded in the cloud and archived for teaching and review purposes.	—

[a]IVR: immersive virtual reality.

[b]Not applicable.

Implementation

The IPE program was delivered through 2 modalities. Quick informal briefing and debriefing sessions lasting 30 minutes were conducted with the participants. Seventeen IVR groups participated in a structured 2-hour face-to-face tutorial during the 7th week of the 13-week semester. The tutorial used 5 IVR setups to simulate clinical rehabilitation environments, where 4-5 IPE teams per tutorial rotated through game-based learning activities in a similar setup during each session. Meanwhile, the web-based groups accessed identical content through a web-based platform over the same week, at their convenience, enabling asynchronous collaboration without time or location constraints.

Harms

The potential harms associated with the intervention were minimal. One possible adverse effect was transient dizziness or nausea (ie, virtual reality sickness) associated with prolonged IVR use. Both students and lecturers were informed of this risk. Students were instructed to stop the activity immediately and report any physiological discomfort to the lecturers so that appropriate support could be provided. If symptoms occurred, students were allowed to take a break or withdraw from the session as needed.

Sample Size

A power analysis determined the sample size. Previous studies of similar educational interventions reported medium to large effect sizes in learning outcomes from pre- to postintervention [36-38]. Adopting a conservative approach, we based our power analysis on detecting a medium effect using a 2×2 mixed multivariate analysis of variance (MANOVA). The results indicated that a sample size of 128 would be sufficient to detect a medium 2-tailed effect at a significance level of $P<.05$ with 80% power. We anticipated a sample size of around 150 - 160 to account for potential missing data. Based on the nurse-physiotherapist ratio, this would translate to approximately 112 - 128 student nurses and 32 - 38 student physiotherapists.

Outcomes

Overview

Participants were assessed at 2 strategic timepoints to capture both modality-specific and comparative learning outcomes. Following completion of their first assigned learning approach (either IVR or the web-based platform) but prior to experiencing the alternative modality, all participants completed self-administered surveys where the knowledge-checking activities were embedded in the IPE learning games. This timing allowed for the independent evaluation of the discrete learning experiences and outcomes associated with each platform. Subsequently, after all groups had engaged with both teaching approaches through the crossover design, we conducted 4 focus group discussions. This later timing enabled the participants to provide informed comparative reflections on the relative strengths and limitations of both modalities, having gained first-hand experience with each approach. The phased assessment strategy thus yielded both platform-specific and holistic evaluation data for a comprehensive understanding of the educational innovations.

Demographic Data

Demographic variables included age, gender, profession (nursing/physiotherapy), course, experience with online games, and total play time per day.

XSL•FO
RenderX

Primary Outcomes

The Readiness for Interprofessional Learning Scale (RIPLS) was used to evaluate the students' preparedness to engage in collaborative IPE. This scale consists of 19 items organized into three factors that assess students' views on: (1) teamwork and collaboration, (2) professional identity, and (3) professional roles and responsibilities [39]. Responses are measured using a 5-point Likert scale (1=strongly disagree, 2=somewhat disagree, 3=neither agree nor disagree, 4=somewhat agree, and 5=strongly agree). Higher scores on the total scale and its subscales indicate increased readiness and more favorable attitudes on the importance of IPE and collaborative practice among health care students [40]. The overall RIPLS demonstrated excellent internal consistency, with a reliability coefficient (Cronbach α) of 0.90 [39,40].

The Brief Sense of Community Scale (BSCS) was used to evaluate the participants' psychological sense of community while playing the games [39,41]. It consists of 18 items measuring 4 dimensions: needs fulfillment (the belief that community members will help each other), membership (a sense of belonging to the community), influence (a sense of contributing to the community), and emotional connection (a shared emotional connection/experience) [41]. A 5-point Likert-type scale, with 1 denoting "strongly disagree" and 5 denoting "strongly agree," was used by participants to answer the BSCS items. A stronger sense of community is indicated by a higher BSCS score [39]. The scale has demonstrated excellent internal consistency (Cronbach α=0.92) [39].

The Intrinsic Motivation Inventory (IMI) questionnaire was used to evaluate different aspects of the students' motivation in relation to the learning approaches [42]. Nine items distributed over 3 subscales were used: interest/enjoyment, perceived competence, and pressure/tension. Interest/enjoyment represents a self-reported measure of intrinsic motivation (the level of interest and joy felt while performing a certain activity). Perceived competence is considered a positive predictor of intrinsic motivation. Perceived competence involves assessing participants' feelings when they are carrying out a task. The pressure/tension subscale, which evaluates whether participants experience pressure to do well during an activity, is thought to be a negative predictor [42]. This version consists of 9 items scored on a Likert scale ranging from 1 (not at all true) to 7 (very true). The Cronbach α coefficients for the interest/enjoyment, perceived competence, and pressure/tension subscales were 0.78, 0.80, and 0.68, respectively, demonstrating generally adequate internal consistency [42]. The overall IMI scale has shown strong internal consistency, with a Cronbach α value of 0.85 [42].

Multiple-choice questions (MCQs) were used to measure students' learning outcomes. The questions and answers were collaboratively developed by academics from the departments of nursing and rehabilitation sciences. A total of 20 questions were developed (10 related to discipline-specific knowledge and 10 related to knowledge of IPE). See Multimedia Appendix 1 for the MCQs that were developed and used to measure students' learning outcomes.

Randomization

Students were organized into 34 interprofessional groups, each comprising 7‐8 nursing students and 1‐2 physiotherapy students. Randomization was conducted at the group level for administrative purposes. A computer-generated random sequence (1:1 allocation) was used to allocate the 34 IPE groups to either IVR training (17 IPE groups) or web-based serious gaming (17 IPE groups). The allocation sequence was generated and implemented by the lecturers (JYWL and CKHW). Owing to the nature of the study design, students were aware of the groups to which they had been assigned. Following a crossover design, the groups used their initial learning modality for 1 week before switching to the alternative modality. All students were invited to complete surveys about their learning experiences, and participation in the focus groups was optional. As the surveys and knowledge-checking tests (MCQs) were self-administered, blinding was not required.

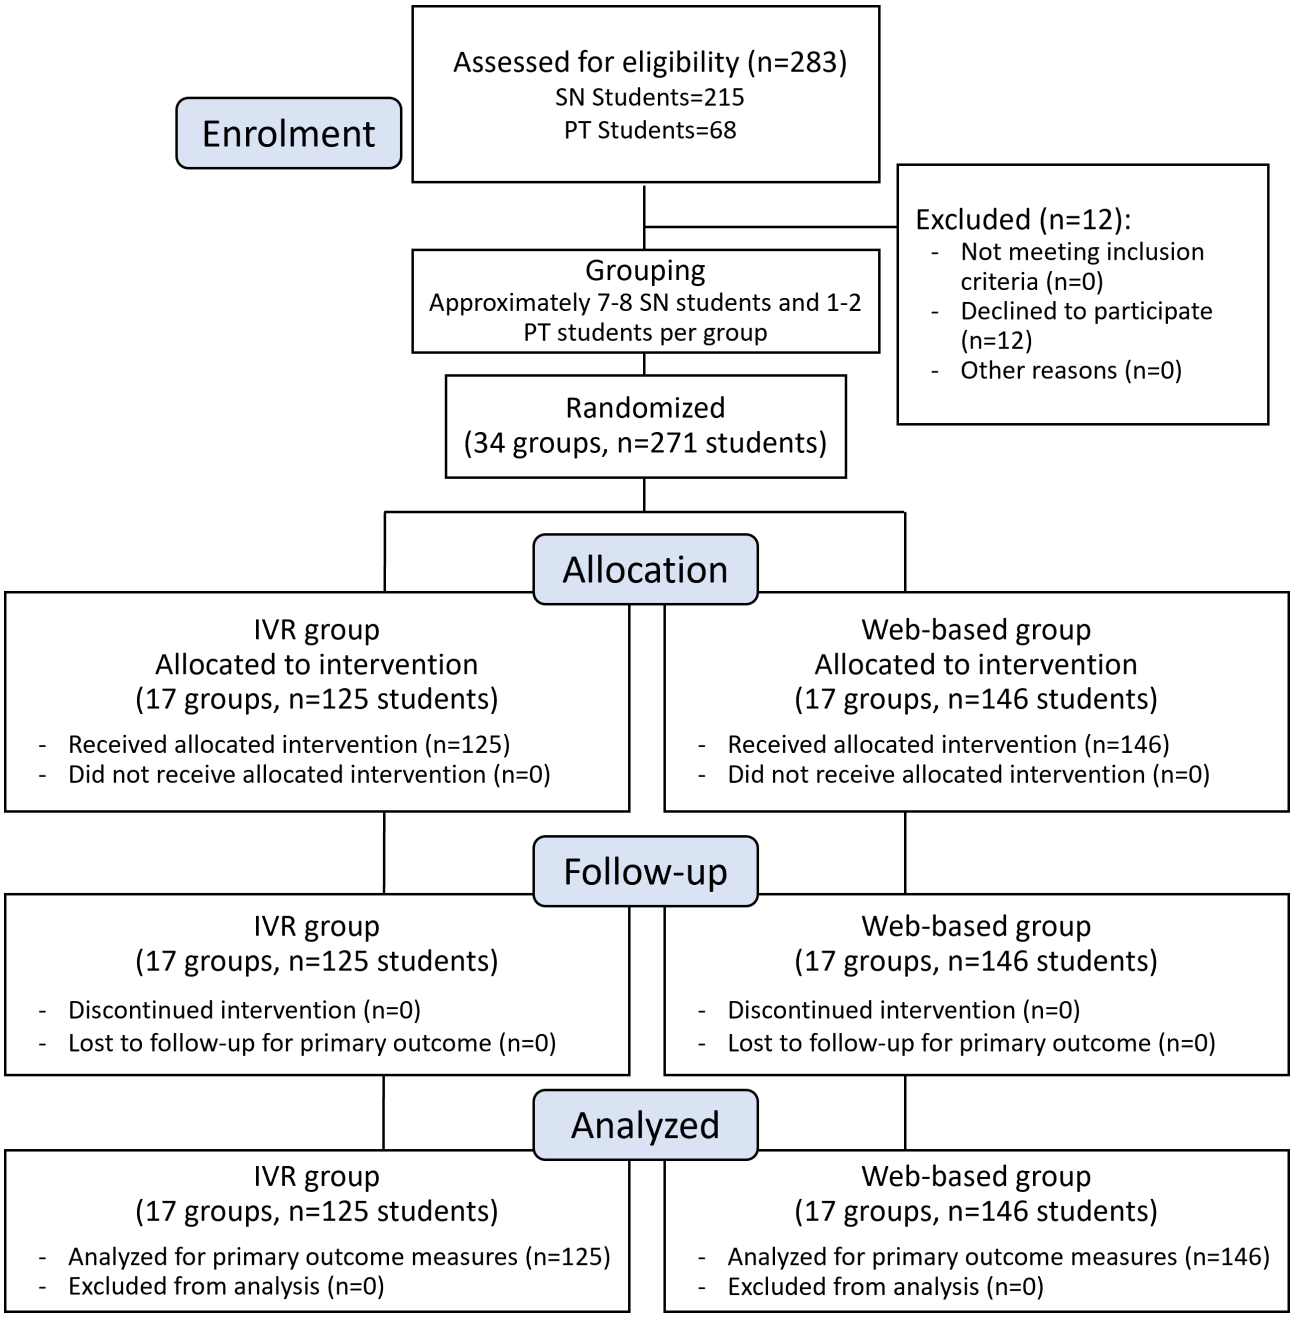
Statistical Methods

Quantitative Data

IBM SPSS 29.0 software was used to analyze the quantitative data. With regard to descriptive statistics, mean and SD were used for continuous data, and frequency and percentage were used for categorical variables. A chi-square test or Fisher exact test was used for categorical variables. According to the trial protocol, a mixed 2×2 MANOVA was prespecified to explore the interactions between group differences and the within-subject factor. However, upon examining the data, the assumption of normality was violated. Consequently, as a deviation from the prespecified analysis, nonparametric tests were used. The median and IQR were used to present outcome measures. Within-group differences were analyzed using the Wilcoxon signed rank test, while between-group differences were analyzed using the Mann-Whitney *U* test. To strengthen the interpretation of the results, effect sizes (*r*) and CIs were used. The level of significance was set at .05. Samples with missing data were excluded from the analysis.

Qualitative Analysis

Qualitative data were collected through focus group interviews. The semistructured interviews, which used overarching questions, were transcribed verbatim and analyzed using thematic analysis (see Multimedia Appendix 2 for the interview questions). The process of analysis began with initial open coding, during which significant statements and phrases were identified for further thematic development. These codes were subsequently grouped with meaningful subthemes. Lastly, the subthemes were condensed to form overarching themes, leading to the identification of key themes. To ensure qualitative rigor, all interview transcripts were independently coded by 2 researchers (RWYW and JYWL). The initial codes were compared and discussed to ensure consistency, and any discrepancies that could not be resolved were reviewed by a third researcher (KC) to reach a consensus. The development of key themes followed a similar iterative process involving comparison, discussion, and consensus among the 2 researchers (RWYW and JYWL) to ensure the credibility and trustworthiness of the findings.



XSL•FO
RenderX

Results

Participant Flow and Recruitment

A total of 283 students were invited to participate. Of these, 271 students (125 in the IVR group and 146 in the web-based group) consented to join the study, yielding a response rate of 95.8% (271/283). Participant flow through the trial is shown in Figure 3. The final sample consisted of 203 nursing students and 68 physiotherapy students.

Figure 3. Participant flowchart. IVR: immersive virtual reality; PT: physiotherapy; SN: School of Nursing.

Baseline Data

The majority of participants were female (160/271, 59.0%), were aged between 19 and 21 years (173/271, 63.8%), and had experience with online gaming (250/271, 92.3%). Significant differences in age distribution (P=.001) and course enrollment (P<.001) were noted between the IVR and web-based groups (Table 2). There were no significant differences in gender, profession, online gaming experience, or daily playtime (P≥.05). In addition, no significant between-group differences were identified for the outcome measures at baseline (P≥.05; Multimedia Appendix 3).

Analyzed Outcomes and Estimation for Quantitative Outcomes

Primary Outcomes

Within-Group Comparisons of RIPLS, BSCS, IMI, and MCQ Scores in the IVR Group

No significant differences were noted in RIPLS scores (*P*=.24). Participants demonstrated significant improvements in BSCS scores (*P*=.001), scores of the “pressure/tension” subscale of the IMI (*P*<.001), and scores of the knowledge-checking MCQs (*P*<.001; Table 3). Significant increases were noted in total BSCS scores (*r*=−0.29, 95% CI 0.06-0.31; *P*=.001) and the scores of the dimensions of “influence” (*r*=−0.32, 95% CI 0.00-0.50; *P*<.001) and “emotional connection” (*r*=−0.33, 95% CI 0.25-0.50; *P*<.001; Multimedia Appendix 4). Significant decreases were noted in the scores of the “pressure/tension” subscale of the IMI (*r*=−0.45, 95% CI −0.05 to –0.25; *P*<.001). Moreover, there were significant improvements in the scores of the knowledge-checking MCQs (*r*=−0.64, 95% CI 2.00-3.00; *P*<.001; Table 3).

Within-Group Comparisons of RIPLS, BSCS, IMI, and MCQ Scores in the Web-Based Group

No significant differences were noted in RIPLS scores (*P*=.90). Participants demonstrated significant improvements in BSCS scores (*P*=.001), scores of all 3 subscales of the IMI (*P*<.05), and scores of the knowledge-checking MCQs (*P*<.001; Table 4). Significant increases were seen in total BSCS scores (*r*=−0.27, 95% CI 0.07-0.31; *P*=.001) and the scores of the dimensions of “influence” (*r*=−0.30, 95% CI 0.00-0.50; *P*<.001), “emotional connection” (*r*=−0.24, 95% CI 0.00-0.50; *P*=.004), and “needs fulfillment” (*r*=−0.18, 95% CI 0.00-0.50; *P*=.03; Multimedia Appendix 4). Regarding the IMI, significant increases were noted in the scores of the “interest/enjoyment” subscale (*r*=−0.17, 95% CI 0.00-0.30; *P*=.043) and “perceived competence” subscale (*r*=−0.19, 95% CI 0.00-0.50; *P*=.02), while significant decreases were noted in the scores of the “pressure/tension” subscale (*r*=−0.46, 95% CI −0.75 to −0.50; *P*<.001). Moreover, there were significant improvements in the scores of the knowledge-checking MCQs (*r*=−0.80, 95% CI 4.50-6.00; *P*<.001; Table 4).

Comparisons of RIPLS, BSCS, IMI, and MCQ Scores Between the IVR and Web-Based Groups

The web-based group demonstrated superior performance in knowledge-checking MCQs compared with the IVR group (IVR group median score: 15.00, web-based group median score: 18.00; r=−0.34, 95% CI −3.00 to −2.00; P<.001). However, no significant differences were observed between the IVR and web-based groups in the total scores of the RIPLS, BSCS, or IMI at the postassessment stage (Table 5).

Ancillary Analyses for Qualitative Results

Focus Group Participants

A total of 34 participants were engaged in the focus groups, and most of them were female (24/34, 71%), were aged 19 - 21 years (23/34, 68%), were studying nursing (24/34, 71%), had experience with online games (23/34, 68%), and had no prior experience with IPE (28/34, 82%; Table 6). The average rating for overall experience was 5.78 (SD 1.97) out of 10 points, and the ratings for IVR and web-based learning were 6.03 (SD 2.24) and 5.47 (SD 2.13), respectively.

Qualitative Outcomes: Focus Groups

Four focus group interviews were conducted, and they included a total of 34 participants engaged with both the IVR and web-based platforms. Six themes and 17 subthemes were identified, and they, along with quotations, are summarized in Table 7. The themes included (1) recognizing value, gaps, and opportunities for deeper collaboration; (2) shared learning, trust, and emotional connection across disciplines; (3) engagement, autonomy, and authenticity in digital learning environments; (4) enhancing knowledge retention; (5) balancing innovation with implementation; and (6) enhancing realism and inclusivity. Data saturation was achieved, as all 4 focus groups yielded consistent themes with no new substantive insights emerging across groups, indicating that the qualitative data adequately captured the range of student experiences across both learning modalities.

XSL•FO
RenderX

Table . Thematic analysis of the focus group semistructured interview.

Themes and subthemes	Quotes[a]
1. Recognizing value, gaps, and opportunities for deeper collaboration	
1a. Recognition of the value of interprofessional collaboration	We rarely have interdisciplinary practice, so this is a great opportunity to understand each other's responsibilities, perspectives, and thoughts. [Student #13]
1b. Desire for deeper role integration	In IVR[b], both PT[c] and SN[d] students can play separately without many tasks needing to be completed together. Adding some content where those from two professions need to think and analyze together would help in understanding each other's roles and how they complement each other. [Student #37]
1c. Perceived lack of collaboration in practice	The collaboration wasn't very extensive. For example, during bed notes, we each handled our own parts, so I don't think it was very helpful for collaboration. [Student #42]
1d. Positive learning through interaction	Because previously, there were very few opportunities to engage in discussions like this with people from other professions. Usually, it was just with my own classmates. This time, it was the first time to collaborate on a project with nursing students, so I learned during the process. Apart from communication, we exchanged knowledge about our respective professions. [Student #15]
2. Shared learning, trust, and emotional connection across disciplines	
2a. A shared learning structure enhances connection for web-based learning	I think I might prefer the web-based platform because I feel like I can learn more from it. There are more multiple-choice questions, mini games, and we go through the whole flow together. There are maybe six or seven checkpoints, which helps relate the content back to what we learned in class. [Student #211]
2b. Interdisciplinary learning enriches understanding	Because we are working with people from different disciplines, you get to see more perspectives, for example to see how PT students experience things differently. Sometimes they even teach us how to analyze a problem or a case where nursing students might skip parts not directly related to our duty. But with PT students involved, you end up learning more. [Student #28]
2c. Collaborative problem-solving builds trust	It felt like teamwork when everyone was looking at the same case together. That created a nice sense of bonding, and we could immediately catch things that others might have missed. [Student #11]
2d. Supportive communication fosters engagement	What I liked most was being able to discuss things as a group. If you didn't understand something, you could just ask others, and they would help you. Through discussion, you gained a deeper understanding of each case, which made me feel more engaged. [Student #11]
3. Engagement, autonomy, and authenticity in digital learning environments	
3a. Engagement through playful design	There are many types and numbers of mini-games, making a web-based game less difficult or tiring to play, which is more interesting. [Student #44]
3b. Empowered and self-directed learning	I think the web-based game allows us to explore more on our own because it is an online platform. We have more preparation time, can learn new knowledge instantly, and get immediate feedback. If we don't understand something, we can ask in lectures later, and there are checkpoints for checking our progress, which is better for learning. [Student #212]
3c. Authenticity enhances value	I think that the setting, elements, and process are very similar to a hospital setting. [Student #13]
4. Enhancing knowledge retention	
4a. Challenge enhances learning depth for IVR	Those students who were playing the IVR had a time limit that forced them to think quickly. So, it might make the memory deeper, and we might actually learn more things. [Student #14]

XSL•FO
RenderX

Themes and subthemes	Quotes[a]
4b. Practice and feedback support web-based learning	Because the web-based platform allows you to play the games many times, it is like practicing exam papers repeatedly. If you play a few more times, you will remember. But in IVR, if you make a mistake, you will only be told that the answer is wrong and then need to move on to the next question. However, with web-based learning, the memory points are deeper. [Student #43]
5. Balancing innovation with implementation	
5a. Appreciation for a creative and engaging instructional design	I understand that the SN and PT teachers worked hard to provide a new experience, making it more interesting than just attending tutorials. [Student #37]
5b. Technical barriers disrupt learning continuity	The connection was very poor, groupmates kept disconnecting, and it wasn't like a normal conference. [Student #31]
6. Enhancing realism and inclusivity	
6a. Expanding interprofessional scope for holistic learning	I think people from more professions should be included, such as doctors and social workers, to make a more comprehensive care plan. [Student #28]
6b. Enhancing the simulation of realism through patient interactions	I think patient reactions should be added. Currently, we can only understand the patient's condition through the layout, but in reality, we would at least ask the patient. [Student #42]

[a]Quotes from focus group participants are attributed using anonymized identification codes based on transcription order.

[b]IVR: immersive virtual reality.

[c]PT: physiotherapy.

[d]SN: School of Nursing.

The focus group interviews were performed to evaluate the students' views on the IPE program in relation to the outcome measures (Table 7). With regard to readiness for interpersonal learning, the students expressed appreciation for the opportunities to engage in interprofessional learning, particularly when such experiences had previously been limited. They recognized the value of understanding different professional roles but also highlighted the need for more integrated tasks that require genuine collaboration. Positive reflections on learning through interaction suggest that when collaboration is meaningful, it enhances both engagement and professional understanding.

The sense of community was strengthened through shared learning structures, interdisciplinary dialogue, and collaborative problem-solving. Students appreciated the opportunity to learn from peers in other disciplines and felt emotionally connected when working together on cases. The web-based format, with its structured checkpoints and group discussions, also contributed to a sense of belonging and engagement.

Intrinsic motivation was enhanced when students found the digital learning environment engaging and motivating, particularly due to its interactive elements, such as mini-games and autonomy in learning from the web-based platform and realistic simulations from IVR. These features supported self-directed learning, made the experience more enjoyable and meaningful, and relieved learning pressure.

Students reported that both the IVR and web-based platforms contributed to knowledge retention in learning, albeit in different ways, which was also supported by improved scores in MCQs that were related to IPE and were field-specific. Students reflected that the time constraints in IVR encouraged quick thinking and deeper memory encoding, while the web-based platform allowed for repeated practice and immediate feedback, reinforcing learning through repetition.

Students also reported some strengths and weaknesses in the focus groups. While students appreciated the innovative and engaging design of the learning experience, technical issues in both the IVR and web-based platforms, such as poor connectivity, disrupted the learning flow and experience. With regard to teaching content for future improvement, students suggested expanding the interprofessional scope to include more health care roles and enhancing the realism of simulations by incorporating patient interactions.

IVR provided an interesting and innovative experience but limited participation due to time constraints, whereas the web-based game offered enjoyment through mini-games and interactive elements, although technical issues were a major obstacle. The high level of flexibility and self-paced learning offered by the web-based game, along with the immersive and realistic experience of IVR, led to high engagement in the IPE program. Students who preferred the web-based game as a learning platform appreciated its stronger interactive elements and rich knowledge content, while those who preferred IVR valued its immersive experience and smooth operation. This satisfaction was reflected in significantly higher BSCS and MCQ scores, as well as in reduced pressure/tension scores. Through the IPE program, students were able to improve their understanding of interprofessional roles as one of the learning outcomes. Both platforms facilitated deeper memory retention in learning, as evidenced by improved scores in MCQs that were related to IPE and were field-specific. The IVR helped to deepen memory with intensive time constraints, while the

XSL•FO
RenderX

web-based game strengthened memory with repeated practice. However, students felt that the 2 platforms had no strong association for enhancing the learning experience. As an interprofessional collaboration training tool, students agreed that it offered a chance for interprofessional collaboration, but some students felt that collaboration in IVR was limited and that there were insufficient interdisciplinary tasks.

Technical issues were identified in both the IVR and web-based game, significantly affecting the user experience. With regard to IVR, some students experienced difficulties with VR controls, and the limited number of devices prevented simultaneous engagement from all group members. With regard to the web-based game, frequent disconnections and login issues were reported, and the limited number of participants allowed in rooms for group discussions hindered the smoothness of the learning process.

In terms of areas for improvement, students suggested enhancing technical support for both platforms, incorporating more interactive tasks, and increasing the duration of sessions for IVR to more than 2 hours. Additionally, for future development, students recommended including professionals from more disciplines in the IPE, such as doctors and social workers, and adding patient interaction in simulation scenarios.

Harms

No adverse events were reported by students in the study.

Discussion

Principal Findings

To our knowledge, this is the first study to directly compare the efficacy of IVR and web-based serious games in fostering interprofessional competencies and learning experiences among health care students. Both approaches yielded notable improvements in community building, motivation, and knowledge acquisition, although no significant changes were observed in readiness for interprofessional teamwork. The web-based approach led to comparatively stronger gains in knowledge clarity and motivation, possibly due to its flexible and diversified learning formats that cater to different learning preferences so as to support knowledge retention. Overall, the findings suggest that both modalities hold practical value in advancing technology-enhanced IPE, with distinct strengths depending on learning context and objectives.

Interpretation

Both groups demonstrated a clear and significant improvement in community building, as reflected by increased scores in the BSCS. Consistent with the quantitative findings, the focus group participants emphasized the importance of interdisciplinary learning, stating that collaborating with peers from different disciplines enriched their perspectives, deepened their understanding, and fostered emotional connection through shared case discussions [43]. The web-based platform's structured checkpoints and group discussions particularly promoted engagement and a sense of belonging, while supportive communication encouraged participation across both modalities.

The existing literature supports these findings, showing that students who perceive themselves as part of a cohesive learning community are better prepared for interprofessional collaboration, a vital skill in delivering high-quality patient care [44]. A strong sense of community is also associated with improved academic performance, greater satisfaction with the learning experience, and better management of stress and anxiety—common challenges among health care students due to their rigorous coursework and examinations [45]. Therefore, cultivating a sense of community with their peers through IPE would not only enhance learning outcomes but also prepare students for the collaborative, team-based practice central to effective health care delivery [46]. This study revealed significant changes in IMI subscale scores among students using both the IVR and web-based learning platforms. The IMI was used to assess different dimensions of motivation related to learning approaches [42], including interest/enjoyment**,** perceived competence**,** and pressure/tension. Both groups demonstrated a statistically significant reduction in pressure and tension. These findings suggest lower anxiety levels and a more supportive learning atmosphere across both modalities [47].

Consistent with these quantitative findings, the focus group participants indicated that the variety of mini-games reduced fatigue and increased engagement, and they appreciated the authenticity of the simulated hospital environment, which enhanced the realism and perceived value of the experience. Together, these insights indicate that the reduced anxiety in both the IVR and web-based contexts can facilitate collaborative learning, as lower stress levels encourage active engagement and deeper comprehension, which are factors critical in health care education [48]. Reduced anxiety promotes active engagement and deeper learning comprehension, which are particularly vital in health care education, while enhancing intrinsic motivation [49].

The observed decrease in pressure/tension among IVR learners is consistent with prior research showing that immersive virtual environments can alleviate anxiety and stress, promoting a more relaxed and receptive learning state [50]. Similarly, a systematic review indicated that IVR significantly bolstered student motivation and engagement, culminating in improved learning outcomes [51]. Likewise, a study determined that the learning environments of IVR-based serious games promote motivation, engagement, and interaction, and enable personalized and collaborative learning [52]. When students establish connections with their peers and encounter reduced pressure, they are more inclined to engage actively in discussions, exchange resources, and collaborate efficiently on projects. This enhances their learning experience and aids in the development of crucial skills necessary for effective teamwork in clinical settings, which are essential for patient care in health care education [53].

Apart from a reduction in pressure, students in the web-based group also showed improvements in intrinsic motivation, as reflected by increased scores in the IMI subscales for interest/enjoyment and perceived competence, with narrow 95% CIs. Students expressed the view that the web-based platform allowed for more self-directed learning, providing opportunities for exploration and instant feedback, which are beneficial for

XSL•FO
RenderX

their learning. This result is substantiated by a prior systematic review revealing that game-based learning is better than learning without gamification in improving students' perceptions of autonomy, relatedness, and competence [54]. Another review indicated that game-based learning has positive effects on students' motivation levels over the short term [55]. Research indicates that intrinsically motivated students are more likely to attain higher levels of academic performance [56].

While both groups demonstrated notable enhancements in learning outcomes, as reflected by an increase in their knowledge-checking MCQ scores after completing the IPE, the web-based group outperformed the IVR group, with a statistically significant and moderately sized advantage. This is consistent with prior research, which indicated that web-based learning typically improves engagement and enhances knowledge retention [57,58]. This difference may be attributed to the time limitations encountered by the IVR group, in contrast to the web-based group, which benefited from increased flexibility and the chance for self-directed learning, allowing for repeated practice and deeper comprehension [59]. A few students noted that the time limit in IVR forced them to think quickly, suggesting that this challenge might enhance memory retention and learning depth in some learners. However, some students pointed out that the web-based platform's ability to allow repeated gameplay is akin to practicing the filling out of examination papers, which more effectively reinforces learning and memory retention. They remarked that in IVR, mistakes are acknowledged but participants quickly move on without deeper engagement, while the web-based format provides a more thorough learning experience. Such feedback indicates that a single approach may not be sufficient to meet the learning styles of all students, who have diverse preferences in terms of their education [60].

In our study, students who participated in IVR and web-based learning did not show improvements in terms of their preparedness for interprofessional collaboration, as measured by the RIPLS. This finding aligns with emerging evidence suggesting that sustained and longitudinal IPE may be necessary to achieve a meaningful impact on readiness for interprofessional collaboration. Research has demonstrated that while brief IPE programs may show limited immediate improvements in RIPLS scores, extended exposure to IPE is often required to detect significant changes [61]. Similarly, longitudinal studies have indicated that the development of interprofessional competency is a gradual process requiring sustained practice and reflection over extended periods [62,63]. Interprofessional collaboration skill development involves the acquisition of a range of competencies, including communication skills, conflict resolution abilities, and effective teamwork [32]. The development of these skills typically requires a substantial amount of time and sustained practice. The current IVR and web-based IPE activities, which were conducted over a period of approximately 1 week, may not have been sufficient to meet these standards [44]. Students may have had limited opportunities to engage in meaningful interactions, reflect on their experiences, and consolidate their learning. Therefore, students may not have attempted to internalize interprofessional teamwork concepts that were actively taught, thus highlighting insufficient pedagogical guidance [64]. Future studies should consider implementing longitudinal serious gaming interventions with sustained exposure over multiple months or academic terms to assess and develop readiness for interprofessional collaboration.

Web-based platforms have demonstrated comparatively greater advantages than IVR approaches in IPE, especially for health care professionals facing scheduling and geographical constraints [17]. They provide flexibility for self-paced learning, remove geographical barriers, and accommodate a larger number of participants, promoting inclusivity [65]. Furthermore, web-based learning supports various formats (eg, videos, quizzes, and interactive modules) that address different learning preferences, thereby increasing engagement [66]. Additionally, the cost-effectiveness of online education minimizes travel and accommodation costs [66]. Real-time collaboration tools also provide immediate feedback and discussion opportunities, enhancing the overall learning experience [65]. Lastly, the vast array of online resources enriches educational experience, making web-based platforms a more effective and inclusive option for IPE.

Limitations

This study has several limitations. First, it included only undergraduate nursing and physiotherapy students, and thus, it may not have captured the full range of perspectives and dynamics present in real-world interprofessional teams. The exclusion of individuals from other disciplines, such as medicine, pharmacy, social work, occupational therapy, and speech-language pathology, may have limited insights into the broader dynamics of collaboration, clinical decision-making, medication management, psychosocial support, and specialized rehabilitation. Second, most outcomes were assessed using self-reported questionnaires, which may have introduced an expectation bias; however, anonymity was implemented to reduce this bias. Additionally, qualitative findings cannot be generalized to a broader population since they are often based on personal experiences rather than on quantifiable data. Third, technical issues, such as difficulties with VR controls and connectivity, likely disrupted learning continuity and negatively affected student perceptions. These disruptions may have impacted immersion and collaboration, confounding assessments of true educational impacts. Lastly, both IVR and web-based platforms lacked integrated patient interactions within simulation scenarios, which may have reduced the realism of the learning experience. Future studies should involve participants from a broader range of health care disciplines to enhance ecological validity; strengthen technical support and user training; and incorporate simulated patient encounters to improve authenticity, clinical reasoning, and engagement. Addressing these limitations will advance the development of technology-enhanced IPE and better prepare students for collaborative, real-world health care practice [67,68].

Conclusion

To our knowledge, this is the first study to directly compare the effects of IVR and web-based serious games on an IPE program. It differs from existing studies by contrasting 2 widely used but rarely directly compared technology-enabled modalities within

XSL•FO
RenderX

the same authentic clinical case flow. Our study combined quantitative and qualitative data to provide a more comprehensive understanding of how the educational tools of IVR and web-based serious games can improve the interprofessional skills of health care students. Both methods demonstrated notable advancements in community feeling and subject-specific knowledge; however, the web-based approach surpassed the IVR method in terms of knowledge clarity and participant engagement. Although both platforms led to decreased pressure or tension, neither method significantly enhanced readiness for interprofessional teamwork, indicating possible shortcomings in the design of activities and educational support. The results underscore the necessity for engaging and supportive learning environments that reduce anxiety/stress and boost motivation while also tackling technical issues to optimize educational outcomes and better equip students for collaborative roles in health care. In real-world practice, these findings suggest that educational institutions can strategically integrate a variety of serious game elements into IPE training to better prepare students for collaborative, patient-centered care.

Acknowledgments

We would like to extend our gratitude to Mr Xavier Leung and his team for their technical assistance. Additionally, we would like to thank the teachers, nursing students, and physiotherapy students who participated in the game and provided feedback.

Funding

This study was supported by the Teaching Development Grant (TDG) 2022-25 and a grant from the Centre for Immersive Learning and Metaverse in Education (CILME) 2019, both from The Hong Kong Polytechnic University. The funders had no involvement in the study design, data collection, analysis, interpretation, or writing of the manuscript.

Authors' Contributions

The principal investigator (JYWL) and co-investigators (KC, PPKK, and CKHW) made significant contributions to developing the immersive virtual reality and web-based game software. JYWL and KC also contributed to the study's concept and design. Additionally, KC contributed to the coordination of team members and the preparation of the proposal for the online training platform. JYWL, PPKK, SW, and CKHW designed the pedagogy to align these teaching innovations with the learning objectives of their respective subjects. RWYW and CKHW managed daily operations, including the student group allocations and data collection. RWYW contributed to data analysis and drafting of the findings for both the quantitative and qualitative components of the study. JYWL, RWYW, and SMP wrote the original draft of all sections of the manuscript, including the Introduction, Methods, Results, and Discussion, while the co-investigators (KC, PPKK, SW, and CKHW) reviewed and commented on this version of the manuscript. JYWL and RWYW revised subsequent versions of the manuscript in response to the comments from the editor and reviewers (a total of 6 revision rounds). All authors approved the final version of the manuscript.

Abstract

Background: Serious games (SGs) are increasingly used to study and enhance team performance in organizational and educational settings. While prior research has explored leadership and communication as isolated factors, the multivariate interactions between behavioral indicators remain poorly understood. A deeper understanding of these relationships can reveal which behavioral and demographic factors most strongly predict successful outcomes, offering insights relevant to both scientific research and practical training design.

Objective: This study aimed to develop machine learning (ML) models to predict team success in SGs. Specifically, it sought to identify the behavioral and demographic predictors that most strongly influence team performance outcomes.

Methods: This study used a cross-sectional retrospective design. Behavioral and demographic data were analyzed from 233 teams participating in escape room–based SGs delivered by JGM Serious eXperiences in The Netherlands. Teams of 2 - 8 players (mean age 25.8 y; 53 all-male, 55 all-female, and 125 mixed-gender) were scored by trained observers across collaboration, communication, and leadership constructs using Likert-scale indicators. Exploratory data analysis compared winning (n=141) and losing teams (n=92) using descriptive statistics, Pearson correlations, and significance testing (independent-samples *t* tests and Mann-Whitney *U* tests). Mean differences were interpreted with 95% CIs. A total of 4 ML models: logistic regression, random forest, multilayer perceptron, and support vector classifier, were trained using 5-fold cross-validation (F_1-score). The best model was interpreted using SHAP (Shapley Additive Explanations).

Results: Winning teams scored higher on several behavioral constructs, but only 4: knowledge sharing, leadership, guidance, and extraversion, showed statistically significant differences between winners and losing teams. These effects were supported by 95% CIs, Shapiro-Wilk tests for normality, and Mann-Whitney *U* tests where assumptions were violated, indicating that only a subset of behavioral indicators meaningfully distinguishes successful teams. Among the ML models, logistic regression achieved the highest accuracy (88%), followed by multilayer perceptron (87%), random forest (87%), and support vector classifier (85%). SHAP analysis showed that gender composition and prior escape-room experience were the strongest demographic predictors of success, while “celebrating progress” (extern5) and “taking initiative when the team is stuck” (sturing5) were the most influential behavioral indicators.

Conclusions: This work demonstrates the usefulness of multivariate analysis in studying and understanding complex human behavior in SG environments as opposed to studying isolated behavioral indicators, often described in previous studies. The ML models developed using behavioral and demographic features of participating teams showed promising accuracies, and their interpretation led to unveiling a set of demographic and behavioral components as the most decisive factors leading to team success. This improved understanding of what makes a team win can be potentially translated into terms of improved productivity in business and organizational settings.

Introduction

Recent advances in data analytics have facilitated machine learning (ML) applications across several domains of science and business. A total of 1 area that has also revolutionized significantly from these developments is sports and gaming [1], where ML techniques can reveal hidden trends [2] that are important for the development of modern sports and provide a glimpse into the intricacy of player performance [1]. Predicting outcomes based on historical evidence has long been a central goal for researchers. This motivation has driven the development of various approaches, including sport-specific statistical simulations and sport-independent machine-learning techniques [2]. By using these tools, trends in sports data can be identified and used for personal, competitive, or economic advantage [2]. By using cutting-edge algorithms, sports analysts can uncover insights that were previously unattainable, ranging from physical attributes to strategic patterns, ultimately enabling a more comprehensive understanding that surpasses conventional analytical techniques [1]. The early work in this regard dates back more than half a century, when Samuel [3] used ML for game strategy optimization, marking the intersection of artificial intelligence (AI) and gaming. More recently, ML models have been applied to predict individual and team performance using historical data, which has enabled refined decision-making in competition [4,5]. For example, in football, variables such as shots on target, ball possession, and passing strategies were studied using ML techniques and subsequently linked to team success [6]. In cricket and basketball, ML models, such as Naive Bayes (NB) and support vector machines (SVMs), have demonstrated high predictive accuracy by accounting for complex interactions between team composition and match conditions [7,8]. ML techniques have also been effectively applied to understand team performance in sports, with methods such as random forest (RF) and Partial Least Squares Discriminant Analysis being applied to identify key performance metrics [9]. On an aggregate level, the application of ML has shown a promising potential in game analysis by capturing intricate performance patterns, which were otherwise difficult to analyze using traditional statistical techniques.

Recent work in the field of serious games (SGs) reflects a similar shift toward data-driven analysis and adaptive systems. Although most SGs do not currently incorporate ML, there is a growing trend toward integrating ML to assess participants and automatically adapt gameplay to individual needs [10]. These adaptive systems can personalize difficulty, improve engagement, and reduce learner frustration, but they also introduce practical challenges, such as selecting appropriate data sources, determining which game elements to modify, resolving cold-start problems, and validating whether adaptive changes genuinely support learning [10]. Evidence shows that ML techniques are increasingly used in SGs to monitor learner behavior, generate real-time feedback, and model player states such as motivation, skill level, or emotional reactions [11,12]. This has led to the emergence of AI-powered SGs that adjust game content based on individual progress, preferences, and training goals, thereby creating more personalized and effective learning experiences [13,14].

A recent systematic review highlights that advanced technologies, such as AI, immersive environments, and biosignal monitoring, can enhance meta-skills training by supporting adaptive learning, targeted practice, and improved monitoring of behavioral and cognitive states [15]. Studies demonstrate that AI-based SGs can develop key meta-skills, such as time management, self-regulation, and motivation, through difficulty adjustment and personalized support. For example, a study [16] used ML models to analyze players' biosignals in real time and modify game difficulty based on their emotional state, resulting in improved time-management skills. Despite these benefits, the integration of AI into SGs also raises several concerns. The development of AI-powered games requires significant technological infrastructure and expertise [11]. Concerns have been raised regarding data privacy, potential algorithmic biases, and inequities related to access and fairness [15,17]. To address these challenges, recent literature emphasizes the need for ethical design principles, secure data practices, and transparent model development to ensure trustworthy and inclusive applications of AI in SGs.

AI-based SGs offer various potential benefits for meta-skills training, but they also introduce important challenges that require mitigation. One key advantage is improved access to personalized training, as AI can adapt learning content and game difficulty to individual player capabilities and provide instant feedback with continuous performance tracking. AI systems can also support a deeper understanding of teamwork, communication, leadership, and behavioral patterns and enable training to be delivered at scale, at low cost, and remotely. However, concerns remain about how AI systems make decisions, the risk of confusing or misleading players, and an increasing dependence on automated feedback. Additional challenges include reduced human interaction, risks related to storing and handling sensitive data, and the possibility of biased or unfair outcomes if AI models are trained on unrepresentative datasets. To address these issues, the literature highlights the importance of transparent and responsible AI design, the use of simple and explainable adaptation rules, balancing automated feedback with human guidance, and maintaining opportunities for reflection and social interaction. Robust data protection measures, including encryption and restricted access, as well as regular bias checks using diverse datasets, are also essential to ensure ethical and effective deployment of AI-based SGs [11,14,15,17-21].

SGs are interactive experiences created with objectives that extend beyond mere entertainment, serving functions such as education, skill development, or problem-solving [22]. They typically represent real-world systems or processes in a simplified manner, enabling participants to engage with and better understand the complexities of real-life structures through a distilled, manageable format [23]. One common implementation of SGs is through escape rooms, where groups of individuals collaborate to solve complex puzzles under given time constraints. During such SGs, an expert technician monitors the teams and assesses their behavioral and psychological attributes and constructs, for example, the abilities of collaboration, decision-making, and leadership. These attributes are often quantitative as scores are assigned on a Likert scale.

XSL•FO
RenderX

The primary game outcome, that is, if the team completed the task within the allotted time, is also recorded. This data is then analyzed through a variety of methods to explore how different team attributes and compositions influence their performance and game outcome. With a promising potential to provide insights into the factors that contribute to team success, SGs are now increasingly recognized as a tool for enhancing teamwork, collaboration, and problem-solving [24].

Despite significant progress in general sports analytics [7,25], the application of ML in analyzing team performance within serious gaming environments and escape rooms is rather limited. The data acquired through escape rooms is usually analyzed using traditional statistical methods, for example, 1-way ANOVA, which cannot capture the multivariate nature of several variables and their interactions, limiting our ability to achieve deeper and accurate insights into complex team behaviors [9]. Some previous studies on serious gaming have focused on aspects such as team cohesion and leadership dynamics [26,27], but the quantification of specific behaviors contributing to team success is not yet fully understood. The growing body of literature on ML in sports analytics already highlights the utility of multivariate models in understanding team performance [4], but its application in serious gaming is yet to be realized. This gap highlights the need to apply data-driven, multivariate analytical approaches to understand the factors that drive team success. This knowledge will eventually contribute to forming better teams, which could lead to improved efficiency and productivity in organizational settings.

In this study, we aim to address the above-described research gap by applying exploratory and ML techniques to identify the multivariate feature combinations which influence team performance in serious gaming, specifically within escape room settings. Various ML-based models were developed using a serious gaming dataset to study key indicators in team behavior and dynamics that can distinguish successful teams from unsuccessful ones. In addition, explainable AI methods were used to tease out the most significant feature combinations that played a decisive role in determining game outcomes. This knowledge can likely be translated into terms of understanding to develop more efficient and productive teams in organizational and business settings.

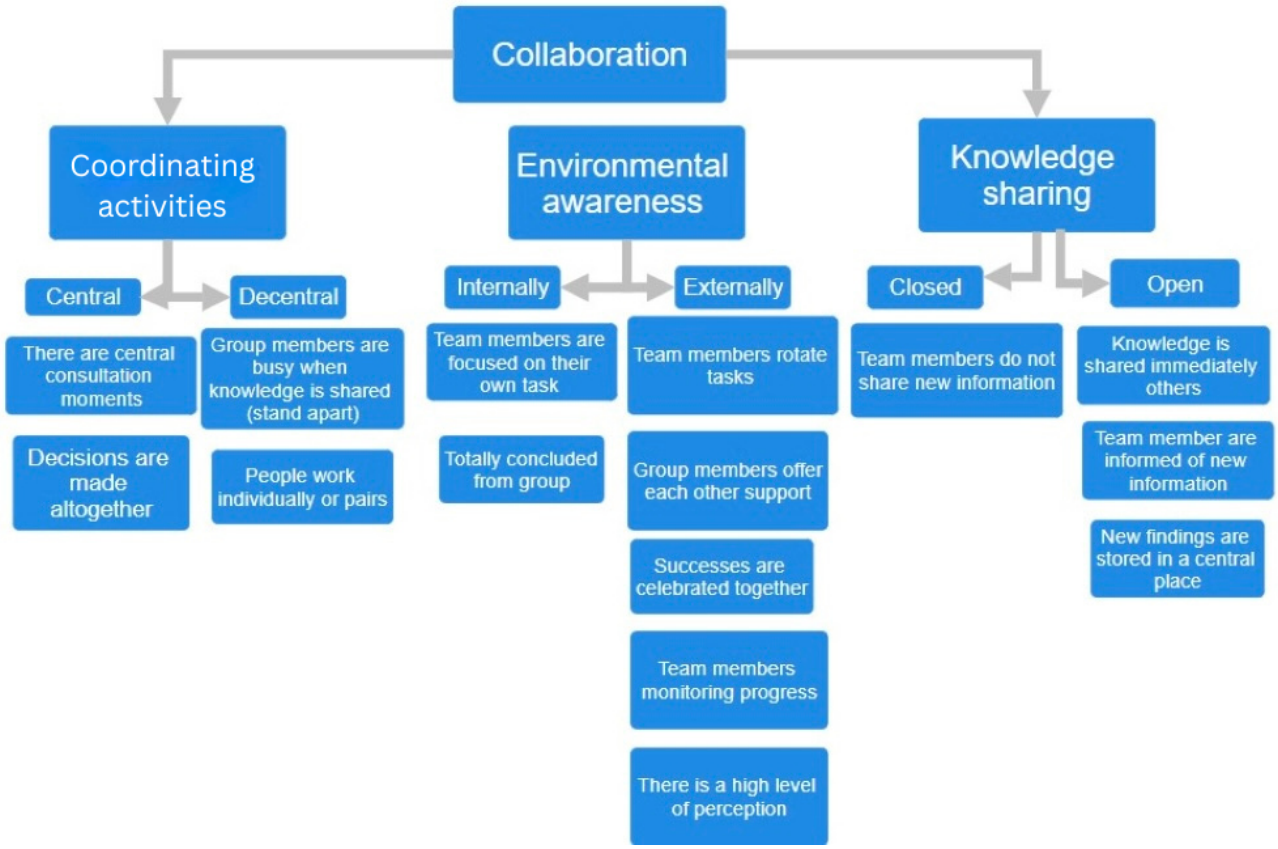
Methods

Data Collection

This study used a cross-sectional retrospective design, as the outcome data had already been collected, and the analysis focused on examining existing data to explore potential relationships. This study was conducted in collaboration with JGM Serious eXperiences, a provider of escape rooms and serious gaming environments designed for corporate and educational training based in Leeuwarden, The Netherlands. The research partnership began in November 2022 and included regular in-person meetings between the research team and JGM staff through July 2023. The concept of SGs, as implemented by JGM, involves using traditional entertainment games for educational and instructional objectives [24]. Using SGs for educational purposes makes it possible to measure how game-based activities influence participant behavior, supporting goals in education and organizational development.

The data collection process was carried out in multiple phases. First, an expert technician documents key demographic information before participants engage in the escape room experience. This includes variables such as age, gender distribution, team size, and prior escape room experience. These demographic factors provide context for the interpretation of behavioral patterns. Any personal data from the consent form of participants is stored in compliance with the relevant privacy regulations. Additionally, participation in JGM's escape room is fully voluntary. Participants are asked to read and sign an informed consent form, and a verbal agreement is also explained to all participants during the introduction session. Participants are also free to withdraw at any time and are properly debriefed afterward.

Second, during the escape room activity, the actions of the participants were continuously recorded using closed-circuit television cameras. Alongside, the expert technicians rated predefined behavioral indicators on a Likert scale, focusing on three constructs: (1) collaboration, (2) communication, and (3) leadership. The behavioral model guiding these observations was adapted from the Anesthetists' Non-Technical Skills (ANTS) Framework [28] and tailored for escape room settings in cooperation with psychologists and academics specialized in personal leadership. Although the ANTS Framework was designed for clinical settings, it draws on general teamwork and organizational behavior theory by focusing on observable behaviors that contribute to effective team performance [28]. The framework entails both interpersonal skills, for example, communication, teamwork, leadership, and cognitive skills, such as situation awareness and decision-making [28], which are critical in high-pressure collaborative environments such as escape rooms. In order to train nontechnical skills effectively, it is essential to first identify which skills are required in a specific environment and then assess them in a structured way. This makes it possible to give clear feedback and evaluate whether training leads to measurable improvement [28]. In collaboration with psychologists and experts in personal leadership, JGM adapted this framework to the escape-room environment, ensuring that each behavioral indicator reflected established constructs in teamwork research while remaining observable. This theoretical foundation helps connect our results to well-established models (such as the ANTS framework) of how teams operate.



Third, upon completion of the escape room session, the participants engaged in a structured reflection process. They reviewed the video recordings of their performance, received feedback from team members, and discussed insights from the analyzer report on aspects related to collaboration, communication, and leadership. The expert technicians also provided personalized feedback, highlighting strengths and areas for improvement on an individual basis. The disagreement of participants on a certain item in the feedback served as a catalyst for discussion on discrepancies between perceived and observed behaviors. Conversely, when there was an agreement, the focus shifted toward the strategies for translating these behavioral insights into real-world contexts, such as professional

XSL•FO
RenderX

settings. This reflective exercise not only served as a learning intervention but also reinforced the reliability of the observations recorded by expert technicians.

Various behavioral components for which the data were recorded on a Likert scale are shown in Figures 1-3. Figure 1 depicts the visual representation of the collaboration construct, Figure 2 shows the communication construct, and Figure 3 shows the leadership construct. For example, Figure 1 illustrates the construct of collaboration, which includes behavioral components such as coordinating activities, knowledge sharing, and environmental awareness. Each of these components is assessed using 2 opposite indicators (central vs decentralized). These indicators are measured through specific variables, and the responses are used to calculate a score for each indicator. The scores reflect how well a team performs in each behavioral area. For instance, a score above 3.5 suggests strong team unity and coordination (central), while a score below 2.5 indicates a more individual, less coordinated approach (decentralized).

Figure 1. Graphical representation of the collaboration construct.

XSL•FO

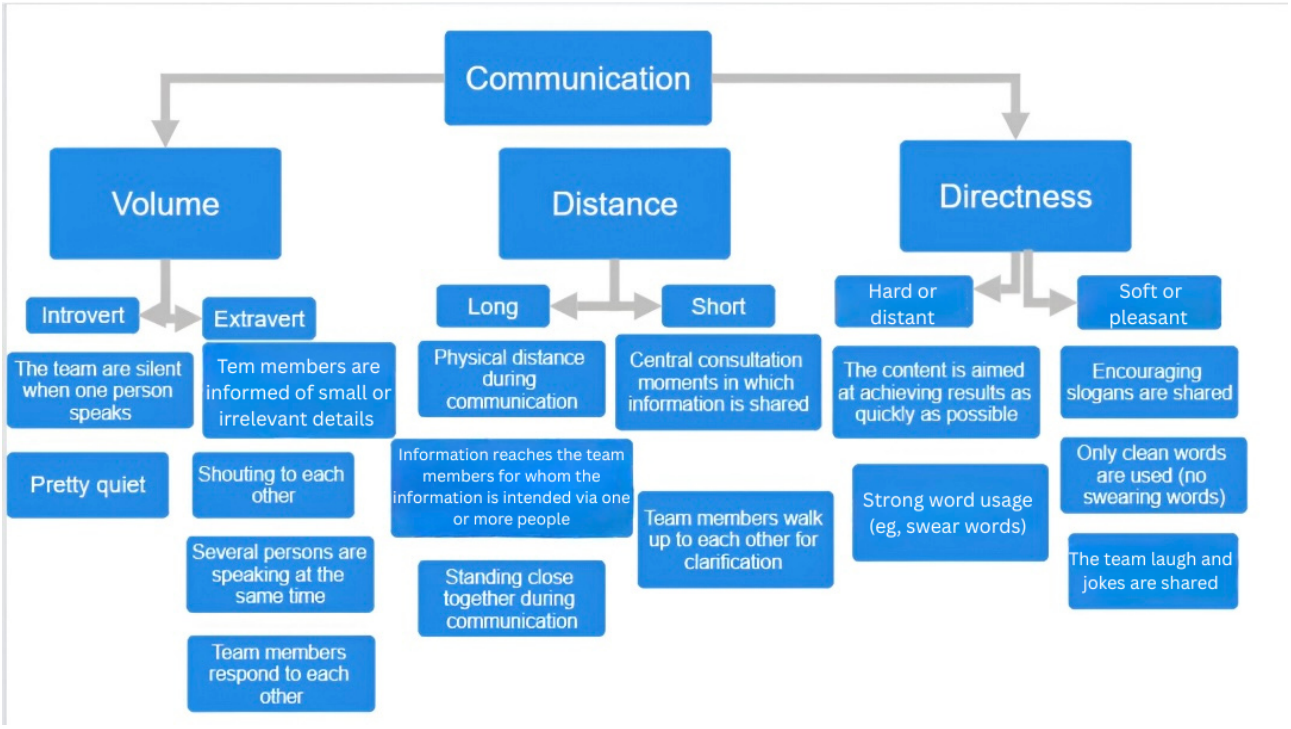
Figure 2. Graphical representation of the communication construct.



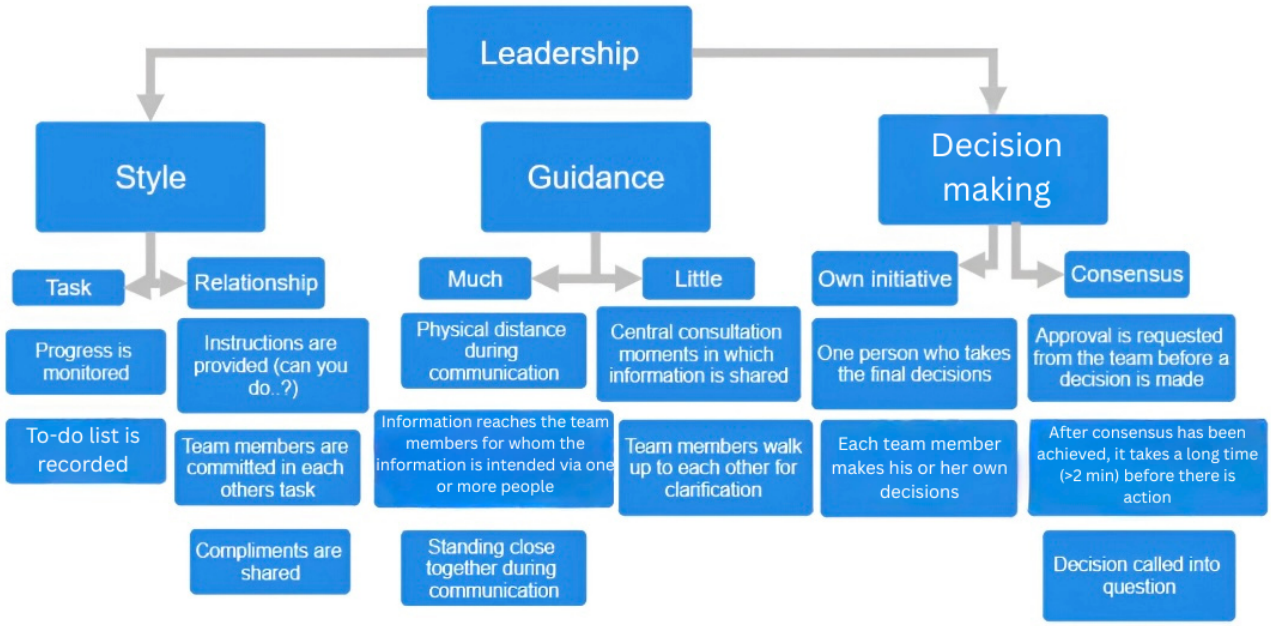


Figure 3. Graphical representation of the leadership construct.

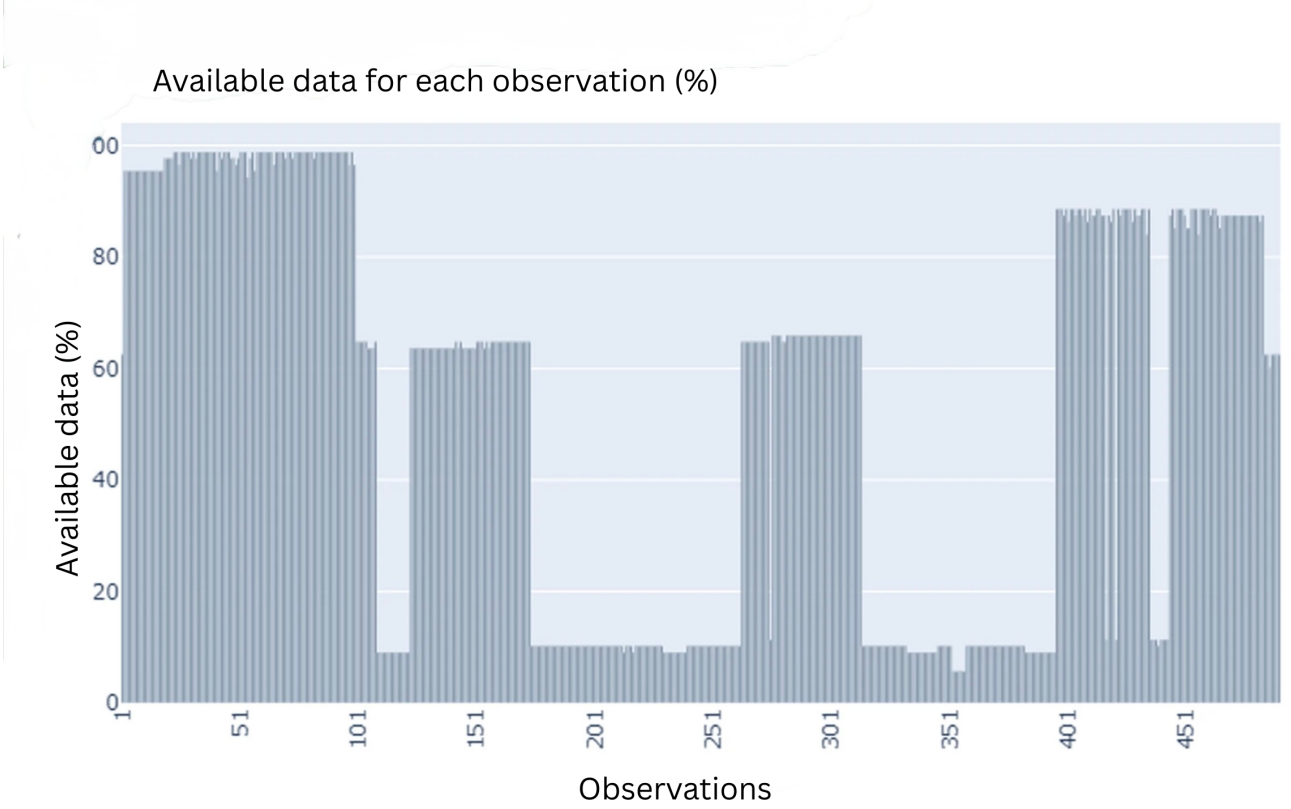


Data Preparation and Exploratory Analysis

Once the collection of data had been completed, JGM's expert technicians stored the dataset in Excel (Microsoft Corp) spreadsheet in compliance with privacy regulations. This resulted in a raw dataset containing 88 features, 490 rows, and 20,246 missing values. Figure 4 illustrates the percentage of available data per observation, grouped in bins of 50 observations. It indicates that missingness is not uniformly distributed across the dataset. The first 100 observations show very high data completeness, with approximately 95% - 100% available data. Several subsequent observation blocks (eg, around observations 100 - 250 and 300 - 380) show substantially lower completeness, often around 5% - 15% available data, indicating a high level of missingness in these cases. Other observation ranges (eg, around observations 250 - 300 and 400 - 470) show moderate to high completeness, typically between 60% - 90% available data. Overall, Figure 4 shows that missing values are unevenly distributed, with some observations containing substantially more missing data than others.

XSL•FO
RenderX

Figure 4. Visualization of the percentage of available data for each observation.

The data preparation was performed using the Pandas library (version 2.2.3) in Python (Python Software Foundation) programming language (version 3.13.1) in Jupyter notebooks. All analyses were performed on an AMD Ryzen (9 processor, 40 GB memory; Advanced Micro Devices, Inc) laptop running Microsoft Windows 11 Pro (version 24H2; Microsoft Corp), provided by University of Groningen (Campus Fryslân). All ML models were developed and tested using the SciKit-Learn (version 1.6.1) library. The visualizations were performed using Plotly and Seaborn packages in a Python programming environment.

To handle missing data, all features and rows that contained more than 50% empty values were dropped. A threshold of 50% provided a balance between retaining as much data as possible. Additionally, rows that contained empty values in columns that were deemed not to be imputable were dropped. Lastly, rows that contained >50% empty values were also dropped, due to there not being enough data to impute them accurately. Any last empty values were imputed using a k-nearest neighbors (KNN) algorithm. The resulting dataset contained 53 features and 233 rows, consisting of 141 winning teams and 92 losing teams.

After the data preparation, an exploratory data analysis (EDA) was conducted to gain an initial understanding of the behavioral constructs and their association with team performance. The dataset was grouped by game outcome, that is, winning and losing teams, enabling comparative assessments across both groups. All 3 constructs, that is, collaboration, communication, and leadership, were analyzed by aggregating individual variables into relevant composite indices. For example, the scores of all behavioral indicators in the leadership construct were added to calculate the value of the leadership construct, and so on.

For each composite variable, statistical descriptors such as mean and SE around the mean were calculated and visually analyzed. In addition, statistical tests for significance were applied to compare the differences between winning and losing teams. The Student *t* test was applied using independent samples, where the assumptions of normality were satisfied, and Mann-Whitney U tests based on Shapiro-Wilk tests [29] were used where the assumption of normality was violated.

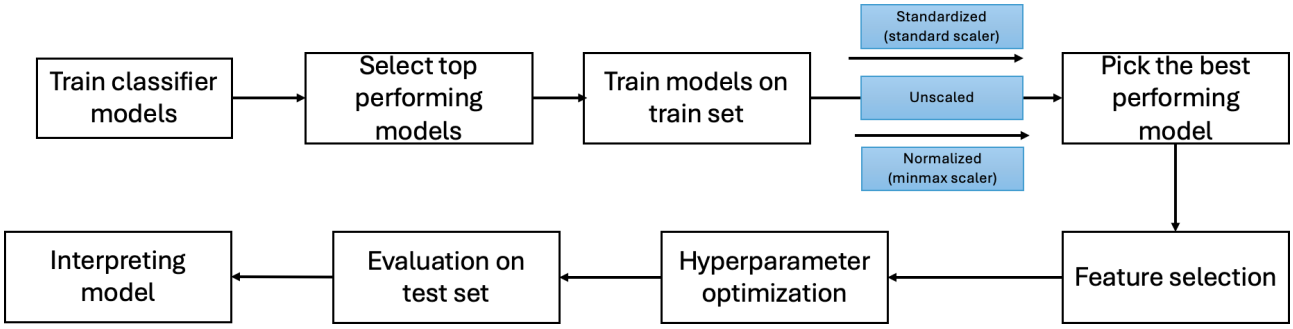
Subsequently, to examine the correlations between behavioral indicators, Pearson correlation analysis was applied and visualized using heatmaps. The correlation analysis quantified the linear associations between behavioral indicators, which were further quantified by fitting a regression model into the scatter plot of respective variable groups. The quantification of linear associations visualized the extent of the difference between behavioral indicators exhibited by the winning and losing teams. The EDA resulted in some interesting insights about underlying group differences between winning and losing groups in the escape room activities.

ML-Based Modeling

In order to develop ML models for classifying between winning and losing teams, the preprocessed dataset was split into train and test sets in a proportion of 80% and 20%, respectively. Due to the unbalanced nature of the dataset, the split was stratified with respect to the target variable, which ensured an equal proportion of the target variable between the train and test sets.

All models were developed in the Scikit-Learn library (version 1.6.1) using the Python programming language (version 3.13.1)

XSL•FO
RenderX



with necessary preprocessing steps, including feature scaling and feature selection. The purpose of feature selection was to enhance the performance of models and reduce potential overfitting. It was implemented using the SelectKBest method [30] with the chi-squared test as its scoring function to evaluate statistical relationships between each feature and the target variables (win or lose) and selecting only the most relevant features based on their chi-squared scores.

A selection of supervised classification models, namely: support vector classifier (SVC), KNN, Gaussian NB, RF, multilayer perceptron (MLP), gradient boosting classifier, logistic regression (LR), decision tree, adaptive boosting classifier, ridge classifier, and linear discriminant analysis was trained twice, once on unscaled dataset and once on a standardized dataset, and subsequently evaluated using a 5-fold cross-validation with F_1-scoring. The hyperparameters were optimized using the GridSearch method, based on the highest 5-fold cross-validation with F_1-scoring (≤3240 fits per model). The optimized hyperparameters were mostly related to the regularization complexity of the models. For SVC, these are C (regularization parameter) and kernel and gamma (kernel coefficient). For RF, these are number of estimators, maximum depth, and minimum samples needed for a split and a leaf. For MLP, the size of the hidden layers, the activation function, the solver, and the maximum allowed iterations. Lastly, LR was optimized on the C (regularization parameter), the penalty function, and the maximum iterations.

Lastly, the best-performing model was selected for interpretation and to identify the importance of each feature in shaping the final prediction. This was achieved by (1) extracting the model coefficients to analyze their weights associated with each feature and (2) the SHAP (or Shapley Additive Explanations) [31] values, which were determined using the SHAP library (version 0.48).

This study followed the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) reporting guideline to ensure transparency and completeness in reporting the development and evaluation of the ML models [32]. A completed TRIPOD checklist has been included as a supplementary file (Checklist 1). The overall workflow used for developing, optimizing, and interpreting the ML models is illustrated in Figure 5.

Figure 5. N - Model Development Workflow.

Ethical Considerations

This study involved secondary analysis of anonymized behavioral data collected independently by JGM Serious eXperiences as part of their standard team-training activities. The Campus Fryslân Ethics Committee confirmed that formal ethical approval was not required for this study. This determination is consistent with the committee's review procedures, under which studies involving the secondary analysis of fully anonymized data with no identifiable information or participant interaction are classified as Tier 1 (no formal review required). The study was conducted in accordance with established ethical standards and institutional guidelines, including the World Medical Association Declaration of Helsinki and relevant data protection regulations such as the General Data Protection Regulation (GDPR). All data were handled in compliance with applicable privacy and confidentiality standards.

All participants who engage in JGM's escape-room training activities are required to read and sign a written informed consent form before participation. Participants are informed about (1) the purpose of the activity, (2) the presence of trained observers, (3) the nature of the behavioral data collected, and (4) their right to withdraw at any time. The provided JGM consent form explicitly states that behavioral and observational data may be used anonymously for scientific research and that all identifying fields (name, age, and email) are removed before data storage and sharing. The consent form confirms that participants grant permission for the anonymized secondary use of their data for research purposes.

To protect participant confidentiality, JGM removes all personally identifying information before data are uploaded to their internal database, otherwise known as the team analyzer. The research team only received anonymized, team-level variables (eg, communication, collaboration, and leadership scores) with no access to names or any other identifying fields. All data was shared securely and stored on encrypted university servers. No reidentification of individuals was possible, as the research team had no access to raw video, audio, or personal data.

The research team did not compensate participants. Participation in JGM sessions occurred voluntarily as part of organizational training programs or recreational use, and JGM's standard activity fees (if applicable) were unrelated to the research component. No images, videos, or audio recordings of participants are included in this paper or supplementary materials. Therefore, no consent for identifiable images was required. All analyses were conducted solely on anonymized

XSL•FO
RenderX

numerical and categorical variables extracted from JGM's internal behavioral coding system.

Results

Characteristics of Data

The final dataset consisted of 233 team-level observations, with an imbalanced distribution of outcomes: 141 teams completed the escape room game (ie, winning teams), whereas 92 teams did not achieve success (ie, losing teams). The team sizes varied between 2 and 8 members, where most of the teams consisted of 4 or 5 members. The smaller teams (2 - 3 members) and the larger teams (6 - 8 members) were relatively uncommon, which resulted in most of the teams in the dataset being midsized. The experience in escape rooms was also recorded on an individual level and then aggregated at the team level. A significant number of teams (n=126) reported no experience. In contrast, a smaller group (n=25) indicated moderate familiarity, and an even smaller number (n=9) reported a higher level of prior engagement.

The mean age of participants across all teams was 25.8 years. The majority of teams (n=107) had a mean age of 24.9 years, whereas only 6 teams had a mean age above 50. In terms of gender composition, 53 teams were composed entirely of male members, whereas 55 teams were entirely composed of female members. The remaining teams were composed of both genders, and the gender proportion varied significantly across groups.

In summary, the dataset captures a diverse sample of teams, mainly composed of younger participants, with limited prior escape room experience and mixed gender composition. These demographic and background characteristics provide context for interpreting teams' performance in the escape room environment.

About EDA

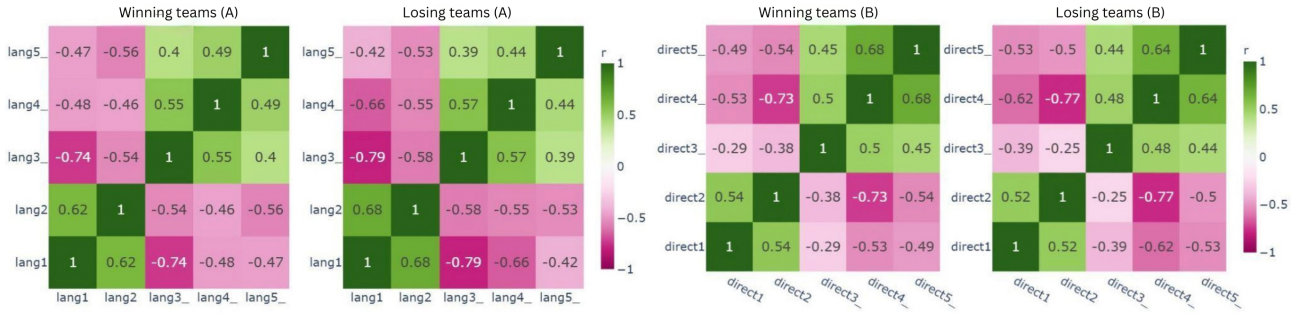
Overall, winning teams showed higher scores in environmental awareness, leadership, guidance, and extraversion, with CIs that were narrow and showed little overlap, indicating more reliable group differences. In contrast, constructs such as coordination, knowledge sharing, consensus, and method of communication showed overlapping CIs, suggesting that any mean differences between winners and losers are small and less precise.

For environmental awareness, the mean difference between winners and losers was 2.33 (95% CI 1.27 to 3.38). Although this suggests a noticeable gap, the Shapiro-Wilk test indicated nonnormality, and the Mann-Whitney *U* test showed no statistically significant difference (U=9595.00, *P*=.68). This means the construct does not reliably distinguish the 2 groups.

Knowledge sharing showed a smaller mean difference of 0.43 (95% CI 0.01 to 0.84). Despite marginal overlap in CIs, the Mann-Whitney *U* test revealed a statistically significant difference (U=13,687.50, *P*<.001), indicating that winners scored meaningfully higher than losers.

Leadership also showed a clear difference, with a mean gap of 1.21 (95% CI 0.46 to 1.95). Normality was violated, so a Mann-Whitney *U* test was used, and it confirmed a statistically significant difference (U=12,502.00, *P*<.001). Guidance showed a similar pattern, with a mean difference of 1.27 (95% CI 1.46 to 2.47) and strong statistical significance (U=14,577.00, *P*<.001).

Extraversion of communication had a mean difference of 0.77 (95% CI 0.28 to 1.25), also supported by a significant Mann-Whitney *U* result (U=12,347.00, *P*<.001). Other communication-related constructs showed weaker differences. Directness of communication had a mean difference of 0.55 (95% CI 0.10 to 0.99), but the Mann-Whitney *U* test showed no significant difference (U=10,842.50, *P*=.17). Consensus within the team slightly favored losers with a mean difference of −0.34 (95% CI −0.86 to 0.19), but again, results were not significant (U=8917.00, *P*=.16). Method of communication showed a small and nonsignificant mean difference of 0.35 (95% CI −0.03 to 0.74; U=10,842.50, *P*=.17).



Coordination showed virtually no difference between groups with a mean difference of −0.09 (95% CI −0.49 to 0.32). This was the only construct meeting normality assumptions for both groups, yet the Mann-Whitney *U* test still indicated no significant difference (U=9595.00, *P*=.68).

In summary, only 4 constructs: knowledge sharing, leadership, guidance, and extraversion, showed statistically significant differences between winners and losers. These findings, supported through CIs, normality testing, and appropriate nonparametric analyses, suggest that only a subset of behavioral indicators meaningfully distinguish successful teams.

In addition, Pearson correlation analysis was used to analyze variable level relationships between the winning and losing groups. Figure 6 shows correlation maps for the communication construct. The winners displayed positive correlations between some individual variables (eg, lang1 and lang2, *r*=0.62) and negative correlations involving the lang3_ variable (eg, lang1 and lang3_, r=–0.74). In contrast, the losing teams mostly exhibited negative associations, suggesting a less differentiated structure.

XSL•FO
RenderX

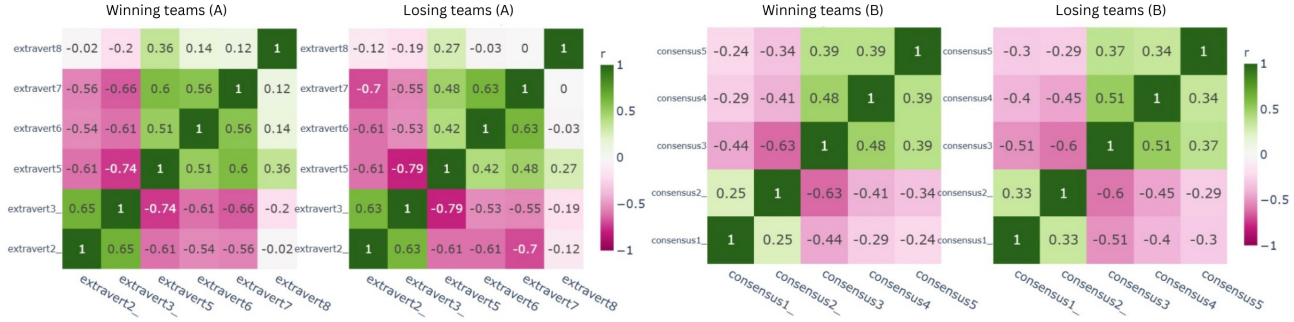


Figure 6. Pearson correlation for (A) communication and (B) directness of communication in winning and losing teams.

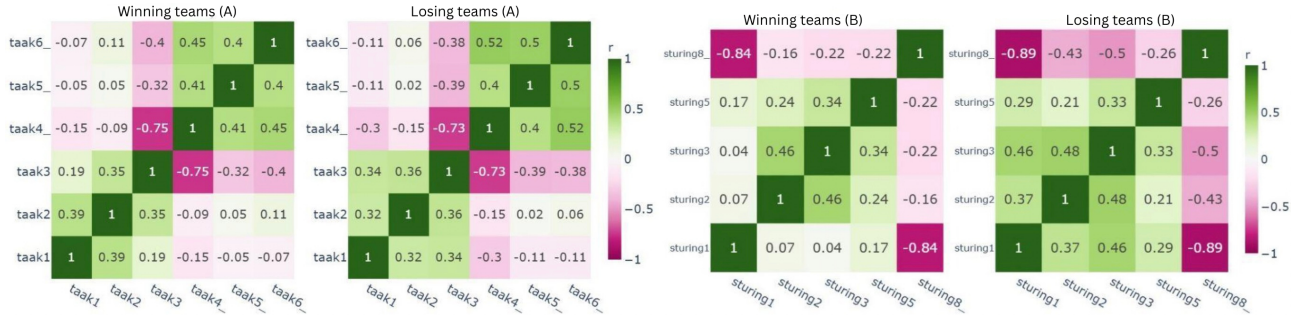
Within the "directness of communication" construct, a negative correlation was found between direct4_ (use of only clean words) and direct2 (use of strong language, including swearing), with coefficients of r=–0.73 for winners and r=–0.77 for losing teams. As both groups show a similar pattern, this construct does not differentiate between winners and losers as shown in Figure 6B.



This mirrored structure was also evident in other constructs. Figure 7A shows the extraversion of communication construct, extravert3 (lack of active communication) and extravert5 (continuous communication) were negatively correlated (r=–0.74 for winners; r=–0.79 for losing teams). Similarly, within the consensus construct in Figure 7B, consensus3 (waiting for team approval before acting) and consensus2 (seeking advice but acting independently) demonstrated a similarly negative correlation (r=–0.63 for winners; r=–0.60 for losing teams.

Figure 7. Pearson correlation for (A) extraversion of communication and (B) consensus-building in winning and losing teams.

Furthermore, Figure 8Adisplays variables in the leadership construct, showing taak4 (instructions are provided) and taak3 (group members give each other instructions) as inversely related, with correlation coefficients of r=–0.75 for winners and r=–0.73 for losing teams. Similarly, the guidance construct in Figure 8B also displayed redundant variables between sturing1 (there is group activity) and sturing8_ (the group has a wait-and-see attitude), with correlation coefficients of $r=-0.84$ for winners and $r=-0.89$ for losing teams.

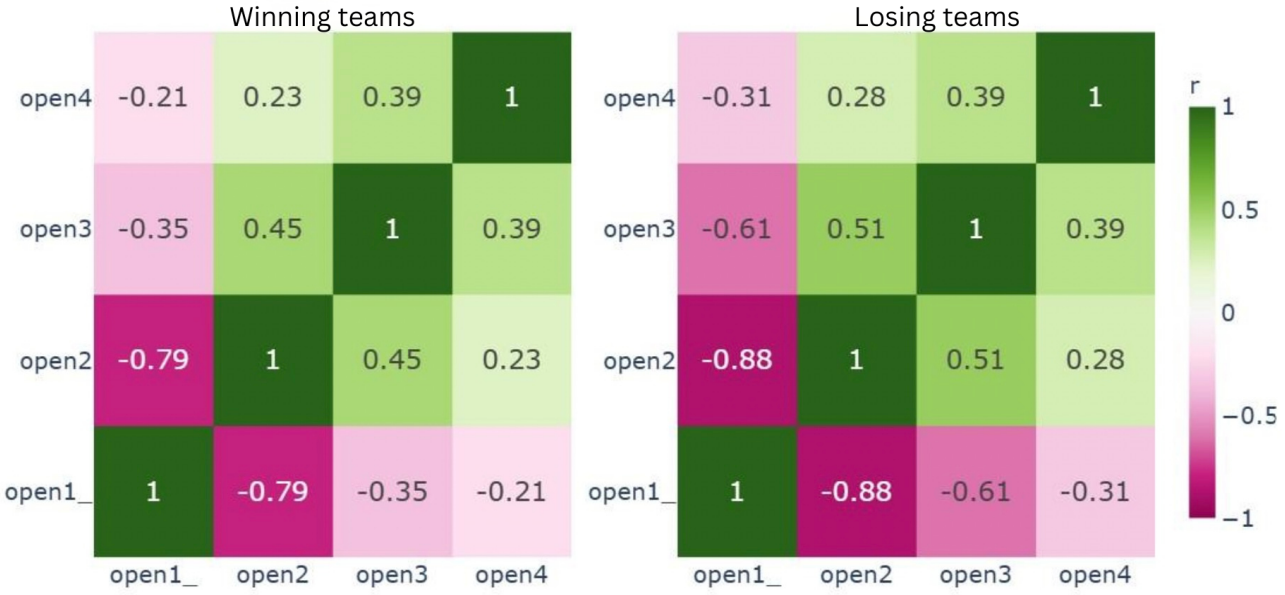


Figure 8. Pearson correlation for leadership and guidance in winning and losing teams.

The final construct showing overlap between variables was the sharing knowledge construct. For instance, open2 (knowledge is shared immediately with the group after learning about it) and open1_ (team members keep the knowledge they have gained to themselves) mirrored each other in winning teams, with correlation coefficients of $r=-0.79$ for winners and $r=-0.88$ for losing teams. These relationships are illustrated in Figure 9, which presents the correlation patterns within the sharing knowledge construct for winning and losing teams.

XSL•FO
RenderX

Figure 9. Pearson correlation for sharing knowledge in winning and losing teams.

However, not all constructs exhibited opposing relationships. Constructs such as coordination within the team and environmental awareness showed generally inconsistent correlations among their variables, suggesting that these behavioral dimensions may capture more independent or multifaceted aspects of team dynamics. Unlike the previously discussed constructs, no clear inverse patterns emerged, indicating that the variables within these domains may reflect complementary rather than redundant behaviors.

Taken together, the exploratory analysis using descriptive statistics and Pearson correlation provided insights into group-level behavioral differences and variable relationships. Descriptive comparisons revealed that winners tended to score higher in constructs related to leadership, guidance, extraversion, and environmental awareness, whereas losing teams displayed less variation across several domains. Furthermore, the correlation analyses highlighted numerous instances of inverse relationships within constructs, such as communication, directness, extraversion, and leadership, suggesting the presence of opposing behavioral features.

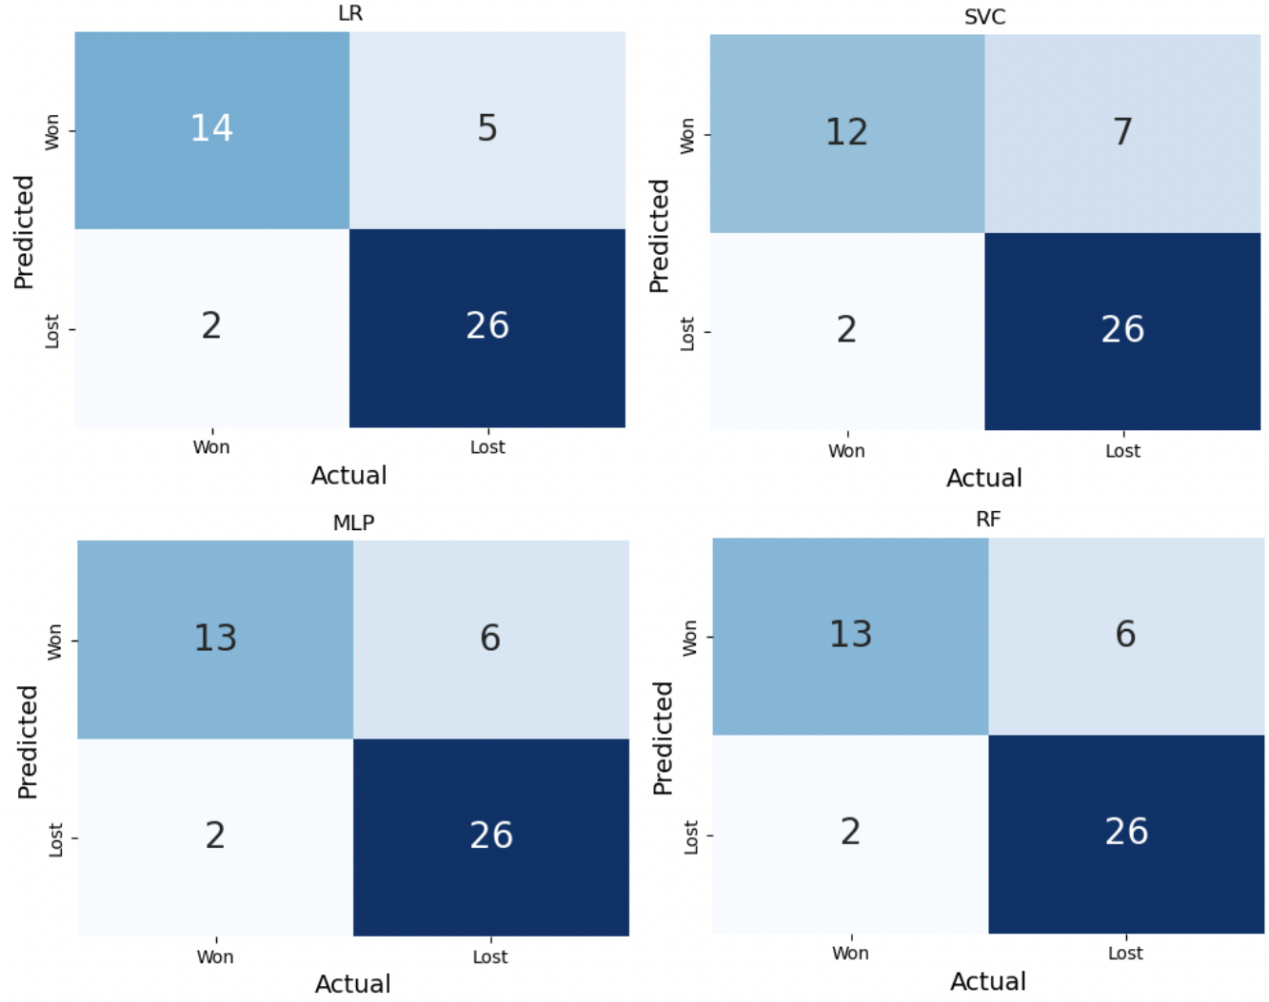
Performance of ML Models

Of the 12 models evaluated, 4 classifiers including LR, MLP, RF, and SVC, demonstrated consistently strong performance on F_1-score across cross-validation. These models were subsequently selected for hyperparameter optimization and interpretation. The remaining models, including Gaussian NB, KNN, and others, showed substantially weaker performance and were therefore excluded from further analysis. Table 1 presents various evaluation metrics associated with 4 ML models developed to classify between winning and losing teams. The results were obtained by evaluating all 4 models on an unseen test set. In addition, 5-fold stratified cross-validation was performed using the F_1-score as the accuracy metric (Table 1).

Table . ML[a] model scores.

	Test-set scores				Cross-validation scores (F_1-score)
Model	Accuracy (%)	Precision (%)	Recall (%)	F_1-score (%)	Mean (SD, %)
Logistic regression	85	84	93	88	79 (0.037)
Support vector classifier	81	79	93	85	81 (0.044)
Multilayer perceptron	83	81	93	87	80 (0.039)
Random forest	83	81	93	87	80 (0.072)

[a]ML: machine learning.



Across the board, all 4 models yielded reasonable accuracies of over 80%. Interestingly, all models had an equal recall score of 93%, with slight differences in terms of precision score, where the LR model slightly outperformed the other models. The LR model also outperformed the other models in terms of accuracy and F_1-score, which is a better representation of the model's performance given a significant imbalance in the target variable. The SVC model accuracy was the lowest on the test set, but it outperformed all other models in terms of cross-validation score. On the other hand, the LR model scored the lowest score on the cross-validation metric (2 percentage points lower than SVC). However, the difference between the

XSL•FO
RenderX

accuracies and cross-validation scores for all 4 models was not substantially different from each other (within 5% range).

Figure 10 presents the confusion matrix for the 4 ML models used to classify team outcomes as "won" or "lost" based on team behavioral indicators. The MLP and RF models both correctly identified 13 winning teams and 26 losing teams, with 6 false positives and 2 false negatives. The SVC model performed similarly, but with slightly more false positives (ie, 7) among winning classifications. In contrast, the LR model demonstrated the optimal balance, that is, correctly classifying 14 winning teams with only 5 false positives and 2 false negatives. Across all models, the number of false negatives stayed consistently low, but the number of false positives varied substantially. The LR model, in particular, achieved the optimal trade-off between sensitivity and specificity in predicting team success.

Figure 10. Confusion matrix for 4 models: LR, SVC, MLP, and RF. LR: logistic regression; MLP: multilayer perceptron; RF: random forest; SVC: support vector classifier.

Explainability of Model

All 4 ML models were trained on 10 features that were selected during the feature selection process. To explain the contribution of each feature to the final classification outcome, the feature importances were extracted using various techniques based on model type. For the LR model, these are the coefficients, which are the internal weights of the model (Figure 11). For RF, its Gini impurities quantify how much a feature helped in decreasing uncertainty (Figure 12). The feature importances of MLP (Figure 13) and SVC (Figure 14) were quantified using permutation importances, a method that finds the most important features by shuffling feature inputs.

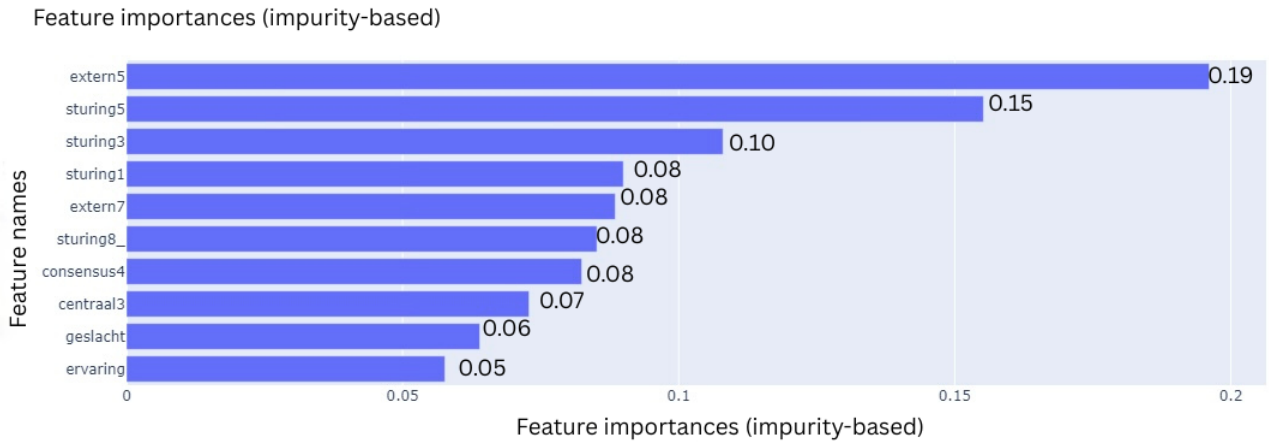

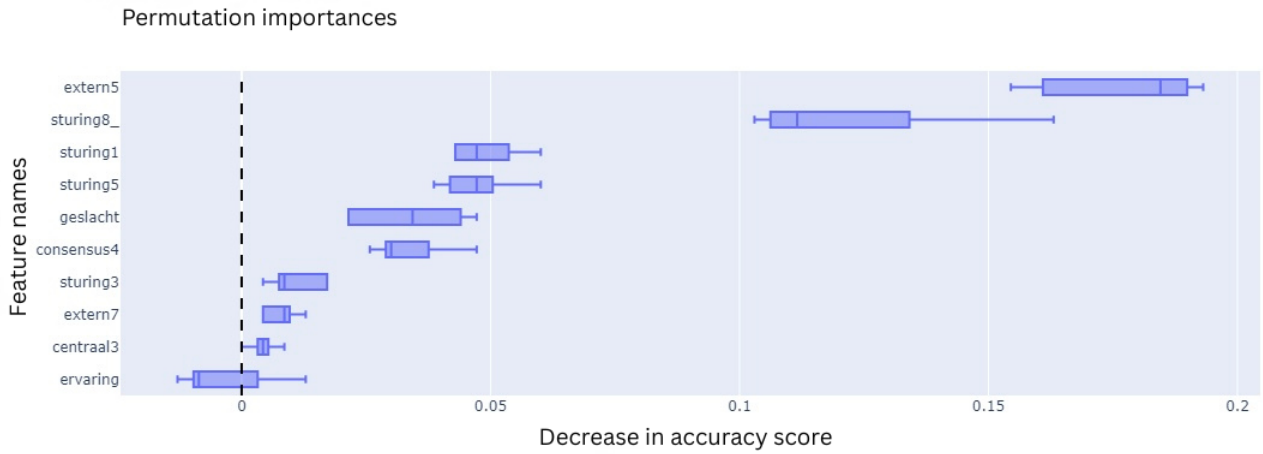

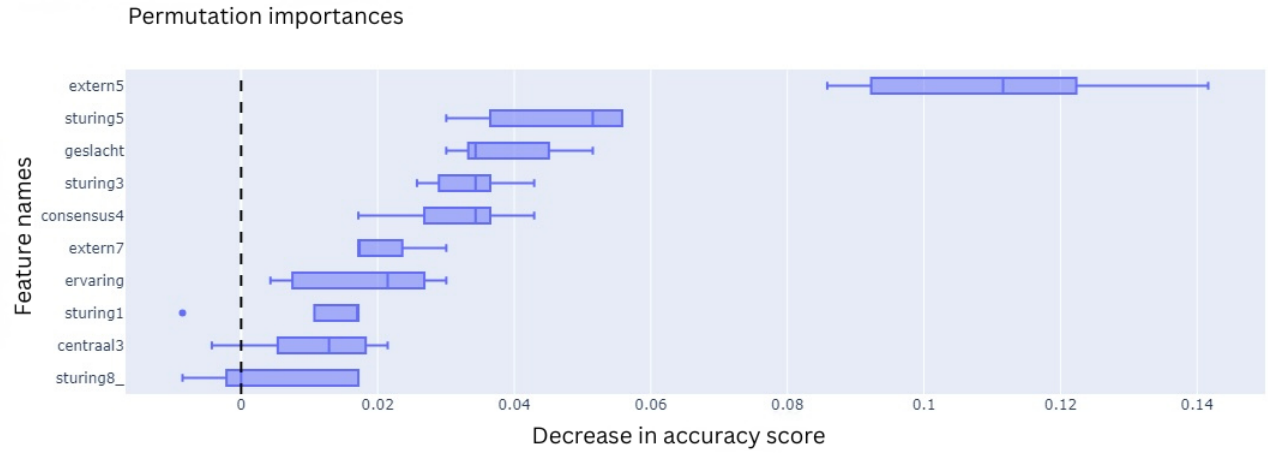

Figure 13. Permutation importance of the support vector classifier

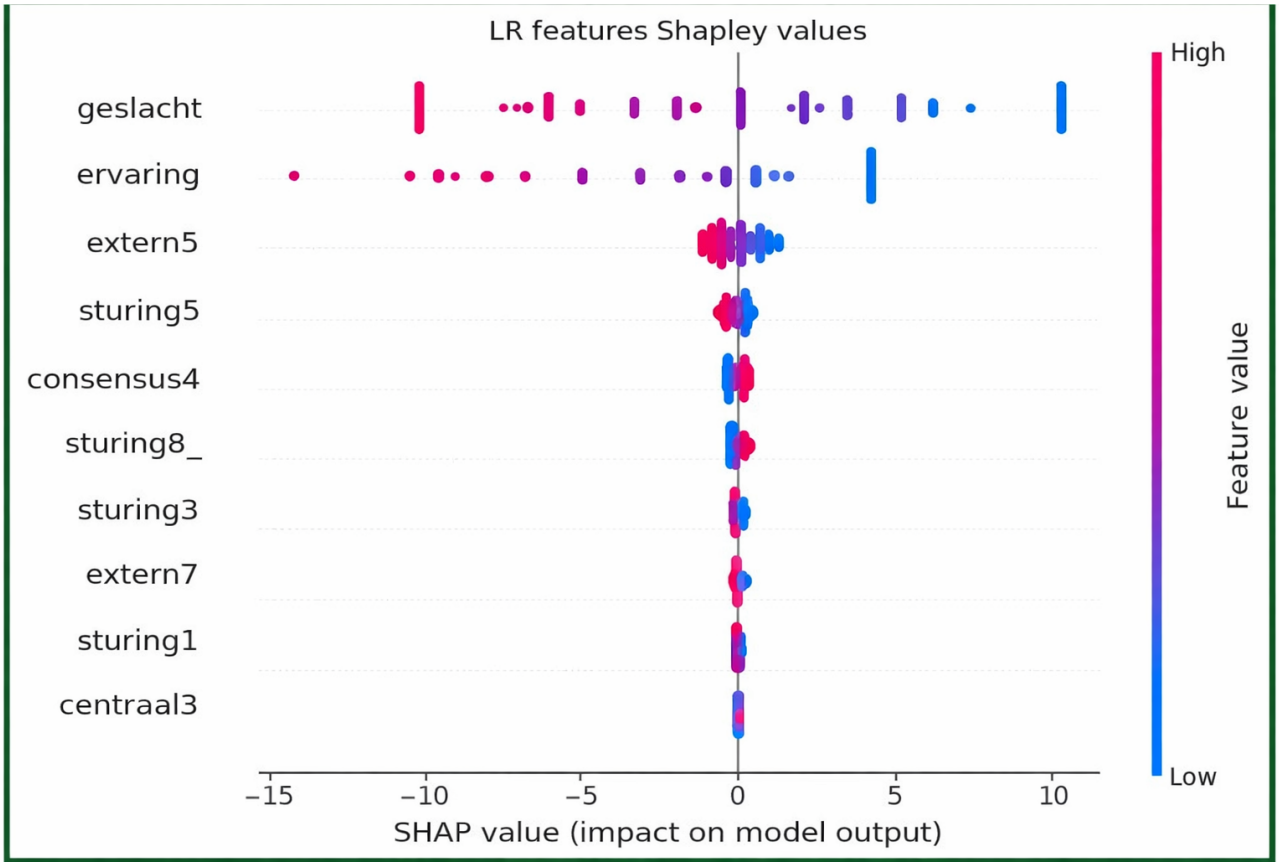
XSL•FO
RenderX

Figure 14. Permutation importance of the support vector classifier.



Across the models, extern5 (team members celebrating progression with each other) and sturing5 (someone taking the lead when the team is stuck) consistently ranked among the top features contributing to the prediction of team success. In the LR model, extern5 had the highest absolute coefficient, followed by sturing5, geslacht (gender distribution), and consensus4 (time to action after consensus). In the RF model, impurity-based feature importance ranked extern5, sturing5, sturing3 (guidance is provided through questioning and progress monitoring), and sturing1 (all team members are actively involved in tasks to find solutions as a group) as the top 4 features. In contrast, the MLP model showed higher permutation importance for extern5, sturing8_ (the team has a wait-and-see attitude), and sturing1, with sturing5 ranking fourth. For the SVC model, permutation importance highlighted extern5, sturing5, geslacht, and sturing3 as the most influential features. While the top-ranked features varied slightly across models, extern5 emerged as the most consistently important predictor.

In addition, SHAP values were computed for the best-performing model, that is, the LR model, to identify the features with the greatest impact on the model's output (Figure 15). The most influential features included geslacht (gender composition) and ervaring (prior escape room experience), both of which showed the highest SHAP value ranges. These were followed by extern5 (celebrating progress) and sturing5 (taking the lead when the team is stuck), which had consistently positive SHAP contributions. Other features, such as consensus4 (waiting after consensus) and sturing8_ (passive behavior), exhibited SHAP values that were negatively associated with the model output, whereas sturing3, extern7, and sturing1 had comparatively lower but consistent influence on predictions. The SHAP summary plot thus reflects a combination of demographic and behavioral predictors, with varying degrees of contribution to the classification of team success.

Discussion

Principal Findings

This study set out to examine whether team success in SGs can be better understood through a multivariate combination of behavioral and demographic factors, rather than through isolated indicators. The findings show that team performance in escape room–based SGs is shaped by multivariate patterns of behavior. Successful teams were not distinguished by single actions alone, but by coordinated behavioral dynamics related to leadership, guidance, and expressive communication, alongside demographic characteristics such as team composition and experience. By applying exploratory analysis together with ML and explainable AI techniques, this study demonstrates that these factors jointly contribute to predicting successful team outcomes. Overall, the results confirm this study's objective by showing that team success in SGs emerges from complex, multivariate behavioral patterns rather than from individual behavioral indicators considered in isolation.

Interpretation of Behavioral Patterns in Team Performance

The exploratory analyses highlight clear behavioral differences between winning and losing teams in serious gaming environments. Winning teams tended to display stronger behavioral patterns related to leadership, guidance, environmental awareness, and expressive communication. These behaviors appeared more consistently and coherently among successful teams, whereas losing teams showed greater variability. In contrast, behaviors such as coordination and knowledge sharing were present in both groups but did not clearly differentiate successful from unsuccessful teams, suggesting that these behaviors alone are not decisive for performance in escape-room contexts.

Differences also emerged in how behaviors were combined within teams. Winning and losing teams often relied on similar behavioral elements, but they appeared to integrate them in distinct ways. For example, successful teams showed more balanced patterns of support, initiative, and shared progress, whereas losing teams tended to exhibit more uneven behavioral interactions. This indicates that team success may depend less on the presence of individual behaviors and more on how these behaviors interact during gameplay.

In particular, behaviors related to guidance and environmental awareness revealed contrasting interaction patterns between groups. While both winning and losing teams engaged in information seeking and guidance-related actions, losing teams appeared to rely more on reactive or delayed coordination, whereas winning teams demonstrated more adaptive behavioral combinations. These findings suggest that winning teams are not simply more active but are better at aligning leadership, guidance, and collective awareness in response to evolving game demands.

Overall, the exploratory findings indicate that team success in SGs is associated with multivariate behavioral patterns rather than isolated actions. Winning teams appear to combine leadership, guidance, and communicative behaviors in a more integrated manner, supporting the view that team performance

XSL•FO
RenderX

emerges from multivariate behavioral dynamics rather than single behavioral indicators.

Interpretation of ML and Explainable AI Findings

The ML analyses further support this multivariate interpretation of team performance. Across all 4 models, extern5 and sturing5 are overall the 2 most important features to determine whether a team will win or not. Extern5 refers to "team members celebrating progression with each other," whereas sturing5 refers to "someone taking the lead when the team is stuck." The significance of these 2 features displays the importance of good leadership and exuberance. The importance of the other features varied from 1 model to another and had a moderate impact on the final prediction. For the LR model, these were geslacht and consensus4, which reflect the "gender distribution of a team" and "the time it takes for a team to take action after consensus has been reached." Sturing3 and sturing1 (which refer to "a team's activity level" and "guidance provided") were ranked third and fourth, respectively, with a moderate impact for the RF model. MLP was the only model for which sturing5 was not one of the two most important features, ranking only fourth after sturing8_ and sturing1, which also reflect a team's activity level. Lastly, geslacht and sturing3 (which refer to "gender distribution of a team" and "guidance provided") were the third and fourth most important features of the SVC model.

The SHAP explainable AI technique revealed that the most impactful features influencing team success were gender composition and escape room experience. Specifically, teams with a higher proportion of female members and greater experience were more likely to be classified as winners. The behavioral traits such as sharing positive emotions when progress was made (extern5) and guiding the team during uncertainty (sturing5) had a mild but positive influence on success. In contrast, passive or hesitant behaviors, such as waiting for others to act (consensus4 and sturing8_), tended to decrease the likelihood of winning. The model also found that early enthusiasm (extern7) and collaborative monitoring (sturing3) were weak but consistent predictors of better performance. These results suggest that successful teams managed uncertainty not simply by dividing tasks, but by enabling collaborative leadership, expressing collective motivation, and establishing situational awareness.

It is important to note that the key variables identified through quantification of feature importances of the ML models and those highlighted by the SHAP explainability technique were not always identical. This divergence is due to the fundamental differences in how these methods evaluate the relationship between predictors and the target outcome. The ML models rank features based on their predictive contribution to classification performance, which the algorithm's internal mechanics influences [33] (eg, regularization in LR, impurity reduction in RF, or learned weights in MLP).

In contrast, SHAP values rank features in a model-agnostic way. They provide an estimate of the marginal contribution of each feature by simulating its effect across all possible combinations of feature inputs. SHAP estimates how much each feature contributes to the predictions by considering its effect across different combinations of inputs. In the results, SHAP highlighted demographic factors such as gender distribution and experience, whereas the ML models gave more weight to behavioral indicators such as extern5 and sturing5. Together, these methods offer complementary perspectives, showing that both demographic and behavioral factors played a role in shaping team outcomes. Recognizing these methodological differences is critical for interpreting the results holistically, as each method offers complementary insights into what drives team success. In sum, predictive models compute outcomes, whereas SHAP explains the underlying contribution of features to those outcomes [33].

Comparison With Existing Literature

Prior work [34] emphasized the importance of team familiarity and communication across subgroup faultlines in shaping performance. Using survival models, they found that team familiarity could exert a negative influence on success, particularly when communication across subgroups was limited [34]. While this study did not explicitly model faultlines or social ties, it identifies behavioral and demographic features that contribute to team success, potentially through similar mechanisms of coordination, engagement, and leadership. For instance, sturing5 (taking initiative when the team is stuck) and sturing3 (guiding others and monitoring progress) reflect adaptive leadership and teamwork, which help teams stay on track, especially in unfamiliar or fast-paced situations [34]. Furthermore, a study [27] conducted one of the few observational studies into collaboration within escape rooms, emphasizing the central role of verbal communication, implicit leadership emergence, and social awareness. Their qualitative insights on players communicating loudly across the room, navigating spatial awareness through verbal cues, and different leadership styles [27] echo the behavioral constructs we identified as significant. For example, their observations that experienced players often assume leadership roles [27] align with the predictive power of ervaring (experience) and sturing5 (leading when stuck) in our models. Their finding that teams converge when stuck [27] also aligns with the identification of sturing1 (early active problem-solving) and sturing3 (task-related guidance) as positive predictors.

Beyond the context of SGs, our findings are aligned with a broader trend in applied ML, where complex, multifactor systems are modeled using data-driven and often hybrid approaches. Recent studies in smart city energy forecasting, groundwater management, CO_2 emissions prediction for electric vehicles, and rainfall classification have combined traditional statistical models or neural networks with metaheuristic optimization and feature-selection techniques to handle high-dimensional, noisy, and context-dependent data while improving predictive accuracy and efficiency [35-39]. In a similar sense, our study uses EDA, supervised ML, and explainable AI to identify a set of behavioral and demographic predictors that capture the significant variables of team performance in escape rooms. Rather than focusing on metaheuristic optimization [35,37], we emphasize data preprocessing, feature selection, and interpretability as practical strategies for organizations that work with limited or expert-coded data. This positions our work within a growing body of research showing that ML techniques can reveal

XSL•FO
RenderX

meaningful patterns in complex systems, whether environmental or behavioral, when combined with domain knowledge and transparent model evaluation. These methodological parallels across domains illustrate a broader trend in ML toward transparent, data-driven analysis, which aligns with the approach taken in this study.

This study makes several contributions to research on team performance in SGs. Methodologically, it advances the field by combining EDA, supervised ML, and explainable AI to examine team success as a multivariate behavioral phenomenon rather than as the outcome of isolated factors. This approach differs from much of the existing serious-games literature [10-13,15,17,21], which has primarily relied on univariate statistical comparisons or qualitative observations [27] and has rarely integrated interpretable ML to explain why certain teams succeed. By identifying multivariate influential behavioral and demographic predictors across multiple models, the current study contributes empirical evidence on which observable team behaviors meaningfully distinguish successful from unsuccessful teams in escape-room settings, which can be translated in terms of improved productivity in business and organization settings.

Implications for Understanding Team Performance in SGs

These findings have several implications for the design, evaluation, and application of SGs as tools for team training and assessment. First, identifying which behavioral patterns meaningfully distinguish successful from unsuccessful teams can support the refinement of observer-coded behavioral frameworks. Rather than relying on a large number of overlapping indicators, SG designers and expert observers can focus on a smaller set of behaviors that capture leadership, guidance, and collective engagement more effectively. This may improve the efficiency of behavioral assessment in game-based training environments.

Second, the results can inform the selection of performance indicators used during and after gameplay. By highlighting behavioral combinations associated with success, SGs can move beyond simple outcome measures, such as winning or losing, toward richer evaluations of how teams function under pressure. This opens opportunities for developing feedback tools that emphasize team strengths and areas for improvement, either through debriefings or automated postgame reports. Such debriefings can support reflection, learning, and skill development by making abstract team dynamics more concrete and observable.

Finally, this study demonstrates the practical value of interpretable ML for translating complex behavioral data into actionable insights. By combining predictive models with explainable techniques, it becomes possible to generate transparent and understandable explanations of team performance rather than opaque scores or rankings. This is particularly important in educational and organizational settings, where trust, accountability, and learning are central concerns [40,41]. Interpretable ML thus offers a promising pathway for integrating data-driven analysis into SGs in a way that supports understanding, feedback, and responsible decision-making.

Limitations of Research

While the findings in this study provide some new insights into team performance in escape room–based serious gaming, several limitations need to be acknowledged.

First, the limited sample size could restrict the generalizability of our results. Additionally, with a significant class imbalance toward losing teams (141 losing teams and 92 winning teams), this could have introduced bias in the model for that specific group. This imbalance could bias model training because standard ML algorithms often assume that classes are equally represented. Prior research shows that when 1 class is larger, models tend to favor the majority class, leading to poorer detection of the minority class or even treating minority cases as noise [42,43]. Class imbalance is a well-known challenge across many applied domains, such as fraud detection, medical diagnosis, and intrusion detection, and can distort decision boundaries, reduce sensitivity to the minority group, and limit overall model fairness [42,43]. Although several methods have been proposed to manage imbalance, there is no universal solution suitable for all datasets [43]. In this study, the unequal distribution between winning and losing teams may therefore influence model performance and should be considered when interpreting the results.

Second, the limitation concerns the dataset size. Although machine-learning studies in fields such as image recognition often rely on datasets with tens of thousands of samples, behavioral research involving team performance rarely allows for such scale due to practical and resource constraints. Our dataset of 233 teams reflects these real-world limitations. As a result, model generalizability is reduced, and findings should be interpreted as proof of concept rather than fully generalizable predictions. Future research with larger, multi-institutional samples would be valuable for validating and extending these insights.

Third, the dataset is geographically and culturally limited to teams recruited in a specific demographic region. The cultural norms around communication, leadership, and emotional expression may influence gameplay behavior in ways that are not generalizable to teams in other countries or contexts. As a result, the applicability of the findings to international, intercultural, or remote teams may be constrained to 1 specific region only.

Additionally, this study focuses exclusively on a single game genre (escape rooms) within 1 specific serious gaming environment. While this provides insight into a certain domain of games, it might have limited transferability to other SGs involving different structures and dynamics, for example, simulations, role-playing, or strategy-based games, where behavioral markers and success criteria may differ substantially.

Finally, it is important to note that the conclusions drawn from this study are based on a cross-sectional retrospective design and therefore reflect associative and predictive relationships rather than causal effects. While the ML models identify behavioral and demographic patterns that are strongly associated with team success, they do not imply that modifying individual behaviors will necessarily lead to improved outcomes. Instead,

XSL•FO
RenderX

the findings should be interpreted as evidence of multivariate patterns that characterize successful teams within the observed serious gaming context. Within these methodological boundaries, this study provides a robust, data-driven foundation for understanding team dynamics and for informing the design of feedback, training, and adaptive systems in SGs.

Ethical and Interpretability Implications

This study relied on the secondary use of fully anonymized behavioral data collected by JGM Serious eXperiences as part of routine training activities. All participants provided written informed consent, all identifying information was removed before data storage and sharing, and the research team received only deidentified, team-level variables. .

Predictive analytics can infer sensitive traits or behavioral tendencies from seemingly harmless data, a concern described as “predictive privacy” [44]. This occurs when models generate inferences about individuals or groups without their awareness, potentially leading to differential treatment or unintended consequences. While our study does not involve such high-stakes decisions, the concept remains relevant for future applications of ML-based team assessment in organizational settings.

Another key issue concerns fairness and bias. Predictive systems can unintentionally reproduce existing social inequalities if model outputs correlate with attributes such as gender, experience, or group composition [44,45]. Demographic variables such as gender composition and experience were influential predictors in this study, reflecting patterns present in the dataset rather than normative judgments. SHAP values were used in this study to provide transparent explanations of model outputs, improving clarity around why certain predictions were made. Prior research shows that explainable AI can increase trust and informed decision-making in human-AI systems [40], whereas poorly explained feedback may negatively affect user engagement and performance [41]. As ML-based evaluation becomes more common, clear ethical safeguards and transparent design are needed to ensure that behavioral insights support learning rather than unfairly labeling participants.

Conclusion

This study demonstrates that team success in serious gaming environments is best understood as a multivariate phenomenon emerging from the interaction between behavioral dynamics and team composition, rather than from isolated actions or traits. By integrating exploratory analysis with ML and explainable AI, the findings show that leadership, guidance, collective engagement, and contextual team characteristics jointly shape performance outcomes under time pressure. More broadly, this study highlights the value of treating SGs not only as training tools but also as structured environments for observing and analyzing complex team behavior using transparent, data-driven methods.

Beyond prediction, the results have broader implications for how SGs and AI-supported assessment systems are designed and deployed. Explainable AI techniques (eg, SHAP) enable behavioral data to be translated into understandable and actionable insights, supporting feedback, reflection, and learning rather than opaque scoring. Consistent with prior work showing that transparency and explainability influence how humans engage with AI systems [40,41], this study suggests that AI-supported SGs can enhance team development when human behavioral insight and explainable analytics are combined responsibly. In this way, the work contributes to a broader understanding of how human-AI systems can support effective teamwork, not by replacing human judgment, but by augmenting it with interpretable, evidence-based insight.

Acknowledgments

The authors would like to thank JGM Serious eXperiences for providing data for this study. The authors declare the use of generative artificial intelligence (GenAI) was not used in the research and writing process. According to the GAIDeT [46] (Generative Artificial Intelligence Delegation Taxonomy; 2025), no generative AI tools were used in the preparation of this manuscript. Responsibility for the final paper lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the outcomes. Declaration submitted by: GGA-R.

Funding

The authors declare that no funds, grants, or other forms of financial support were received for the preparation of this paper.

Data Availability

The datasets analyzed during this study are available in the GitHub repository [47].

Conflicts of Interest

None declared.

Abstract

Background: Serious games (SGs) have emerged as a promising tool in nursing education, providing interactive learning environments for clinical simulation, skill development, and feedback. These games enhance knowledge, clinical reasoning, and psychomotor skills. However, evidence on their effectiveness is dispersed across various platforms and outcome measures, making it difficult to derive clear guidelines for their integration into nursing curricula.

Objective: This scoping review aimed to systematically identify and map existing evidence on the use of SGs in nursing education, analyze game characteristics, and identify critical gaps to inform future research and practice development.

Methods: This scoping review followed the JBI framework and the PRISMA-ScR checklist. Nine databases (PubMed, Web of Science, Embase, CINAHL, the Cochrane Library, CBM, Wanfang Data, CNKI, and VIP) were searched from inception to January 15, 2026. Eligible studies were those reporting on original research on SGs in nursing education. Two reviewers screened titles, abstracts, and full texts. Risk of bias was assessed using a standardized checklist. The extracted data encompassed study characteristics, study design, participant information, sample sizes, application context, teaching content, and SG characteristics. Data were extracted and synthesized with descriptive statistics and content analysis. An evidence gap map was created to show the study distribution across course categories and outcome domains.

Results: We screened 6078 records and included 24 studies. Publications were from 2021 to 2025 (n=13, 54%), with the majority conducted in Europe (n=13, 54%). Quasi-experimental designs (n=10, 42%) and randomized controlled trials (n=8, 33%) were predominant. SGs were mainly used in fundamental or skills training and adult nursing courses. Scenario-based decision points (n=20, 83%) and points, badges, or leaderboards (n=20, 83%) were the most common game mechanics, while progression or unlocking and collaborative elements were less frequent. Outcomes most often assessed were knowledge (n=16, 67%), skills (n=10, 42%), and engagement or usability (n=13, 54%). Objective use metrics were rarely reported (n=1, 4%), indicating limited data on in-platform learning behaviors. Most SGs were delivered as digital non–virtual reality applications or computer-based simulation games. Follow-up assessment beyond immediate postintervention outcomes was infrequent. An evidence gap map showed studies concentrated in skills-based training and adult nursing, with fewer studies in maternity or neonatal nursing, critical care, and foundational sciences.

Conclusions: This review extends earlier work on SGs in nursing education by mapping evidence across curricular areas, intervention reporting, and outcome assessment, rather than focusing mainly on effectiveness or specific formats. It shows where evidence is concentrated and where important gaps remain, particularly in underrepresented course areas, intervention descriptions, follow-up assessments, and objective use data. These findings provide a clearer picture of the evidence base and can inform curriculum planning; the use of SGs in skills-based and clinical training; and future decisions about their design, implementation, and evaluation.

Introduction

Serious Games in Nursing Education

Nursing education faces the growing challenge of delivering competency-based training at scale while maintaining learner engagement. This is especially challenging in nursing, where opportunities for clinical exposure and repeated skills practice are often limited due to patient safety concerns and restricted training resources [1]. Limited clinical placement capacity and variability in supervision can further restrict opportunities for standardized practice and skills assessment. Digital learning technologies can provide interactive, repeatable training beyond traditional lectures and demonstrations [2,3]. Alongside advances in commercial video game technologies, serious games (SGs) have emerged as educational applications that integrate engagement with explicit instructional aims [4]. SGs typically incorporate structured challenges, timely feedback, and progression or reward systems intended to support competency development [5]. Through scenario-based tasks and iterative problem-solving, SGs can provide standardized, low-risk environments for rehearsal and skills consolidation and have been associated with improvements in learning outcomes, including knowledge acquisition and skill performance [6].

Within nursing education, the use of SGs has expanded as programs seek scalable approaches aligned with competency-based curricula [7,8]. SGs have been applied across learning domains, including knowledge, psychomotor skills, clinical reasoning, teamwork, and communication [7,8]. SGs may also support self-regulated learning by clarifying goals, enabling frequent performance feedback, and facilitating repeated practice [9]. In this review, SGs are defined operationally as game-based learning interventions designed for educational purposes that include identifiable game mechanisms such as rules, structured challenges, feedback, and progression or reward systems [10,11]. SGs were distinguished from gamification-only activities by requiring a rule-based game structure with progression aligned to learning objectives, rather than the isolated addition of points or leaderboards to conventional teaching [11].

SGs are conceptually related to gamification, defined as the application of game design elements in nongame contexts to support motivation and behavior change [10,11]. Gamification is commonly described in terms of learner dynamics, alignment with curricular objectives, and mechanics such as rules, feedback, and progression structures [11]. In practice, these elements are often operationalized through points, badges, leaderboards, and milestone schedules that structure engagement and perceived progress [12]. In this review, classroom-based gamified activities delivered via web platforms or experiential formats were included when implemented as structured learning games with explicit educational objectives and reported outcomes.

Existing systematic reviews and meta-analyses of SGs or game-based interventions in nursing education have predominantly examined effectiveness under controlled trial conditions. Meta-analyses of randomized controlled studies report that SGs may improve learning outcomes, most frequently assessed using knowledge tests and performance-based skills measures [13-15]. A systematic review and meta-analysis focusing on knowledge outcomes further supports the potential of game-based interventions to enhance nursing students' knowledge [16]. In addition, a systematic review and meta-analysis examining feedback elements suggests that feedback-related design mechanics may contribute to learning gains, underscoring the relevance of design components for educational impact [17]. Collectively, these syntheses summarize and, in some cases, quantify the extent to which SGs are associated with improvements in predefined outcomes and, in some cases, the contribution of specific design mechanics [18]. However, these reviews largely prioritize randomized controlled trials and short-term postintervention outcomes, with limited attention to implementation context, competency-domain coverage, and heterogeneity in outcome measurement.

Research Gap and Objectives

Nonetheless, important gaps remain that constrain interpretation and implementation. First, effectiveness-focused syntheses offer limited coverage of quasi-experimental, qualitative, and mixed methods evidence that can inform feasibility, acceptability, contextual fit, and plausible mechanisms in nursing education [19]. Second, there is limited characterization of how outcomes are operationalized across studies, including the instruments used and the alignment between outcome selection, targeted competencies, and learning context [20]. Third, the intervention landscape remains insufficiently characterized with respect to SG types, instructional topics and settings, delivery modalities, and the distribution of evidence across these categories [19]. These limitations reduce comparability across studies and make it difficult to translate effectiveness estimates into actionable guidance for curriculum design and evaluation [19].

Accordingly, this study follows the JBI scoping review framework to systematically identify, map, and synthesize the evidence on SGs in nursing education. This review addresses three questions: (1) What SGs have been developed for nursing education or practice? (2) In which teaching or clinical contexts and competency domains have these SGs been implemented? and (3) How have their effectiveness and related outcomes been evaluated and reported?

Methods

Study Design

This study followed a scoping review approach in accordance with the JBI framework for scoping reviews [21]. The review process included defining the objectives and questions; developing the inclusion criteria; planning the search, selection, data extraction, analysis, and presentation methods; conducting the search; selecting and extracting the evidence; analyzing the evidence; presenting the results; and summarizing the findings in line with the purpose of the review [21]. The findings are reported in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist (Checklist 1) [22].

Protocol and Registration

No registration was undertaken for this scoping review; the protocol is provided for transparency (Multimedia Appendix 1).

Search Strategy

The literature search was developed by the review team and combined controlled vocabulary terms and free-text keywords related to SGs and nursing education. English-language databases included PubMed, Web of Science, Embase, CINAHL, and the Cochrane Library. Chinese-language databases included China Biology Medicine, Wanfang Data, China National Knowledge Infrastructure, and VIP. These databases were initially searched from database inception to June 28, 2024, and the searches were rerun on January 28, 2026, to identify newly published records. Each database was searched individually, and no simultaneous multidatabase searching on a single platform was used. No additional search methods were used, including study registry searching, manual searching of reference lists, forward citation tracking, website browsing, conference proceedings searching, or author or expert contact. No published search filters were used or adapted in this review. The search strategies were reviewed by a library specialist to improve completeness and accuracy before the searches were conducted. The full search strategies for each database are provided in Multimedia Appendix 2.

Eligibility Criteria

To ensure the selection of relevant studies, specific inclusion and exclusion criteria were established based on the scope of this review. The eligibility criteria are shown in Textbox 1.

Textbox 1. Study eligibility criteria.

Inclusion criteria

- Participants: undergraduate or graduate nursing students (including nursing interns or trainees when clearly identified as nursing learners).
- Concept: serious game (SG)–based teaching and learning interventions (digital, offline, or hybrid or blended formats) with an explicit educational or training purpose.
- Context: nursing education activities (eg, coursework or lectures, skills training, simulation, or clinical skills learning). Interventions were classified as SGs only if they included an explicit game structure (rules with a defined goal or end point), a trackable progression system (eg, multiround missions or levels with unlocking), and performance feedback tied to the intended learning objectives; otherwise, they were coded as gamification only and excluded.
- Article type: original study, journal article, or conference paper.
- Language: English or Chinese.

Exclusion criteria

- Secondary evidence syntheses (eg, reviews or meta-analyses) and nonempirical publications (eg, protocols, guidelines, expert opinions, editorials or commentaries, letters, or policy documents).
- Studies not meeting the population, concept, and context definitions.
- Duplicate reports of the same study or studies for which the full text was not available.

Selection of Sources of Evidence

Title and Abstract Screening

The retrieved records were first deduplicated using EndNote. Two reviewers (QS and ZH) independently screened the titles and abstracts of all remaining records to identify studies that potentially met the inclusion criteria.

Full-Text Screening and Eligibility Assessment

Following title and abstract screening, the same 2 reviewers (QS and ZH) independently conducted a full-text assessment of potentially eligible studies to determine final eligibility. Discrepancies were resolved through discussion and cross-checking; if consensus could not be reached, a third reviewer (YF) provided adjudication.

Final Study Selection

Studies that met the eligibility criteria were included in the final review. The overall selection process is presented in a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Data Charting Process and Data Items

Data extraction was independently performed by 2 reviewers using a piloted, standardized form developed by the review team. The form was designed in line with the review objectives and eligibility criteria to capture bibliographic details (country, authors, year), study design, participant information, sample sizes (for context), application context (course or setting), intervention measures, basic design info, intervention duration, teaching content, and SG characteristics, including modality or platform, delivery format, brief game description, game design (standardized), key game design features (mechanics), and evaluation indicators. For data charting and comparison across studies, the extracted information was further organized into broader categories, including study characteristics, educational context, intervention characteristics, game design features, and outcome assessment. Disagreements were resolved through discussion with a third reviewer.

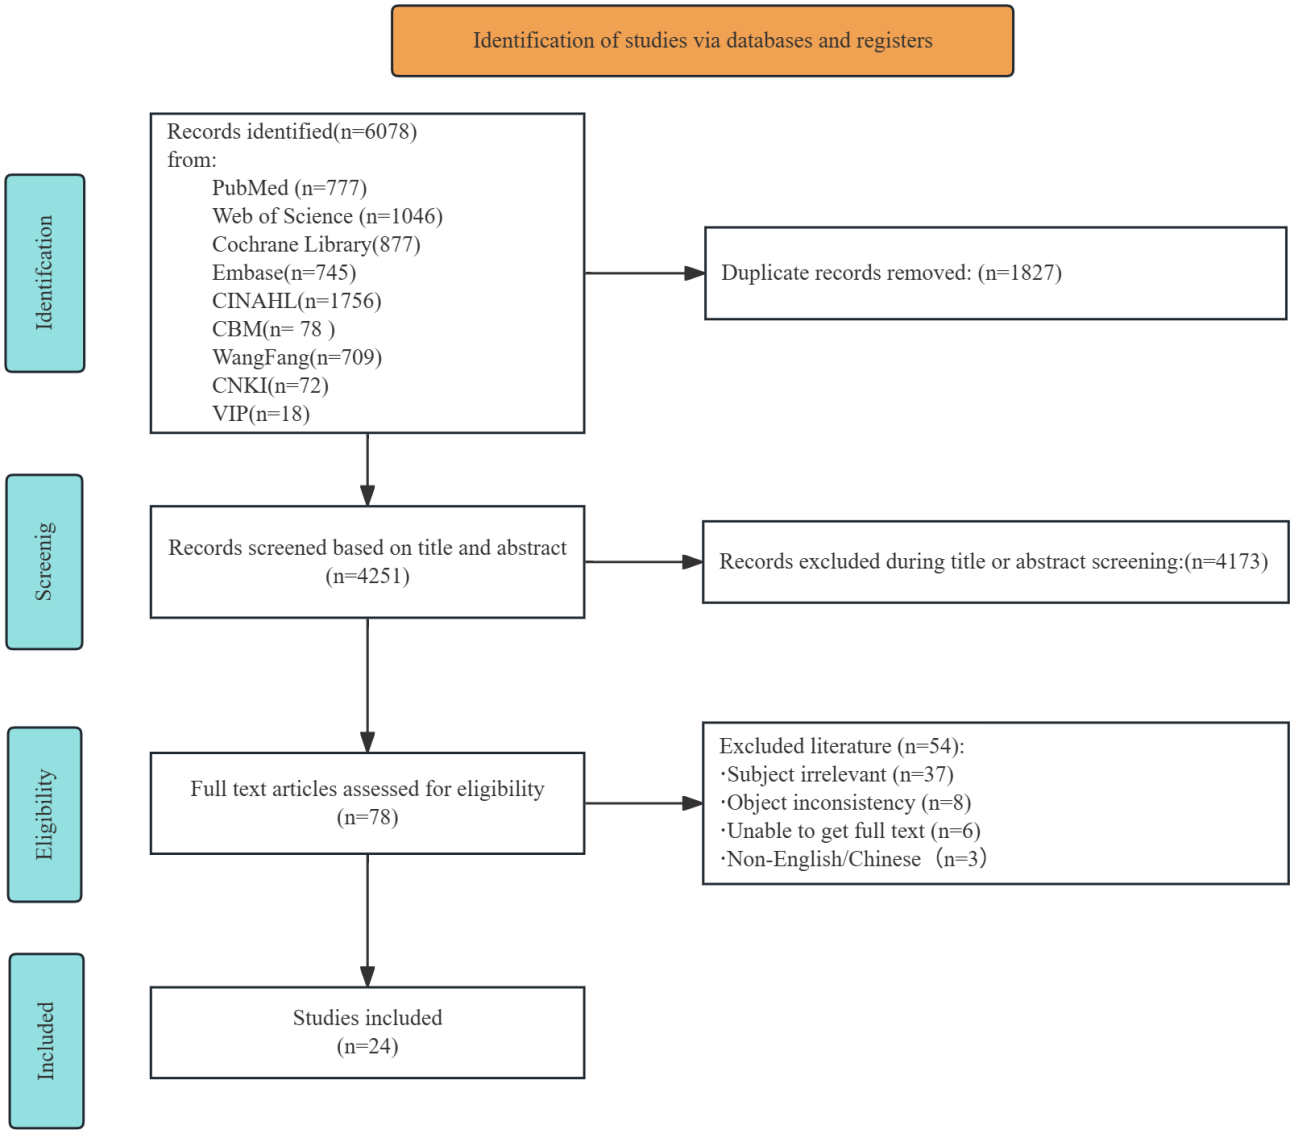
Synthesis of Results

Descriptive statistics (frequencies or percentages) and narrative synthesis were used to summarize the data; no meta-analysis

XSL•FO
RenderX

was conducted. Study characteristics such as country, year of publication, study design, and sample size were summarized to provide an overview of the distribution of the included studies. Educational context data were categorized by nursing course type and teaching content to highlight the areas where SGs were most commonly applied. Intervention characteristics, including modality or platform, delivery format, intervention duration, brief game descriptions, standardized game design, and key game mechanics, were summarized across the studies. Evaluation indicators were grouped into broader outcome domains such as knowledge, skills, attitudes, and engagement or usability to facilitate cross-study comparison. The extracted data were presented in descriptive tables to ensure transparency, and a narrative thematic synthesis was conducted to identify patterns across different game types, educational contexts, and outcome domains. Additionally, an evidence gap map was developed to visualize the distribution of studies across nursing course categories and outcome domains.

Critical Appraisal



We appraised methodological quality using JBI critical appraisal tools tailored to study design. Two reviewers independently assessed each included study using item-level ratings of yes, no, unclear, or not applicable; disagreements were resolved by discussion, with third-reviewer adjudication when necessary. Consistent with scoping review methodology, studies were not excluded based on appraisal; findings were used to contextualize confidence in the evidence and to inform interpretation of results and evidence gaps.

Results

Study Selection

The initial search yielded 6078 records, of which 1827 (30.06%) were duplicates and 4173 (68.65%) were excluded after screening titles and abstracts. Of the remaining 78 full-text articles assessed for eligibility, 24 studies [23-46] met the inclusion criteria. The PRISMA-ScR flowchart (Figure 1) provides further details.

Figure 1. PRISMA flow diagram of study selection.

XSL•FO
RenderX

Characteristics of the Included Studies

Of the 24 included studies, publication dates clustered from 2021 to 2025 (n=13, 54%), followed by 2017 to 2020 (n=7, 29%) and 2012 to 2016 (n=4, 17%). Studies were predominantly from Europe (n=13, 54%), with additional studies from Asia (n=5, 21%) and North America (n=4, 17%); Oceania and South America were each represented by 1 study (n=1, 4%). Quasi-experimental designs were most common (n=10, 42%), followed by randomized controlled trials (n=8, 33%), mixed methods studies (n=4, 17%), and qualitative studies (n=2, 8%; Table 1).

Table . Characteristics of included studies on serious games in nursing education (N=24).

Characteristic	Studies, n (%)
Publication year	
2012 - 2016	4 (17)
2017 - 2020	7 (29)
2021 - 2025	13 (54)
Country or region (continent)	
Europe	13 (54)
Asia	5 (21)
North America	4 (17)
Oceania	1 (4)
South America	1 (4)
Study design	
Randomized controlled trial	8 (33)
Quasi-experimental	10 (42)
Mixed methods	4 (17)
Qualitative	2 (8)

Results of Individual Sources of Evidence

The extracted data from the included studies are presented in Multimedia Appendix 3, including study characteristics, educational context, intervention details, SG characteristics, and evaluation indicators, and form the basis for the analyses presented below.

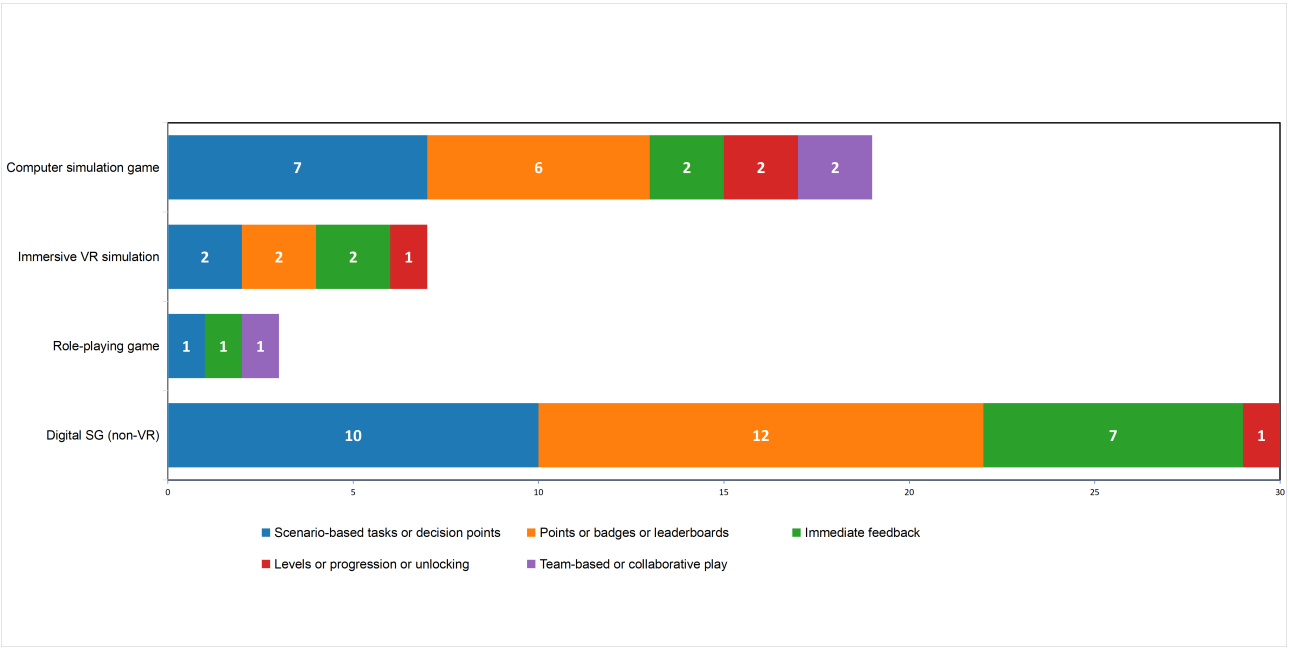
Synthesis of Results

Delivery Format and Key Game Design Mechanics of SGs

Each study was assigned to 1 primary delivery format based on the main platform reported. Digital SGs delivered via non–virtual reality (VR) platforms were most common (14/24, 58%), followed by computer simulation games (n=74, 29%), immersive VR simulations (n=2, 8%), and role-playing games (n=1, 4%). Scenario-based tasks and decision points were reported in 20 (83%) studies, as were points, badges, and/or leaderboards (n=20, 83%). Immediate feedback was reported in 12 (50%) studies, whereas levels or progression or unlocking (n=4, 17%) and team-based or collaborative play (n=3, 13%) were less frequently reported (Table 2). Figure 2 provides a visual representation of the data summarized in Table 2, illustrating how the reported game design mechanics are distributed across delivery formats.

XSL•FO
RenderX

Table . Delivery format and key game design mechanics of serious games used in nursing education (N=24)[a].



Characteristic	Studies, n (%)
Delivery format	
Computer simulation game	7 (29)
Immersive VR[b] simulation	2 (8)
Role-playing game	1 (4)
Digital SG[c] (non-VR)	14 (58)
Key game design mechanics	
Scenario-based tasks or decision points	20 (83)
Points, badges, and/or leaderboards	20 (83)
Immediate feedback	12 (50)
Levels or progression or unlocking	4 (17)
Team-based or collaborative play	3 (13)

[a]One study may contribute to multiple design mechanics; scenario-based tasks or decision points were coded when studies explicitly described case-based scenarios and learner choices affecting task progression or responses; points, badges, and/or leaderboards indicate reporting of 1 or more of these mechanics; and levels or progression or unlocking indicate an explicit staged progression or unlocking pathway.

[b]VR: virtual reality.

[c]SG: serious game.

Figure 2. Distribution of key game design mechanics by serious game (SG) delivery format in nursing education studies. VR: virtual reality.

Nursing Course Categories and Supported Topics

SG-supported learning was predominantly used in skills-based courses, with additional implementation observed in specialty nursing areas. Across the 24 included studies, SG-supported learning activities were most commonly implemented in fundamentals and skills training courses (7/24, 29%), followed by adult nursing and medical-surgical courses (n=6, 25%). Fundamentals and skills training applications focused on core procedural competencies such as cardiopulmonary resuscitation and life support, safe transfusion management, and intramuscular injection skills training. Adult nursing applications covered medical-surgical topics including electrocardiogram interpretation, chronic disease care, symptom recognition and management in acute heart failure, tracheostomy care, early warning and recognition of postoperative hip bleeding, and diabetic ketoacidosis care. Pediatric nursing and community or primary care nursing were each represented by 3 (13%) studies addressing pediatric assessment or care topics and community-oriented competencies such as nurse-patient communication and environmental risk assessment. Critical care nursing was represented by 2 (8%) studies, while maternity or neonatal nursing, emergency care, and foundational sciences were each represented by 1 (4%) study. Table 3 summarizes the course categories and topics addressed.

XSL•FO
RenderX

Table . Course categories and nursing courses or topics supported by serious games (SGs; N=24)[a].

Course category	Studies, n (%)	Nursing courses or topics supported by SGs
Fundamental or skills training	7 (29)	• Cardiopulmonary resuscitation training • Basic and advanced life support training • Safe transfusion management • Intramuscular injection skills training
Adult nursing (medical-surgical)	6 (25)	• Electrocardiogram interpretation • Care of patients with chronic diseases • Identification and care of acute heart failure symptoms • Nursing care of patients with tracheostomies • Early warning and recognition of postoperative hip bleeding • Nursing care of patients with diabetic ketoacidosis
Pediatric nursing	3 (13)	• Clinical assessment of respiratory problems in premature infants • Nursing care of children after appendectomy • Teaching pediatric respiratory system knowledge
Maternity or neonatal nursing	1 (4)	• Neonatal cardiopulmonary resuscitation training
Community or primary care nursing	3 (13)	• Nurse-patient communication • Community and public health nursing competencies training • Risk assessment of the living environments of older adults
Emergency care	1 (4)	• Team collaboration in the emergency department
Critical care nursing	2 (8)	• Assessment of critical care nursing skills • Analysis of pneumonia complicated by sepsis
Foundational sciences	1 (4)	• Pathophysiology teaching

[a]Each study was assigned to 1 primary course category based on the main educational setting or course described by the authors; course labels were harmonized across studies into common nursing curriculum modules.

Evidence Gap Map Across Course Categories and Outcome Domains

Of the 24 included studies, outcome domains and measurement approaches were unevenly distributed, revealing several clear evidence gaps. Knowledge was the most frequently assessed outcome, reported in 16 (67%) studies using tests. Skills were assessed in 10 (42%) studies, including 3 (13%) studies using tests and 7 (29%) studies using checklists. Attitudes were measured in 8 (33%) studies using scales, and engagement or usability in 13 (54%) studies, also mainly using scales. By contrast, use metrics were reported in only 1 (4%) study, limited to backend interaction data such as frequency of use and time spent, indicating a substantial lack of evidence on how learners actually use SGs in practice. A total of 2 (8%) qualitative studies did not report specific quantitative outcome measures, further suggesting limited evidence on learners' experiences outside narrative accounts (Table 4). The evidence gap map (Figure 3) showed that existing studies were concentrated in fundamentals or skills training and adult nursing, whereas maternity or neonatal nursing, emergency care, critical care nursing, and foundational sciences were represented by very few studies. Across outcome domains, the evidence was heavily weighted toward knowledge and, to a lesser extent, skills and engagement or usability, while attitudes, use patterns, and qualitative experience-related outcomes were comparatively sparse. Overall, the main evidence gaps lay in underrepresented course categories and in the limited assessment of implementation-related and experience-related outcomes beyond knowledge-based evaluation.

XSL•FO
RenderX

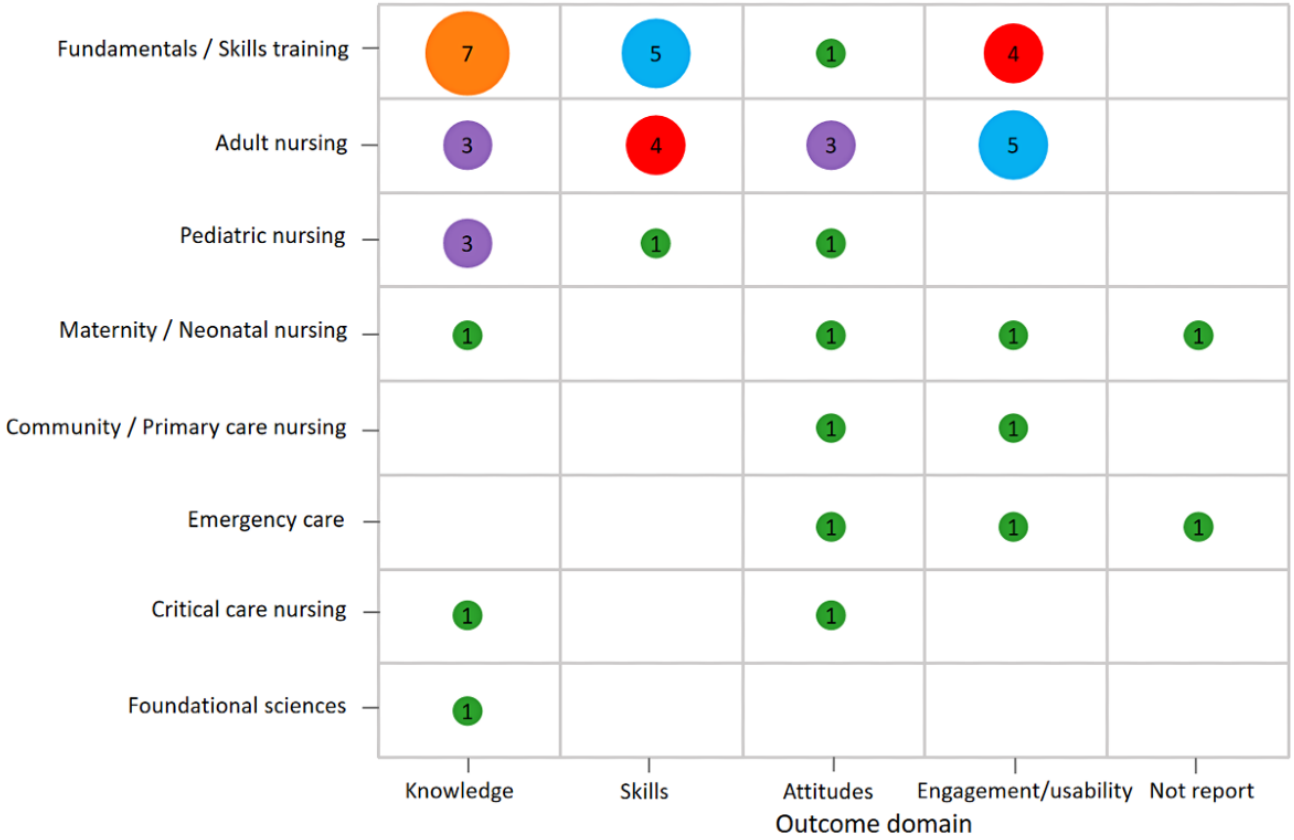


Table . Outcome domains, measurement types, and corresponding studies across included studies (N=24)[a].

Outcome domain	Measurement type	Studies, n (%)	Included studies
Knowledge	Test	16 (67)	[29-36,38-42,44-46]
Skills	Test	3 (13)	[27,32,37]
	Checklist	7 (29)	[29,33-36,44,45]
Attitudes	Scale	8 (33)	[23,28,31,32,40,41,43,45]
	Use metrics	1 (4)	[30]
Engagement or usability	Scale	13 (54)	[23,24,27,28,31-33,37,39-41,45,46]
Not reported	—[b]	2 (8)	[25,26]

[a]Use metrics refer to backend use data of user interaction or engagement (eg, frequency of use and time spent). Not reported means that studies did not report specific outcome measurements due to their qualitative design.

[b]Not applicable.

Figure 3. Evidence gap map of serious game studies in nursing education by course category and outcome domain.

Critical Appraisal

Methodological quality was assessed using design-appropriate JBI critical appraisal tools and the mixed methods appraisal tool (Multimedia Appendix 4). Overall, of the 24 studies, 19 met at least 75% of appraisal criteria, meaning they satisfied three-quarters or more of the applicable checklist items for their study design, with relatively few items rated as “no” or “unclear.” By study design, 7 out of 8 randomized controlled trials and 8 out of 10 quasi-experimental studies met at least 75% of criteria, compared with 1 out of 2 qualitative studies and 3 out of 4 mixed methods studies. Across designs, the most frequent limitations or unclear reporting concerned internal validity items and reporting transparency, which may constrain confidence in longer-term outcomes and implementation-related inferences.

Discussion

Principal Findings

This scoping review mapped the characteristics, curricular distribution, and outcome evaluation of SGs in nursing education and identified several important gaps in the existing evidence base. The literature was concentrated in practice-oriented areas, particularly skills training and adult nursing, and most commonly evaluated knowledge, skills, and learner-reported engagement or usability. By contrast, instructional rationale, implementation context, objective use data, and outcomes

XSL•FO
RenderX

beyond the immediate postintervention period were infrequently reported. These findings suggest that SGs are currently used primarily as supplementary tools for practice-oriented learning in nursing education, while the uneven distribution of evidence and limited reporting constrain more robust inferences about their educational function, contextual suitability, and broader implementation.

Geographic concentration of the literature was another notable pattern in this review. One plausible explanation is that the development and evaluation of SGs require resources that are unevenly distributed across settings, such as reliable connectivity, access to appropriate devices, and technical support for deployment and data management [47-49]. Institutional capacity may also play a role in determining whether SGs can be integrated into teaching and assessment workflows and evaluated with sufficient rigor for publication [50]. Although this review was not designed to test these explanations directly, the geographic concentration of studies in better-resourced contexts suggests that nursing programs with fewer resources may be underrepresented in the published literature. This has implications for both the generalizability and equity of the findings and emphasizes the need for clearer reporting of implementation conditions, resource barriers, and local adaptations.

A recurring issue in the literature was that studies often described game features more clearly than the underlying educational logic. While many studies reported visible features such as scenario-based decision points and reward structures, fewer clearly articulated the instructional rationale behind these features or explained how feedback and progression were designed to support learning [18]. This lack of clarity weakens the interpretation of findings. In educational terms, the value of SGs lies not just in their digital or game-based format but in whether they support repeated practice, provide timely feedback, and calibrate challenge to maintain learner engagement while enhancing competence [17]. These principles align with experiential learning and self-determination theories, which suggest that short-term improvements in motivation, self-efficacy, and persistence are achievable [51]. However, the studies included in this review rarely specified these mechanisms in testable ways. As a result, it is difficult to determine which components of SG design are most effective in driving learning gains. Future research would benefit from moving beyond platform labels and providing more detailed descriptions of mechanics, feedback processes, progression rules, and the pedagogical assumptions linking these features to learning outcomes. This is particularly important given that different platforms (eg, mobile, web, and VR) may be more suitable for different educational goals: low-cost web or mobile formats may be more feasible in resource-limited settings, while immersive VR may be better suited for psychomotor training or spatial interaction when time, technical support, and usability allow [52,53].

The curricular pattern identified in this review also revealed significant trends. SG applications were predominantly clustered in skills training and adult nursing, which aligns with learning goals that are easier to operationalize through rules, cues, branching decisions, and feedback loops [18,19]. These game mechanics are well suited to practice-based learning, providing opportunities for repetition and error recovery [18,19]. In contrast, theory-heavy content requires more explicit conceptual scaffolding and progression structures that support abstraction, integration, and reflective reasoning [54]. Without such scaffolding, theoretical content risks being reduced to quiz-like gamification rather than facilitating deeper learning [18]. Additionally, the availability of commercially available products and off-the-shelf training modules may have influenced the prevalence of procedural training, as skill acquisition is easier to measure than conceptual understanding [55]. These patterns suggest that SGs are most effective when they offer educationally distinctive features such as safe repetition, exposure to rare or high-risk situations, or dynamic decision-making environments, rather than simply replicating traditional lecture content or assessments in a game format [42]. However, there is considerable potential to expand SG applications into more complex competencies such as clinical reasoning, communication, interprofessional collaboration, and patient safety habits [24,39]. Team-based simulation research supports the potential for improving teamwork and leadership in dynamic care environments, but these outcomes will require mechanics that foster coordination, communication, and shared situational awareness [56].

The way outcomes were measured also shaped the conclusions that could be drawn from the studies. Most studies relied on knowledge tests or learner-reported experiences, which are common in short-course evaluations [20]. While these measures provide useful insights into immediate educational effects, they do not capture sustained learning, transfer to clinical performance, or the mechanisms driving these effects [39]. This limitation is particularly evident in studies that lacked standardized measurement tools or sufficient follow-up, raising concerns about novelty effects or short-term gains. The predominance of quasi-experimental designs and small sample sizes further complicates the interpretation of findings [32,46]. A major gap in the literature is the lack of objective use data such as time on task, frequency of play, progression, or error patterns [57,58]. Without these indicators, it is difficult to explore dose-response relationships, evaluate which aspects of gameplay are most impactful, or understand how learners engage with SGs [59]. This limitation is critical, as the effectiveness of SGs relies on learners' interaction with the game, not just the design itself. When properly captured, gameplay data could provide valuable insights into decision-making processes, feedback uptake, and error recovery; however, this potential remains largely untapped.

These patterns highlight several priorities for future research. Development, implementation, and evaluation of SGs should be treated as interconnected tasks rather than separate phases. SGs are unlikely to produce meaningful results if learning objectives are not clearly defined, usability is not sufficiently tested, or delivery conditions are misaligned with the curriculum [19]. A more robust approach would begin with clear articulation of learning goals and contextual constraints, followed by an explicit linking of those goals to game mechanics, feedback logic, and progression design. Iterative user-centered refinement is also essential, particularly where usability or acceptability

XSL•FO
RenderX

may influence uptake. Evaluation should extend beyond short-term effectiveness, incorporating indicators such as acceptability, satisfaction, perceived usefulness, usability, adoption, and engagement [60,61]. Objective use metrics are particularly important to assess dose, fidelity, and mechanisms. Where feasible, longer-term outcomes such as retention, transfer to practice, cost-effectiveness, and equity-related effects should be included to better inform adoption decisions across diverse nursing programs [62,63].

Limitations

This review has several limitations. First, only studies published in Chinese or English were included, and relevant evidence in other languages may have been missed. Second, gray literature and unpublished work were not included, and some SGs are privately developed with limited disclosure of development and evaluation details. Third, substantial heterogeneity in interventions and outcome measures, together with short follow-up and limited reporting of use data, constrained comparability and precluded quantitative synthesis. Finally, incomplete reporting of implementation context and reliance on self-report or nonstandardized measures limit reproducibility and warrant caution when interpreting improved learner experience as competence gains.

Conclusions

This review extends earlier work on SGs in nursing education by mapping the evidence across curricular areas, intervention reporting, and outcome assessment, rather than focusing mainly on effectiveness or specific formats. The available evidence is concentrated in practice-oriented topics, while important gaps remain in underrepresented course areas, intervention description, follow-up assessment, and objective use data. Together, these findings offer a clearer picture of how SGs are being studied in nursing education and where stronger evidence is still needed. They may inform curriculum planning, support more targeted use of SGs in skills-based and clinical training, and guide decisions about design, implementation, and evaluation in real educational settings. Future studies should describe interventions more clearly and assess implementation and longer-term outcomes more consistently.

Acknowledgments

The authors confirm that no generative artificial intelligence tools were used in the writing, editing, or preparation of this manuscript.

Funding

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Data Availability

All data generated or analyzed during this study are included in this published article. No additional datasets were generated or analyzed. In accordance with JMIR Publications' data-sharing policy, the authors affirm that all relevant materials are fully available within the manuscript and supplementary files.

Abstract

Background: Training practitioners to implement functional communication training (FCT) is resource intensive. Emerging technologies, such as virtual reality (VR) and chatbots, may deliver training at scale. Their comparative effectiveness and whether skills taught in one modality transfer to another remain uncertain.

Objective: This exploratory study evaluated the effect of multicomponent training packages featuring either VR or a chatbot on (1) posttraining performance on FCT implementation probes administered in both formats and (2) changes in participants' self-perceived knowledge, confidence, and usefulness.

Methods: A convenience sample of 23 university students (mean age=24 y; 15/23, 65% female) were recruited through classroom announcements and peer referrals. Eligible participants (at least 18 years of age, available to attend trainings, and who had no history of discomfort associated with VR) were randomly assigned to either VR (n=12) or chatbot (n=11) training. Groups did not differ significantly across demographic characteristics. In-person trainings consisted of video-recorded instruction and rehearsal of steps in VR or with the chatbot during a single session. Approximate times of sessions, including tutorials and assessments, were 45 minutes (VR) and 55 minutes (chatbot). All participants' performance on FCT procedures was measured using 2 formats: a VR-based observed mastery probe (OMP) and a text-based probe (TBP). Participants also completed a survey measuring their self-perceptions.

Results: The number of FCT steps participants performed correctly (of 18) was analyzed using a binomial generalized linear mixed model, with random intercepts for participant and fixed effects of training group (chatbot vs VR), time (pretest vs posttest), and probe modality (OMP vs TBP); α=.05. Results indicated a main effect of time (odds ratio [OR] 36.09, 95% CI 20.75 - 62.75; P<.001). A significant 3-way interaction (time × probe modality × training group) indicated that the pattern of skill transfer differed by training condition and probe type (OR 6.10, 95% CI 2.08 - 17.86; P<.001). At posttest, the chatbot group significantly outperformed the VR group on the TBP (OR 4.14, 95% CI 1.20 - 14.24; P=.049), completing, on average, 4 more steps in the procedure (average marginal effect 0.22, 95% CI 0.04 - 0.41). Differences between groups on the OMP were not significant (OR 0.61, 95% CI 0.18 - 2.07; P=.43). Across all self-report measures, there was no differential improvement by training condition at posttest.

Conclusions: This study provides the first comparison of chatbot- and VR-based training for FCT. This extends prior work that compared VR against didactic instruction or assessed performance using a single modality. Findings contribute to the field by supporting the viability of text-based chatbots in training and underscoring the importance of the alignment between training and assessment modalities. Chatbot-enhanced training systems may extend access to evidence-based techniques, such as FCT, in areas with limited training resources. More work is needed to confirm effects and demonstrate applicability to practice.

Introduction

Problem

Self-injurious behavior and aggression manifest in as many as 30% of individuals with intellectual and developmental disabilities (IDD) [1]. Beyond physical harm, these behaviors produce chronic stress for families, economic strain on service systems, and overall disruptions to stakeholder well-being [2]. Restrictive placement, chemical/physical restraints, and punishment often used to suppress severe challenging behaviors are not long-term solutions and are associated with negative outcomes [3]. Educators and other personnel in service settings require training in nonpunitive, effective methods for reducing challenging behaviors and achieving optimal outcomes for people with IDD [4].

Challenging behaviors have many potential causes [5]. Functional communication training (FCT) is one of the most widely validated interventions for reducing aggression and self-injury associated with social causes in children with IDD by teaching appropriate communication alternatives (ie, replacement behaviors, [6,7]). Instead of hitting adults to escape from difficult tasks, for example, children can be taught to request assistance (eg, "I don't understand," [8]). FCT has been shown to be effective at reducing challenging behaviors, often yielding improvements in behavior and communication [6,9].

Despite its demonstrated effectiveness, the dissemination of FCT may be hindered by the complexity of the procedure and intensive nature of staff preparation [10]. Effective training typically involves didactic instruction, modeling, rehearsal with feedback, and in-situ performance checks, all of which require expert trainers and access to clients or trained confederates [10,11]. These logistical and resource-intensive demands pose challenges to scaling FCT, especially when opportunities for rehearsal are limited. Recent reviews note that, although effective training improves implementation of FCT, studies vary widely in their use of role-play, simulations, and direct client application [10]. Such constraints can impede skill fluency and may slow adoption in schools and settings facing shortages in personnel or other resources.

Review of Relevant Scholarship

Advancements in digital training have increasingly positioned immersive virtual reality (VR), or interfaces (eg, head-mounted displays, motion sensors) that situate participants within virtual space [12], as a promising modality for training educators and service providers (eg, [13,14]). For the purposes of training individuals to use FCT, VR places trainees inside realistic, 3-dimensional scenarios populated by avatars that emit challenging behavior, with feedback adjusted based on the trainee's performance. Clay and colleagues [13] demonstrated the feasibility of VR-based opportunities for practice among small cohorts (n=6‐13) of novice graduate students and clinicians [15]. Training consisted of lecture, modeling the technique within VR, prompting, and feedback. Trainees demonstrated mastery of the procedure by engaging with a scripted avatar within the simulation. Across studies, some trainees acquired the procedure without proceeding through the entire training [13]; others required additional training from clinicians following VR rehearsal [15]. Gains from VR training transferred to brief live role-play simulations [15].

One barrier to the use of VR simulations for training is the need for professional oversight; VR provides opportunities to rehearse a wide range of skills but, on its own, does not alleviate shortages of qualified supervisors in disability service fields. Artificial intelligence (AI), broadly defined as software capable of acquiring, processing, and acting upon information [16], has the potential to reduce the need for human assistance for tasks such as assessment and feedback in VR simulations [17]. Generative AI and natural language processing can create speech for avatars and assess written or spoken trainee responses; however, much of this work involves speech or text-based interaction, with limited emphasis on the behaviors often addressed through FCT [10].

King and colleagues [18] evaluated an AI-augmented FCT simulation in VR using an automated training model incorporating speech-to-text, text-to-speech, text classification, and motion sensing. In 2 small, single-case design studies, participants received prerecorded instruction, video models, and automated systematic prompting, with performance measured through in-simulation speech and motion tracking. Trainees exhibited improved FCT skills within the simulation following training. A subsequent randomized controlled trial [19] evaluated the simulation with 49 general education undergraduates using a waitlisted design, randomly assigning participants to either an intervention group receiving lecture, modeling, and VR practice or a control group receiving lecture and modeling only. Results indicated that the VR group demonstrated significantly more correct FCT steps at posttest (d=2.45) and maintenance (d=1.58) compared with controls, with correspondence between AI-administered and human-observed assessments averaging approximately 90%, though groups did not differ on content knowledge tests or self-reported confidence and assessments were conducted exclusively within the simulation environment.

Despite these promising findings, VR remains less attractive as an instructional platform due to concerns regarding the cost of hardware and its acceptability across diverse learners [19]. Trainee motions that the system acknowledges, as well as characteristics of the avatar and virtual world, must be programmed into the lesson in advance. Thus, opportunities to provide trainees with multiple exemplars of practical situations are limited. The cumbersome nature of VR, which can be difficult to implement in crowded spaces and difficult to use for individuals without previous experience, represents an additional impediment to its application in many training settings. Additionally, there are critical issues that undermine positive findings of many VR training studies [20]. One of the most persistent involves the frequent misalignment between intervention conditions featuring VR and control conditions, which often differ in terms of both opportunities for practice and other crucial elements of instruction [21]. The imbalance impedes attempts to isolate the unique advantages of immersive training. However, comparing AI-augmented VR to high-quality training featuring multiple opportunities to rehearse practice may also be inappropriate, as these systems are often intended

XSL•FO
RenderX

to compensate for resource constraints that prevent optimal training [19].

Chatbots—or computer-based applications that can engage humans in conversations through spoken or written text—represent an increasingly popular AI tool in higher education settings [22]. Uses for chatbots range from the generation of learning exercises, planning documents, conversation partners, and assistance in writing assignments [23,24]. Role-play activities designed to assist in the acquisition of procedural skills, such as those facilitated by VR, are relatively scarce in the chatbot literature [22]. Nonetheless, the studies that have examined this topic suggest that chatbots designed to engage students in role-play might improve procedural accuracy and fluency (eg, [25]). Compared with VR, chatbots may be able to provide a wider range of learning scenarios and, when coupled with large language models (LLMs; eg, ChatGPT), may be able to provide rich feedback in relation to targeted skills. On the other hand, King and colleagues [26] suggested that immersion and opportunities to rehearse relevant physical activities might make VR more suited to learning complex procedures such as FCT. Given the relative ease at which chatbots may be deployed, the extent to which skills learned in a purely textual format generalize to physical activities as well as the utility of chatbots in learning steps in the procedure more generally warrant further examination.

Chatbots can process learner input, provide adaptive feedback, and simulate interactive dialogue in a manner similar to supports featured in previous instructional VR studies (eg, [19]). In educational contexts, chatbots are increasingly regarded as scalable tools to support personalized learning and address the diverse needs of classrooms [23]. However, text-based formats do not simulate aural and visual stimuli encountered in authentic environments or require the learner to engage in physical or spoken behaviors associated with appropriate practice. These features are associated with effective training in behavioral service fields [27] and represent one of the purported advantages of the VR format [28], particularly in the context of behavior analytic theories of learning emphasizing correspondence between the modalities engaged during learning and performance [29-31]. More specifically, instruction and assessment can be characterized as learning channels that represent both how stimuli are perceived (eg, see) and how a response is produced (eg, say) [29,30]. The primary implication is that instruction must explicitly support this relationship, particularly if the learner does not have experience with the relevant channels [31].

Cognitive load theory, which proposes that humans have limited mental capacity for processing information and storing it in long-term memory [32], has further implications for training simulation. Intrinsic cognitive load refers to the mental demands associated with the complexity of the information and interactions relevant to instructional goals (eg, breadth of information required for adequate performance); extraneous load refers to additional mental resources expended in processing stimuli irrelevant to instructional goals (eg, reconciliation of various media used in instruction) [33]. Although this would appear to support the deployment of chatbot simulations or simulations that do not require management of controllers or other materials [34], VR may be better positioned to fill the gap between text and the physical and mental demands of practice [13,15,18]. Recent research further suggests greater task complexity can be tolerated by trainees [35] and may promote deeper learning [36].

Research on chatbot-based training for preservice teachers, and especially for teaching FCT, remains limited. No published studies have directly compared VR-based FCT training simulations to text-based alternatives, leaving questions about their relative effectiveness and generalization. Additionally, a primarily text-based medium may not be suitable for teaching skills comprising both speech and physical action, which has motivated much of the VR scholarship in this area [13,15,18]. This gap highlights the need for systematic evaluation of chatbot training alongside VR in the context of FCT.

Aims and Objectives

This exploratory study addresses questions regarding both the relative advantages of VR-based training compared with aligned alternatives and the viability of chatbots as tools for teaching instructional procedures. Building on two recent works that established the technological infrastructure and preliminary empirical support for automated VR–based behavioral skills training in FCT [18,19], we examined performance within and across VR and chatbot training modalities to examine whether skills acquired in one modality generalize effectively to the other. By investigating these aspects, this study explored the potential of various instructional modalities for training individuals in evidence-based behavioral interventions. The study was guided by the following primary question: To what extent does improved performance from pre- to posttraining differ by training modality and probe format? A secondary question pertained to participant perceptions of learning following the intervention: To what extent do participants' perceived knowledge, confidence, and utility of the procedure vary based on training modality?

Methods

Ethical Considerations

All study procedures and consent forms were approved by the institutional review board (IRB) of a midwestern public university in the United States as exempt prior to the commencement of participant recruitment (2022409364). Although all procedures were disclosed to the IRB, this study was not registered. The first author met with interested students via teleconferencing software to describe the study in greater detail and confirm participation. Written consent was obtained prior to the initiation of procedures. Study exclusion criteria were developed to prevent discomfort or exacerbation of conditions associated with the use of VR. Participants were advised to terminate sessions if they experienced discomfort; no attrition or adverse events occurred, however. All initial data were confidential, with numbers used in the place of names; all codes linking individuals to data were destroyed after the conclusion of the study. Text transmitted to OpenAI during chatbot sessions consisted of typed statements, described actions, and other procedurally constrained responses directed at a simulated student within partially scripted scenarios. No names,

XSL•FO
RenderX

codes, or identifying information were disclosed. Data-sharing options in the OpenAI platform were disabled across all settings for model feedback, evaluation, inputs, and outputs. Consent procedures therefore addressed confidentiality and chatbot participation without specifically itemizing data transmission. No figures or supplementary materials permit the identification of participants. Secure digital media were used for data storage; paper forms were secured in a locked office. A US $10 gift card was offered as an incentive for participation. All participants accepted payment upon conclusion of the study. This study is reported in accordance with CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) [37].

Inclusion and Exclusion

Eligibility criteria included being at least 18 years old, a currently enrolled student at the university in which the study was conducted, proficient in English, having no history of epilepsy or discomfort associated with virtual reality usage, and availability for on-campus meetings scheduled in March 2025 and April 2025.

Participant Characteristics

A total of 23 participants voluntarily enrolled in the study. Participants ranged in age from 19 years to 42 years (mean 24.0, SD 5.3 years). Of the participants, 15 identified as female, 7 identified as male, and 1 did not disclose. Most (21/23, 91%) were undergraduates, with an average of 2.8 (SD 1; range=1 - 5) years in their respective programs including education, special education, and fields outside of education. Demographic surveys indicated there were no significant differences in participant characteristics or familiarity with VR or AI assistants prior to the study. We assigned participants to either the VR training (n=12) or chatbot training (n=11) groups.

Sampling Procedures

Recruitment, which extended from January 2025 to March 2025, was conducted through convenience sampling with a snowball component. Specific methods included (1) in-class announcements by the instructor of a classroom management course with a total enrollment of 90 and (2) peer referrals among students enrolled in computer engineering courses. Participation through both channels was determined via self-selection. Ten students from the classroom management course participated, resulting in a participation rate of 11% (10/90). Given the nature of snowball sampling, it was not possible to determine a recruitment rate for students from engineering courses.

The project was conducted over 2 weeks in April 2025. Each participant completed 1 session per week across 2 consecutive weeks, with sessions scheduled to ensure approximately 7 days elapsed between sessions. For each session, the first author scheduled individual, face-to-face meetings at a time of convenience for participants. Sessions were conducted individually in an office area equipped with reliable internet access and the necessary equipment.

Sample Size, Power, and Precision

No a priori power analysis was conducted. To our knowledge, no published study had compared chatbot and VR training in the current instructional model. Consequently, no effect size was available to derive a target sample. No target sample size was set in advance, and no interim analyses nor stopping rules were used. Enrollment was constrained by the limited number of people who responded through recruitment channels, in addition to restricted availability of personnel and funds beyond the study window. All recruited participants successfully completed the study. Precision of parameter estimates of the exploratory analyses was determined using 95% confidence intervals.

Measures and Covariates

Primary outcomes included the observed mastery probe (OMP) and the text-based probe (TBP). Secondary outcomes related to participants' perceptions and experiences were obtained through responses to the SKIL Survey [38]. No covariates were included. A social validity survey assessing acceptability of the intervention was also administered. Participants completed a demographic survey used for describing the sample and assessing equivalence between groups.

Primary Measures

Observed Mastery Probe

The OMP measured the percentage of steps, including statements and gestures, of an FCT procedure completed correctly by participants while interacting with a child avatar in the simulation [18,19]. Scenarios required the exhibition of specific responses in relation to a simulated child whose headbanging or tantrums were linked to accessing a preferred item or avoiding an academic task. Replacement behaviors could include vocal requests (eg, "I want a break"), use of hand gestures, or a response card (ie, touching a card corresponding with a request; eg, [39,40]). Researchers provided a scripted description of the challenging behavior, its function, and the proposed behavior intervention (ie, encourage the child to use a replacement behavior). The sequence and content of probes differed from those featured in VR training sessions to reduce the possibility of memorization. The precise content of each OMP appears in King et al [19]. We calculated results by dividing the number of steps correctly exhibited by the total number of steps in each lesson (ie, 18 steps).

Text-Based Probe

The TBP measured the percentage of typed responses correctly corresponding with the steps of an FCT procedure participants exhibited while interacting with a simulated child using a text-based messaging interface. Scenarios represented series of text passages designed to correspond with individual instances that occurred in the VR simulation (eg, "Student begins pounding their hands on a desk; Student says 'Can I have a break'"). As with the OMP, researchers described the context of the situation (eg, challenging behavior) before initiating the TBP. Participants responded to the simulated child by typing messages, which were exchanged in a back-and-forth format. Messages describing actions and statements of the simulated child were generated by an LLM (GPT-4o) configured to role-play within each scenario. The sequence and content of probes differed from those featured in chatbot training sessions to reduce the possibility of memorization. The order of steps

XSL•FO
RenderX

matched those featured in the OMP. Scores were calculated in accordance with methods used for the OMP.

Secondary Measures

SKIL Survey

The SKIL Survey was used to assess participants' self-reported knowledge, confidence, and perceived usefulness of concepts relevant to training. This survey has a 4-point Likert-type scale ranging from 1 (none/very low) to 4 (substantial/very high). Participants rated 9 items across all scales (eg, functional assessment-based intervention).

Social Validity

A survey adapted from previous studies (eg, [19,41]) was used to assess the acceptability of the simulation to participants. The survey assessed 4 domains: acceptability (the extent to which participants found the intervention agreeable and appropriate), effectiveness (perceived improvement in relevant skills), VR (ease of use of the VR system), and chatbot (ease of use of the chatbot system). Participants responded to statements concerning the project (eg, "The use of VR was acceptable to me"; "I had no difficulty using VR") using a 6-point scale (1=strongly disagree; 6=strongly agree). Participants also answered a series of open-ended questions related to their experiences in the simulation.

Data Collection

OMP data were collected through direct observation of participants' use of VR at baseline and training sessions. All OMPs were terminated by observers as soon as participants exhibited an incorrect response or failed to respond within 4 seconds (ie, single-opportunity method; [42]). Steps participants did not complete due to termination were counted as incorrect. Feedback was not provided following OMPs.

As with the OMP, researchers observing typed responses from a secondary screen assessed responses during the baseline and training sessions. TBPs were terminated immediately following an incorrect response. Participants who did not initiate typing after 4 seconds were reminded that they could opt out at any time. A time-based discontinuation rule was not observed due to unpredictable duration of typed responses relative to actions or brief statements required during OMPs. However, the interval between each simulated student message and participants' submission of responses—which includes the duration needed to read, compose, and type the response—was logged by the system. Participants did not receive feedback during TBPs.

Participants completed the SKIL Survey during baseline and the training sessions. Participants accessed a digital version of the SKIL Survey using a Qualtrics link. A digital social validity survey was completed at the end of the training session.

Quality of Measurements

Interobserver agreement (IOA) was collected for OMP and TBP across multiple phases of the project. The first author trained observers prior to the project by scoring videos depicting nonparticipants. Observers were required to master the training criteria of scoring 3 consecutive videos with greater than 90% agreement with the first author before finishing training. Agreement was defined as 2 observers independently recording an identical participant response for the same step of the procedure. Scheduling allowed IOA collection for 87% (20/23) of all probes administered within baseline and 61% (14/23) of all intervention session probes across VR and chatbot groups (ie, VR=58.33% and chatbot=63.64%).

Instrumentation

The OMP was created by a multidisciplinary team including engineers, behavior analysts, and school psychologists and subsequently evaluated by a panel of experts in behavior intervention [18,19]. The TBP was directly modeled after the OMP by the original development team. The SKIL Survey is commonly featured in personnel preparation studies involving behavior intervention [43,44]. Adapted SKIL Surveys have demonstrated acceptable Cronbach α for knowledge (0.91), confidence (0.88), and usefulness (0.92) at baseline (eg, [43]). The social validity survey was adapted from previous VR studies [19,41].

Psychometrics

IOA was calculated by dividing the number of agreements by the total number of steps observed. Average IOA for baseline sessions was 100% for OMP and 98.75% (SD 5.59%; range=75% - 100%) for TBP. The average training session IOA for the VR group was 92.21% (SD 12.01%; range=66.67% - 100%) for the OMP and 94.29% (SD 12.42%; range=66.67% - 100%) for the TBP. For the chatbot group, the average IOA for the OMP and TBP was 100%. Disagreements were reconciled via consensus, and reconciled scores were subsequently analyzed. For the SKIL Survey, Cronbach α for all subscales among the current sample was acceptable (knowledge, 0.95; confidence, 0.90; usefulness, 0.92) at baseline.

Conditions and Design

Conditions were experimentally manipulated. We analyzed the effectiveness of the 2 multicomponent training packages using an independent measures pretest-posttest design with 2 conditions: the VR condition (ie, lecture, model, and VR practice) or a chatbot condition (ie, lecture, model, and chatbot practice). All participants completed both the OMP and TBP at baseline and following training regardless of assigned condition.

Random Assignment Method

Individual participants were the unit of randomization. The first author enrolled and randomly assigned participants using a stratified randomization procedure [45] based on the results of the OMP and TBP (see the Measures and Covariates section) following the baseline session. Participants who scored >11% of items correctly on either the VR or text probe were assigned separately. Randomization was achieved using Excel (Microsoft Corp).

Random Assignment Implementation and Concealment

Participants were randomly assigned codes following enrollment. The first author assigned participants without reference to participant identities using a file containing only codes and baseline probe scores. Participants were unaware of

XSL•FO
RenderX

their assigned condition until after baseline assessment and randomization were complete.

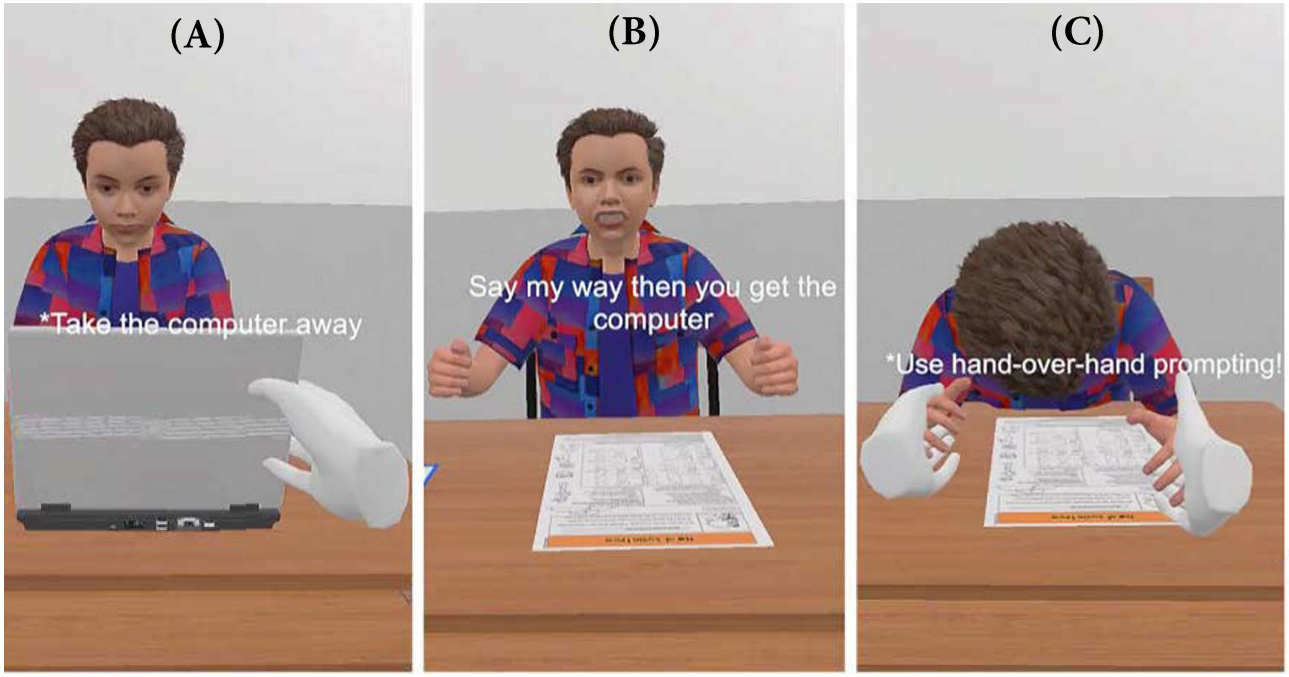
Masking

Masking was not feasible in this study. Participants were never directly informed of their training assignment and used both the chatbot and VR in baseline and training regardless of assignment. It is likely, however, that participants knew which of the 2 technologies was used for training. The first author, who administered all sessions, was likewise aware of condition assignments, as were observers scoring OMP and TBP. Scorer influence was nonetheless constrained by the scoring of probes against a fixed task analysis and collection of IOA across a high proportion of sessions.

Experimental Manipulations

Baseline

During the baseline session, researchers collected demographic information and administered custom tutorials involving the use of the VR and chatbot systems unrelated to FCT. For the VR tutorial, participants received a brief, scripted description of the headset and motion controls from the researchers. Participants then completed a series of actions in the virtual space, including activating the microphone to speak, raising a hand until acknowledged by the simulation, moving a small cube, placing a hand on a specified area, and holding the student avatar's hand. A full description of the tutorial appears in King et al [19]. The chatbot tutorial addressed similar content (eg, hand raising) but emphasized (1) using different regions of the screen for message exchanges or feedback and (2) using asterisks to denote physical actions. Following the tutorials, participants completed OMP and TBP probes with accompanying descriptions (see the Measures and Covariates section) in random order using VR and a laptop computer, respectively. Afterward, they completed the SKIL Survey. Average completion time for baseline sessions was approximately 30 minutes.



Training

Participants received the training session approximately 1 week after the baseline session. Regardless of group assignments, participants reviewed the VR and chatbot tutorials in random order. Each group also observed 2 randomly presented video-recorded lectures totaling approximately 8 minutes in length concerning challenging behavior maintained by escape from assignments and access to preferred objects. Models of FCT applications appeared in each video. Additional detail regarding video content appears in King et al [18].

The same instructional sequence followed each video in the participant's assigned modality: (1) an error-free prompting probe, in which step-by-step hints appeared immediately before each component of the FCT procedure, and (2) two delayed prompting probes, during which prompts describing the correct response were withheld unless the participant made an error (both conditions) or hesitated for more than 4 seconds (VR only). For both conditions, prompts consisted of on-screen text describing the appropriate action. An example of a prompt in VR appears in Figure 1. In both conditions, participants were required to complete the prompted step correctly before proceeding through the simulation—steps that participants continued to complete incorrectly were prompted until the correct response was exhibited. In sum, training consisted of 1 individually administered session with the following components: 2 video-recorded instructional models, 2 error-free probes, and 4 delayed prompting probes delivered either within VR or via chatbot. Neither intervention was tailored nor modified during the study. All participants within each condition received the same instructional components, lesson sequence, and prompt structure.

XSL•FO
RenderX

Figure 1. Depiction of interactions and on-screen prompts within the virtual reality (VR) simulation during training sessions in an exploratory randomized trial comparing chatbot- and VR-delivered instruction in functional communication training (FCT): (A) trigger for challenging behavior (removing the computer), (B) vocal prompt for communicative replacement behavior, and (C) physical guidance of a hand signal.

Across conditions, participants completed both the OMP and TBP. As in baseline, OMP and TBP were presented in random order. Sessions concluded with the administration of the SKIL and social validity surveys. Approximate durations of VR and chatbot group sessions including tutorials, training, and all completed assessments were 45 minutes and 55 minutes, respectively.

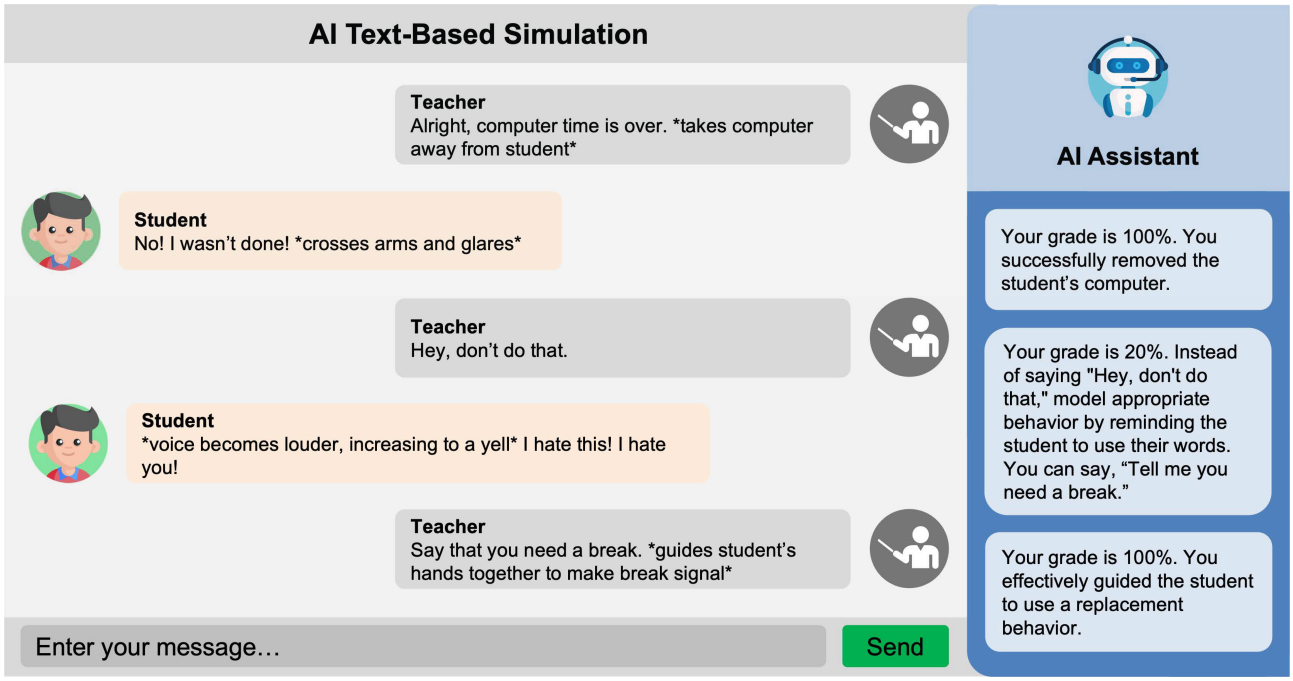
Method of Experimental Manipulation Delivery

Virtual Reality

The VR simulation featured in this study extends a platform developed over several years by an interdisciplinary team of faculty in special education and computer engineering [18,19,41]. These simulations are predicated on behavioral theories of learning and instruction. A task analysis of FCT was arranged into branching pathways based on the range of responses a student might present (eg, target behavior, replacement behavior, compliance), with the resulting flowchart approved by experts in function-based intervention and used to derive individual lessons [46]. Developed in Unity, the simulation allowed trainees wearing a head-mounted display to interact with a virtual student in a simulated classroom. Trainees pressed a controller button to record vocal responses, which Google Cloud speech-to-text transcribed and Google's Natural Language AI classified against phrases used to train the system; statements exceeding a confidence threshold of 0.75 were scored as correct. All in-situ AI scoring was immediately reviewed and approved by researchers before the simulation advanced. The simulation also assessed motion (eg, modeling a sign, physically guiding a response) using Unity's motion-tracking features. A depiction of multiple sequences from the VR simulation appears in Figure 1. A complete description of the VR simulation, its development, and its assessment capabilities appear in King et al [18,19].

Chatbot

The text-based chatbot simulation was designed under the supervision of doctoral faculty in computer engineering to resemble the lessons and instructional logic of the VR simulation within a messaging interface. Student-teacher interactions were derived from the same flowcharts guiding the VR lessons, in which flowchart nodes represented a student action or a trainee response. Trainees interacted with the simulation on a laptop, selecting a lesson then responding to the simulated student through messages. A central panel displayed the exchange and a text field for trainee responses, while a side panel delivered prompts or feedback. Statements were typed without any special punctuation. Asterisks were used to denote physical actions described by the trainee.



The web interface was constructed in HTML, JavaScript, and CSS using the Svelte framework, with trainee data stored locally in a PostgreSQL database and lesson logic managed by a Flask (Python) backend. Lessons were implemented as fixed state sequences derived from the same FCT flowcharts used for VR. Identical lesson state sequences were used for all participants. Text generation was provided by OpenAI's GPT-4o [47] through 2 distinct chatbot instances, one configured to role-play the simulated student and one to serve as an instructional assistant. The model was accessed through the OpenAI API using the "gpt-4o" identifier, which potentially represented successive versions of GPT-4o during data collection. Each instance was initialized with a system message specifying the classroom scenario, the student's target behavior and its function, and the replacement behaviors being taught, along with instructions to remain in character and refrain from feedback regarding spelling or grammar. Instances were additionally initialized with a brief set of example exchanges from an unrelated instructional scenario that illustrated the required message structure and feedback format. The student instance generated target,

XSL•FO
RenderX

replacement, and nonspecified behaviors appropriate to the scenario; the assistant instance generated feedback. Prompts differed across scenarios and target behaviors but were otherwise held constant. Each produced responses based on the accumulated context of the interaction. TBPs used the same state sequences without trainee-facing prompts. The student instance recorded student and trainee messages, whereas the assistant instance additionally recorded its own feedback, providing each chatbot with the context relevant to its role. Additional information regarding system prompts appears in Multimedia Appendix 1.

The model determined the surface wording of student responses but not their occurrence, content, or order. Each state specified both the instruction presented to the trainee (eg, “Verbally tell the student to complete the problems on a worksheet”) and a constraint on the simulated student’s response (eg, “the student engages in their target behavior”), which was rendered as text. Temperature, a hyperparameter that controls randomness and creativity of generative models ranging from 0.0 to 2.0, was maintained at the default 1.0 to preserve a balance of reproducibility and flexibility in LLM responses. No seed parameter was specified, allowing minor variation in wording across sessions within a fixed lesson structure. No generation failures were observed during data collection. As in VR, trainees passed a step when their response was approved by a researcher. A depiction of the chatbot interface appears in Figure 2.

Figure 2. Depiction of interactions within the text-based chatbot simulation during training sessions in an exploratory randomized trial comparing chatbot- and virtual reality (VR)–delivered instruction in functional communication training (FCT). Trainees responded to the simulated student by typing messages in the field at the bottom of the interface. Text bracketed in asterisks denotes described actions accompanying statements.

Apparatus and Materials

A commercially available desktop, connected to 2 external monitors, was used to project the two 4-minute instructional videos. The monitor view was mirrored to the researchers’ computer, allowing them to confirm playback quality and timing. Chatbot simulations were run on a high-performance Windows laptop connected to a fast campus network, which enabled the experimenters to mirror participants’ screens in real time and verify the automated scoring routines. The laptop was connected to a portable secondary monitor and keyboard, which allowed the principal investigator to monitor trainee performance and maintain control of the chatbot during training sessions.

For the VR condition, participants interacted via standalone Meta Oculus Quest 2 head-mounted displays equipped with native motion controllers. The headsets’ inside-out tracking obviated the need for external sensors, and the built-in microphones and speakers enabled natural voice exchanges with the simulated students. After completing the VR or chatbot sequences, participants used standard Windows desktops to complete project assessments.

Personnel and Administration

The first author, a faculty member with a PhD in special education and certification as an applied behavior analyst, led all sessions. Four graduate students with backgrounds in special education and school psychology assisted with observations, with no more than one additional observer attending each session. An undergraduate student pursuing a BA in computer science provided technical assistance as needed. All sessions were conducted in English.

Data Analysis

Units of Delivery and Analysis

Simulations were delivered individually, and individual participants were the unit of random assignment.

XSL•FO
RenderX

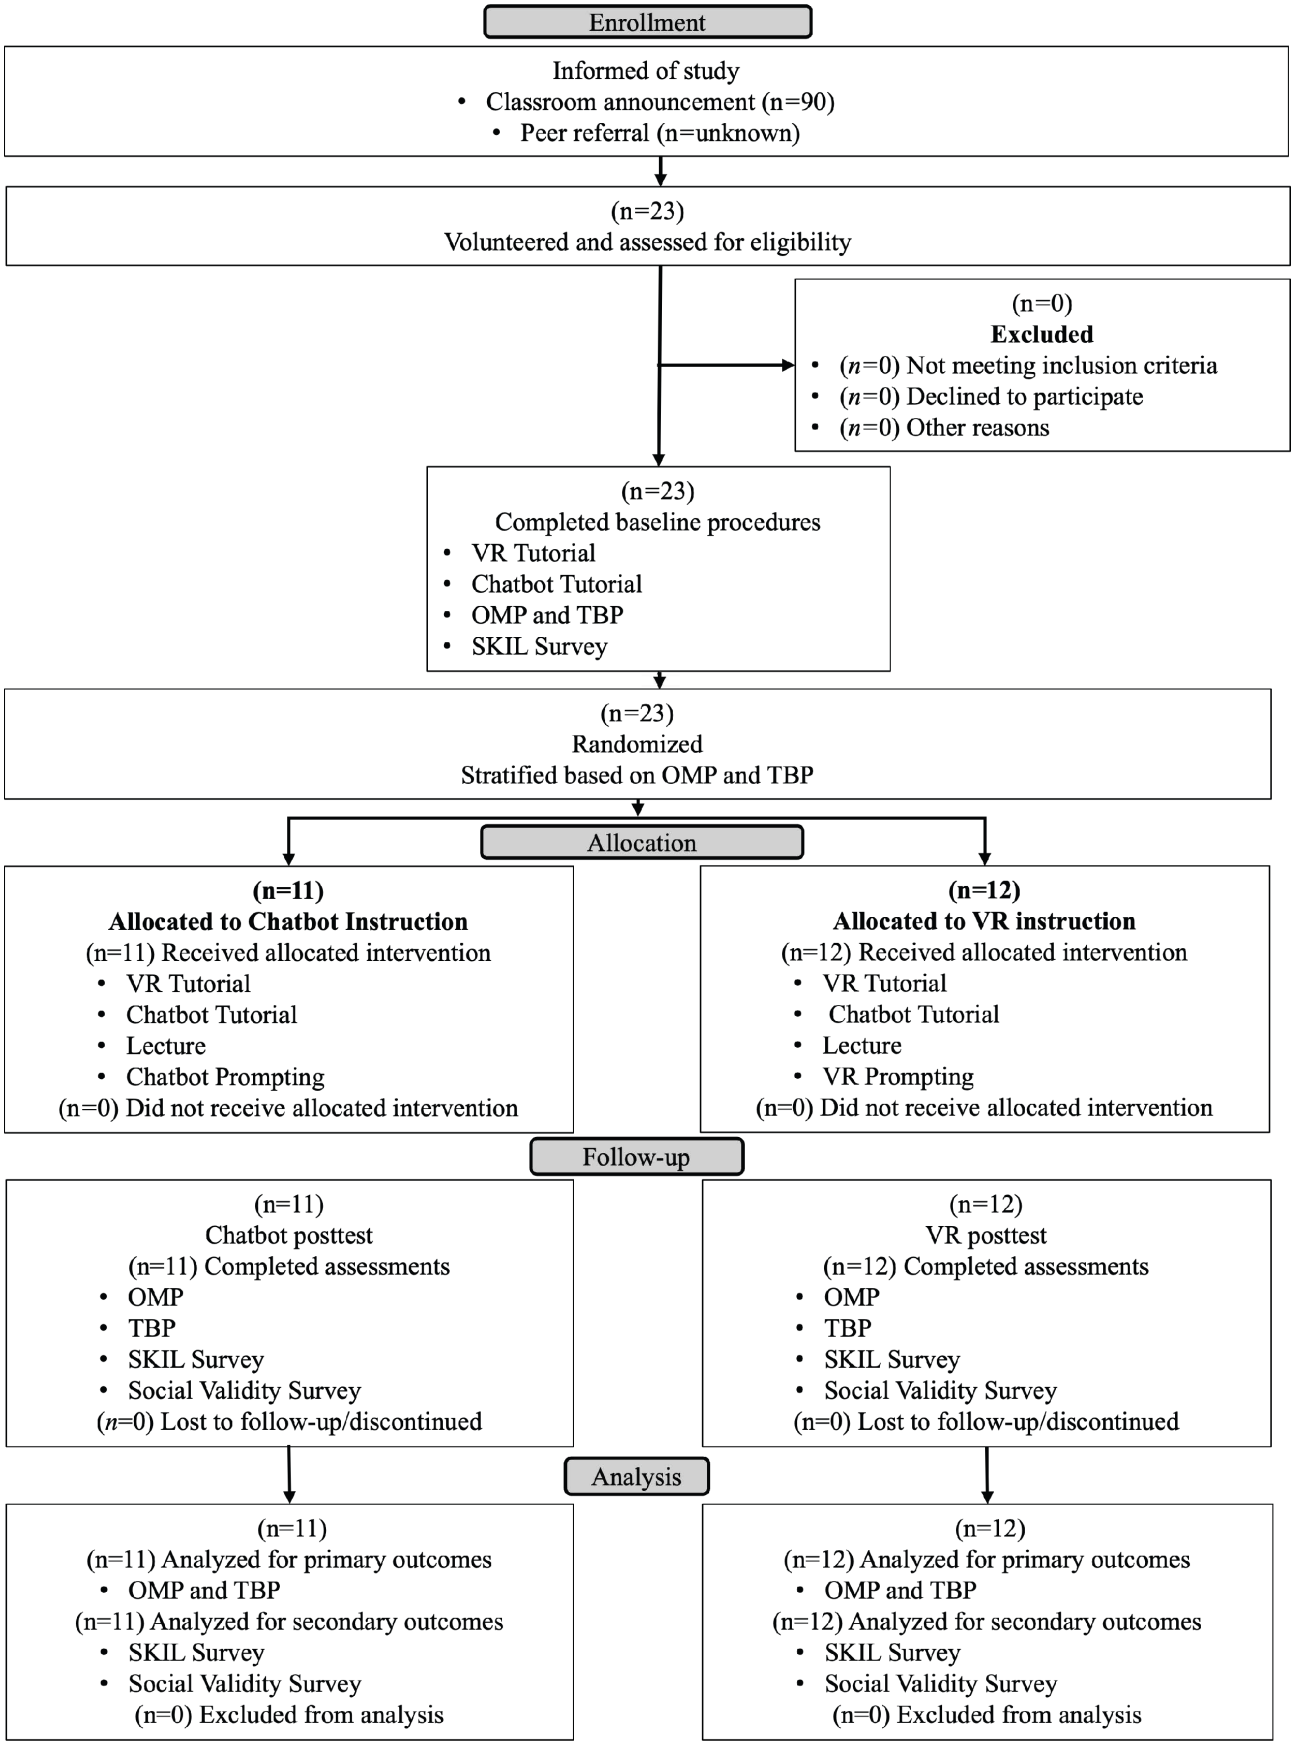
Data Diagnostics

No participants were excluded following enrollment, and no criteria for postenrollment exclusion were applied. We did not anticipate missing data given the scope and administration of the study; however, methods such as imputation would have been selected based on the mechanism responsible for data loss (eg, random, nonrandom). For example, random missingness attributed to momentary technical failure, as encountered in previous studies [19], would be addressed using multiple imputation [48]. Assumptions for the binomial generalized linear mixed model (GLMM; see the Analytic Strategy section), including tests of dispersion, residual uniformity, detection of outliers, and the distribution of random effects, were assessed using the DHARMa package [49] in *R*. Modeling of outcomes as binomial step counts (ie, steps correct out of 18) precluded the need for data transformations.

Analytic Strategy

All analyses were conducted in *R* (α=.05). FCT implementation performance was analyzed using a binomial GLMM, with a random intercept for participants who contributed repeated OMP and TBP observations in baseline and training sessions. We also modeled fixed effects of training group (chatbot or VR), time (pretest, posttest), probe modality (OMP, TBP), and their interactions. Fixed effects are reported as odds ratios (ORs) with 95% CIs. Simple effects following a significant interaction were estimated as pairwise ORs using estimated marginal means and corrected for multiple comparisons across the 2 posttest contrasts using the Holm adjustment [50]. Given limitations in the interpretation of ORs [51], average marginal effects (AMEs) representing the differences in the proportion of steps completed correctly were also calculated. We did not adjust outcomes by subgroup, and no moderator nor mediator analyses were performed. Models were fit and AMEs calculated using the lme4 [52] and marginaleffects [53] packages.

Differences in pre- and posttest SKIL Survey responses were implemented with an Aligned Rank Transform (ART) ANOVA using the ARTool [54] package. This nonparametric approach enables factorial analysis of ordinal outcomes while preserving the ability to test interaction effects in designs involving both between- and within-subjects factors. The analysis included a within-subjects factor of time (pre, post) and a between-subjects factor of intervention group (VR vs chatbot), with repeated measures nested within participant. We corrected for multiple comparisons across the 9 tests across the 3 subscales using the Holm adjustment [50]. The differences between social validity surveys administered in the final session were analyzed using the Mann-Whitney *U* test, a nonparametric alternative for comparing group differences [55].



Results

Participant Flow

Following baseline assessments, the 23 participants were randomly assigned to groups who received either the chatbot (n=11) or VR (n=12) training. No participants withdrew or switched conditions; both groups completed the OMP, TBP, and all secondary measures at follow-up without losses; and all were included in the analysis. A diagram depicting participant flow appears in Figure 3.

RenderX

Baseline Equivalence

Groups did not differ significantly on demographic characteristics (Table 1). Descriptive statistics for baseline outcomes, including mean TBP response times, appear in Table 2. Differences between VR and chatbot groups at baseline were not significant for either the OMP (OR 0.89, 95% CI 0.40 - 2.01; *P*=.78) or TBP (OR 0.80, 95% CI 0.36 - 1.76; *P*=.57).

[a]OMP: observed mastery probe.

[b]OMP scores represent percentage of steps completed correctly out of 18. OMP was discontinued if response not provided within 4 s or an incorrect response.

[c]TBP: text-based probe.

[d]TBP scores represent percentage of steps completed correctly out of 18.

[e]TBP response duration represents seconds between the simulated student's message and the trainee's submitted response. TBP was discontinued after an incorrect response exclusively to permit composition.

[f]Knowledge, confidence, and usefulness of FCT determined using 4-point scales featured on the SKIL Survey, with 1=none/very low and 4=substantial/very high [38].

[g]Social validity was assessed across acceptability, effectiveness, and ease of use using a 6-point scale, with 1=strongly disagree and 6=strongly agree.

Statistics and Analysis

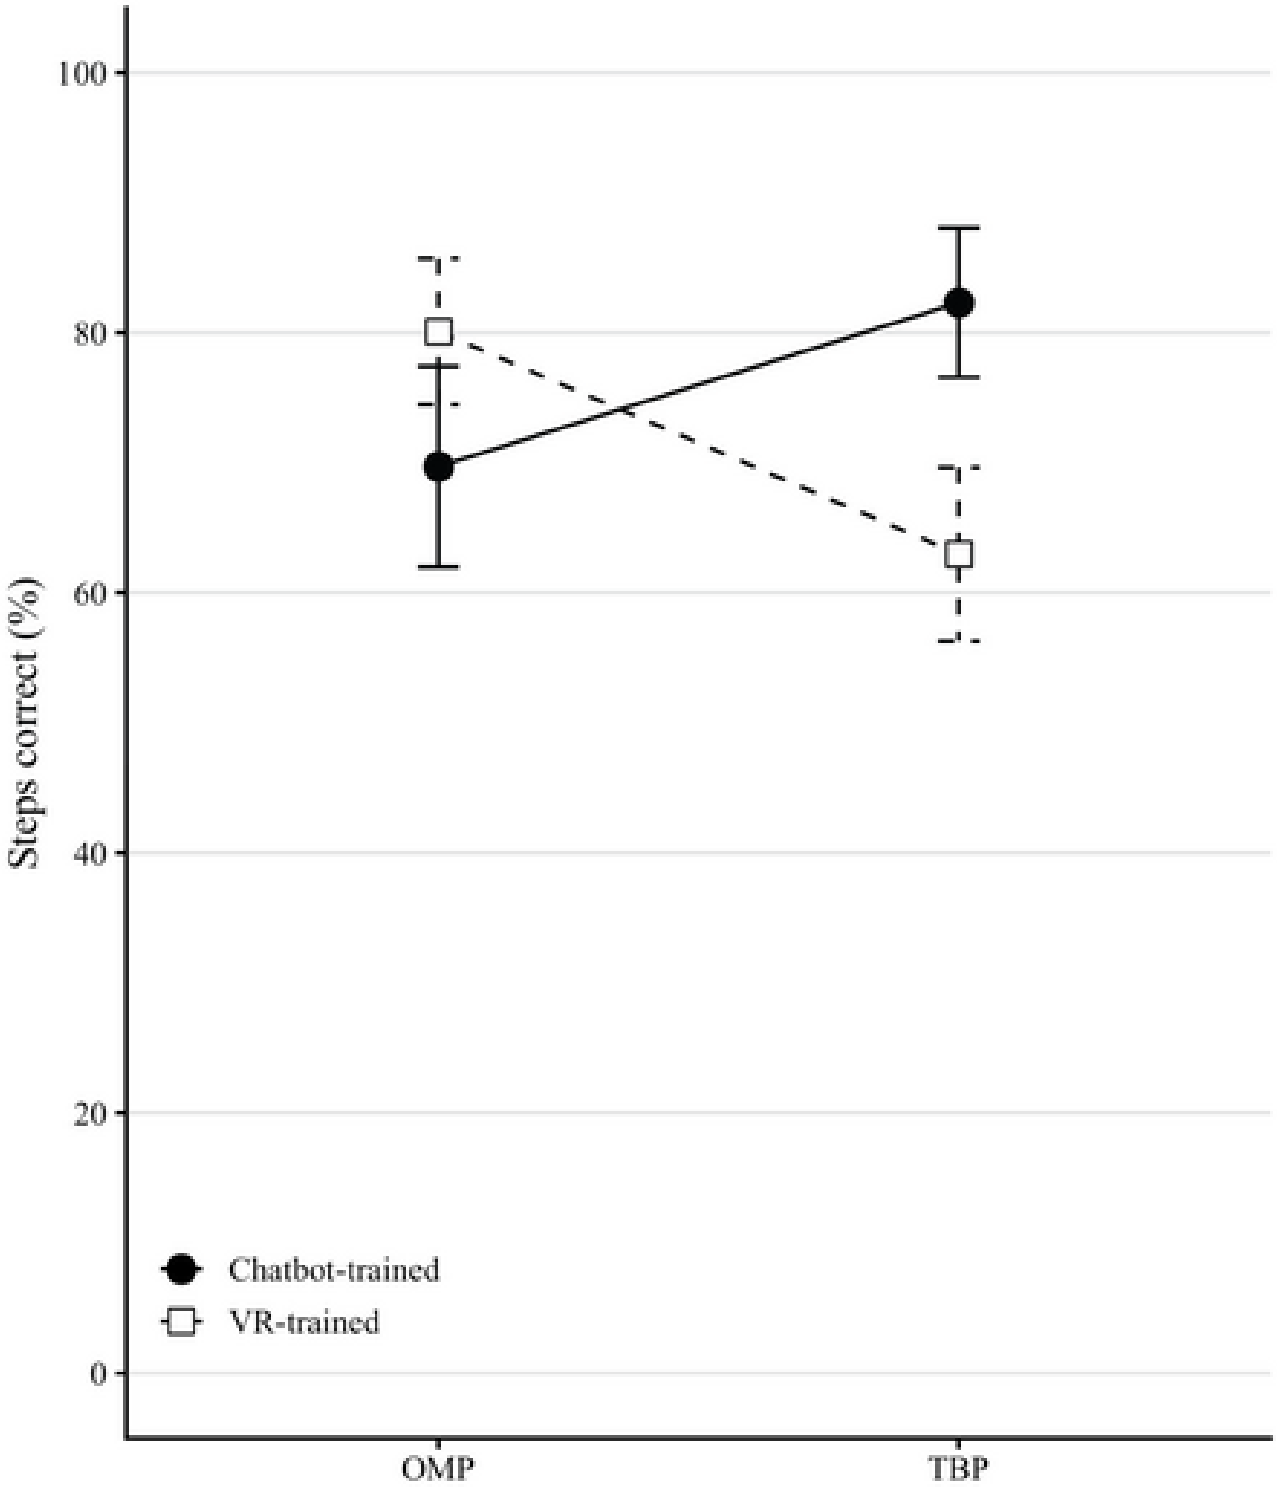
Missing Data

All participants completed all sessions and measures. No data were missing on any probe or survey.

Assumptions

Model assumptions were evaluated for the binomial GLMM using simulation-based residual diagnostics in DHARMa [49]. These indicated no evidence of overdispersion or underdispersion (dispersion ratio=1.06, P=.26) and no outliers.

XSL•FO
RenderX



Random effects approximated a normal distribution (Shapiro-Wilk P=.10). Although a residual uniformity test indicated a marginal deviation (Kolmogorov-Smirnov D=.14, P=.04) consistent with bounded, discrete outcomes [49], the absence of dispersion or outliers suggested no substantial violation of model assumptions under binomial models.

OMP and TBP Assessments

Descriptive statistics for measures across groups appear in Table 2. A main effect of time (OR 36.09, 95% CI 20.75 - 62.75; P<.001) indicated significant learning gains for both groups. The 3-way time × probe modality × training group interaction was also significant (OR 6.10, 95% CI 2.08 - 17.86; P<.001), indicating that the pattern of transfer from pre to post differed by training and probe type. Following the Holm adjustment [50], the chatbot group significantly outperformed the VR group on the TBP (OR 4.14, 95% CI 1.20 - 14.24; P=.049), completing, on average, approximately 22% more of the steps in the FCT procedure (AME 0.22, 95% CI 0.04 - 0.41). On the OMP, differences between groups were not significant (OR 0.61, 95% CI 0.18 - 2.07; AME –0.08, 95% CI –0.27 to 0.11; P=.43). This pattern of performance appears in Figure 4.

XSL•FO
RenderX

Figure 4. Mean percentage of functional communication training (FCT) steps performed correctly at posttest, by training group and probe modality, in an exploratory randomized trial of chatbot- and virtual reality (VR)–delivered preparation in FCT. On the observed mastery probe (OMP), administered in VR, the 2 groups did not differ significantly; on the text-based probe (TBP), chatbot-trained participants outperformed VR-trained participants. Error bars represent ±1 SE.

SKIL Survey

Following the Holm adjustment [50], the ART ANOVA revealed a significant main effect of time for knowledge ($F_{1,21}$=26.92, P<.001). There was no significant main effect of intervention ($F_{1,21}$=2.74, P=.68) nor a significant interaction ($F_{1,21}$=0.04, P>.99). For self-reported confidence, there was a significant main effect of time ($F_{1,21}$=36.80, P<.001). Neither the main effect of intervention ($F_{1,21}$=1.58, P>.99) nor the interaction ($F_{1,21}$=1.24, P>.99) reached significance. For perceived usefulness, there was a significant main effect of time ($F_{1,21}$=24.11, P<.001). The main effect of intervention ($F_{1,21}$=0.03, P>.99) and the interaction ($F_{1,21}$=0.03, P>.99) were not significant.

XSL•FO
RenderX

Fidelity

Checklists corresponding with appropriate steps for each session were created prior to the beginning of the project and used to assess protocols across all sessions. Specific steps pertained to the use of correct instructions, administration of required assessments, and management of the simulation. All observers were trained by the first author to assess the procedural fidelity prior to the project. Fidelity observers were required to reach the mastery criterion (>90% agreement with the first author) before coding independently. Fidelity observers were required to observe the first author administer 3 sessions and administer a session in the presence of the first author before administering sessions independently. Administrators consulted fidelity checklists during sessions. The research team collected fidelity in baseline (13/23, 57%), VR training (5/12, 42%), and chatbot training (3/11, 27%) sessions. Fidelity was calculated by dividing the number of items on the observation checklist correctly performed by the session administrator by the total number of checklist items. Mean fidelity was 99.70% (SD 1.07%; range 96.15% - 100%) in baseline sessions. Mean fidelity for both VR training and chatbot training sessions was 100%.

Social Validity

Participants rated the intervention favorably across all domains (Table 2). Mann-Whitney *U* tests indicated no significant differences between the chatbot and VR groups on any domain (U=55.50 - 62.50, all P>.05). On the social validity survey, 10 participants (10/23, 44%) left open - ended comments. Representative comments, though not formally analyzed, illustrate participant impressions of the training. Several participants noted positive impressions of the VR sessions (eg, “VR session [was] more helpful than chatbot”) but also offered constructive feedback on its mechanics and design (eg, “Eyes in the VR creep me out,” “I had some issues getting the VR system to detect my voice”). A chatbot participant noted that “It was difficult to tell which parts of the screen I should be looking at, or when I needed to try again.” Others praised the video training components (eg, “I liked the diagrams and the video summary”), although some felt the videos were overly dense. One participant expressed reservations about the behavioral strategies, and another felt uneasy rushing through the practice sessions. Despite these concerns, several participants described the project as interesting or beneficial (eg, “This was wild”).

Adverse Effects

No adverse effects were observed or reported in either condition.

Discussion

Principal Findings

This exploratory study compared the effectiveness of 2 aligned multicomponent training packages featuring either VR or chatbot simulations for teaching steps in FCT. Our first question pertained to the improvement participants in each condition exhibited across the OMP and TBP. Although participant performance improved following both training packages, results suggest the pattern of transfer differed by training condition. Whereas participants who trained in the chatbot simulation outperformed VR-trained participants on the TBP, there was no significant difference between the 2 groups on the OMP—yielding a significant 3-way interaction. Notwithstanding the limited power of this study, these findings indicate that the chatbot group’s learning was maintained across both text-based and physical assessments. Our second question pertained to changes in participants’ self-perceived knowledge, confidence, or intervention utility. Across groups, no differences were identified. Participants reported that both modalities were generally acceptable and easy to use. Findings provide tentative support for the use of chatbot training for skills involving speech and movement while underscoring the importance of considering the alignment of training and assessment modality in training evaluation.

This study differs from earlier scholarship concerning VR simulations and chatbots. Few studies have compared immersive simulations with comparison conditions aligned in terms of content and instructional methods [20,21]. The disparity between control conditions in VR studies—which frequently consist of didactic instruction—and immersive learning conditions has previously been justified by the absence of scalable methods of role-play and other activities facilitated through VR [19,57]. That even the modest comparative advantages associated with immersive VR instruction [58] did not materialize in this study is therefore notable given the large advantages of VR simulations identified in our previous scholarship [19]. This likely reflects the nature of the comparison: VR previously outperformed didactic instruction because the latter lacks opportunities for rehearsal, whereas the chatbot condition provided aligned rehearsal of the same procedure.

Previous chatbot instructional literature generally does not pertain to acquisition of procedural skills such as the use of FCT [23]. The within-subject effects demonstrated here suggest that chatbots may be a viable format for procedural rehearsal. As both VR and the chatbot were embedded within the same instructional approach [18], the 2 technologies should be viewed as supplemental to effective instruction rather than the active ingredient [19,20]. The apparent asymmetry in transfer effects between the two modalities, or the extent to which chatbot-trained participants’ performance on OMP did not differ significantly from that of the VR group while outperforming them on the TBP, represents a potential advantage of the chatbot medium that merits closer consideration.

Our findings, which support an advantage of chatbot training for text-based assessment and nonsignificant differences on a VR-based assessment when compared with a group trained using VR, must be interpreted cautiously given the small sample. Leaving this aside, there are additional explanations of the asymmetry in transfer effects. The tutorial included many of the motions needed in the OMP (eg, manipulating objects, grabbing the avatar’s hands). Combined with their text-based training of FCT procedures, this motor experience may have assisted OMP performance. As both groups completed identical VR and chatbot tutorials, their effects were likely constant across conditions. Neither group performed more than a few steps correctly on baseline probes completed after the VR and chatbot tutorials. Results of prior studies similarly suggest the tutorial,

XSL•FO
RenderX

in the absence of rehearsal, was not equivalent to the VR training condition [18], even when accompanied by a video explaining the FCT procedure [19]. Given that the tutorial, on its own, was insufficient to produce comparable gains, the chatbot group's OMP performance in this study is better attributed to the combination of tutorial exposure and text-based FCT rehearsal than to incidental motor practice. The possibility that motor practice divorced from knowledge of the goal—such as the VR tutorial—may support future goal-directed performance has been considered, and rejected, in theoretical work (see [59]). This phenomenon also did not emerge in our previous work [19]. Regardless, tutorials are necessary to separate the challenges of engaging with new technology from effective training [46]. Acclimating learners to any supplemental technology is a critical aspect of equity in service delivery [60]. The extent to which preparing learners for a novel instructional format (ie, VR) unavoidably overlaps with the content is worth considering in future simulation research.

The asymmetry in transfer may also reflect the relative familiarity of the learning channel or the combination of learners' sensory engagement with content (eg, reading, hearing) and the requirements of any subsequent response (eg, act, write; [61]). These transfer relations do not emerge uniformly and develop as a result of an individual's instructional history [29-31]. For the chatbot group, transferring skills to the OMP meant generalizing steps acquired through reading and typing (ie, read/type) to a format in which the observation of simulated events—previously rendered in textual terms during the chatbot training—occasioned specific statements or actions (ie, see/say, see/do). This form of transfer is consistent with typical instructional practices [31]. In contrast, VR participants learned to speak or act in response to simulated events and were required by the TBP to read descriptions of events then type a description of the appropriate action. Translating action into description represents a channel most learners have little occasion to develop [31]. In terms of cognitive load, an unfamiliar channel requires learners to allocate resources to deciphering the stimulus–response relation rather than the task itself [35]. Conceptualizing the alignment between instructional and assessment channels in these terms may help developers streamline the demands that instruction and assessment place on learners.

Although responses on the SKIL survey did not differ across conditions, participant perceptions of their knowledge and confidence, as well as the utility of FCT, improved following training. Apart from the asymmetry in skill transfer across modalities, these findings are consistent with the observed improvement in performance and previous research (eg, [18]). Given the dissociation between participant perception and performance, we recommend future work in this area incorporate multiple outcomes [62]. Social validity measures indicated that several aspects of VR (eg, grasping virtual objects via controllers) and the chatbot (eg, orientation of feedback) presented challenges for students. Although technological advances—such as controller-free VR interfaces—may address some of these challenges, an emphasis on user experiences across modalities and diverse user populations is warranted [46].

A discussion of AI-enhanced instructional simulations would be remiss without reference to ethical concerns, including privacy [63] and effective treatment [46]. Reserving technologically advanced, yet functionally inferior, methods for underserved areas could perpetuate poor outcomes for certain groups [64]. Future research must focus on efficacy and the equitability of underlying assessment [46]. Automated systems (eg, speech recognition) typically score performance against local criteria [19]. Standardized procedures for establishing the validity of automated assessment would permit meaningful comparisons across studies and increase the generality of findings [65].

Limitations

This study has several limitations. The small sample in this underpowered exploratory study reduced our ability to detect small to moderate effects. Thus, the absence of significant effects between VR and chatbot groups on the OMP may be a statistical artifact rather than an indication of the equivalence of the two formats. Significant effects were estimated with wide confidence intervals that warrant replication. Future studies should analyze multiple factors in the context of adequately powered comparisons of modally distinct but fundamentally aligned instruction [66]. Observers responsible for scoring probes were aware of participant training conditions, which introduces a risk of expectancy bias. Additionally, the sample consisted of a relatively homogeneous group of college students, some of whom studied topics with little relation to FCT. Future studies should incorporate broader and more diverse participant samples, including in-service professionals and individuals from varied educational or clinical settings, as well as those from culturally and linguistically diverse backgrounds whose experience or attitudes toward technology may differentially affect results.

Although probes were functionally aligned, there were differences in procedures. The most salient of these is the lack of a time-based discontinuation rule for the TBP. This difference was a property of the probe rather than training group: All participants, regardless of group, completed both the OMP and TBP. The advantage of chatbot training on the TBP cannot be attributed to the timing asymmetry exclusively, as both groups completed the probe under identical conditions. Mean response time on the posttest TBP (Table 2), which indicated that the VR group took more time to complete responses despite their lower scores, suggests the VR group did not benefit from the absence of the time constraint on the TBP. The chatbot training sessions, including assessments and tutorials, were approximately 10 minutes longer than the VR sessions. This may have resulted in a difference in engagement time, yet this does not appear to have led the chatbot group to outperform the VR group on both probes. Research interested in standalone measures of performance should align administration parameters to the greatest extent possible and validate the results against applied performance. This study did not evaluate in vivo generalization. Future research should examine how skills acquired through VR or chatbot interactions transfer to naturalistic or live settings, such as classrooms, community-based environments, or homes.

XSL•FO
RenderX

Future Directions

This study compared the effectiveness of two emerging approaches to procedural training. Results are tentative and may be attributed to methodological factors. Future work might also manipulate the alignment between training and assessment channels directly, testing whether the transfer asymmetry observed here reflects the relative familiarity of the response channels each modality requires. The extent to which aligned instruction produces differential outcomes across specific training modalities such as high-fidelity or virtual simulations [66]—and efforts to facilitate the development and alignment of evaluation platforms—represents an important area for further study [21]. A related area concerns the use of technologies such as AI-augmented VR and chatbots within more authentic contexts (eg, coursework), as opposed to isolated simulations [67]. At minimum, the study provides support for the use of chatbots in the acquisition of procedural skills, which may serve to support ongoing work examining the incorporation of chatbots into various instructional settings as well as their interplay with other technology platforms [68].

The ultimate utility of instructional simulations is determined by the extent to which they influence practice. The same features that necessitate automated simulations for skills such as FCT—risk for injury and fluidity of clinical situations [13,19]—also impede efforts to evaluate effects of instruction on professional practice and client outcomes. Validating the instructional model on lower-risk skills amenable to this approach may be warranted.

Conclusions

This study—to our best knowledge, the first comparison of aligned chatbot- and VR-based FCT training simulations—suggests that multicomponent trainings featuring either chatbot- or VR-delivered rehearsal improved participants' acquisition of a complex educational procedure, with similar improvements in participant knowledge, confidence, and perceived usefulness. Whereas many studies compare VR to didactic instruction or assess performance within a single modality, this study compared VR with a chatbot capable of providing comparable opportunities for rehearsal. Findings contribute to the field by supporting the viability of chatbots for procedural training and by increasing the salience of alignment between modalities emphasized in training and assessment. Positive findings for chatbots are particularly encouraging given the potentially lower costs of development and deployment relative to VR, which could increase access to effective practices in behavior intervention and related fields. Additional work with larger samples is needed to confirm the observed transfer asymmetry and to examine the effects of these approaches on practitioners in applied settings.

Acknowledgments

We thank our colleagues at the University of Iowa's Colleges of Education and Engineering for their support of this project. We also thank Dr. Derek Rodgers for his assistance with the statistical analysis.

Generative artificial intelligence was not used in the preparation of this manuscript.

Funding

This study was supported by research grants from the Office of Teaching, Learning, and Technology at the University of Iowa.

Data Availability

The datasets generated and analyzed during this study are not publicly available, as they contain open-ended responses and demographic characteristics potentially identifiable from a small sample (n=23). Additionally, public release was not covered by the consent obtained under the study's ethics approval. Deidentified data may be made available from the corresponding author upon reasonable request, subject to approval from the first author's institutional review board.

Abstract

Background: Exergaming can promote adolescent health by encouraging repetition of game-related tasks, potentially contributing to academic success by developing motor and cognitive skills. Studies have highlighted the influence of exergaming on motor skill learning but have not clarified its effects on general motor coordination. Other studies suggest that exergames may influence math success, particularly with nonmathematical, dance-based exergames, possibly through mental rotation or general motor coordination training. However, the influence of a single exergaming sequence on these abilities and on math achievement in the same participants has not been studied.

Objective: This study aimed to determine whether nonmathematical dance-based exergaming (DEx) improves mental rotation, general motor coordination, and math achievement in adolescent students.

Methods: An experimental group (EG: 15 girls and 15 boys; mean age 14.0, SD 0.7 years) and a control group (CG: 14 boys and 12 girls; mean age 14.2, SD 0.9 years), with no contraindications to physical activity or special educational needs, participated in this nonrandomized controlled study. EG performed DEx involving varied locomotion and interlimb coordination, while CG performed precision ball-throwing exergaming (TEx), requiring catching and throwing. Only DEx involved mental rotation; neither of the two involved mathematical content. Both consisted of 5 weekly 45-minute sessions, implemented using the Lü platform. A pretest-posttest design compared effects on (1) a mental rotation test, (2) locomotion and sprint tests, and (3) quantity comparison plus simple and complex addition and multiplication tests. Each session led to noninstrumented observation, and sessions 3 and 5 included instrumented tracking of physical activity and situational interest.

Results: Monitoring of the sequences highlighted a significant between-group difference in triggered situational interest in session 5 (multivariate analysis of variance: $F_{1,54}$=9.15; P=.004; η_p^2=0.14). This variable was added as a covariate in the analyses of covariance (ANCOVAs), with generalized linear model approach performed further. ANCOVA results showed an advantage for EG over CG in terms of mental rotation ($F_{1,52}$=6.17; P=.02; η_p^2=0.11), number of correct simple additions ($F_{1,52}$=8.26; P=.006; η_p^2=0.14), and error rate in complex addition ($F_{1,52}$=8.40; P=.005; η_p^2=0.14). No other significant results were found.

Conclusions: This study helps clarify the previously unexplored influence of the same exergaming sequence on mental rotation and math skills by showing the positive influence of DEx on mental rotation and only on calculations involving mental rotation, according to the literature. Further research on exergaming is needed to clarify whether such improvement in calculation is linked to mental rotation training itself and might be amplified by the development of general motor coordination. However, the study encourages consideration of integrating exergames into active learning approaches in schools.

Introduction

Problem

The digital revolution belongs to a new techno-economic paradigm that has led to the development of a gaming sector with a commercial and entertainment aim [1]. Since the 1970s, this has led to the creation of different genres of video games played using an audiovisual device to interact with a virtual environment under defined rules, conditions, and complexity levels [2]. Such games became part of popular culture, and researchers gradually saw them as potentially useful for academic learning [3]. Studies reported positive effects of practicing entertainment video games on cognitive functions and abilities that promote school achievement [4,5]. The literature also emphasized that video games that embed a pedagogical aim, thus considered serious games, proved useful for sustaining learning activity over time and promoting learning success [6]. Moreover, manufacturers have developed *active* video games, also known as exergames, for entertainment and educational purposes. Although sharing characteristics with conventional video games, exergames require locomotion and movements of bodily segments, not limited to the use of keyboards, joysticks, or other portable controllers [7]. These video games are thus likely to encourage physical activity, and as a result, to have a significant influence on health but also school achievement [8], which remains to be further examined.

Review of Relevant Scholarship

From the outset, authors have argued that exergames may influence health by favoring physical training and a positive attitude toward physical activity [9]. Consistently, studies showed that exergaming generally elicits, at least in the short term, positive emotions [10-12] and well-being [13,14] in children and adolescents. Other studies showed that the eventual decline over time in the appeal of a given exergame [15] can be avoided by specific practice modalities [10]. Furthermore, the literature reported that such influence on interest may favor energy expenditure [16]. Accordingly, studies found that exergaming may reduce perceived exertion [17], promote intense efforts [18], and have a positive impact on physical fitness [19,20]. On the other hand, the attractiveness of practicing an exergame might favor the repetition of the tasks to be performed when exergaming, thus learning these tasks, as authors have long considered repetition to be a key element of learning [21,22].

Most studies examined the possible influence of exergaming on motor learning outside the school context, and especially fundamental motor skills learning. These encompass “balance/stability skills” (eg, 1-foot balance), “object control skills” (eg, throwing), and “locomotor skills” (eg, jumping), rooted in physical fitness (eg, coordination), and form a basis for learning and performing different types of physical activity [23-25]. Mastery of these motor skills is thus likely to encourage long-term commitment to physical activity, with all its attendant health benefits [26,27]. Interestingly, reviews and meta-analyses highlighted that exergaming may develop balance and postural stability [23,28]. A meta-analysis also found a positive influence of exergames involving actions, such as catching or kicking, on performance in a test assessing object control skills [25]. On the other hand, although a few experimental results suggested the possible influence of exergaming on locomotor skills in children and adolescents [29,30], reviews and meta-analyses found that such findings require confirmation [23]. Especially, whether exergaming might develop general motor coordination (ie, the ability to coordinate several limbs and the whole body [31] as a basis for locomotor skills [23]) remains, to our knowledge, to be clarified.

Furthermore, the influence of exergaming on school achievement has been little studied to date, although studies emphasized that active learning, which links movement and learning, may be a promising way to reduce sedentary behavior while improving academic performance [32,33]. Two recent studies reported a positive influence of practicing exergames with math content on motivation and learning in the areas involved by the exergames, which is in line with the literature on serious games [6]. One of these studies found a positive influence on motivation in math, but not on math achievement, and on physical literacy level [34]. The other study found that exergaming, based on ball throws to hit points after identifying them in a Cartesian coordinate system, increased the performance of a paper-and-pencil task of identifying points in such a coordinate system, as well as the accuracy of ball throws at a target [35]. A 2013 study also reported the influence of practicing a nonmathematical exergame, based on aerobic dance, not only on children’s performance in a 1-mile run, but also on math scores on the Utah Criterion-Referenced Test [36]. The last result thus suggests that practicing an exergame might positively influence school achievement beyond the areas that this exergame targets, which requires further investigation, as such a possibility would be of great pedagogical interest.

This result might be due to the influence of exergaming on executive functions reported in the literature [13,37], as these functions include working memory, attentional flexibility, inhibitory control, and higher-level functions such as reasoning, planning, and problem-solving [38]. However, the explanation seems insufficient, as meta-analyses found that training a cognitive function such as working memory generally leads to progress only in tasks similar to those used in the training [39,40]. Another explanation might lie in the development, thanks to exergaming, of spatial ability, that is, a component of intellectual ability [41] and a predictor of math achievement [42]. A meta-analysis found a correlation between video game skill and spatial ability, but no training influence of video game playing on spatial ability [43]. However, another meta-analysis found that spatial ability may be improved by training, with possible transfer effects [44]. Interestingly, studies found that the practice of physical activities in which the processing of spatial information is decisive (eg, wrestling [45] and dance [46]) may improve mental rotation, that is, a component of spatial ability that allows one to rotate the mental image of an

XSL•FO
RenderX

object [47,48]. Other studies showed that mental rotation training may positively influence math achievement [49]. More results suggested the existence of links among mental rotation, general motor coordination, and math achievement, particularly in arithmetic [50-52].

Hypotheses, Aim, and Objectives

The literature led us to consider that dance-based exergaming (DEx), without explicit math content, could influence mental rotation, general motor coordination, and math achievement. Our study, therefore, aimed to clarify this possible influence in adolescent students.

This study differed from previous studies that examined whether exergames based on math problems and ball-throwing may favor math achievement, physical activity, and ball-throwing accuracy [34,35]. Instead, our study focused on DEx as potentially practiced during physical education (PE) lessons, but also during school periods without formal teaching, or as part of the preparation for a school event. This aimed to examine whether such practice may favor school achievement, as suggested by a previous study that showed a positive influence of exergaming based on aerobic dance on the performance of both an endurance run and a math test [36]. Compared with this study, our study had the distinction of focusing on a dance-based exergame selected as being well-suited to train mental rotation and whose practice was organized to scaffold this training.

The main objective of this study was to determine the influence of this DEx practice on mental rotation efficiency, general motor coordination, and math achievement in an experimental group (EG). This was done by comparison with a control group (CG) involved in precision ball-throwing exergaming (TEx), using a pretest-posttest design. Students' intensity levels of physical activity during exergaming and the situational interest [53] that this practice generated in them were also measured to monitor their involvement.

Methods

Participant Characteristics

This study focused on 2 groups, EG and CG, comprising students aged 13-16 years from a regular secondary school based in Switzerland (Canton of Vaud). A total of 56 students (27 girls and 29 boys) participated in the entire study; EG consisted of 30 students (15 girls and 15 boys) with a mean age of 14.0 (SD 0.7) years, and CG consisted of 26 students (12 girls and 14 boys) with a mean age of 14.2 (SD 0.9) years.

Two qualified PE teachers, with experience in teaching (10 years) and familiarity with their school's Lü exergaming system, participated in the study (implementation of the exergaming sequences). One was the regular PE teacher for the 2 classes forming EG, and the other for the 2 classes forming CG.

Inclusion and Exclusion Criteria

We constituted the EG from 2 classes of the school where the experiment took place, and the CG from 2 other classes of this school. On this basis, the inclusion criteria were no known contraindications to physical activity and, for harmonization purposes, no known or presumed special educational needs; thus, not meeting one or more of these criteria led to the a priori exclusion from the study.

Sampling Procedures

In the enrollment stage (January 2023), 72 students were eligible to participate in the study, 37 as potential EG individuals, and 35 as potential CG individuals. These numbers were likely to decrease depending on consent to participate and then, due to a series of requirements relating to the different phases of the experiment (from February to April 2023): pretests (presence), exergaming (participation in the 5 planned exergaming sessions), and posttests (presence). Among the individuals meeting these criteria, compliance (vs noncompliance) with instructions during testing was the final selection criterion.

Sample Size, Power, and Precision

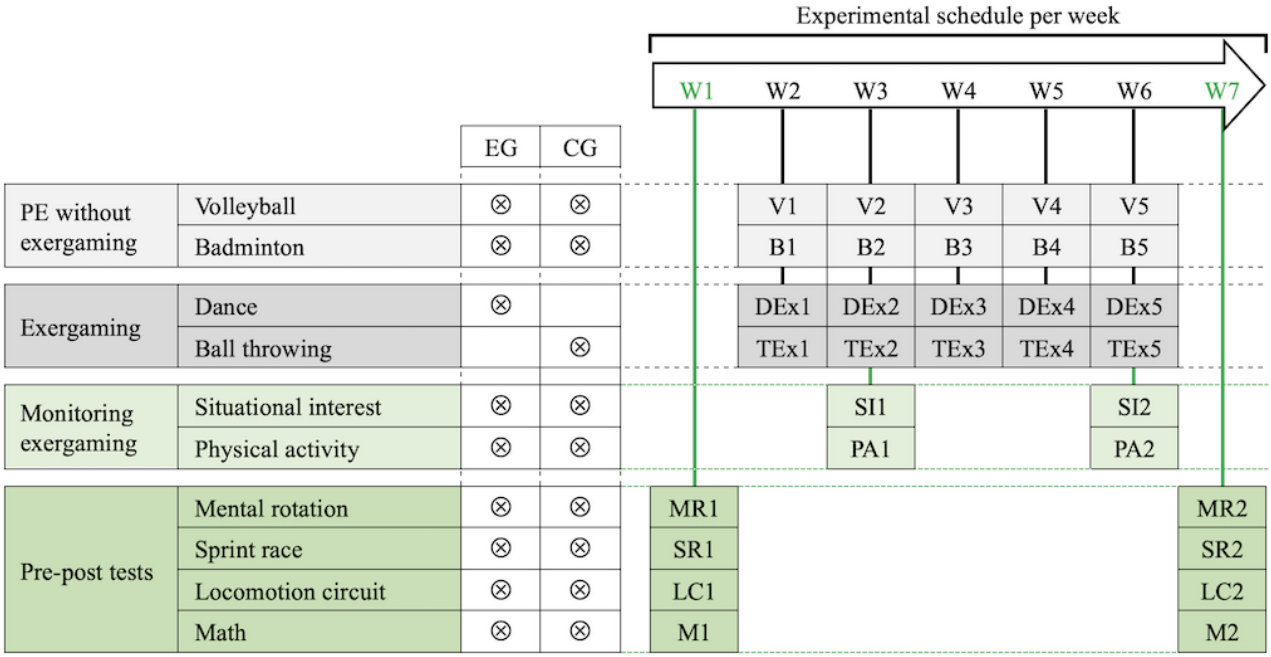
Based on preliminary data, a sample size calculation, using the *pwr* package in R software (version 4.5.2; R Foundation for Statistical Computing), indicated that 21 participants per group would be required to achieve 90% power (α=.05, effect size of 0.5) to detect differences in the primary outcomes of the study. Consequently, EG (n=30) and CG (n=26) were deemed acceptable for the study. However, it should be noted that since power calculations were performed for the primary outcomes, other outcomes may have been underpowered.

Ethical Considerations

The study was conducted in accordance with the Helsinki Declaration of 1975, as revised in 2000. In accordance with local procedure, the project for this pilot interventional study was submitted to the research coordination committee of the host university (University of Teacher Education, Lausanne, Canton of Vaud, Switzerland). This committee approved the project (RCC-pro ID 767) without requiring further submission to the Cantonal Commission for Ethics in Human Research. Subsequently, this project has been integrated into the university's research project repository.

We also obtained official authorization to implement the study in schools located in the Canton of Vaud and selected 1 secondary school for the study due to its exergaming facilities. We presented the project to the school's headteacher, who agreed to its implementation. The teachers involved in the experiment, the parents of the students, and the students completed written informed consent forms gathered prior to data collection, which gave them the option to withdraw their consent at any time. No specific compensation was provided for participation in the research. The data were anonymized and stored on a secure university computer. In addition, we have verified that no images that could identify the study participants were used in the study (including in the manuscript and multimedia appendices).

Design and Conditions



Experimental Design

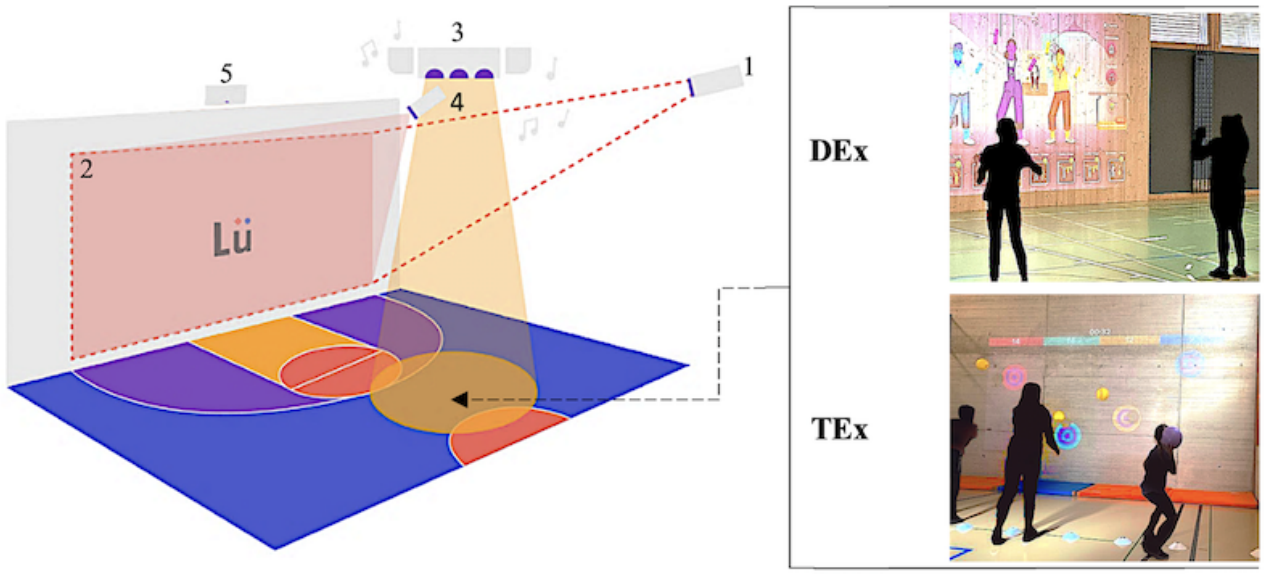
The sequences of DEx in EG and TEx in CG were implemented for 5 weeks during the regular PE timetable of the classes involved in the experiment. The participants attended 2 weekly PE lessons: one 90-minute lesson ("2-period lesson") and one 45-minute lesson ("1-period lesson"). Only the first period of

XSL•FO
RenderX

each 2-period lesson differed between EG and CG, with DEx sessions in EG and TEx sessions in CG; each of these weekly exergaming sessions lasted 45 minutes. No student declared previous experience of the exergames practiced during these sequences. Both EG and CG practiced badminton during the second period of each 2-period lesson and volleyball during each 1-period lesson (Figure 1).

Figure 1. Experimental design to study the influence of a dance-based exergaming sequence, compared with a precision ball-throwing exergaming sequence, on mental rotation, general motor coordination, and math achievement in adolescent students. B1-B5: badminton lessons 1-5; CG: control group; DEx1-DEx5: dance-based exergaming sessions 1-5; EG: experimental group; LC: locomotor circuit, performed during pretests 1 and posttests 2; M1: math tests performed during pretests; M2: math tests performed during posttests; MR1: mental rotation test performed during pretests; MR2: mental rotation test performed during posttests; PA: physical activity monitoring; PE: physical education; SI: situational interest assessments; SR1: sprint race performed during pretests; SR2: sprint race performed during posttest; TEx1-TEx5: precision ball-throwing exergaming sessions 1-5; V1-V5: volleyball lessons 1-5; W1-W7: week 1-7.

The same experimenters observed each session of DEx and TEx to check whether the teacher had implemented it as planned. Furthermore, the intensity levels of the EG and CG participants' physical activity were measured to check whether these were in line with the respective exergaming demands (Figure 1). This also allowed an estimation of the exergaming contribution to the moderate to vigorous physical activity (MVPA) recommended daily by the World Health Organization [54]. Measurements were done during sessions 3 and 5. The experimenters monitored physical activity, as in previous studies [55], during the sessions, at the end of which situational interest was assessed to control for possible differences between EG and CG likely to have influenced activity during exergaming (Figure 1). These sessions were chosen to avoid novelty bias (session 3) and allow time for possible evolution of situational interest (session 5, ie, the last of DEx and TEx), as in previous studies [35]. Instrumented monitoring of physical activity and situational interest was carried out with each EG and CG participant.



The students completed pretests during the week preceding the beginning of DEx and TEx and posttests during the week after DEx and TEx. During both pretests and posttests, EG and CG performed a mental rotation test, a sprint race, and a locomotion circuit used to assess general motor coordination, and math tests.

Exergaming System

The teachers participating in the study implemented DEx and TEx using a Lü Üno system, that is, an audiovisual infrastructure devoted to exergames practice and coming with gaming applications. In this system, the so-called "heart" module (comprising a PC with a webcam activated by remote control) is connected to an image projection module, a light and sound module, and a camera module for motion detection, for example, to detect the contact of a ball with the wall serving as a projection screen (Figure 2).

XSL•FO
RenderX

Figure 2. A diagram of the Lü Üno system used to study the influence of dance-based exergaming (DEx), compared with precision ball-throwing exergaming (TEx), on mental rotation, general motor coordination, and math achievement in adolescent students. This system consists of a single-wall configuration with (1) high-definition laser projection (5200 lumens), (2) image (6 m × 3 m), (3) multicolored LED lighting system with moving lights and sound system with dual speakers (2400 Watts), (4) movement detection camera allowing interaction with the projected images, and (5) internal computer with a webcam. The photographs show examples of practice during the experiment with Grööve and Target.

DEx in EG

During DEx, EG practiced the exergame Grööve (Figure 2) involving no overt math content. Grööve leads to the practice of various dancing steps that drawings indicate, and avatars demonstrate. Grööve also allows one to progressively learn an entire dance using different practice modalities (Figure 3). The choice of this application was in line with the local PE program ("CM32: Develop one's coordination skills and use one's own body as a means of expression and communication").

Figure 3. Using the exergame Grööve to implement a dance-based sequence and study its influence on mental rotation, general motor coordination, and math achievement in adolescent students. The screenshot shows an example of movements included in the dance learned during the experiment that were visualizable on a screen. The available options to adapt the practice difficulty to the participants are also shown; these allowed one to control the movements' speed (x1.00, x0.75, or x0.50) and/or the sound played (metronome only, metronome and music, or music only). The application also allows one to pause the video ("Pause" button) and to save the progress of the participants ("Mastered" button).

EG practiced Grööve with the explicit aim of learning a dance based on a song including 4 verses and a chorus. The EG participants had to learn the dance by observing and imitating avatars' movements (Figures 2 and 3). Sessions 1, 2, and 3 focused respectively on the first and second verses, the refrain, and the third and fourth verses, while sessions 4 and 5 were

XSL•FO
RenderX

devoted to reviewing the entire dance (Multimedia Appendix 1). During sessions 1-3, the teacher organized movement learning using part practice [56] and progressively combining the learned parts; during sessions 4-5, the participants reviewed the dance part by part and then entirely, leading to whole practice [56]. Consequently, the content of the sessions varied from one session to another, while ensuring continuity and progressivity in the learning. The teacher also used available options on Grööve (Figure 3) to allow progressive learning from lessons 1-3, as well as repetition under facilitating conditions and in final conditions during lessons 4 and 5, respectively (Multimedia Appendix 1).

Each part of the dance was largely composed of asymmetric movements that avatars showed facing the EG participants; however, the avatars were also turning, so that the EG participants were seeing them in profile (Multimedia Appendix 1). Thus, mental rotation was useful to observe and imitate the avatars' movements. However, it was possible to imitate correctly part of these movements without using mental rotation. For example, when the participants viewed an avatar from the front, arms uncrossed, they could imitate an arm elevation seen on their left by deciding, without using mental rotation, to elevate their own right arm.

Thus, to maximize the use of mental rotation, the teacher had to instruct the EG participants to imagine themselves dancing in the position of one of the avatars facing them, that is, to rotate their own body mentally to get into this position. The teacher had to give this instruction before each dancing phase, to reiterate it during learning, and when providing feedback. Each session, the teacher also had to film the dance movements of the EG participants, with the Lü camera used facing them (Figure 2). At the end of the session, the teacher had to use the videos for formative evaluation and to train the participants to analyze freeze-frames with the same instruction as when imitating an avatar (eg, to determine which arm of the viewed participant was outstretched).

TEx in CG

During TEx, exergaming in CG was based on precision ball-throwing (Figure 2), which was compliant with the local PE program ("CM32: Coordination training [...] using balls"). TEx involved no overt math content and no relevant use of mental rotation.

The teacher implemented TEx using 8 Lü applications, each leading to throwing a ball at a target, in addition to catching it and performing simple walk or run locomotion (Multimedia Appendix 2). These applications were (1) Target (throw a ball at a circular target, with the target location changing automatically as the game progresses), (2) Galactic (throw a ball at asteroids to protect a spaceship), (3) Relé (relay race with a run to reach a floor line, a ball-throw at the team zone on the screen, then a ball catch to throw it to a partner), (4) Spörts (perform basketball shots at a virtual basket), (5) Germ (throw a ball to create obstacles preventing a virus to reach own zone and allowing to direct this virus to the adverse zone), (6) Vïka (throw a ball at targets to answer questions, then propel a boat toward a village, and protect villagers from a monster), (7) Lüvia (puzzle solving: throw a ball at the correct answer displayed on the screen among other possible answers), and (8) Brüsh (throw a ball at candy before it hits an avatar's teeth, while avoiding the floss heading toward the avatar).

Throughout TEx, the common thread in terms of learning consisted of practicing precision ball-throwing. On this basis, the experimenters and the teacher involved in TEx designed the sessions to ensure a mix of continuity, variety, and progressivity in practice. Each session involved the use of 3 of the applications described above in the following chronological order: Target, Galactic, and Relé during session 1, Target, Galactic, and Spörts during session 2, Germ, Vikä, and Relé during session 3, Lüvia, Brüsh, and Spörts during session 4, and Lüvia, Spörts, and Vikä during session 5. In addition to this mix of novelty and reuse in applications from one session to another, the teacher initially had to adjust the task requirements to suit the participants' capacities, then gradually increase these requirements, using the options available for each application. For example, the participants had to play Target with targets shown in the same screen column and then scattered across the entire screen (Multimedia Appendix 2).

Volleyball and Badminton Sequences

During the experiment, EG and CG separately took part in the same weekly 45-minute badminton and volleyball lessons (Figure 1). Each lesson began with a conventional warm-up (running, stretching, and muscle strengthening), followed by tasks focused on a sport-specific technique, and then regular matches. The content of the lessons was in line with the local PE program ("CM34: Master basic sports techniques, adapt to the game situation").

Measures and Covariates, Data Collection, Quality of Measurements

Before the experiment, each sequence was tested with other students than those forming the EG and CG. This enabled the teachers involved in the study to perfect their use of the Lü Üno system, as DEx and TEx included elements (content, practice options) that they needed to explore further. This also led to adjusting the sequences for subsequent implementation.

The experimenters conducted a noninstrumented observation of each of the 5 DEx and TEx sessions implemented (Figure 1) to enable comparison between the observed session and the planned session regarding content, teacher intervention, and participant activity.

For confirmation purposes, during sessions 3 and 5 of DEx and TEx, the experimenters measured the intensity levels of physical activity achieved by each EG and CG participant (Figure 1). The examined variables were (1) the moderate and vigorous intensity levels, expressed in seconds and percentage of time activity, and (2) MVPA, expressed similarly to the moderate and vigorous intensity levels. Given the exergaming characteristics in DEx and TEx described above, we expected EG to be more involved than CG in vigorous-intensity activity, and CG more involved than EG in moderate-intensity activity, as the musical tempo in DEx was to be increased during session 3 and remain at peak in session 5, whereas no such activity peaks were planned in TEx.

XSL•FO
RenderX

Directly after sessions 3 and 5, the experimenters assessed the situational interest of each EG and CG participant to control for possible between-group differences likely to have influenced participants' activity (Figure 1). The measurement of interest, as conceived in the field of educational psychology [57], is well-suited to examine the closeness and sustainability of a person's relationship to learning depending on the content to be learned [58]. The triggered situational interest in a person depends on the present situation and personal characteristics [53]. This may lead to maintained situational interest, eventually allowing the gradual stabilization of interest. Interestingly, studies also showed that situational interest may influence physical activity intensity levels and energy expenditure during physical activity [59].

During both pretests and posttests (Figure 1), the EG and CG participants performed a mental rotation test and math tests at the beginning of 2 separate math lessons. On the days these tests were administered, no specific physical activity was performed beforehand (PE classes or otherwise) to promote harmonization of testing conditions. The participants performed a sprint race during the 1-period PE lesson (45 minutes) of the week, and a locomotion circuit during the 2-period PE lesson (90 minutes).

The experimenters also asked science and math teachers in classes of the EG and CG participants not to provide any specific training on mental rotation and the mathematical content covered in the pretests and posttests during the experiment.

Instrumentation

Monitoring Intensity Levels of Physical Activity and Situational Interest

During sessions 3 and 5 of DEx and TEx, the experimenters measured the intensity levels of physical activity (moderate, vigorous, and MVPA) achieved by each EG and CG participant using hip-worn GT3X+ accelerometers (Actigraph LLC), providing a receivable estimation of physical activity in free-living conditions [60]. The accelerometer data were processed using ActiLife6 (Actigraph LLC). This led to converting the data into activity counts that were summed and recorded using a specific time interval known as an "epoch" (selectable duration from 5 seconds to 1 minute). The selected epoch was 5 seconds, as the study was focused on acute and intermittent exercise bouts.

In this study, situational interest was assessed using the French situational interest questionnaire [61] that contains three factors: (1) triggered situational interest (participant's perception of the game demanding full attention), (2) maintained situational interest feeling (to what extent the activities were found enjoyable), and (3) maintained situational interest value (importance allocated to success during the game). To complete the questionnaire, the participants had to rate statements on a 5-point Likert scale (Multimedia Appendix 3 [53,57,58,61]); for each factor, this led to scores ranging from 1 (lowest possible score) to 5 (highest possible score).

Pretests and Posttests

The EG and CG participants completed the French version [62] of Vandenberg and Kuse's mental rotations test [63] based on a comparison of images of geometrical structures made of 10 cubes (Multimedia Appendix 4 [52,62-70]), the scores ranging from 0 to 40 points, with 40 corresponding to a perfect performance.

These participants also performed a locomotion circuit called the Harre circuit test in the literature [64] to assess general motor coordination [65], with reaction to an audible signal, a forward roll, running phases with direction changes, and phases with jumping over a bench, then crawling under it (Multimedia Appendix 4). In line with previous studies [52,66], a sprint race (20 meters) was performed separately to control for the influence of sprinting capacities on the circuit performance. The performance of the locomotion circuit and of the sprint race was timed using the same timing system (Race Link Racing System; Brower Timing Systems).

Moreover, the participants performed 2 separate paper-and-pencil series of quantity comparisons, based on a previous study [67] (Multimedia Appendix 4), that is, a series of comparisons between 2 sets of points and a series of comparisons between 2 single-digit numbers. The participants also performed 4 separate paper-and-pencil series of mental calculations, based on a previous study [68] (Multimedia Appendix 4), that is, a series of simple additions (2 single-digit numbers), complex additions (three 2-digit numbers), simple multiplication (2 single-digit numbers), and complex multiplication (a 2-digit number and a single-digit number). For each task series listed above, we considered the total number of processed items, the number of correct results, and the error rate.

Masking

The EG and CG students, as well as the teachers involved in the study, were informed of the main lines of the study but were left unaware of any expected results. DEx and TEx sessions have been designed separately, each by a group including the researchers and the PE teacher who would teach the sequence (either to EG or to CG).

Data Diagnostic, Psychometrics, and Analytic Strategy

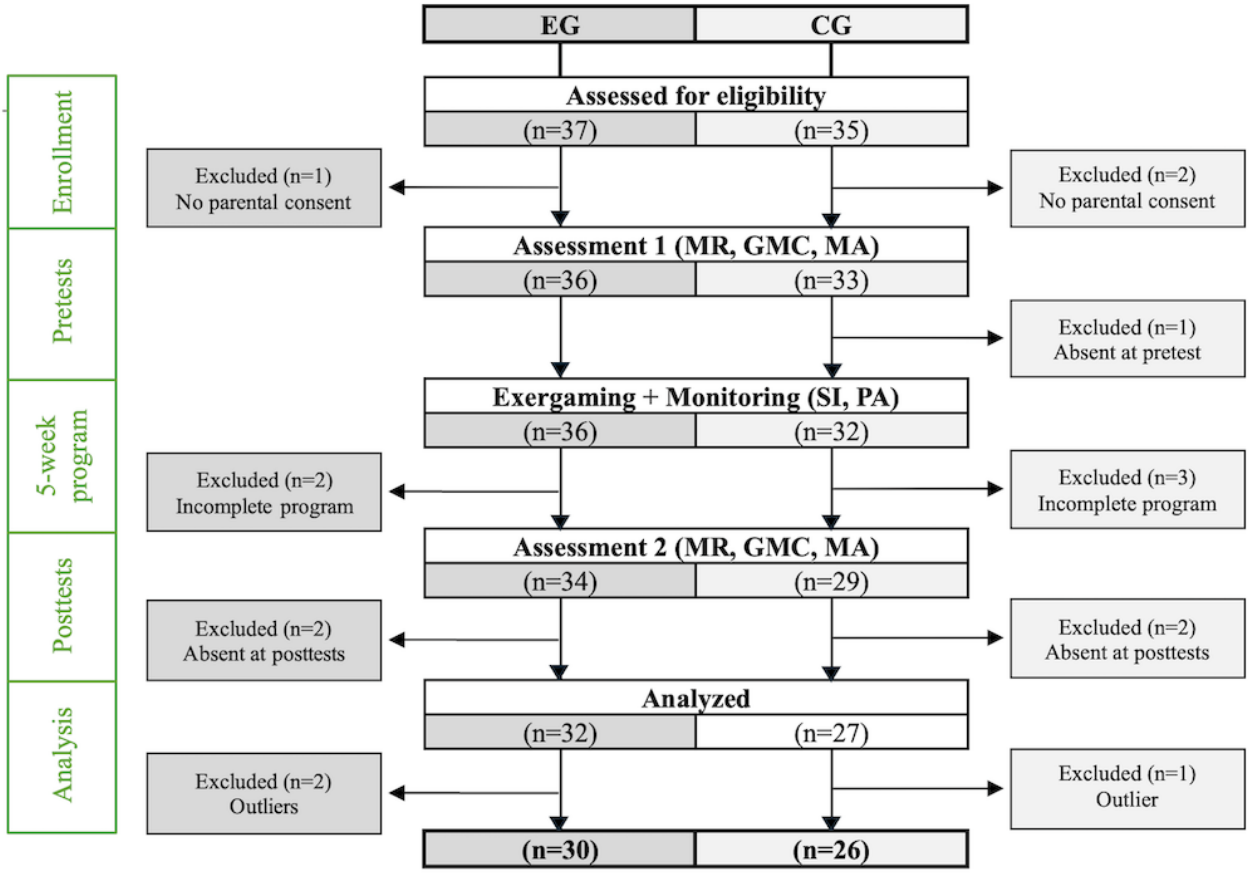
Statistical analyses were performed without missing data, due to sampling procedures (see "Sampling Procedures" subsection above) using IBM SPSS Statistics (version 30.0.0.0; 171). On this basis, the normality of the numerical variables was preliminarily checked, and the internal reliability of the situational interest scales was evaluated using Cronbach α coefficients.

Multivariate analysis of variance (MANOVA) tests were performed to compare the intensity levels of physical activity in EG and CG during sessions 3 and 5 of DEx and TEx. The scores for each intensity level considered were specified as dependent variables and the group condition (EG vs CG) as a fixed factor. Similarly, MANOVA tests were done to examine possible differences between EG and CG in scores for each of

XSL•FO
RenderX

the 3 situational interest factors measured after sessions 3 and 5.

For each variable measured at pretest and posttest, analysis of covariance (ANCOVA) tests were performed using a generalized linear model approach [71]. The model included basically the posttest score as the dependent variable, the group (EG vs CG) as a fixed factor, and the pretest score as a covariate; in the event of a between-group difference regarding a situational interest variable, it was planned to add the variable as a covariate. Beyond data normality, variance homogeneity, heteroskedasticity, and regression homogeneity were checked; on such a basis, ANCOVA was computed either on untransformed data or on ranks, using the same method for the computations [71,72].



For all the analyses, partial eta squared (η_p^2) provided an index of effect size characterizing the effect as small, medium, or large, depending on whether the value of η_p^2 was between 0.01 and 0.06, between 0.07 and 0.14, or >0.14, respectively [73]. Contrast analyses were applied in the case of significant results.

Results

Recruitment and Participant Flow

The different stages involved in forming the groups, which resulted in the selection of 30 students (15 girls and 15 boys) for EG (mean age 14.0, SD 0.7 years) and 26 students (12 girls and 14 boys) for CG (mean age 14.2, SD 0.9 years), are presented in Figure 4.

Figure 4. Study flowchart. Steps to form experimental group (EG; dance-based exergaming) and control group (CG; precision ball-throwing-based exergaming) to study the influence of dance-based exergaming, compared to precision ball-throwing exergaming, on mental rotation (MR), general motor coordination (GMC), and math achievement (MA) in adolescent students: enrollment stage (January 2023), pretest, 5-week program, and posttests (from February to April 2023). Three participants, among those having participated in all pretests, posttests, and exergaming sessions, were excluded due to failure to follow instructions during testing (random responses). PA: physical activity intensity levels; SI: situational interest.

Statistics and Data Analysis

Intensity Levels of Physical Activity and Situational Interest

The observation of each DEx and TEx session led to the conclusion that the sessions were taught as planned and that the students completed the exergaming tasks. Such observation was supplemented by the results of analyses of physical activity intensity levels and situational interest during sessions 3 and 5.

The data relating to physical activity intensity levels were normally distributed (skewness values ranging from –0.64 to 0.79, SE 0.32; kurtosis values ranging from –0.58 to 2.56, SE 0.63). For each MANOVA (Table 1), Pillai trace values ranged from $F_{3,52}$=10.44 to F3,52=63.63 (P<.001).

XSL•FO
RenderX

Table 1. Results of multivariate analysis of variance (MANOVA) tests for physical activity intensity levels. Physical activity intensity levels were monitored during sessions 3 and 5 of 2 exergaming sequences (5 weekly sessions of 45 minutes each) as part of a study of dance-based exergaming (DEx) influence on mental rotation, general motor coordination, and math achievement in adolescent students. The influence of DEx (experimental group [EG]) was compared to that of precision ball-throwing exergaming (control group [CG]).

	EG (n=30), mean (SD)	CG (n=26), mean (SD)	MANOVA tests			Contrasts
			F test (*df*)	*P* value	η_p^2

MVPA	52.8 (6.9)	51.7 (10.3)	0.17 (1, 54)	.68	0.003	N/A

[a]MVPA: moderate to vigorous physical activity.

[b]N/A: not applicable.

[c]Intensity levels of physical activity in percentage of the total physical activity time during session 3.

[d]Intensity levels of physical activity in percentage of the total physical activity time during session 5.

On average, during session 3, the EG participants spent 1180.7 (SD 173.5) seconds in MVPA, that is, 57.4% (35420/61770 seconds) of total physical activity time, and the CG participants, 1419.2 (SD 290.3) seconds, that is, 56.1% (36900/64745 seconds) of total physical activity time. During session 5, the values were 1189.3 (SD 154.1) seconds and 52.8% (34110/64765 seconds) in EG, 1311.9 (SD 291.7) seconds and 51.7% (35680/67680 seconds) in CG (Table 1).

CG had more MVPA time than EG in sessions 3 (P<.001; large effect size) and 5 (P=.05; small effect size), but no between-group difference was found when considering MVPA as a percentage of total physical activity time in sessions 3 (P=.59) and 5 (P=.68). As expected, MVPA relied on (1) significantly higher moderate-intensity values in CG than in EG, in seconds and percentage of total physical activity time during sessions 3 and 5 (P<.001; large effect sizes), and (2) higher vigorous-intensity values in EG than in CG, in seconds and percentage of total physical activity time during sessions 3 and 5, with significant differences (P<.001; medium to large effect sizes), except for values in seconds during session 3 (P=.08).

On the other hand, data on situational interest in sessions 3 and 5 were normally distributed (skewness values from –0.50 to 0.47, SE 0.32; kurtosis values from –1.19 to –0.83, SE 0.63). In addition, the Cronbach α coefficients were good for each situational interest factor measured after sessions 3 (from 0.89 to 0.92) and 5 (from 0.90 to 0.92). Results of MANOVA tests reached statistical significance for session 5 (Pillai trace with $F_{3,52}$=3.93; P=.01), but not for session 3 ($F_{3,52}$=1.09; P=.36), due to a higher score for triggered situational interest in EG than in CG (P=.004; large effect size) in session 5 (Table 2). Consequently, triggered situational interest during session 5 was added as a covariate to perform ANCOVA tests in further analyses.

Pretests, Posttests, and Exergaming Influence

ANCOVAs were performed on ranks for the total number and the number of correct comparisons of dot ensembles performed (heteroskedasticity test with $F_{1,54}$=4.88; *P*=.03 and $F_{1,54}$=4.18; *P*=.046), all data series for number comparison (kurtosis values from 2.60 to 4.90, SE 0.63), the total number of calculations in simple addition (Levene's test with $F_{1,54}$=7.94; *P*<.001), error rate in simple (kurtosis values of 3.02 and 14.82, SE 0.63) and complex (Levene's test with $F_{1,54}$=18.72; *P*<.001) additions, and in simple multiplication (kurtosis values of 3.26 and 15.50, SE 0.63). Untransformed data were used in any other case. No significant regression homogeneity issue was found (results ranging from $F_{1,50}$=0.003; *P*=.95 to $F_{1,50}$=3.05; *P*=.08).

The results showed that EG had a statistically significant advantage (medium to large effect sizes) over CG regarding the Vandenberg and Kuse mental rotations test scores (*P*=.02), the number of correct results of simple additions (*P*=.006), and the error rate in complex additions (*P*=.005). No other significant differences were found, either in terms of additions or in measurements relating to the sprint race, the locomotion circuit, quantity comparisons, or multiplications (Table 3).

Discussion

Principal Findings

This pilot interventional study aimed to verify whether DEx, involving mental rotation to perform different types of locomotion and interlimb coordination, may influence (1) mental rotation efficiency, (2) general motor coordination, and (3) math achievement (quantity comparisons, simple and complex additions, and multiplications) in an EG of adolescent students (Multimedia Appendix 6). This was done using a pretest-posttest design, including a CG involved in TEx and monitoring physical activity intensity levels and situational interest.

Noninstrumented observation suggested that the sessions proceeded as planned. This was corroborated by physical activity monitoring (Table 1), which also showed that MVPA timed values approached one-third of the daily 3600 seconds recommended for beneficial effects on adolescent health [54], that is, from 1137 (31.6%) seconds to 1372 (38.1%) seconds. The monitored amounts of moderate and vigorous physical activity were consistent with the expectations based on the planned sequences, which suggested that situational interest did not impede the physical activity required by DEx and TEx [59]. Only the scores for the triggered situational interest factor in session 5 significantly differed between groups, with a higher score in EG than in CG (large effect size), possibly due to the choice of the DEx and TEx activities and how they were perceived by the participants [58] (Table 2). ANCOVAs were performed controlling for this variable, considering the possible influence of situational interest on energy expenditure [59], thus exergaming task repetition and related learning [22].

The main ANCOVA results showed an advantage for EG after DEx over CG after TEx on mental rotation efficiency, the number of correct simple additions performed, and the error rate in complex addition (medium to large effect sizes). No other statistically significant ANCOVA results were found.

Interpretation

Exergaming Influence on Mental Rotation Test Scores

Previous meta-analysis found that spatial ability (including mental rotation) may be improved by training [44], whereas in our study, DEx in EG, but not TEx in CG, was likely to elicit mental rotation training. The advantage for EG over CG regarding mental rotation found, once DEx and TEx were completed, may thus be due to mental rotation training in EG during DEx [44]. This influence of DEx on mental rotation in adolescents is consistent with the results of previous studies showing the influence on mental rotation of exergaming based on leg movements, but in adult patients with chronic stroke [74], and of certain physical activities (eg, wrestling vs endurance running) in healthy students, but which were practiced outside the exergaming framework [45].

Furthermore, in this study, DEx influence on mental rotation was found using a test [63] with tasks and stimuli (geometrical structures to be compared to a reference) different from mental rotation training tasks and stimuli (images of avatars and humans to be related to one's own body). This supports that mental rotation training may elicit transfer to tasks and stimuli different from those used for training. Such a result, in line with those of previous studies obtained without physical activity during mental rotation training [75], contributes to fuel a long-standing and still running debate in the literature [76].

Exergaming Influence on General Motor Coordination

This study showed no significant difference regarding general motor coordination between EG and CG, once DEx and TEx were completed (Table 3). No difference was expected for sprinting, as neither DEx nor TEx trained sprinting capacities. Sprint performance times recorded in EG and CG during pretests and posttests (Table 3) showed that EG and CG had similar and stable potential to achieve the run parts of the locomotion circuit used to assess general motor coordination [52]. Thus, DEx and TEx showed similar influence on the performance of the other parts of the circuit, and the averaged performance improved by 3% (0.69/22.41 seconds) in EG and by 5% (1.22/22.42 seconds) in CG.

It remains that these variations did not lead to significant between-group differences in terms of ANCOVA results, while movement requirements differed between DEx and TEx. Considering that general motor coordination is a multidimensional construct [77], both DEx and TEx might have developed abilities influential on the performance of the locomotion circuit used for assessment. For example, DEx influence on mental rotation might have impacted this performance [52], but TEx may have developed other abilities with such an impact, particularly those related to the ability to react to a signal involved in moving to catch a ball [78]. On such a basis and considering the existing literature [23], further research remains needed to clarify whether, and under which conditions, exergaming might influence general motor coordination.

Exergaming Influence on Math Achievement

A previous study reported the positive influence of exergaming based on aerobic dance on the *global* score of a test assessing

XSL•FO
RenderX

math achievement [36]. Our results confirmed such an influence of DEx when compared with TEx. However, this influence was found to be limited to peculiar mathematical tasks (Table 3). No significant differences between EG and CG were found regarding the "number tasks" [79] of quantity comparison (ie, with numbers and quantities but without requirements in formal calculation). On the other hand, mixed results were obtained regarding the "calculation tasks" [79] (ie, requiring the application of operation rules to numbers), with (1) no significant between-group differences in multiplications, and (2) a significant advantage for EG over CG regarding the number of simple additions correctly performed and the error rate in complex additions. Calculation of simple additions was thus faster in EG than in CG, without detrimental effect on the error rate, and the error rate in complex additions was lower in EG than in CG, without detrimental effect on calculation speed.

According to the literature, this advantage for EG might be limited to tasks primarily requiring procedural strategies for calculating, rather than strategies for retrieving memorized results [80]. In support of this possibility, additions, even simple (eg, 7+5), have been found to rely on procedural strategies more than simple multiplications (eg, 7 × 5), mainly based on retrieval strategies [80]. This explanation appears plausible, though we found no differences between EG and CG in terms of complex multiplications. Such multiplications may involve a mixture of simple multiplication and addition (eg, for adding the retrieved results of 2 × 7 and of 10 × 7, when calculating 12 × 7), that is, retrieval strategies, combined with calculation procedures [81,82]. Although EG had an advantage over CG in additions (Table 3), this might have elicited a weak impact on efficacy in complex multiplications. Overall, this is also consistent with the advantage in mental rotation efficiency for EG over CG found in our study (Table 3). Indeed, studies showed that mental rotation may improve calculation efficiency by promoting appropriate access to a representation of numbers as a mental number line [83], particularly involved during addition, but not multiplication [84].

Limitations

Although our study helps to fill a gap in the literature concerning the possible influence of exergaming on academic performance, it is not without its limitations. One limitation is linked to the implementation of scientific research in a school environment. Notably, this did not allow us to allocate students randomly between EG and CG. Possible generalization of the results should also be questioned, especially as these results might depend on features of the exergaming sequences implemented, of the school of implementation, and of the students involved in the sequences. Confirmation of our results should also be sought using larger samples. Especially, in this pilot study, no formal correction for multiple comparisons was applied to the ANCOVA tests since applying strict corrections could have increased the risk of type II errors, given the sample size, the number of factors, and related outcomes [85]. Larger samples would also be needed to clarify the extent to which the selected DEx and TEx activities may modulate our results, by controlling for physical activity (eg, varying the levels of physical activity intensity in 2 or more DEx sequences, as well as in 2 or more TEx sequences), and situational interest [59]. Furthermore, larger samples would allow for proper examination of possible gender differences in the influence of exergaming on spatial abilities and math performance, ideally taking age into account [86,87]. Longer sequences than those used in this study could also be implemented for confirmation purposes [22].

Perspectives

The results of this study encourage us to clarify whether mental rotation training through exergaming may influence math achievement. These results also encourage further investigation to determine if the influence of exergaming on the performance of arithmetical tasks is limited to tasks requiring procedural strategies for calculation. This also raises the question of whether such influence might depend on age, gender, or math experience. Analysis of task repetition and participants' experience when exergaming might be useful in clarifying these points. Moreover, this study found no evidence of an effect of exergaming on general motor coordination, but a slight improvement in general motor coordination scores was observed in both exergaming sequences considered. This encourages further research to clarify the possible influence of exergaming on general motor coordination and its potential links to mental rotation training during exergaming. It would also be of interest to assess the potential added value of specific exergaming features (eg, avatar demonstration or options for managing exercise variety and progression) in achieving the effects observed in our study [88]. Teacher interventions directly linked to such features could complementarily be considered [23]. This assessment might be done by comparison with a conventional physical activity.

Conclusion

The possible benefits of exergaming in schools have been little studied to date, except in relation to promoting physical activity and health [20]. Especially, no studies have yet been conducted to determine whether a given exergaming sequence may positively influence mental rotation, general motor coordination, and math achievement. For the first time, to our knowledge, our study provides support for the possibility that the same DEx sequence without math content may have a positive influence, in the same adolescent students, on performance in a mental rotation test and in tasks of addition. The results of this study encourage complementary investigations, especially to delimit the possible influence of practicing an exergame on math achievement and determine to what extent such influence might depend on mental rotation training, and possibly motor coordination training, during this practice. However, these results suggest that it would be appropriate to integrate exergames into an active learning approach at school, to promote both PE and math outcomes.

Abstract

Background: Social engagement is critical for the developmental progress of children with autism spectrum disorder (ASD). While tangible technologies and serious games (SGs) show promise, a dual-purpose platform that both facilitates collaborative interaction and enables sensing of collaborative task engagement is required. Existing tangible interfaces often lack integrated sensing capabilities, while devices designed for complex input are typically not optimized for the sensory and interaction needs of this population.

Objective: This study aims to present InteractiSense, a tangible prototype designed to support collaborative play while enabling engagement estimation for children with ASD through embedded multimodal sensing. Our primary objectives were twofold: (1) to evaluate the prototype's preference, usability, and workload, and (2) to assess the feasibility of its embedded sensor data in generating valid inputs for preliminary machine learning (ML)-based engagement classification.

Methods: We developed InteractiSense, a spherical, soft-textured prototype embedded with 7 physio-behavioral sensors, alongside a collaborative SG promoting key social skills, and evaluated it against a familiar Xbox controller as a practical baseline. Fifteen children with ASD (mean age 11, SD 3 years; 10 males and 5 females) participated in a cross-sectional feasibility evaluation using a within-subjects mixed methods design. Preference data were analyzed using the McNemar test and Bayesian analysis, and usability and workload scores were compared using 2-tailed paired *t* tests. Qualitative caregiver interviews on InteractiSense and the SG were analyzed using thematic analysis, with device-related themes contextualizing quantitative findings during interpretation. To validate sensing feasibility, we analyzed the signal-to-noise ratio (SNR) of the sensor data and trained a preliminary extreme gradient boosting (XGBoost) model, comparing it with baseline models to classify binary engagement states using video-coded ground truths.

Results: InteractiSense showed a tendency toward higher preference and comparable usability and workload metrics relative to the Xbox controller. Caregivers associated its round shape, soft texture, and simplified configuration with favorable perceptions and noted peer collaboration during the SG and interest in home use. Signal quality varied across sensing modalities: selected modalities provided analyzable data, whereas audio quality was low and pressure data were excluded from SNR and ML analyses. XGBoost achieved 83% (CI 0.76-0.90) balanced accuracy in binary engagement classification, exceeding random and majority-class baselines.

Conclusions: These findings provide initial evidence that InteractiSense can serve as a dual-purpose platform supporting collaborative play and engagement-aware sensing within the same tangible interface. Unlike prior systems focused on either interaction support or separate monitoring, InteractiSense combines embedded multimodal sensing with a social play interface in one platform for children with ASD. This study offers a proof-of-concept for extending tangible play systems toward engagement-related sensing and inference, with implications for future therapeutic and educational tools that monitor play and support adaptive intervention. However, feasibility was shown only at a preliminary level, requiring validation in larger cohorts and over longer observation periods.

Introduction

Background

Social engagement, defined as coordinated attention toward both a social partner and a shared physical activity [1], plays an important role in supporting developmental progress in children with autism spectrum disorder (ASD), serving as a foundation for developing communication and interpersonal skills [2]. Due to delays in cognitive, motor, and social development, they are prone to boredom and disengagement, which can hinder their participation in daily and social activities [2,3]. Therefore, measuring and understanding engagement is essential for improving and managing engagement [4]. Within the peer-based gameplay context examined in this study, we focus on a narrower, context-specific construct, collaborative task engagement, defined as observable participation in a shared game task with a peer; this construct does not necessarily require direct peer-oriented attention or interaction at every moment. Accordingly, engagement-promoting technologies for children with ASD have been explored through interactive and tangible approaches [5], such as soft interactive social prototypes [6,7], wearable companions [8], and Mazi, a soft, round tangible prototype developed to encourage spontaneous and collaborative play [9]. These can be beneficial in fostering social skills by increasing engagement through spontaneous interaction [10] initiated by children. Studies have focused on leveraging tangibility with soft, textile-based approaches that are nonvulnerable, easy to handle, and particularly appealing to children with ASD, who often show a preference for physically graspable and soft materials that provide comforting tactile sensations, helping sustain active engagement [7,11,12]; yet most of these efforts have centered on enhancing engagement, with limited attention to how participation in collaborative tasks can be systematically assessed.

Measuring engagement and sustained participation can inform the assessment of social-skill development in educational or therapeutic settings for children with ASD [4]. Prior work has integrated sensors into interactive, tangible, and commercial systems, including SuperpowerGlass [13] and sensorized toys [14], and explored soft interactive companions with the potential to support social skills [8]. Sensor-integrated forms such as spheres, tori, and soft dolls with feedback have also been proposed for nonautistic children [15] and may be particularly relevant to ASD settings requiring engagement monitoring and, potentially, tailored automated support [16]. Because engagement is complex, multimodal sensing is important; however, commercial devices often constrain sensor integration, conflict with engagement-monitoring requirements, and lack adaptability to ASD-related needs such as sensory sensitivity and safe, familiar, and robust form factors [17-19]. These challenges motivate a tangible platform that combines multimodal sensing and interaction while accounting for user reception, usability, and workload. Accordingly, we developed InteractiSense as a preliminary dual-purpose prototype and evaluated it through expert interviews and a user study with caregiver postinterviews. The prototype was developed to estimate collaborative task engagement during a peer-based collaborative serious game (SG), referring specifically to participation in the shared game task rather than broader social engagement.

The goal of this study is to evaluate the feasibility of InteractiSense as a dual-purpose platform across 2 dimensions. First, interaction feasibility requires the prototype to yield usability and workload metrics comparable to, or exceeding, those of an Xbox controller, a baseline device reflecting users' long-term exposure. Second, sensing feasibility requires the embedded multimodal sensors to capture data with sufficient signal fidelity to support a preliminary machine learning (ML) model for engagement classification. To achieve this, we address the following two research questions: (1) How do children with ASD perceive and interact with InteractiSense, a tangible interface for social and collaborative gameplay, compared with an Xbox controller, in terms of preference, usability, and workload? (2) How feasible can InteractiSense be in generating sensor signals that serve as valid inputs for implementing ML models to estimate collaborative task engagement in children with ASD?

Related Works

Measuring Engagement

Engagement is a multidimensional construct encompassing mental, behavioral, and emotional components [20]. Sensor-based assessment is promising for children with ASD, who may have difficulty self-evaluating and expressing their experiences [21,22], while multimodal sensing can improve engagement prediction [4,23]. Accordingly, InteractiSense integrates diverse physio-behavioral and peripheral modalities to examine their individual use for engagement assessment.

The sensor metrics used are as follows: galvanic skin response (GSR), which measures skin conductance, detects affective and attentional states associated with engagement [24,25]. Heightened GSR serves as an indicator of increased engagement during interactions, making it a promising metric for identifying the engagement status [26]. Heart rate (HR), measured through changes in beats per minute, showed potential for detecting engagement in nonautistic students during structured writing activities [27]. Skin temperature (ST), a thermal response indicator, can also be used to assess arousal and attentional states [28,29]. Inertial measurements, comprising accelerometers and gyroscopes, quantify physical involvement and serve as an indicator of engagement by capturing behavioral patterns, activity levels, and synchronization with others [30-32]. In addition, physical involvement, such as grasping and progressing actions, is associated with engagement, as tasks and given interactions like applying pressure [12,33,34] and providing user input through buttons connect fundamental sensory and motor activity [35,36]. Therefore, pressure and button inputs were included for their high relevance in assessing engagement. Audio amplitude generated by children with ASD correlates with their engagement and attention during social activities [37,38], offering a noninvasive method for monitoring behavioral states as a measure of perceived loudness [28]. In this study, we integrated these multidimensional sensors into InteractiSense, which we propose to enable engagement estimation while supporting interactions for children with ASD.

Necessity of Novel Interacting and Sensing Prototype

Video games were among the earliest digital interventions used to entertain and encourage participation among children with ASD. Their associated console controllers have since become familiar in daily life and have been linked to behavioral regulation and reductions in stress and stereotyped behaviors [39,40]. However, familiar devices such as the Xbox controller may activate leisure-oriented associations [41], potentially constraining openness to SGs for educational, therapeutic, skill-building, or structured collaborative purposes [42,43]. Their familiar form may therefore constrain interpretive flexibility, motivating alternative interaction modalities [44,45]. Such alternatives should provide usability comparable to or better than that of console controllers [46] without imposing greater task-related demands [47], making the Xbox controller an appropriate reference interface [48].

Recent systems have combined interaction support with social engagement monitoring for children with ASD. Ward et al [32] used accelerometers to examine interpersonal synchrony in theatrical interactions, while Lanini et al [14] used a commercial wireless sensorized toy to assess ASD-related behaviors. Using a commercial toy rather than a wearable or camera-based system also offers a less invasive approach intended to improve generalizability and promote spontaneous engagement [9]. Varma et al [49] used smartphone-based gaze measures to identify social engagement during semistructured parent-child gameplay. However, these systems often rely on single modalities [14,32], limiting their ability to capture the multifaceted nature of engagement. Although multimodal sensing can improve engagement prediction [20], it remains underexplored in tangible prototypes [49]. The transitional wearable companions of Ozcan et al [8] similarly emphasize soft, interactive, and tangible designs intended to support social-skill development [11,12], child-initiated interaction, and multimodal feedback. Although tangible and spontaneous interactions can benefit peer engagement [9], systems combining them with multimodal engagement sensing remain scarce [12]. This gap motivates dual-purpose prototypes that support both interaction and sensing in SG contexts, providing a basis for future research on targeted interventions.

Methods

Research Design Overview

This study presents the development and expert-informed refinement of InteractiSense, a tangible prototype integrating interaction and multimodal sensing, together with a collaborative SG designed to support peer-based collaborative task engagement. Its feasibility was evaluated in children with ASD using a cross-sectional, within-subjects mixed methods design, in which each child completed both the InteractiSense and Xbox controller conditions with condition order alternated across pairs. Interaction feasibility was assessed through device preference, usability, and workload measures supplemented by postsession qualitative interviews, whereas sensing feasibility was assessed through sensor-signal quality analysis and preliminary ML-based engagement classification.

Ethical Considerations

This human participants study involving children with ASD was reviewed and approved by the Institutional Review Board (IRB) of the Gwangju Institute of Science and Technology (GIST; approval number HR-61-04-04, including subsequent approved amendments). The study was not exempt from ethics review, and no waiver of informed consent was used. All procedures were conducted in accordance with the IRB-approved protocol and applicable institutional ethical guidelines. The approved protocol covered the involvement of professionals from multiple disciplines and the participation of children with ASD and their legal guardians.

Prior to participation, the experimental procedures and the role of the proxy user in the usability and workload evaluations were explained to each child's parent or legal guardian. Written informed consent for each child's participation was obtained from their parent or legal guardian. In addition, parents or caregivers who participated as proxy users provided written informed consent for their voluntary participation and the use of their data for research purposes. Parents or legal guardians were informed that participation could be discontinued at any time at the request of the child, legal guardian, or therapist. The experiment commenced only after the child's willingness to participate had been confirmed.

Each participant received monetary compensation equivalent to approximately US $35, which was transferred to a designated bank account. All collected data were de-identified immediately upon collection, and each participant was assigned a unique identification code. Personally identifiable information was stored separately from the research data in a secure, password-protected database, with access restricted to the primary researcher. No individual participant or user is identifiable in any image included in the manuscript or supplementary materials.

Inclusion and Exclusion

Children were eligible to participate if they were aged between 6 and 15 years and had either a diagnosis of ASD or ASD-related characteristics identified by the special education center. Children younger than 6 years or older than 15 years were excluded to maintain a sample within the predefined developmental age range. During the initial screening, 2 children younger than 6 years and one high-school–aged student older than 15 years were excluded based on these criteria.

Participant Characteristics

Following screening, 15 eligible children were recruited from a local special education center in accordance with the IRB-approved recruitment procedures (Table 1). Participants ranged in age from 6 to 15 (mean 11, SD 3) years and included 10 males and 5 females. They represented a broad range of functional profiles, including 7 children with co-occurring intellectual disability (ID) and 2 with co-occurring attention-deficit/hyperactivity disorder (ADHD).

P15	11	11	Male	ASD + ID	L-4	G-6	15.1

[a]Standardized clinical severity levels, consistent with *Diagnostic and Statistical Manual of Mental Disorders, 5th edition* (*DSM-5*) criteria, could not be uniformly documented due to jurisdictional variations in regional disability registration policies. In lieu of official classifications, caregiver-reported severity levels were included to provide an overview of the participants' functional and behavioral status.

[b]Symptom severity was quantified through a self-report measure, where respondents indicated the degree of impairment associated with the child's specific disability type (survey question: "Please indicate the severity level of the symptoms pertaining to the child's disability category identified in the previous section.")

[c]To ensure a continuous measure of educational development, we adopted a standardized grading system ranging from G1 to G9. This corresponds to the cumulative years of schooling in South Korea, encompassing both primary (Grades 1 - 6) and secondary (Grades 1 - 3) levels.

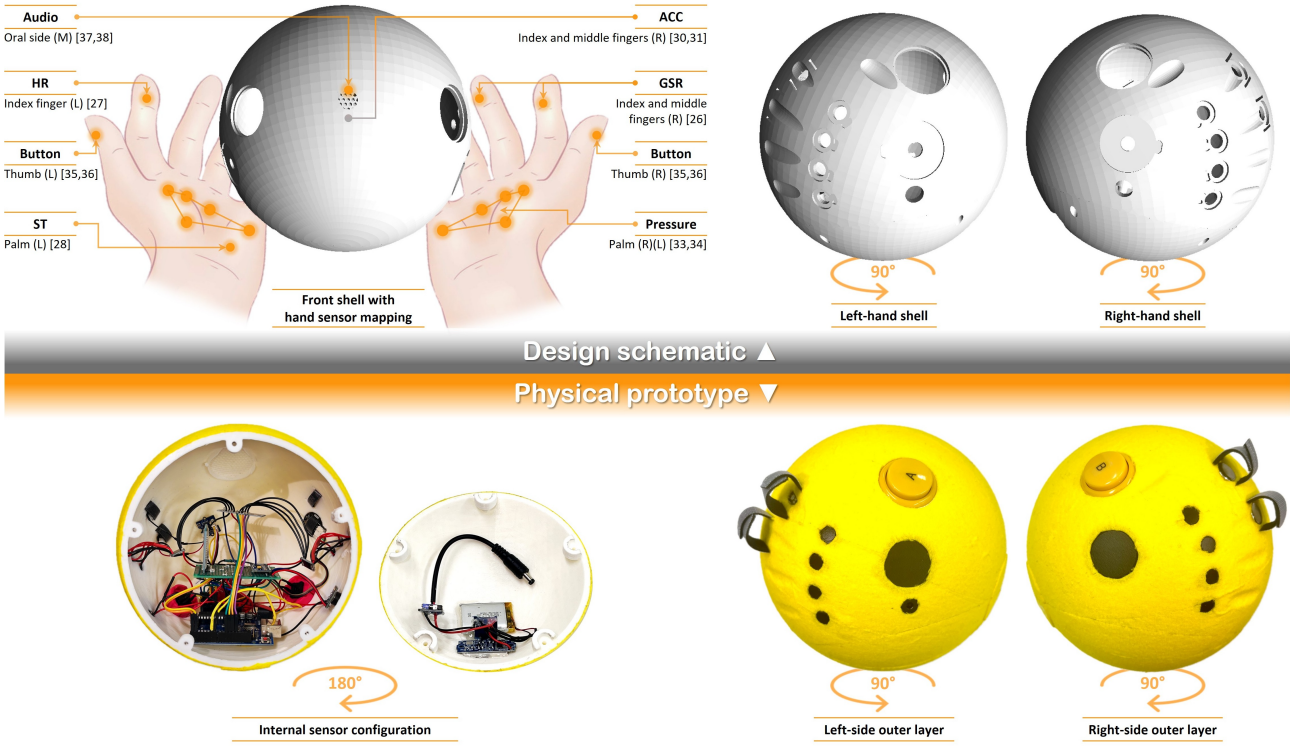
InteractiSense Design



InteractiSense Prototype

The InteractiSense adopts a spherical form, as its round and soft design minimizes the risk of injury for children with ASD during play [15]. This design also aligns with the natural communicative and collaborative mechanisms of socialization [50], providing a familiar and safe structure that fosters spontaneous interactions in both their daily life and therapeutic settings [9,51]. Our design process considered prior concepts from the TangToys workshop, soft animal-shaped dolls, a torus, a cube, and a sphere, which aimed to support communication and well-being [15]. The torus was excluded due to constraints in sensor deployment, and the cube due to concerns about edge sharpness [51]. A spherical structure was selected not only for its physical safety but also due to its capacity to accommodate various forms of interaction (eg, holding, pressing, and rotating) [9,51].

Designed with an outer diameter of 18 cm to support 2-handed manipulation for a typical 10-year-old (whose average hand length is approximately 15 cm), the body was fabricated using 3D printing to ensure precise placement and integration of 7 sensor positions (Figure 1). The 18 cm measurement refers to the overall spherical enclosure rather than the required grip span. To enhance its affordance and tactile experience, the handle of InteractiSense features finger grooves for a secure and comfortable grip, while its surface is covered with yellow-colored [51,52] and felt fabric, a soft textile and comforting color that reflects the characteristics of transitional objects (Figure 1) [53,54]. Furthermore, a hook-and-loop hand strap is attached to ensure a stable mount, promoting self-directed interaction by the child. The prototype (Multimedia Appendix 1) was also presented in an extended abstract for a public demonstration [55]. In this study, InteractiSense is evaluated more broadly through a mixed methods feasibility approach, including preliminary ML-based engagement classification.

Technical Specification

InteractiSense integrates 7 physio-behavioral sensors aimed at monitoring engagement status (Figure 1 and Multimedia Appendix 2). Sensor data are wirelessly transmitted via low-energy Bluetooth at 2.1 Mbps with a 10-meter range (≤314 m^2 circular range), ensuring real-time multimodal transmission without data loss in spacious environments. The power uses a 1200 mAh lithium polymer battery, accounting for total power consumption and supporting continuous operation (≤10 hours), allowing for use in home settings and extended interaction periods.

Collaborative and Social SG Design

The selection of game elements in "Treasure Hunters" was based on existing literature regarding evidence-based behavioral interventions for children with ASD. Clinical studies indicate that foundational social skills serve as essential precursors to social communication development [56,57]. Furthermore, research on interactive systems demonstrates that incorporating these clinical targets into collaborative gameplay mechanics effectively supports shared focus and physical peer engagement [58,59].

The SG was designed to enhance the social skills through gaming modules incorporating turn-taking, joint attention, and imitation [60]. These skills were integrated into a collaborative gameplay framework called "Treasure Hunters," developed using Unity3D, where players progress along a rail track by completing gaming modules (Figure 2). Turn-taking involves taking actions alternately with another player, such as performing an action and then waiting for the other player's turn [59,61], while joint attention emphasizes focusing on a shared goal [62,63]. Both are integrated into the timing slider game, where players defeat monsters with button (B) and mine treasures with button (A) (Figure 3), either by taking turns or working together (Figure 2A). Imitation involves following guidance, embracing each other before reaching the fall zone on the rail (Figure 2C) [61,63]. During gameplay, pairs of children played through 21 gaming modules, with each module assigned using a balanced Latin square. Between gaming modules, we incorporated a Game Refresher, a monotonous running-on-rails scene, intended to serve as a sensory break and provide cognitive rest [64]. The game ends by reporting the performance from the previous gameplay. The game featured 3 difficulty levels, with stronger-looking monsters, higher-value treasures, and reduced scores at higher levels. Considering the hypersensitivity and sensory delays of ASD [65], we prioritized simplified interactions and streamlined feedback.

For C2 (Xbox controller), only the A and B buttons, the most accessible for right-hand operation, were activated, while all other buttons were disabled to ensure consistency.

Expert-Involved Iterative Design

Expert Interview

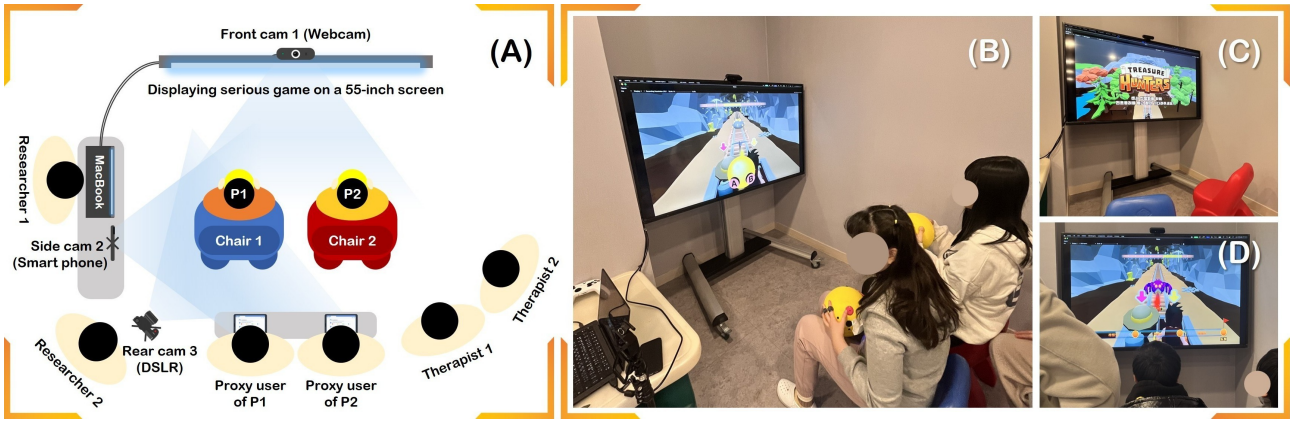
We conducted expert interviews and a pilot test for iterative design with 3 teachers who work in special school (>17-year experience). The experts were given an overview of the study and participated in a pilot test of InteractiSense and the SG, assuming a child with moderate to severe ASD. We then requested a quantitative evaluation of InteractiSense through questionnaires on workload NASA Task Load Index (NASA-TLX) [47] and System Usability Scale (SUS) [46], as well as qualitative feedback on the prototype and SG, including insights on how they were perceived and the specific contexts in which the prototype could be applied in real classroom settings.

Expert Insights and Findings

The need for enhancing the tutorial was identified by 3 experts to better support tutorial and explicit visual guidance, fostering gameplay confidence in children with ASD. We incorporated visual feedback through button-pressing animations that map the player's input interaction to each device (Figure 2 [Tutorial]). In the initial version of the game, a small spiderweb was displayed to the player waiting for the other's turn. This was later improved by enlarging the spiderweb and adding a colored arrow to indicate the player's turn. The importance of emphasizing success feedback was raised, leading to

XSL•FO
RenderX

enhancements, confetti effects, success reflections on in-game characters (embracing effects), and reinforced cheering sounds. Incidentally, experts noted that soft, ball-like objects are often used in therapeutic settings to promote gentle, tactile engagement, which informed our decision to adopt a spherical design. Quantitative evaluation revealed that experts' workload and usability scores were positioned as moderate-to-high workload (mean 57, SD 17) and excellent usability (mean 84, SD 11.8), with both showing appropriate difficulty and ease of application.



Data Collection

Data Collection Setting

Following an iterative expert review, the study involving children with ASD was conducted at the Dream Tree Children Education Center in Gwangju Metropolitan City, Republic of Korea, from January 16 to 22, 2025. The center is a community-based institution that provides educational and support services for children with special educational needs, including programs addressing basic motor function, physical fitness, and physical and psychological health. Participants with ASD were recruited from children attending the center. Recruitment began approximately 1 week before the experimental sessions. During this period, study information was posted at the center and provided to parents and caregivers of potentially eligible children. Parents and caregivers who were interested in the study were invited to indicate their willingness for their child to participate. Potential participants subsequently underwent preliminary screening for eligibility, and the final study sample was selected according to the predefined inclusion and exclusion criteria.

The experimental setup is illustrated in Figure 4. Paired children were seated side by side in front of a 55-inch display connected to an Apple MacBook Pro with an M4 Pro chip running the Unity3D-based SG. InteractiSense and the Xbox controller were connected to the MacBook Pro via Bluetooth for gameplay input, with InteractiSense additionally transmitting its embedded sensor data to the computer. Each session was recorded from front, side, and rear viewpoints using 3 cameras, providing complementary views for subsequent behavioral coding and review.

Figure 4. Experimental setting for the InteractiSense evaluation. (A) Schematic floor plan detailing the spatial arrangement of the screen, device, participants (children with autism spectrum disorder, therapists, proxy users, and experimenters) and video-recording cameras (eg, a webcam, an iPhone 12 mini smartphone, and a digital single-lens reflex camera). (B) Side view of the tutorial session, illustrating participants familiarizing themselves with the InteractiSense device and the serious game. (C) Unoccupied physical setting of the main screen and the children's seating area. (D) Observation view from the perspective of proxy users and therapists monitoring the children during a collaborative task. DSLR: digital single-lens reflex camera.

Sampling Procedures

Accompanying parents participated as proxy respondents to provide assessments on behalf of children with ASD, or, when parents were unavailable, caregivers attended in their place [21,22]. They were informed about the experiment and completed consent and demographic forms, while a tutorial was conducted to familiarize participants with the experiment (Figure 3). Paired children were assigned 2 conditions (C1: InteractiSense, C2: Xbox controller) that alternated the order for each pair, following a within-subjects design. Given its widespread familiarity and established role in gaming, the Xbox controller was selected as the baseline input device, as its form [66] and usage are already well-integrated into the experiences of children with ASD [48], a decision further supported by expert feedback indicating its common use in regionally implemented educational and recreational purposes. For the Xbox controller (C2), the interaction was specifically mapped to the A and B buttons, the most accessible for right-hand operation, while all other buttons were deactivated to ensure a consistent control assessment (Figure 3). Using this recognized standard allowed us to evaluate InteractiSense as a promising option for practical applications. After each condition, proxy users completed interim questionnaires. During the experiment, 2 therapists and proxy users observed the children and managed unexpected actions. After completing all assigned experimental conditions, the accompanying parent, or a caregiver when the parent was unavailable, participated in an approximately 10-minute face-to-face semistructured interview. The postsession semistructured interviews were conducted by one of the researchers, who had no prior relationship with the study participants. Children with ASD who were able and willing to respond were also invited to share their views, which were incorporated into the qualitative findings. With consent, the interviews were audio-recorded, transcribed, and analyzed thematically to identify recurring themes. During the analysis, plausible alternative interpretations were considered, and no substantively new themes emerged from the later interviews,

XSL•FO
RenderX

indicating that thematic saturation had been reached. The complete interview guide is provided in Multimedia Appendix 3.

Sample Size, Power, and Precision

This cross-sectional study focused on evaluating the interaction and sensing feasibility of InteractiSense. The planned sample size was 25 children, and the final sample comprised 15 eligible children. Recruitment was restricted to a single special education center to maintain observational consistency. Data from 8 participants were retained for the preliminary ML analysis. Uncertainty in the interaction-related estimates was summarized using 95% CIs for the preference odds ratio (OR) and device-specific mean usability and workload scores, together with a 95% credible interval for the Bayesian estimate of preference probability.

Measures and Covariates

The measures evaluated in this study addressed 2 dimensions of feasibility: interaction feasibility and sensing feasibility. Device condition (InteractiSense vs Xbox controller) was the within-subjects experimental factor for the interaction-feasibility comparisons. Interaction feasibility was assessed through device preference, usability using SUS [46], and workload using NASA-TLX [47,67,68]. Postsession semistructured interviews further assessed perceived enjoyment, task performance and assistance needs, device-related facilitators and barriers, participation in the shared task, potential home use, and suggested improvements.

Sensing feasibility was assessed through signal-to-noise ratio (SNR) analysis of the analyzable sensor modalities and preliminary ML-based engagement classification. Sensor-derived features from the retained modalities served as predictors, while video-coded binary engagement states (engaged vs not engaged) served as the classification target. Balanced accuracy was the primary classification metric, supplemented by precision, recall, F_1-score, and confusion matrices. Participant characteristics were reported descriptively in Table 1. No covariate adjustment was applied to the device-condition comparisons. To reduce potential order effects, game-module order was counterbalanced using a balanced Latin square, and device-condition order was alternated across pairs.

Data Sources

Data were collected from children with ASD and their accompanying parents or caregivers during the study. Demographic and clinical characteristics were obtained from questionnaires completed by parents or caregivers. Device preference, usability, and workload were assessed using study questionnaires, with SUS and NASA-TLX completed by proxy users after each condition. Qualitative data were obtained from postsession semistructured interviews with parents or caregivers, with additional comments from children who were able and willing to respond. Interviews were audio-recorded and transcribed; the interview guide is provided in Multimedia Appendix 3.

Sensor data were obtained from the modalities embedded in InteractiSense, with sampling details provided in Multimedia Appendix 2. Engagement labels were derived from video recordings and annotated in EUDICO Linguistic Annotator (ELAN) by 2 independent coders (WK and CL) according to the criteria. Only labels agreed upon by both coders were retained for analysis.

Engagement Classification

We assessed the validity of the embedded sensor signals and their potential to support engagement-level classification, using a preliminary ML implementation aimed at evaluating feasibility rather than optimizing performance. Given the small sample size and class imbalance, we did not assume that a more complex model was inherently warranted; instead, we used baseline comparisons to examine whether the sensor-derived features contained predictive structure beyond simple decision rules.

Annotation and Ground Truths

Researcher-coded engagement labels for children with ASD were derived from video recordings. Each session was recorded using 3 cameras, and the ELAN software was used to annotate engagement status. The start and end times of each behavioral event were marked with second-level granularity. Each event was assigned to 1 of 2 labels (0: not engaged, 1: engaged) based on the specific criteria (Table 2). Two independent coders (WK and CL) performed the annotations, and interrater agreement was evaluated following [69], yielding an agreement score of 0.94. Only events where both coders assigned the same label were retained as the ground truth for subsequent analyses. These annotations served as the ground truths for training and evaluating the classification models.

XSL•FO
RenderX

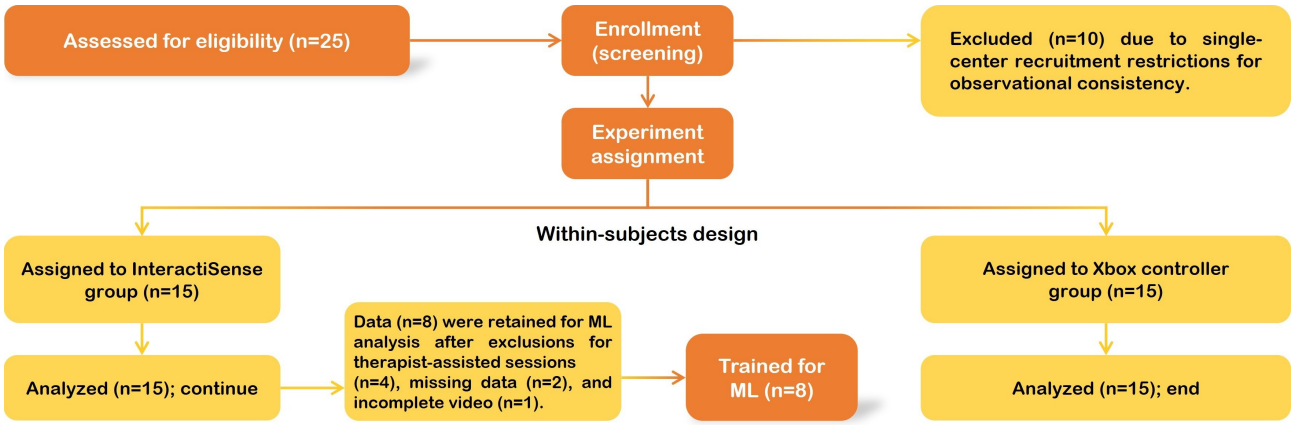


Table . Operational definitions and behavioral criteria for engagement labeling within a peer-based social gaming context, detailing specific indicators for "Not engaged" (0) and "engaged" (1) states across visual, verbal, and physical dimensions.

Engagement	Conceptual definition	Operational criteria
0 (Not engaged)	A state where the participant is detached from the social gaming context or the shared task with a peer.	Any of the following behaviors occurred: (1) gaze: looking at areas unrelated to the game content, (2) verbalization: speaking about topics unrelated to the game (excluding mumbles or babbling), (3) physical: releasing the InteractiSense device, (4) external: intervention by an experimenter, parent, or teacher.
1 (Engaged)	A state of sustained participation in the social gaming context and collaborative task.	All other instances where the participant is actively interacting with the game and none of the "Not engaged" criteria are met.

Data Segmentation and Feature Construction

Given the limited number of available datasets, ML methods were used, particularly those suited for imbalanced distributions and small-sample contexts (Figure 5). Input data were segmented into 25-sample windows with a step size of 0.5 seconds. To mitigate the scarcity of minority-class windows that would result from a strict majority rule, each window was labeled as 0 if the proportion of label-0 frames was greater than or equal to 0.2, and as 1 otherwise. This threshold corresponds to at least 5 label-0 frames (=0.17 seconds within a 25-sample window) and was empirically chosen to preserve the minority class while maintaining temporal consistency with observed engagement dynamics.

Figure 5. Participant flow diagram. The flowchart details the enrollment process, the within-subjects allocation to both experimental conditions, and the subsequent data filtering steps for the machine learning analysis. ML: machine learning.

Feature vectors concatenated the raw samples with 12 summary statistics (mean, SD, minimum, maximum, range, median, IQR, slope, energy, root-mean-square, zero-crossing rate, and dominant frequency ratio) computed for each sensing channel. The sensing modalities used as ML inputs included inertial measurements (orientation: Yaw, Pitch, Roll; ACC: ACC_X, ACC_Y, ACC_Z; gyroscope (Gyro): Gyro_X, Gyro_Y, Gyro_Z), physiological signals (HR, GSR, and ST), and audio amplitude data. Pressure input was excluded because its sensing configuration required a low activation threshold to register brief and localized contacts, which led to a high proportion of missing values and rendered the data unsuitable for regression-based analysis and window-level labeling. Data were collected from 15 children with ASD, and samples from 8 participants were retained for ML analysis due to therapist-assisted sessions (n=4), missing data from connectivity issues or gameplay interruptions initiated at the child's request (n=2), and annotation infeasibility due to incomplete video coverage of the child's participation (n=1). The final dataset comprised 5745 windows after segmentation and labeling, with an imbalanced distribution (class-0: 139, 2.4%, class-1: 5606, 97.6%, ≈1:40 ratio). Model training was conducted on 4596 windows (class-0: 111, class-1: 4485).

Classification Model and Evaluation

Extreme gradient boosting (XGBoost) was selected for its capacity to handle structured sequential inputs, generate probabilistic outputs for threshold tuning, and incorporate class-imbalance handling [70]. Class imbalance was handled at two levels: (1) class-prior correction using *scale_pos_weight* = N_0/N_1, where N_0 and N_1 are the counts of labels 0 and 1 in the training split, and (2) sample-level weights to give higher weight to minority-class and borderline windows near the labeling threshold. For comparison, 3 baselines were also implemented: majority, which predicts the most frequent class in the training split; and random (uniform), which samples labels with equal probability; and logistic regression, a linear classifier included as a stronger baseline. Performance was assessed using balanced accuracy (primary), precision, recall, F_1-score, and confusion matrices to characterize class-wise behavior.

Model evaluation used Group 8-fold cross-validation to prevent data from the same participant appearing in both training and

XSL•FO
RenderX

validation folds. Hyperparameters were tuned via random search over standard XGBoost ranges for tree depth, minimum child weight, subsample ratio, column subsample ratio, , and L_1/L_2 penalties (Multimedia Appendix 4). Early stopping monitored validation log-loss within each fold. The decision threshold τ was selected to maximize balanced accuracy using the validation data only and was then fixed before application to the test set; no test-set information was used for threshold selection. Predictions from 3 models trained with different random seeds were averaged. All stochastic processes, including data splitting, parameter search, and model training, were initialized with fixed random seeds to ensure reproducibility.

Analysis

Data-Analytic Strategies

Quantitative user preferences were analyzed using the McNemar test and ORs for discordant pairs because the preference responses were paired within participants across the 2 device conditions, thereby accounting for the within-participant dependency of the observations. The preference analysis was supplemented by a Bayesian analysis using a uniform Beta(1,1) prior, representing no a priori preference for either device. Proxy user-reported usability and workload scores, measured using the SUS and NASA-TLX, respectively, were compared using 2-tailed paired *t* tests, with the proxy user as the unit of analysis (n=15). To validate physiological data fidelity, the SNR was calculated via an autocorrelation function with a second-order polynomial fit.

Qualitative interview data on InteractiSense and the SG were analyzed using thematic analysis. Quantitative findings and interview themes were integrated during interpretation in the Discussion, where caregivers' accounts of device characteristics and familiarization were used to contextualize preference and usability findings.

Methodological Integrity

During the qualitative analysis, plausible alternative interpretations were considered. No substantively new themes emerged from the later interviews, which was interpreted as evidence of thematic saturation within the dataset. Findings concerning InteractiSense and the SG were grounded in interview accounts and illustrated with quotations from caregivers and children who contributed comments.

Results

Quantitative Evaluation

Out of 15 participants, 10 (67%) indicated a preference for InteractiSense and 5 (33%) for the Controller (Table 3). McNemar test showed that this difference was not statistically significant, *P*=.30. The OR for discordant pairs was 2 (95% CI 0.62-7.46). Updating a uniform Beta(1,1) prior with the observed preference data yielded a Beta(11,6) posterior distribution. The posterior mean was 0.65 (SD 0.11), with a 95% credible interval of (0.41-0.85) and a posterior probability of 0.89 that the preference probability exceeded 0.50.

Table . Comparison of device preference, usability, and workload between InteractiSense and the Xbox controller (n=15).

Measures	InteractiSense	Controller	Test statistics	*P* value
Preference, n (%)	10 (67)	5 (33)	McNemar test[a]	.30
Posterior preference probability[b]				
Mean (SD)	0.65 (0.11)	—[c]	—	
95 % credible interval	0.41 - 0.85	—	—	
P (preference >0.50)	0.89	—	—	
SUS[d] score			–0.22[e] (14)	.83
Mean (SD)	65.8 (14.7)	67.1 (16.4)	—	
95% CI	56.91 - 74.63	57.20 - 77.04	—	
NASA-TLX[f] score			–0.37 (14)	.71
Mean (SD)	46.6 (9.1)	47.9 (9.7)	—	
95% CI	41.04 - 52.08	42.06 - 53.84	—	

[a]2-sided McNemar test; odds ratio for discordant pairs 2 (95% CI 0.62-7.46).

[b]Beta(11,6) posterior distribution of the probability of preferring InteractiSense, derived from a uniform Beta(1,1) prior. CrI: credible interval.

[c]N/A: not applicable.

[d]SUS: System Usability Scale. Scores for both devices fell within the marginal range of acceptability.

[e]2-tailed paired *t* test.

[f]NASA-TLX: NASA Task Load Index. Scores for both devices corresponded to a somewhat high workload level.

Regarding performance, both measures showed only subtle differences, with the controller yielding higher usability and InteractiSense leading to lower workload. However, 2-tailed paired *t* tests did not indicate significant differences: for usability, InteractiSense (mean 65.8, SD 14.7) and Controller (mean 67.1, SD 16.4) yielded (t_{14}=–0.22, *P*=.83); for workload, InteractiSense (mean 46.6, SD 9.13) and Controller (mean 47.9,

XSL•FO
RenderX

SD 9.7) yielded (t_{14}=–0.37, P=.71). Separate analyses of the NASA-TLX subscales and SUS items also yielded no significant condition differences. The results indicate that InteractiSense demonstrated usability and workload levels that were slightly lower but similar to those of the robust baseline (ie, the familiar Xbox controller). Its potential as a tool for children with ASD was identified, supported by additional insights from postexperiment interviews.

Qualitative Evaluation

Our postinterviews gathered insights into children's preferences, feedback, and the applicability of InteractiSense and the SG. Caregivers noted that while children were not accustomed to InteractiSense at first, they recognized its distinct advantages over the Xbox controller. One caregiver (P8) remarked:

> *The child seemed to prefer the simple button configuration of InteractiSense, as it was easier to map the game elements to the buttons. With only two buttons, once the child becomes accustomed to it, using InteractiSense will be easier than a traditional controller (also echoed by P1, P11 and P12).*

Children's preference for InteractiSense was not solely due to its functionality; the device's physical attributes, such as its round shape, soft touch, and bright color, also played a noticeable role. The round shape, in particular, was noted as offering psychological comfort and aiding fine motor development, such as movements of the fingers and palms (P2, P3, and P7). One child shared his excitement, exclaiming, "I liked the egg yolk!" However, some caregivers pointed out limitations due to the fixed size of InteractiSense and suggested that a more flexible and soft design could enhance its usability (P8, P10, and P11). Given the Xbox controller's familiarity to most children (P4), caregivers noted that once adapted, the prototype's simplified form and operation could yield practical usability benefits (P6 and P9). While its usability scores were comparable to those of the controller, the streamlined design of our prototype, featuring tangible elements such as its round shape, bright appearance, and soft texture, was perceived more favorably for children with ASD compared to the controller.

The social and collaborative SG, integrated with InteractiSense, was noted for several advantages, one of which was its ability to encourage paired interaction, as caregivers appreciated its application for children with ASD, who often engage in solitary play due to their characteristics. Caregivers shared notable observations during gameplay, stating:

> *Children waited for their turns (P10), enjoyed collaborating (P1), and even encouraged distracted peers to rejoin the game (P12). One child, in particular, showed a positive change in behavior, remaining calm even when the game did not proceed as planned, which differed from their usual pattern (P6).*

Expanding on these insights, several caregivers added:

> *This game seems to provide a medium for our children to learn collaboration, an advanced form of social interaction (P1), and foster closer relationships (P4, P5).*

Following the game, P4 and P5, who were not initially close, were even observed holding hands, playing together, and sharing their belongings. More than 13 caregivers expressed their willingness to use InteractiSense, along with its functional games or educational content, if it were made available for home use, and highlighted its potential for use with other family members.

Validation of InteractiSense Data

SNR was calculated in dB to validate data using raw signals, based on the autocorrelation function with a second-order polynomial fit. The average SNR values showed that ST yielded the highest (26.8 dB), followed by GSR (15.6 dB) and HR (15.7 dB), while audio exhibited the lowest (3.1 dB; Table 4). ST maintained continuous acquisition despite intermittent separation, which likely arises from its noncontact nature. In contrast, GSR and HR are contact-based modalities, driven by electrodes and optics, and are sensitive to detachment, looseness, and motion, which introduced artifacts and reduced SNR in segments. Audio yielded signals heavily mixed with ambient noise, as persistent background sounds from caregivers, therapists, and other children masked participant speech and reduced the effective SNR. The pressure modality produced sparse, discontinuous signals due to recurrent separation, and thus SNR analysis was not performed. These results indicate that ST provided consistently high-quality signals (>20 dB) [4], while HR and GSR yielded signals of sufficient quality for analysis, which aligns with thresholds considered acceptable for clinical practice (>14 dB) [71]. Potential improvements include optimizing sensor placement, considering alternative sensing mechanisms, and applying postsignal processing techniques (eg, frequency filtering and wavelet transform).

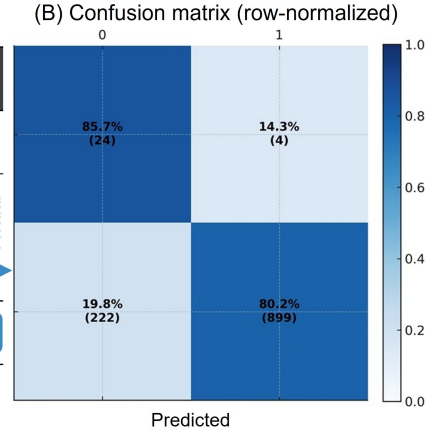
[b]HR: heart rate.

[c]ST: skin temperature.



InteractiSense Classification

On the binary engagement classification task (engaged vs disengaged) for children with ASD, the XGBoost model achieved a balanced accuracy of 83% (Figure 6A). This value is higher than the random guess and majority baselines (both 50%), showing that the model surpasses trivial classifiers. This performance indicates that InteractiSense can serve as a feasible approach for distinguishing engagement states. In addition, class-wise recall reached 85.7% for the disengaged class and 80.2% for the engaged class, demonstrating discriminative performance for both classes despite the class imbalance (Figure 6B). Taken together, these results provide preliminary evidence of InteractiSense as a feasible prototype for differentiating engagement states in children with ASD.

Figure 6. Model evaluation results. (A) Classification metrics of extreme gradient boosting and baseline methods. (B) Row-normalized confusion matrix. In (A), the column header Acc. denotes accuracy, and Bal. Acc. denotes balanced accuracy. XGBoost: extreme gradient boosting.

(A) Evaluation metrics

Model	Acc.	Bal.Acc.	Precision	Recall	F_1-score
Majority baseline	0.97	0.5	0.97	1.00	0.99
Random guess	0.95	0.5	0.97	0.97	0.97
Logistic regression	0.76	0.74	0.93	0.75	0.82
XGBoost	0.8 (0.78-0.82)	**0.83 (0.76-0.9)**	0.97 (0.96-0.99)	0.8 (0.78-0.82)	0.87 (0.8-0.9)

Discussion

Principal Findings

InteractiSense Reached Functional Parity With a Familiar Baseline While Eliciting Favorable Reception

In this short-term feasibility study, preference was included as an exploratory indicator of initial receptivity to the unfamiliar interaction concept and form factor, rather than as a proxy for usability or therapeutic effectiveness. InteractiSense tended to be preferred over the conventional Xbox controller, which served as the comparison baseline in this study, although remarkable differences were not confirmed; Bayesian analysis suggested a high probability that InteractiSense was favored, indicating favorable initial reception despite its unfamiliarity. In terms of usability, InteractiSense performed slightly below the conventional Xbox controller, whereas on workload it performed marginally above; however, neither measure indicated statistically significant differences. These outcomes suggest that InteractiSense achieved a level of performance comparable to the baseline. Considering that the Xbox controller represents a familiar and widely accepted interface for children with ASD [48], achieving functional parity in these short-term usability and workload measures supports the interpretation that the prototype is usable and holds potential for practical deployment in ASD-oriented play contexts.

The tendency for InteractiSense to be preferred over the Xbox controller was echoed in postinterview accounts. Caregivers emphasized that the simplified 2-button configuration reduced the effort required to map game actions, and that the prototype's tangible qualities, its round shape, soft texture, and bright appearance, contributed to comfort and engagement, consistent with prior work showing that tangible designs with enriched sensory cues can promote attention and collaborative play among children with ASD [51]. These characteristics helped explain why children were reported to show enthusiasm for our device despite its unfamiliarity and their tendency to favor familiarity [36]. Some caregivers also noted that once children

XSL•FO
RenderX

adapted, the streamlined design could offer practical advantages, although improvements in size and flexibility would be desirable. Together, the quantitative pattern and interview accounts converge to suggest that while InteractiSense achieves functional parity with familiar interfaces, its positive reception is more accurately attributed to its ability to become an object of interest for the children, a finding that aligns with prior work underscoring the centrality of user interest [72].

Given that the Xbox controller represented a robust baseline grounded in longer-term familiarity [36,48], whereas InteractiSense was evaluated after short-term exposure, the comparable pattern observed here may be interpreted as encouraging. However, this interpretation should be considered in light of the limited sample and the absence of repeated exposure over time, highlighting the need for further validation in a larger cohort.

InteractiSense Demonstrated Feasibility as a Sensing Platform for Engagement Classification

The integration of SNR analysis with the preliminary ML implementation indicated that selected InteractiSense modalities exhibited sufficient stability for engagement modeling, while signal quality varied across sensors. Among the sensing modalities, ST yielded consistently robust signals, even during movement, while HR and GSR provided valid and analyzable data, although somewhat less stable due to their susceptibility to detachment and motion artifacts [73,74]. The reduced stability observed for GSR is consistent with prior ambulatory GSR research showing that movement-related artifacts can compromise signal quality [75]. In the present setting, this contrast suggests a relative advantage of noncontact sensing in dynamic play contexts, while also highlighting the need for careful handling of contact-based modalities. Overall, these results indicate that InteractiSense can function not only as an interaction tool but also as a preliminary sensing platform that provides multimodal inputs for engagement modeling.

Building on this stability, preliminary ML indicated that InteractiSense holds potential to support binary classification of engagement states, with XGBoost performance exceeding baselines (eg, random guess, majority baseline, and logistic regression). Classification outcomes further indicated balanced accuracy above 0.8 across both classes, with disengagement classified with higher accuracy. However, given the inclusion of only 8 participants, the temporal dependence among windows, and the extreme class imbalance, the aggregate balanced accuracy should be interpreted cautiously and only as preliminary feasibility evidence. The model may also have captured movement- or sensor contact-related patterns associated with the annotated labels rather than engagement itself.

Valid sensing and preliminary classification together indicate that InteractiSense extends beyond its role as an interaction device, demonstrating a dual role as both a participatory social interaction medium and a sensing platform for engagement inference. In doing so, this work realizes the conceptual goals for such “TangToys” [15], while extending the capabilities of earlier sensorized toys [14] from single-modal behavioral observation to complex, multimodal engagement inference. The findings underscore its potential to guide monitoring approaches that may evolve into adaptive support strategies that, in line with the growing demand for interventions [4,76], can adjust the assistance provided based on a child’s inferred state of engagement [20]. This serves as a proof-of-concept for embedding engagement-aware sensing into tangible play environments, providing methodological direction for subsequent system development.

Perceptions of the Social and Collaborative SG

The integrated social and collaborative SG revealed further advantages beyond the device itself. Caregivers observed that the SG encouraged paired interaction among children who often prefer solitary play [77], with instances of turn-taking, peer encouragement, and calmer responses to setbacks. Such observations suggest that the game context provided a medium for practicing collaboration and building peer relationships, which are often difficult to nurture in children with ASD [59,78]. This finding aligns with a body of research suggesting that the clear rules and shared goals inherent in digital SGs can provide a crucial scaffold for children with ASD, simplifying the complex social demands of unstructured play [59,79]. Caregivers also expressed interest in adopting this type of content for home use, highlighting its potential to extend engagement beyond structured settings [80]. In sum, these accounts indicate that collaborative SGs integrated with novel interaction tools can amplify social affordances and point toward future directions for designing social play that fosters collaboration in children with ASD [59,78].

Limitation and Future Works

Our findings should be interpreted in light of several limitations, which in turn inform a clear agenda for future research.

A key limitation of this study, reflecting a common challenge in ASD research [4], is the modest sample size (n=15 vs a planned n=25). This sample size was further constrained by our strategic decision to recruit from a single therapeutic center to ensure observational consistency. This approach was chosen to ensure that all sessions were conducted by the same group of participating therapists, who were deeply familiar with the children’s behavioral profiles, thereby ensuring observational consistency. While this strategy enhances the consistency of our observations, it could limit the generalizability of the findings, particularly given the cohort’s heterogeneity in chronological age (CA), functional age (FA), comorbidities, and ASD severity. In addition, only 8 of the 15 participants were retained for the ML analysis. Although the exclusions were based on data-quality and annotation considerations, some excluded sessions involved therapist assistance or interruptions. The retained analytic subset may therefore overrepresent children who could participate more independently and continuously, introducing potential selection bias. Consequently, the reported model performance may not represent the full study cohort or children with greater support needs. The study’s short-term nature is another limitation. Feedback from both caregivers and therapists highlighted the need for a longitudinal study to understand the long-term effects of using InteractiSense [81]. Prolonged exposure may be necessary for children to fully adapt to the novel device, potentially revealing usability benefits not apparent in a short-term evaluation and providing a more

XSL•FO
RenderX

equitable comparison with highly familiar devices like the Xbox controller. However, this study did not examine longitudinal changes in collaborative task engagement, include standardized social outcome measures, or evaluate improvements in social skills. Accordingly, the current findings should be interpreted as evidence of the technical feasibility and short-term usability of InteractiSense rather than evidence of therapeutic effectiveness, intervention-related benefits, or improvements in collaborative task engagement or social skills.

Another limitation concerns the fixed physical dimensions of the prototype. Although the 18 cm measurement represents the outer diameter of the spherical enclosure rather than the required grip span, P9—the youngest participant and the participant with the shortest hand length, experienced some difficulty manipulating the device, suggesting that its overall form factor may have been relatively large for this child. The remaining participants were able to complete the assigned interactions using the device, but the small and heterogeneous sample did not permit a systematic assessment of usability differences by age or hand length. Future iterations should therefore evaluate smaller enclosure variants or adjustable gripping components to accommodate a broader range of users.

While securing large participant cohorts is a recognized constraint in special needs research, expanding the sample to establish the generalizability of these findings is essential. Future work should therefore address this limitation by validating our findings with a larger and more varied cohort over a longer period. Such a rich, longitudinal dataset would be crucial for advancing the engagement prediction model beyond its current, preliminary stage. It would enable not only a more definitive statistical analysis of user preference trends but also the systematic exploration of state-of-the-art (SOTA) architectures, feature engineering techniques, and parameters such as time-window size [82]. Furthermore, our poststudy interviews provided a clear, caregiver-driven roadmap for future iterations. A recurring theme was the need to enhance the device's interactivity, for instance by adding light-up button cues or expanding its function into a responsive [6,9], playful companion that can generate its own sounds or haptic feedback [8]. On the gameplay side, caregivers advocated for a diverse and customizable library of SG content that can be tailored to the unique interests and needs of each child on the spectrum, such as incorporating preferred topics like numbers and puzzles or adjusting difficulty based on the child's state [83]. InteractiSense is intended for researchers and practitioners in therapeutic and special education settings. It is not designed as a consumer product or a validated therapeutic intervention; rather, it serves as a proof-of-concept for examining the feasibility of multimodal sensing and data acquisition under controlled conditions, while also providing a preliminary investigation of how children with ASD engage with and respond to a novel multimodal device in terms of usability and interaction workload [84]. This work provides a methodological basis for future empirical studies examining the potential application of InteractiSense in therapeutic or adaptive contexts and its potential contribution to supporting collaborative task engagement.

Conclusions

In this study, we proposed and evaluated InteractiSense, a tangible prototype designed to support interaction while enabling collaborative task engagement estimation through embedded sensing modalities, together with a collaborative and social SG intended to facilitate peer interaction among children with ASD. In a study involving 15 children, InteractiSense showed usability and workload levels comparable to those of a conventional Xbox controller, along with a tendency toward higher preference for the prototype. As the Xbox controller served as a familiar baseline shaped by longer-term use, whereas InteractiSense was evaluated after short-term exposure, this pattern provides initial support for feasibility at the interaction level. Signal quality varied across the embedded sensing modalities: ST yielded the strongest signals, HR and GSR were analyzable but susceptible to artifacts, audio quality was low, and pressure data were too sparse and discontinuous for analysis. Separately, a preliminary XGBoost model achieved 83% balanced accuracy in binary engagement classification, exceeding the Random Guess, Majority, and Logistic Regression baselines. However, these findings should be interpreted within the limits of the current sample, and the ML results in particular remain preliminary. Larger-scale and more longitudinal validation, together with expanded learning and sampling procedures, will be needed to clarify the robustness and generalizability of the observed performance.

Acknowledgments

The authors are grateful to Director Choongman Lee of the Dream Tree Children Education Center for his invaluable support. We also thank the participating children with ASD, their parents, and caregivers, along with the 3 special education teachers for their essential contributions and perspectives. The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy) 2025, GenAI use was limited to proofreading and language editing under full human supervision. The tool used was ChatGPT-5.2. Responsibility for the final manuscript lies entirely with the authors, and GenAI tools are not listed as authors or responsible for the final outcomes. This declaration is submitted under collective responsibility.

Abstract

Background: Out-of-hospital cardiac arrest (OHCA) is a global health issue with low survival rates, for which bystander cardiopulmonary resuscitation (CPR) is crucial. In China, bystander CPR rates and public proficiency remain low. Children—an important future first-responder group—also lack adequate training. Gamification and virtual reality (VR) technologies show potential in enhancing training effectiveness, but research on the needs, acceptability, and functional requirements of gamified CPR training kits from children's and parents' dual perspectives is insufficient, providing a realistic basis for this study.

Objective: This study aimed to investigate children's and parents' needs, acceptability, and functional requirements for the development of gamified CPR training kits.

Methods: A cross-sectional qualitative design was adopted. Inclusion criteria were children aged 6 to 12 years, their parents, adequate communication skills, and voluntary informed consent, with purposive sampling to recruit 13 parent-child dyads from a primary school in Changsha, Hunan Province. The participants included children aged 6 to 12 years (average age 9.50, SD 1.50 y, 6 boys and 7 girls) and their parents (average age 38.50, SD 2.50 y, 6 female and 7 male individuals). Semistructured interviews were conducted separately for children and parents, with audio recording and verbatim transcription. The NVivo 12.0 (QSR International Pty Ltd) software was used for thematic coding and analysis, and dual independent coding (by 2 researchers) was performed to ensure rigor, with discrepancies resolved through team discussion. Thematic saturation, defined as codebook stabilization and no new themes across 3 consecutive interviews, was achieved after 13 dyads. The study followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines, and all procedures were approved by the ethics committee.

Results: Four main themes and 9 subthemes emerged from the data: (1) children's approaches to acquiring CPR-related knowledge and skills (through school-organized first aid activities, family members, or social media platforms), (2) attitudes toward gamified training kits (children's receptiveness and parental preferences regarding such tools), (3) expectations for gamified CPR training kits (child-friendly design, effective skill training, personalized feedback, and scientifically grounded content), and (4) challenges in gamified science education (ensuring product safety and professionalism and contextualizing game scenarios to everyday life).

Conclusions: As children are an important reserve force for future first responders, cultivating their first aid awareness is crucial for improving public emergency response capabilities. Effective gamified CPR training kit development requires integrating children's and parents' perceptions to balance entertainment, education, and practicality. This study innovatively explores dual user needs, differing from prior research focused on training outcomes rather than predevelopment requirements. It addresses gaps in pediatric first aid tool design and provides evidence-based references for the development of child-friendly, professional, gamified training resources—laying a foundation for gradually enhancing CPR literacy and emergency response awareness among children in China.

Introduction

Cardiac arrest represents a critical public health emergency, with out-of-hospital cardiac arrest (OHCA) survival rates remaining low worldwide [1,2]. In China, the prospective BASIC-OHCA registry reported a crude emergency medical services–assessed OHCA incidence of 95.7 per 100,000 population in 2020, and the overall survival rate at hospital discharge or 30 days was only 1.2% [3]. This survival figure is substantially lower than the 10% to 16% reported in high-income settings, such as the United States [4]. The provision of immediate and high-quality cardiopulmonary resuscitation (CPR) by bystanders is the single most crucial factor in improving survival outcomes [5,6]. In China, however, the prevalence of bystander CPR training remains critically insufficient. A 2023 survey of Chinese middle school students found that only 9.87% had received CPR training [7], and a 2024 study of university freshmen reported that 82.61% cited a lack of first aid knowledge as the main barrier to performing CPR [8].

Global resuscitation bodies, including the International Liaison Committee on Resuscitation (ILCOR) and the European Resuscitation Council (ERC), have promoted universal first aid education. ILCOR launched the World Restart a Heart initiative, while the ERC's 2015 Kids Save Lives campaign advocates formal school-based CPR training [9]. Many high-income countries (eg, the United States, Norway, and Japan) have mandated CPR training in primary and secondary school curricula through legislation, a policy that has significantly improved bystander CPR rates [10]. In China, however, this skills deficit is particularly pronounced among children—potential future first responders—a group that currently receives minimal effective training [11]. School-age children aged 6 to 12 years have sufficient cognitive ability for basic CPR [10], which corresponds to the primary school stage in China—a critical period for health education. Early first aid education fosters long-term response capabilities, and skills acquired can be retained throughout life. Moreover, children can share first aid knowledge with families and friends, thereby contributing to broader public awareness.

Current approaches to CPR training for children face several critical challenges, including a shortage of instructors, monotonous training formats that are insufficient to maintain engagement, and a lack of intrinsic motivators [12,13]. Moreover, existing training models and equipment may not be optimally aligned with children's developmental characteristics (eg, shorter attention spans and a need for play-based learning) [14]. Consequently, conventional methods may fail to sustain children's engagement, a key factor for long-term retention.

The 2020 AHA Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care suggest that gamified learning may be considered for CPR training among lay rescuers [15]. Gamification uses elements such as points, badges, and leaderboards to boost learners' engagement and self-efficacy and has been shown to improve skill mastery, knowledge levels, and long-term retention [16,17]. A 2024 systematic review and meta-analysis of randomized controlled trials, published in *JMIR Serious Games*, concluded that serious games are comparable to traditional training methods in terms of theoretical knowledge, skill assessment, compression depth, and chest compression rate [18]. Recent interventional studies have further demonstrated that game-based approaches—including mobile apps, board games, and virtual reality (VR)–based scenarios—increase motivation and short-term skill retention in children aged 6 to 12 years [19,20]. VR and serious games further enhance this approach by providing immersive, safe environments for repetitive practice and by delivering immediate performance feedback [21-24].

Nevertheless, research exploring user-centered perspectives on gamified CPR training kits for children remains scarce. Existing studies have largely focused on short-term learning outcomes rather than user-centered acceptability and functional requirements [18,25]. The acceptability of such tools among children remains unclear. Likewise, their functional requirements from the perspectives of both children and their parents are largely unknown. To address this gap, this study aims to explore the needs, acceptability, and functional requirements for gamified CPR training kits among children aged 6 to 12 years and their parents in China, using a qualitative interview design. In this study, "needs" refers to participants' perceived necessity for CPR training and their desired functional features (eg, personalization, real-time feedback, and social learning). The findings will identify key functional requirements from the dual perspectives of children and their parents, thereby providing targeted design references for the development of child-friendly, professional, gamified CPR training kits.

Methods

Research Design Overview

This study used a cross-sectional qualitative design using semistructured interviews. The study adopted a pragmatic epistemological stance, prioritizing the generation of actionable knowledge for intervention design while acknowledging that participants' accounts reflect their situated realities. The central focus of this study was participants' acceptability of gamified CPR training kits, operationally defined as their willingness to use and recommend the kits. The interviews also explored how specific kit features—namely interactive design, operational difficulty, and content relevance—are related to participants' acceptability. The interview method was selected for its ability to elicit rich, detailed narratives and clarify complex perceptions regarding the acceptability and functional requirements of gamified CPR training kits. Furthermore, interviewing child-parent dyads was essential to capture the interdependent dynamics and potential consensus or divergence in opinions within the family unit, which individual interviews might overlook.

Study Participants or Data Sources

The final cohort therefore consisted of 13 child-parent dyads (children: C1-C13; parents: P1-P13). To create a comfortable environment for children to express their views openly, interviews were conducted separately for the children and their parents. The mean age of the children was 9.50 (SD 1.50; range 6 - 12) years, and the mean age of the parents was 38.50 (SD

XSL•FO
RenderX

2.50; range 35 - 45) years. Children's age and gender, as well as parents' educational background, were considered participant characteristics of analytical interest during purposive sampling and analysis. No refusals or dropouts occurred.

Participant Recruitment

Overview

From August 2024 to January 2025, we recruited child-parent dyads from an elementary school in Changsha, Hunan Province, using purposive sampling to ensure diverse representation in terms of children's age, gender, and parents' educational background and occupation. The inclusion criteria were as follows: (1) children aged between 6 and 12 years, (2) parents of children within this age range, (3) adequate communication skills, and (4) voluntary participation with informed consent obtained. The exclusion criteria were as follows: (1) cognitive impairments or psychiatric disorders in either the child or parent and (2) inability to complete the interviews.

Sample Size and Saturation

The sample size was determined based on the principle of thematic saturation. We conducted interviews with an initial 7 dyads and performed a preliminary analysis. Recruitment and analysis continued iteratively until no new themes emerged from subsequent interviews; saturation was achieved after including 6 additional dyads. Saturation was defined as codebook stabilization with no new themes emerging across 3 consecutive interviews. This assessment was performed across all interviews combined (rather than separately for children and parents) owing to the interdependence within each dyad.

Data Collection

The original English interview guide was translated into Mandarin Chinese by a native Chinese-speaking researcher. A second bilingual researcher independently back-translated the Chinese version into English, and the research team compared the back-translated version with the original version to ensure conceptual equivalence. The final Chinese version was pilot-tested with 2 child-parent dyads (not included in the final sample) to verify cultural and linguistic appropriateness.

September 2024 to January 2025 served as the data collection period. The interviews adhered to the following standardized procedure: (1) preparation: all interviews were conducted in a private, quiet room at the participating elementary school. The room was arranged to create a comfortable, nonthreatening atmosphere for children. The researcher arrived 10 to 30 minutes before each session to prepare the environment and audio recording equipment. To capture the distinct perspectives of both groups, children and their parents were interviewed separately. Pilot interviews with 2 child-parent dyads (not included in the final sample) were conducted prior to formal data collection to refine the interview guide. (2) Introduction and informed consent: upon arrival, the researcher provided a clear explanation of the study's purpose, procedures, and data handling practices using child-friendly language. Written informed consent was obtained from all parents, and verbal assent was obtained from all children after confirming their understanding. Participants were informed that all obtained information would be used solely for research purposes and would remain confidential. Once consent for recording was obtained, the audio recorder was activated. (3) Discussion: the researcher introduced topics based on the prepared interview-guiding questions (see Textbox 1) and cultivated an environment where participants were encouraged to share their views freely. To ensure the children started with a common understanding, a brief (3 - 5 min) age-appropriate introduction to CPR and when it is needed was provided using simple videos and slides. Simple verbal questions were then used to confirm each child's basic comprehension before the formal interview began. During the interviews, the researcher maintained methodological neutrality by using bracketing techniques; using verbatim restatement for clarification; and posing neutral, reflective questions (eg, "Could you tell me more about that idea?"). When interviewing children, the researcher used simplified language and concrete examples to facilitate comprehension. Particular attention was paid to documenting nonverbal cues (eg, facial expressions, body language) and paralinguistic features (eg, tone of voice, enthusiasm). Each interview lasted approximately 15 to 40 minutes. (4) Conclusion: based on participants' responses, the interviewer reviewed the main discussion points. Each participant was provided a chance to add additional comments. After the interview, participants were offered a small token of appreciation.

Textbox 1. Semistructured interview guide for parents and children participating in a qualitative assessment of cardiopulmonary resuscitation (CPR) training needs in Changsha, China (August 2024-January 2025).

1. For children: Could you describe how you typically learn about first aid, particularly CPR procedures?

2. For both children and parents:

- From your perspective, what essential functionalities should an ideal gamified CPR training toy incorporate to ensure it is both educational and engaging for children?
- What are your expectations regarding the training efficacy of gamified CPR kits compared to traditional methods? Please elaborate.
- What design elements (eg, narrative structure, reward systems, interface characteristics) would you prioritize when developing an age-appropriate gamified CPR training device?
- What potential challenges or barriers do you anticipate in implementing gamified CPR kits within training environments?

Data Analysis

Overview

The interviews were transcribed verbatim by 2 independent researchers within 24 hours of each session. The transcripts included notations of notable nonverbal cues where appropriate. To ensure accuracy, we conducted member checking by returning the transcripts to participants to verify accuracy. The verified transcripts were then imported into NVivo 12.0 (QSR International Pty Ltd) to facilitate data management and coding. We analyzed the data using thematic analysis following the systematic 6-phase approach outlined by Braun and Clarke [26]. This analysis was conducted from a pragmatic epistemological perspective, focusing on identifying patterns and themes directly relevant to intervention design decisions for CPR training kits.

Codebook Stabilization

To ensure a stable codebook, we adopted an iterative team-based approach. After the first 4 interviews (2 child-parent dyads), 2 researchers independently performed line-by-line coding of the transcripts. They met to compare codes, discuss discrepancies, and merge or refine codes to form a preliminary codebook. This process was repeated after coding an additional 4 interviews (2 dyads), during which no new codes emerged and existing codes were considered sufficient to capture new data segments—indicating that codebook stabilization had been achieved. The final codebook was then applied to the remaining interviews.

Theme Development

Following codebook stabilization, 1 researcher coded the remaining transcripts. Through team discussion, we grouped similar codes into subthemes (eg, children's receptiveness, parental preferences) and then combined these into main themes (eg, attitudes toward gamified training kits). A thematic map was drawn to visualize the theme structure. The resulting themes were checked against the original transcripts to confirm they accurately reflected participants' views, and any disagreements were resolved through team consensus.

Researcher Reflexivity

The research team consisted of investigators with academic backgrounds in emergency medicine and medical education. All interviews were conducted by the first author (female), who had prior experience working with children. All researchers involved in interviewing and analysis had formal training in qualitative research methods and experience in conducting interviews with child and adolescent populations. The team acknowledged prior assumptions that gamified kits would be acceptable to children and that children would prefer game-like features. To minimize the influence of these preconceptions on data collection and analysis, we emphasized reflexivity through bracketing (eg, noting judgments or emotional responses during interviews) and maintained a reflexive journal throughout the study.

No prior relationship existed between researchers and participants before the study. Researchers maintained a neutral and supportive role during interviews, particularly with children, to minimize power imbalances. Clear boundaries were established regarding the educational and research nature of the interaction, and no identifiable personal relationships were established beyond the interview context.

Methodological Integrity

Trustworthiness was established through multiple strategies: (1) member checking, in which participants reviewed transcripts for accuracy; (2) thick description of participants and context to support transferability; (3) reflexive journaling to document researchers' positions and potential influences; and (4) peer debriefing to challenge and refine interpretations.

Ethical Considerations

Ethics approval was obtained from the Medical Ethics Committee of Hunan Provincial People's Hospital (The First Affiliated Hospital of Hunan Normal University; approval number [2024]-236). Participant consent was obtained before interviews were conducted, following strict ethical procedures for underage research participants. This process involved first providing detailed study information to all parents or legal guardians, from whom written informed consent was secured. Subsequently, age-appropriate explanations were provided to each child, and verbal assent was obtained after confirming their understanding. This study involved original primary data collection; no secondary data or existing datasets were used in the analysis. Participants could withdraw at any time without any negative consequences. Furthermore, we implemented strict confidentiality measures to protect participant privacy. All personally identifiable information was anonymized during data transcription and was securely stored, with access restricted to authorized research team members. No financial compensation was provided to participants. A small souvenir (valued at approximately 10 CNY, equivalent to ~US $1.40 as of January 31, 2025) was offered as a token of appreciation after the completion of the interviews. No identifiable images, photographs, or videos were collected or included in this study. Therefore, no additional consent for visual materials was required, and no related files were uploaded. The study adheres to the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines [27].

Results

Overview

A total of 26 participants (n=13 children and n=13 parents; children's average age: mean 9.50, SD 1.50 years; parents' average age: mean 38.50, SD 2.50 years) were included in this study (Table 1). The participant recruitment process is shown in Figure 1. After an initial comprehensive review of the data, a total of 108 codes were developed, and 9 subthemes were identified. These subthemes were then further refined and 4 main themes emerged, including (1) children's approaches to acquiring CPR-related knowledge and skills, (2) attitudes toward gamified training kits, (3) expectations for gamified CPR training kits, and (4) challenges in gamified science education (Table 2). Figure 2 presents a thematic map of these themes and subthemes.

Modalities of CPR Knowledge Acquisition Among Children

School-Based First Aid Education Programs

Children predominantly acquired CPR knowledge through structured first aid initiatives conducted by professional medical teams within school settings. While recognizing these programs as engaging and credible, participants consistently highlighted limitations in the duration of sessions and insufficient opportunities for hands-on practice. Representative verbatim accounts are as follows:

> *Healthcare professionals such as doctors and nurses conducted 45-minute CPR training sessions at our school, combining theoretical instruction with practical demonstrations. However, the practice time was insufficient for all participants to sufficiently practice the techniques.* [C2]

> *The hospital-organized first aid lectures effectively utilized clinical case scenarios to enhance knowledge retention. Nevertheless, the limited availability of manikins limited the extent of our practical engagement during the training.* [C3]

> *During weekly safety education assemblies, teachers covered basic first aid concepts such as emergency call procedures, though CPR skill practice was notably absent from these sessions.* [C5]

Family and Social Media–Based Knowledge Acquisition

Our analysis identified 2 distinct yet limited pathways for CPR knowledge acquisition beyond school settings. First, family-mediated learning occurred exclusively among children whose relatives were health care professionals (2/13 participants), characterized by improvised training using household items (pillows, stuffed animals) to demonstrate proper technique. Second, all participants reported exposure to CPR content through social media platforms (Douyin or Xiaohongshu) and television, though they expressed uniform skepticism regarding technical accuracy. Notably, emotionally compelling survival narratives (eg, child-saving-mother scenarios) significantly enhanced the perceived importance of CPR skills despite recognized knowledge gaps. Representative accounts include the following:

- C1: describing physician-led home practice (“My mother demonstrates compression rhythm using pillows”)
- C6: recalling impactful media stories (“The child hero narrative made me value CPR”)
- C10: observing platform limitations (“Douyin tutorials seem daunting without guidance”)

These findings underscore both the potential and the limitations of informal CPR education channels in pediatric populations.

Perspectives on Gamified CPR Training Kits

Children’s Attitudes Toward Gamified CPR Training Kits

Despite limited prior exposure to first aid educational games, participants expressed universal recognition of the potential value of gamified CPR training tools. Three key themes emerged regarding their anticipated benefits: (1) significant enthusiasm for interactive elements and game mechanics (C5: “A toy that teaches CPR step-by-step would be extremely meaningful”), (2) enhanced learning engagement (C11: “Learning CPR through games seems both fun and educational”), and (3) potential to mitigate traditional learning barriers (C2: “Medical knowledge seems abstract, but gamification might make CPR techniques more accessible and memorable”). Notably, children’s positive expectations centered on game design’s potential to transform complex medical procedures into engaging, achievable tasks—a perception especially prevalent among those who had previously

XSL•FO
RenderX

struggled with conventional training methods. These findings suggest that while pediatric users lack experience with existing products, they possess a nuanced understanding of gamification's educational potential in skill acquisition contexts.

Parental Preferences Regarding Gamified CPR Training Kits

Parental perspectives revealed 3 primary considerations in evaluating gamified CPR training tools: (1) product design—emphasis on age-appropriate esthetics and cost-effectiveness (P11: "We regularly purchase educational kits and would consider a reasonably priced CPR training product"), (2) educational value—concerns regarding the balance between engagement and substantive learning outcomes (P3: "While innovative, many gaming kits prioritize entertainment over education—effective CPR tools must maintain this balance"), and (3) safety assurance—universal priority placed on material safety and child-friendly features (P1: "Convenience matters, but safety certification is non-negotiable"). Notably, parents demonstrated critical discernment, advocating for kits that integrate playfulness with medical accuracy—a demand unmet by existing products. These findings underscore the need for rigorously designed interventions that address parental concerns while meeting children's learning needs.

Expectations for Gamified CPR Training Kits

Child-Friendly Design With Training Efficacy

Stakeholders proposed 6 evidence-based design principles to enhance engagement and educational outcomes in gamified CPR training tools: (1) developmentally appropriate interfaces incorporating vibrant colors and cartoon characters (P3: "Narrative scenarios like rescuing a collapsed teddy with stepwise CPR guidance"), (2) progressive challenge systems featuring level-based advancement (P1: "Tiered difficulty modes sustain engagement with complex content"), (3) multimodal feedback mechanisms that combine haptic and auditory cues (P4: "Real-time corrective feedback such as vibration and verbal prompts ensure proper 30:2 compression-ventilation ratios"); (4) positive reinforcement systems with immediate verbal praise (P10: "Affirmative audio feedback enhances motivation"); (5) behavioral incentive structures including reward systems (C7: "Mission-based point accrual and leaderboards"), and (6) clinical fidelity maintenance ensuring medical accuracy (P4: "Must authentically simulate CPR mechanics beyond superficial gameplay"). These recommendations reflect a sophisticated synthesis of play pedagogy and resuscitation science, indicating that optimal designs must reconcile entertainment value with uncompromised training effectiveness through three core elements—(1) segmented skill-building modules; (2) authentic biomechanical feedback; and (3) intrinsic motivation systems—while maintaining American Heart Association (AHA)– or ERC-compliant performance standards.

Acquisition of Scientifically Standardized CPR Knowledge and Skills

Parents emphasized the critical need for gamified CPR training kits to integrate medically accurate content with engaging design features to overcome the limitations of traditional training methods. Three essential requirements emerged: (1) expert-validated content—parents strongly advocated for physician-reviewed instructional materials (P8: "The CPR content must be medically accurate, ideally verified by healthcare professionals, to ensure reliable learning"), (2) core skill mastery—a focus on teaching standardized techniques, including correct hand positioning, compression depth (5 - 6 cm), rate (100 - 120/min), and ventilation methods (P9: "Children must learn precisely where, how, and how fast to perform compressions, preferably through professional animated demonstrations"), and (3) retention optimization—strategies to address skill decay through repetitive practice (P12: "School training is easily forgotten without reinforcement—an engaging toy could enable regular practice"). Notably, parents demonstrated sophisticated understanding of AHA/ERC guidelines while recognizing the need for developmentally appropriate delivery methods. These findings highlight the necessity of balancing rigorous adherence to resuscitation science with child-centered pedagogical approaches in toy design.

Personalized Learning Feedback and Motivational Guidance

Analysis revealed two critical challenges in pediatric CPR skill acquisition: (1) difficulty maintaining technique accuracy and (2) low engagement during repetitive practice. Participants proposed four evidence-based solutions through gamified design: (1) real-time corrective feedback, as described by P3: "Children frequently forget proper positioning—the toy should provide immediate correction as an instructor would," and P9: "Gentle corrective prompts for inadequate depth/rate ('Press deeper') are essential"; (2) adaptive difficulty systems, with P5 noting: "The toy should auto-adjust to children's physical capabilities—different depth standards for preschoolers and older children"; (3) developmentally appropriate instruction, exemplified by P2: "Use child-friendly cues such as 'Place hands in the center of teddy's chest' for positioning"; and (4) multimodal rhythm guidance, per P7: "Incorporate auditory/visual metronomes (eg, music or light cues) to pace compressions." Parents particularly emphasized progression tracking systems to sustain motivation (P8: "Level-based advancement with visible progress metrics would maintain engagement"). These findings align with the Vygotsky zone of proximal development, suggesting that optimal kits should provide scaffolded, individualized feedback while adhering to AHA technique standards.

Challenges in Gamified Science Education

Safety and Professionalism of Gamified Training Kits

Parents prioritized two fundamental requirements in gamified CPR training kits: (1) evidence-based educational value: over 80% (21/26) of the participants emphasized the primacy of medical accuracy over entertainment features (P8: "The core objective must be knowledge acquisition—engagement elements, while beneficial, should not compromise educational integrity"); and (2) child-safe design: 3 key safety concerns emerged as predominant: material safety (P13: "Battery safety standards must prevent thermal hazards"), ergonomic considerations (P4: "10-min segmented training modules to

XSL•FO
RenderX

prevent fatigue"), and age-appropriate interfaces. Notably, stakeholders explicitly rejected purely entertainment-focused designs, advocating instead for pedagogically optimized tools designed to balance brief, focused sessions (≤10 min) with uncompromised resuscitation science fidelity. Collectively, these findings underscore the necessity for rigorous safety certifications (eg, CE/ISO markings) and medical expert validation throughout product development.

Contextualization of Game Scenarios in Daily Life

Both children and parents consistently favored realistic emergency scenarios over abstract game mechanics, emphasizing the imperative for contextual learning experiences. Participants specifically identified two critical needs: (1) authentic scenario simulation: the recreation of plausible emergency situations (C1: "Rather than complex rules, depict recognizable scenarios like assisting a collapsed classmate during running") and (2) adaptive response systems: contextually adaptive feedback systems based on user actions (P13: "The toy should simulate real emergencies to enhance practical response capabilities"). These findings demonstrate a clear user demand for scenario-based training that facilitates the transfer of skills from game environments to real-world applications.

Discussion

Summary of Principal Findings

The main findings indicate that both children and their parents recognized the necessity of early CPR education and were receptive to gamified approaches, provided that safety and educational validity are assured. Both children and parents accepted gamification, but with different priorities: parents' endorsement was conditional on safety and educational credibility, while children showed strong engagement with visual narratives and virtual scenarios. Despite these different priorities, both groups converged on a shared set of expectations for a training kit. Three core functional requirements were identified from the dual perspective: personalization, real-time interactive feedback, and social learning features. This study assessed acceptability—willingness to use and recommend—rather than effectiveness or usability.

Interpretations and Comparisons

The demand for real-time, multimodal feedback can be effectively framed through the theory of self-efficacy [28]. Positive, performance-based feedback likely serves as a powerful source of mastery experience, enhancing a child's belief in their capability to perform CPR correctly. For children who have never encountered medical procedures before, this external validation matters more than it would for adults—they cannot draw on past experience to judge their own performance, so they rely on what the feedback tells them in the moment [29]. This finding is consistent with previous research on game-based learning in health education, which shows that immediate feedback increases motivation and skill confidence [24,30]. Given children's developing self-regulatory capacities, parents emphasized a balance between entertainment and educational substance, advocating for designs that prioritize skill acquisition [31]. This highlights that for this demographic, perceived usefulness is a prerequisite for parental acceptance, even within a highly gamified context [32].

A pivotal finding was children's significantly greater engagement with visual narratives and virtual scenarios compared to conventional methods. The gamified approach may address 2 key barriers in CPR training among laypeople: the complexity of technical medical content and the anxiety associated with skill practice [33]. By simulating real-life emergencies in a safe, controllable, and repeatable game environment, this method may enhance a sense of mastery and self-efficacy, which could reduce initial apprehension and build operational confidence. Several parents in our study raised this exact concern that if the game design leans too far into entertainment and loses sight of medical accuracy, it could give children the wrong impression that cardiac arrest response is less serious than it actually is. Therefore, the design needs to find a middle ground—keeping children engaged while staying grounded in clinical reality—a balance that has been similarly emphasized in VR medical training studies [22,34].

Participants called for phased training objectives, which aligns with established findings that well-designed reward mechanisms bolster achievement motivation and goal attainment [35]. Competitive elements, as demonstrated by de Sena et al [36], were also acknowledged as effective drivers of program completion. That said, not all children in our study cared about rewards—a few said that it did not matter to them. This suggests that the effect of game mechanics may vary across individuals [37]. Consequently, these results suggest that optimal designs could implement scenario-based progressive learning, incorporate evidence-based motivational systems, and uphold rigorous medical accuracy across all gamified elements.

Parents in our interviews expressed high expectations regarding safety and educational value. Whether these expectations translate into actual adoption depends on the product's reliability, educational worth, and cost [38]. At the school level, integration also hinges on curriculum flexibility and whether such tools can be situated within existing instructional routines [39]. At the policy level, experience from high-income countries suggests that incorporating CPR training into school curricula has relied on government support and resource allocation [10]; in China, relevant policy frameworks are still emerging, which presents both a challenge and an opportunity for developers and researchers to work with education authorities toward the systematic adoption of such tools [40]. Therefore, alongside the kit itself, user-friendly guidance materials and basic training protocols should also be developed to help teachers, children, and parents get started without friction, minimizing the risk of nonuse due to operational difficulties or inadequate preparation.

While previous research has measured CPR training outcomes in children [41-43], a notable gap exists in the co-design process that involves children users, which may have contributed to the low training coverage and implementation gaps reported in the literature [44]. This study fills this gap by systematically investigating the perceptions and requirements of both children and parents prior to development. Unlike prior studies that focused primarily on skill outcomes, our findings show that both children and parents view acceptability and user

XSL•FO
RenderX

engagement as essential for a training tool to be effective. We also demonstrate that these perspectives can be elicited through qualitative methods before prototyping.

Limitations

This study has several limitations. First, its qualitative nature provides rich insights into perceptions and attitudes but does not quantitatively measure actual CPR skill acquisition, retention, or behavioral outcomes in a real emergency. The expressed willingness to use such training kits may not directly translate into effective learning or action. Moreover, this study focused on acceptability rather than the physical realism of chest compression, which is essential for hands-only CPR training. The extent to which gamified tools alone can deliver the tactile feedback needed for skill mastery remains unknown based on this study. Second, the participant sample was drawn from a single elementary school in a specific sociocultural context (urban China), which further limits the generalizability of the findings to other regions, school settings, or cultural contexts with different attitudes toward play and education. In addition, the sample was limited to children aged 6 to 12 years, and the findings may not generalize to adolescents or other populations. Third, the small sample (13 dyads) from 1 school limits statistical generalizability, but qualitative research prioritizes detailed understanding over broad representation. Future multischool studies could test the transferability of our findings, and our volunteer sample may have introduced positivity bias.

Conclusions

Gamified CPR training kits are acceptable to children and parents in China when designed with safety, medical accuracy, and engaging mechanics. This study moves beyond outcome-focused research by foregrounding the voices of end users in the co-design process. The identified design parameters—personalization, interactive feedback, social learning, and a balance between engagement and educational credibility—provide a road map for developing age-appropriate CPR training kits. Beyond the immediate design implications, our findings have broader significance. For developers, the requirements we identified can inform design standards, with particular attention to balancing entertainment and educational credibility. For educators and policymakers, our results support incorporating gamified CPR training into school health curricula, but only after kits have passed certified safety and medical accuracy checks. For researchers, this study demonstrates the value of capturing child and parent perspectives before prototyping; future research could move beyond acceptability to test actual learning outcomes through randomized controlled trials and examine how co-designed features influence long-term skill retention. These contributions advance a user-centered agenda for CPR education and gamified health tool design.

Acknowledgments

The authors declare the use of generative AI (Gen AI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to Gen AI tools under full human supervision: (1) proofreading and editing and (2) adapting and adjusting emotional tone. The Gen AI tool used was DeepSeek-V3. We used DeepSeek-V3 to refine the language and structure of the abstract, discussion, and response letter during the revision process. Responsibility for the final manuscript lies entirely with the authors.

Gen AI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: Early rehabilitation is important after transplantation and critical illness, but profound weakness, fatigue, and motivational, psychological, and safety barriers may limit participation. Exergaming may facilitate rehabilitation, but the feasibility of full-body in-bed exergaming in this population remains unclear.

Objective: We evaluated the feasibility and observed safety of individually prescribed in-bed exergaming using Nintendo Ring Fit Adventure (NFA; Nintendo Co, Ltd) in posttransplant inpatients after intensive care unit (ICU) care.

Methods: This prospective, single-center, single-arm interventional feasibility study (October 2024-October 2025) enrolled 26 posttransplant adults with prior ICU care and Functional Ambulation Category (FAC) scores ≤3. Participants were referred after ward transfer by transplant-team advanced practice nurses, and the principal investigator confirmed eligibility based on prespecified inclusion and exclusion criteria. Ten individually prescribed, supervised in-bed NFA sessions, each scheduled for 30 minutes, including setup and operation, were planned alongside usual physical therapy. Data were obtained from medical records, standardized session logs, and prespecified clinical and questionnaire assessments. Outcomes included retention; session delivery, completion, and interruptions; exercise-item completion and interruptions; session-terminating adverse events; net exercise time; satisfaction; and exploratory strength, mobility, and health-related quality-of-life changes.

Results: Participants (mean age 53.0, SD 12.4 y; 14 men) included 23 liver and 3 bilateral lung transplant recipients. Mean ICU stay and mechanical ventilation duration were 24.3 (SD 11.0) days and 21.3 (SD 11.6) days, respectively; median baseline FAC and Medical Research Council Sum Score were 0.5 (IQR 0.0-1.0) and 38.0 (IQR 30.5-42.0), respectively. None had an FAC score above 2. Twenty completed the final assessment (20/26, 76.9%, 95% CI 57.9%-89%). Of 227 delivered sessions, 223 (98.2%, 95% CI 95.8%-100%) were completed. Of 2161 prescribed exercise items, 2072 (95.9%, 95% CI 93.4%-97.9%) were completed. No session-terminating adverse events were observed (0/227, 0%, 95% CI 0%-1.6%). Median within-participant net exercise time increased by 159.0 (IQR 35.5-296.3) seconds from sessions 1 to 10 (95% CI 81.0-284.0; Wilcoxon signed-rank test, $P<.001$). Friedman tests followed by Bonferroni-adjusted Wilcoxon signed-rank tests (2-sided $\alpha=.05$) showed baseline-to-final median within-participant changes of 8.0 Medical Research Council Sum Score points (IQR 2.3-10.3; 95% CI 4.0-10.0, $P=.004$), 2.0 Intensive Care Unit Mobility Scale points (IQR 1.0-4.3; 95% CI 1.0-3.5, $P<.001$), and 15.0 EQ-VAS points (IQR 0.0-30.0; 95% CI 5.0-25.0, $P=.009$). Questionnaire responses were favorable.

XSL•FO
RenderX

Conclusions: Under therapist supervision, the individually prescribed in-bed NFA program showed favorable operational feasibility, with no session-terminating adverse events. By combining the accessibility of a commercial off-the-shelf exergame with individualized exercise prescription, the program extended bedside exergaming to posttransplant inpatients with substantial functional impairment after ICU care who had not achieved independent ambulation.

Trial Registration: ClinicalTrials.gov NCT06937463; https://clinicaltrials.gov/study/NCT06937463

KEYWORDS

exergaming; rehabilitation; critical illness; intensive care unit-acquired weakness; organ transplantation

Introduction

Advances in critical-care medicine have substantially improved survival after severe illness and complex surgery, including organ transplantation. However, following critical illness or organ transplantation, a substantial proportion of individuals experience functional decline characterized by sarcopenia and intensive care unit (ICU)-related neuromuscular impairment, including intensive care unit–acquired weakness (ICU-AW) [1-3]. These impairments often persist beyond the acute phase, contributing to prolonged disability and reduced health-related quality of life (HR-QOL) [2,4-6]. Early rehabilitation and mobilization are therefore key strategies for mitigating muscle wasting and promoting functional recovery [3,5,7,8], particularly in transplant recipients, in whom postoperative catabolic and nutritional disturbances and the metabolic effects of immunosuppressive therapy may create additional barriers to physical recovery [3,9].

Despite the growing emphasis on early mobilization, delivering sufficient rehabilitation to patients with critical illness-related functional impairment remains challenging. For high-acuity patients who have not achieved independent ambulation, profound weakness, fatigue, and psychological barriers can limit sustained exercise participation [1,10-12]. These barriers may be especially relevant to posttransplant patients, in whom transplant-related fatigue, fear of movement, and low self-efficacy can further limit exercise participation despite substantial rehabilitation needs [13-15]. Systemic constraints, including limited staffing and reimbursement structures, may also restrict the frequency and duration of supervised one-to-one therapy sessions [16-18]. Together, these patient- and system-level barriers contribute to prolonged inactivity during hospitalization.

In this context, technology-assisted rehabilitation has been explored as an adjunct to conventional therapist-led care. Exergaming integrates physical exercise with interactive video game elements, often using motion-sensing technology [12,19-21]. A distinguishing feature of exergaming is that it embeds physical movements within goal-directed, game-like tasks and provides immediate performance feedback [20,22-25], features that may support enjoyment, motivation, and engagement in ways consistent with self-determination theory [22,26]. Exergaming-based interventions have demonstrated feasibility and acceptability across diverse populations [19,27-29]. Adapted interactive virtual reality has also been feasible for supine upper-limb exercise in bed-restricted patients with prolonged critical illness [30]. Nevertheless, evidence regarding the feasibility and safety of exergaming during or after critical illness remains limited [25,30-32]. To our knowledge, in-bed full-body exergaming incorporating upper and lower extremity and trunk movements has not been studied in posttransplant recipients with post-ICU functional decline and profound mobility impairment.

Nintendo Ring Fit Adventure (NFA) is a commercially available video game that enables full-body exercise through motion-sensing technology. Although not developed for clinical use, NFA's custom mode allows built-in exercise items to be selected and sequenced according to clinical status and tolerance, while some exercise items (Fit Skills) have movement patterns amenable to modification for supported in-bed performance. Together, these features may facilitate bedside application in patients with marked functional impairment and limited physiological reserve. Published studies on NFA have mainly been conducted in populations with relatively preserved physical function [33-35], whereas evidence for its use in medically complex inpatients with severe functional impairment after ICU care or transplantation remains lacking.

Therefore, we evaluated the feasibility and observed safety of NFA as an individually prescribed in-bed exergaming rehabilitation program for posttransplant inpatients with marked functional impairment after ICU care. Secondary objectives were to (1) describe the characteristics and longitudinal trends in exercise performance and (2) descriptively characterize physical function and HR-QOL over the intervention period and assess patient satisfaction.

Methods

Conditions and Design

This prospective, single-center, single-arm interventional feasibility study was conducted at Asan Medical Center (a tertiary university hospital in Seoul, Republic of Korea) between October 2024 and October 2025. The trial was retrospectively registered at ClinicalTrials.gov on April 20, 2025 (NCT06937463). Reporting of this study was guided by the Journal Article Reporting Standards for Quantitative Research [36], and the intervention was described according to the TIDieR (Template for Intervention Description and Replication) framework [37] (Checklist 1).

Inclusion, Exclusion, and Sampling Procedures

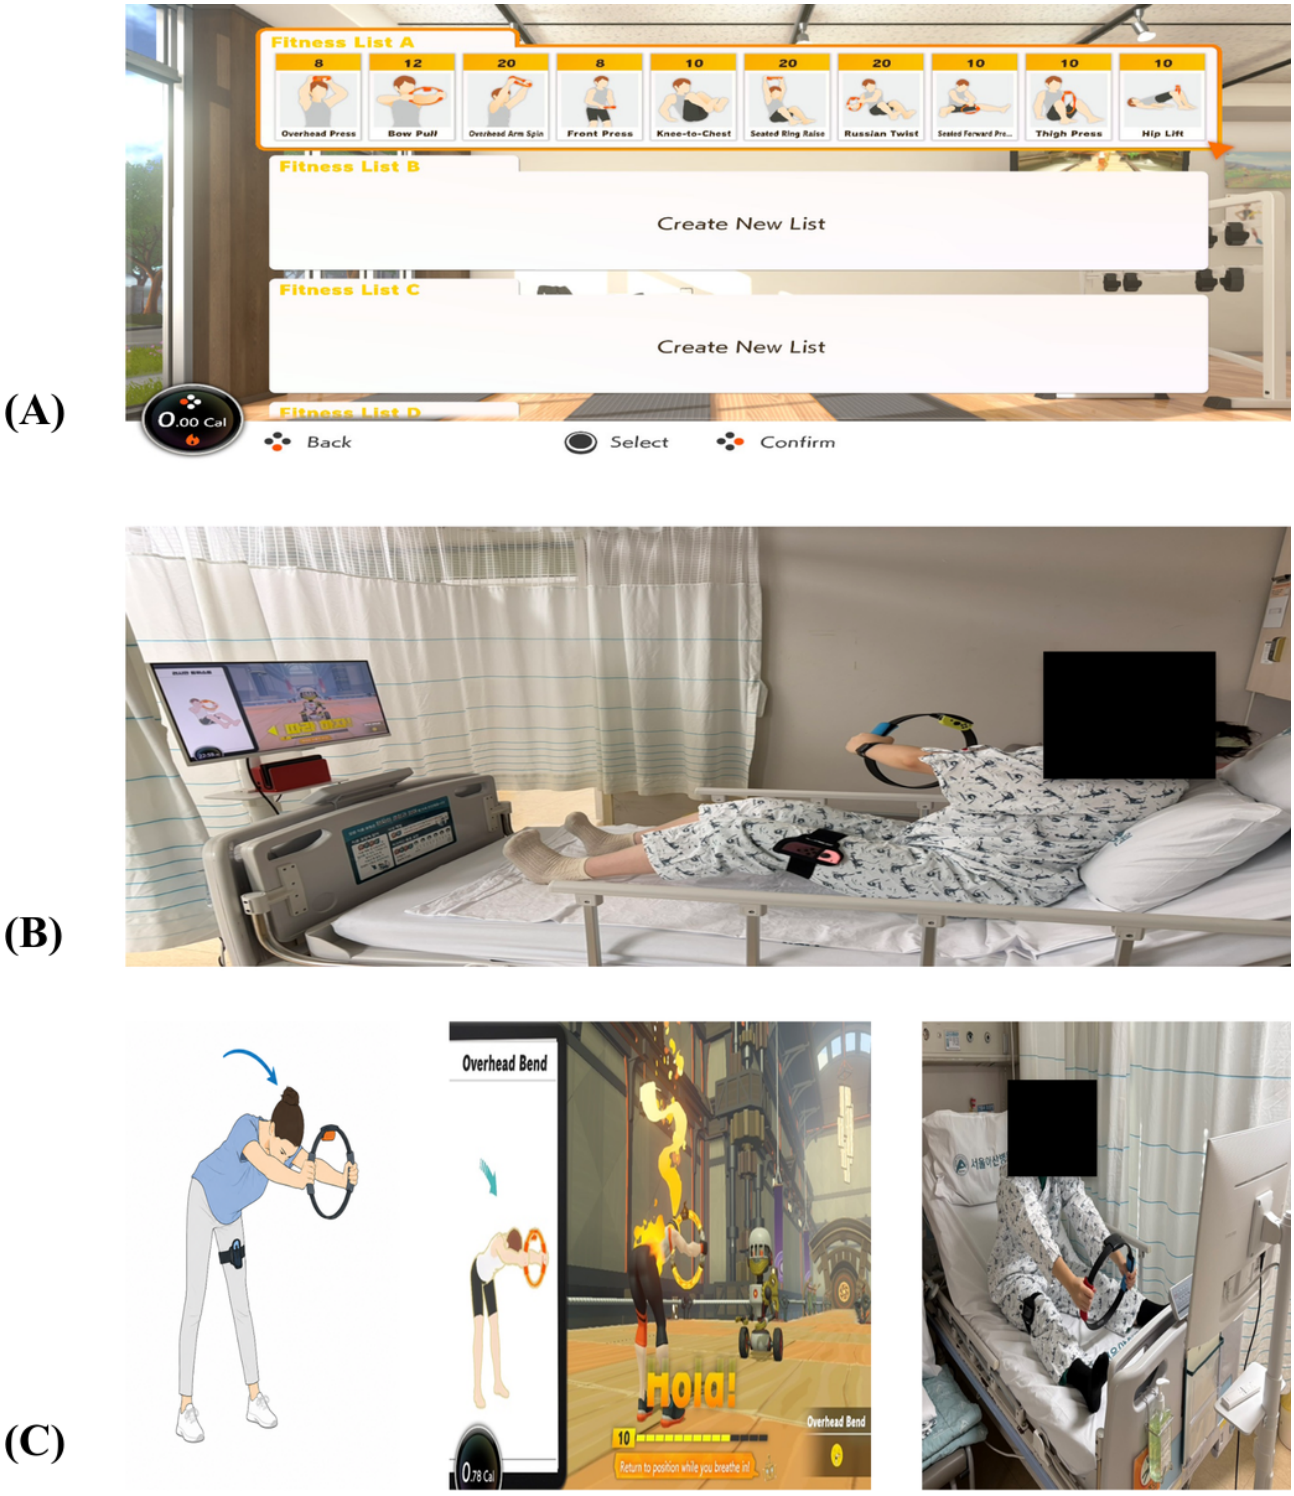
Patients were included if they were organ transplant recipients, aged 18 years or older, had received ICU care during the hospitalization in which transplantation was performed, and

XSL•FO
RenderX

had not achieved independent ambulation; inability to ambulate independently was defined as a Functional Ambulation Category (FAC) score of 3 or less. Patients were excluded if they met any of the following criteria: (1) inability to follow instructions owing to cognitive impairment or sedation; (2) hemodynamic instability precluding rehabilitation (uncontrolled shock with persistent hypotension despite vasopressor therapy, an arrhythmia causing hemodynamic compromise, or uncontrolled active bleeding); (3) severe musculoskeletal limitations (eg, unstable fractures or recent amputations) preventing exercise participation; and (4) significant sensory impairments (eg, hearing loss or visual impairments) hindering interaction with the exergaming system. A convenience sampling approach was used. After transfer from the ICU to a general ward, potentially eligible patients were referred by advanced practice nurses from the relevant transplant teams to the principal investigator for study participation. The principal investigator, a physiatrist, subsequently confirmed eligibility, obtained written informed consent, and finalized enrollment. The intervention was delivered exclusively at the bedside on the general ward.

Participant Characteristics

Baseline characteristics specified for descriptive reporting included demographic and anthropometric characteristics, cognitive status, vital signs, transplantation- and hospitalization-related characteristics, ICU and mechanical ventilation courses, respiratory support, timing of intervention initiation, and baseline muscle strength and mobility.



Intervention Protocol and Instrumentation

NFA Hardware and Software

The NFA system comprises a Nintendo Switch console, a ring-shaped resistance controller (Ring-Con), and a leg-mounted motion sensor (leg strap), which together capture upper-extremity, lower-extremity, and trunk movements. The Ring-Con detects pressing and pulling force and, together with the attached Joy-Con, captures arm movement, enabling real-time interaction with the game. The software links these motion inputs to interactive exercise tasks. For this study, NFA custom mode was used to individualize exercise prescription by selecting and sequencing up to 10 of 43 built-in Fit Skills exercises for each session (Figure 1A).

XSL•FO

Figure 1. Implementation of the in-bed exergaming program for posttransplant inpatients after intensive care. (A) Custom mode interface of Nintendo Ring Fit Adventure (NFA), used to create individualized exercise item lists. (B) Representative bedside setup. The height-adjustable monitor was positioned at the foot of the bed within the participant's line of sight, with the Nintendo Switch console placed immediately below the monitor. Depending on their functional status and the selected exercise item, participants performed the exercises in a supported seated or semirecumbent position. The Ring-Con, fitted with one Joy-Con controller, was held with both hands, while the second Joy-Con controller was secured to the thigh using the leg strap. (C) Comparison of standard and modified exercise implementations: (left) an illustration based on an NFA reference image depicting the standard exercise item posture; (middle) in-game screenshot of the corresponding movement; and (right) modified exercise posture adapted for in-bed performance. The adaptation retained the primary target body region but was not considered biomechanically equivalent to the standard exercise item.

NFA-Based In-Bed Exergaming Program

The program comprised 10 planned bedside sessions, scheduled once daily when the participant's clinical condition and hospital schedule permitted. Before each session, a physician confirmed that the participant was clinically able to participate. A certified physical therapist then brought the NFA equipment and a height-adjustable monitor to the participant's room and set them up at the bedside, with the console positioned below the monitor at the foot of the bed. This setup allowed the participant a clear

XSL•FO
RenderX

view of the game screen while using the Ring-Con with the leg strap secured to the thigh in a supine, semirecumbent, or seated-in-bed position (Figure 1B). Each session was planned within a 30-minute window, including equipment setup and operation. Before each session, the same treating physical therapist calibrated the Ring-Con using the therapist's own maximum force rather than the participant's force to standardize the setting across participants and sessions. Before the first session, the therapist provided a brief explanation and demonstration of device use and basic game-controlled movements.

For this study, 13 exercise items were selected by the physiatrists and physical therapists involved in the study a priori based on clinical judgment regarding their feasibility for modified in-bed performance and clinical relevance, while aiming to include exercises targeting the upper extremities, lower extremities, and trunk. Each exercise item was categorized according to the primary body region targeted. Exercise items originally designed for standing were adapted for in-bed use and performed in a seated position, with ranges of joint motion adjusted as needed while preserving the intended movement pattern (Figure 1C; more details in Multimedia Appendix 1).

All patients received an individually prescribed in-bed exergaming program in addition to usual physical therapy (PT). At the beginning of each session, a physical therapist assessed the clinical status (including general condition, strength, and range of motion) of the patient and selected up to 10 exercise items from the 13-item library, tailoring the combination of upper extremity, trunk, and lower extremity exercises to the individual. For each selected item, the therapist typically prescribed one set of 8‐14 repetitions. The number of repetitions was individualized based on an overall assessment of muscle strength, available range of motion, hemodynamic stability, and the participant's response to exercise, including perceived exertion, pain, and fatigue. Following therapist demonstration, the participant briefly tested each prescribed item, and the therapist determined whether to include it in that day's exercise item set. No prespecified quantitative intensity target was used, and the Fit Skills used in this study did not provide a separate difficulty setting within custom mode. Instead, exercise dose was individualized within and across sessions by adjusting the selected exercise items, the number of items, and the prescribed number of repetitions. As the participant's clinical status and exercise tolerance improved, the therapist could modify the selected items and increase the number of items or prescribed repetitions. Whenever the patient could perform the movement through a substantial portion of the intended range of motion but could not achieve the full range, the therapist provided mild manual assistance as needed to facilitate movement toward the desired range while maintaining active participation.

Safety Monitoring

Clinical safety was monitored throughout each NFA session by the supervising physical therapist, who made the initial decision to continue, modify, or discontinue exercise. Heart rate (HR) and oxygen saturation were monitored during every intervention session for real-time application of the prespecified safety criteria. For analysis, only resting and peak HR values were formally recorded during sessions 1, 6, and 10. When additional clinical assessment was needed, the therapist conferred with the participant's physician or advanced practice nurse. Prespecified safety criteria for pausing, modifying, or discontinuing exercise included respiratory distress (respiratory rate >35 breaths/min or use of accessory respiratory muscles), cyanosis, oxygen saturation below 90%, tachycardia (an increase in HR of ≥40 beats/min from baseline), hypotension (mean arterial pressure <60 mm Hg), participant intolerance (eg, diaphoresis, tremor, dizziness, or severe pain), unanticipated tube or line removal, and falls. If any of these criteria were met, exercise was paused or modified by reducing its intensity and could be resumed after recovery; the session was discontinued if the participant did not recover within 2 minutes. Immediate discontinuation occurred in the event of a fall or unplanned tube or line dislodgement. Sessions could also be interrupted in the absence of these criteria because of patient refusal or when the therapist determined that the participant was unable to continue for reasons such as fatigue or reduced tolerance.

Usual PT

Participants received usual PT according to standard institutional care. The therapy followed a stepwise ICU-AW mobilization protocol: stage 1, in-bed passive range-of-motion exercises; stage 2, in-bed active range-of-motion exercises; stage 3, edge-of-bed sitting; stage 4, standing; and stage 5, ambulation as tolerated with or without an assistive device. Progression was guided by the same safety criteria described in the "Safety Monitoring" subsection and stage-specific functional readiness, including the ability to follow commands, maintain head control, and generate sufficient upper- and lower-limb strength, as relevant to each successive stage. Usual PT was generally scheduled once daily, with each session lasting approximately 30 minutes; actual delivery varied according to the participant's clinical condition and schedule.

Measures and Covariates

Overview

Measures included participant-, session-, and exercise-item–level exercise metrics used to characterize operational feasibility, observed safety indicators, exploratory clinical outcomes, and patient-reported outcomes. No covariates were prespecified or included in adjusted analyses.

Exercise Metrics and Safety

At the session level, the metrics were interrupted sessions and net exercise time per session, defined as the cumulative duration of active exercise excluding the preparation time and rest periods. A session was considered interrupted if it was terminated before completion of the planned exercise set. At the exercise-item level, a prescribed item was defined as an exercise selected and configured in the NFA software at the beginning of the session. Prescribed items included in that day's exercise set after brief testing were classified as attempted. Attempted items were considered completed when all prescribed repetitions were performed with correct form, as judged by the therapist, with or without manual assistance; items terminated before completing all prescribed repetitions were classified as

XSL•FO
RenderX

interrupted. HR during exercise was monitored using an optical armband sensor (Verity Sense, Polar Electro). HR responses were assessed using resting HR before exercise, peak HR during exercise, and absolute HR change, calculated as peak HR minus resting HR. Any interruption due to a prespecified safety criterion was classified as a session-terminating adverse event. For all interruptions, the reason and the exercise item being performed were recorded.

Muscle Strength and Functional Measures

Overall muscle strength was assessed using the Medical Research Council Sum Score (MRC-SS), which grades six bilateral upper and lower limb muscle groups (shoulder abduction, elbow flexion, wrist extension, hip flexion, knee extension, and ankle dorsiflexion) on a 0‐5 scale (0: no visible contraction; 5: normal strength), yielding a composite score ranging from 0 to 60 [38]. Additional muscle strength measures included the handgrip strength (HGS) and knee extensor strength (KES), assessed using a digital hand dynamometer (TKK-5401, Takei Scientific Instruments) and a handheld dynamometer (Commander Echo MMT, JTECH Medical), respectively. HGS was measured with the participant in a seated or semi-Fowler position, with the dynamometer kept free from contact with the bed or body. KES was measured with the participant seated at the edge of the bed when possible or in a semi-Fowler position with knee flexion supported by a pillow. The dynamometer was positioned against the distal anterior tibia and manually stabilized by the therapist. Each side underwent 3 maximal-effort trials separated by 30-second rest intervals, and the highest of the 6 values was used for analysis. Mobility was assessed primarily using the Intensive Care Unit Mobility Scale (ICUMS) [39], which was designated as the principal exploratory mobility measure. The ICUMS is a 0‐10 ordinal scale that captures the highest level of mobility achieved, from passive movements in bed to independent ambulation. Additionally, as an ancillary measure, mobility was assessed using the FAC [40], a 6-point scale describing the level of assistance required for walking (0: nonfunctional ambulation, 1: continuous physical assistance, 2: intermittent physical assistance, 3: supervision or standby assistance, 4: independent on level surfaces, and 5: independent on all surfaces, including stairs). Functional lower-limb movement was evaluated using study-specific ordinal grading systems for the graded straight leg raise (SLR; grade 0: unable; grade 1: <30°; grade 2: ≥30° with <10 repetitions; grade 3: ≥30° with ≥10 repetitions) and bridge tests (grade 0: unable; grade 1: bridge height allowing a flat hand to pass; grade 2: bridge height allowing a fist to pass for <5 repetitions; and grade 3: the same height for ≥5 repetitions).

Patient-Reported Outcomes

Patient-reported outcomes included HR-QOL and acceptance of the NFA-based program. HR-QOL was assessed using the widely applied and validated EQ-5D-5L instrument [41]. The EQ-5D-5L descriptive system evaluates five domains (mobility, self-care, usual activities, pain or discomfort, and anxiety or depression), from which a summary index score is derived using the Korean population value set [42]. The instrument also includes the EQ-VAS reflecting the self-rated overall health status of the participant. Acceptance and user experience were evaluated using a study-specific self-reported satisfaction questionnaire composed of 11 items rated on a 5-point Likert scale. For descriptive presentation, the items were grouped by content into 3 groups: satisfaction and motivation, convenience and suitability, and perceived effectiveness of the program. The same questionnaire included a single item on perceived exercise intensity, rated on a 5-point difficulty scale (1: very easy, 3: appropriate, and 5: very difficult; Multimedia Appendix 2).

Data Collection

A session log was completed by the physical therapist at every session to document the prescribed exercise items, their attempt and completion status, reasons for any session interruption or exercise-item interruption, and the net exercise time for that session. Standardized muscle strength, functional measures, and EQ-5D-5L scores were collected at sessions 1, 6, and 10, which corresponded to the baseline, midpoint, and final evaluations, respectively. The study-specific questionnaires were administered at the midpoint and final evaluations only. During sessions 1, 6, and 10, the HR was monitored continuously, and both the presession resting HR and in-session peak HR reached were recorded. Baseline demographic and clinical characteristics were obtained from electronic medical records.

Quality of Measurements, Psychometrics, and Masking

Measurements were obtained by physical therapists using the standardized positioning, instructions, scoring procedures, and assessment schedules described in the preceding subsections of "Measures and Covariates." Multiple maximal-effort trials were used for HGS and KES, and the MRC-SS, ICUMS, FAC, and EQ-5D-5L were administered according to their established scoring systems. Formal psychometric properties were unavailable for the study-specific graded SLR, bridge test, and satisfaction questionnaire. Masking was not applicable because all participants received the same intervention. Treating therapists also conducted outcome assessments and were not blinded to previous results. The questionnaires were distributed and nonanonymous but were completed independently without the therapist present.

Sample Size, Power, and Precision

A pragmatic target of approximately 24 participants completing the final assessment was selected to support preliminary estimation of feasibility outcomes within the planned single-center recruitment period. Based on experience at our center, approximately 85% of enrolled participants were expected to complete the study; allowing for approximately 15% attrition, the enrollment target was set at 28 participants. At this sample size, an assumed completion proportion of 85% would yield a 2-sided 95% Wilson CI of approximately 68%‐94%. No formal hypothesis-testing power calculation was performed because this was a feasibility study. The predefined recruitment period ended before the target enrollment was reached.

Data Diagnostics

Before analysis, the data were reviewed for completeness, out-of-range values, and internal inconsistencies. No participant was excluded after data collection solely on the basis of a

XSL•FO
RenderX

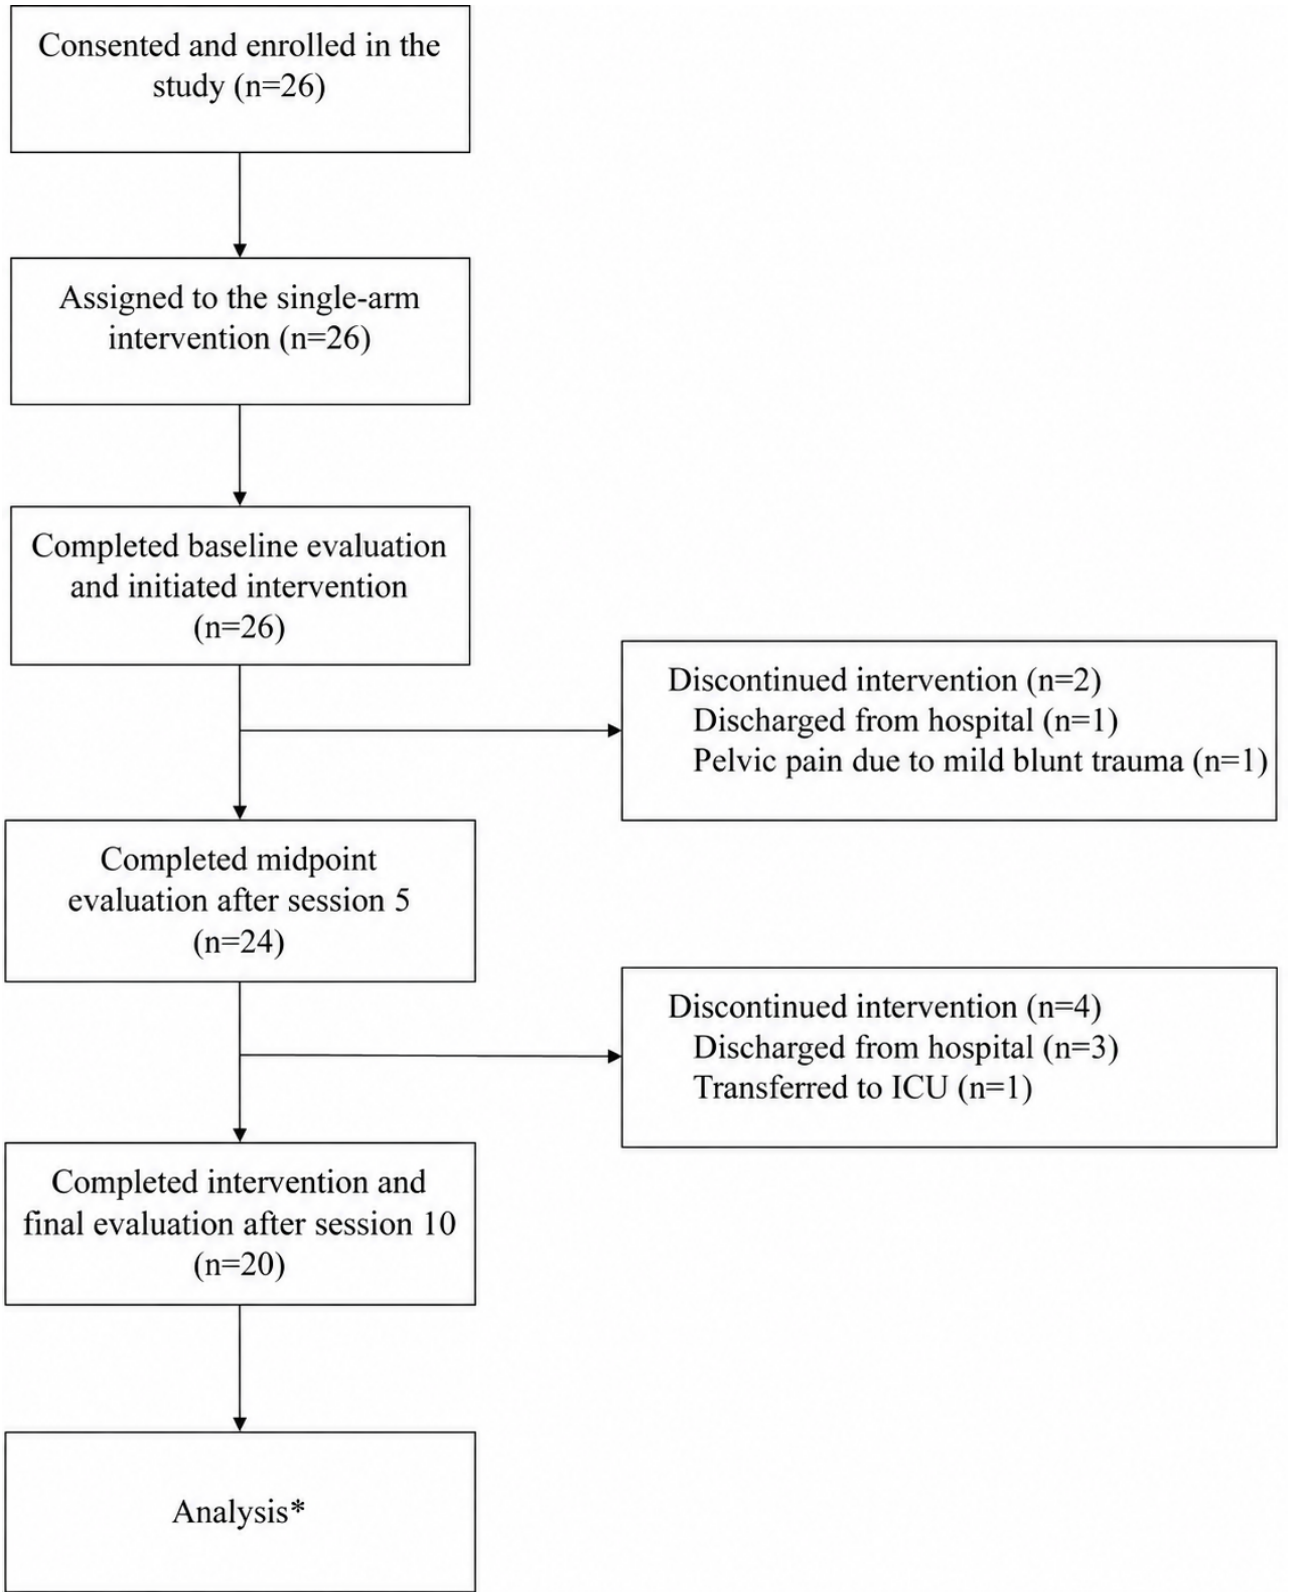
statistical outlier, and no winsorization or data transformation was applied. Measurements that could not be obtained reliably were treated as unavailable, and missing values were not imputed. A Little test of missing completely at random was performed using repeated MRC-SS, ICUMS, EQ-VAS, and absolute HR change measures.

Analytic Strategy

All statistical analyses were performed using SPSS Statistics (version 31.0; IBM Corp) and R software version 4.5.2 (R Foundation for Statistical Computing). Continuous variables were summarized as means (SDs) or medians (IQRs), as appropriate, and categorical variables as counts and percentages. At each assessment, clinical and patient-reported outcomes were summarized using all available observations. Paired changes were calculated among participants with data at both corresponding time points and summarized as median within-participant differences; 95% CIs were estimated using a nonparametric percentile bootstrap with 10,000 resamples. Changes in muscle strength, functional measures, HR-QOL, and absolute HR change across the 3 assessments were analyzed using Friedman tests in outcome-specific complete cases. Significant overall Friedman tests were followed by 2-sided Wilcoxon signed-rank tests, with *P* values Bonferroni-adjusted for the 3 comparisons within each outcome. Among final-evaluation completers, exploratory Spearman rank correlations were calculated between the number of usual PT sessions received during the intervention period and baseline-to-final changes in MRC-SS and ICUMS, with 95% CIs estimated using a bias-corrected and accelerated bootstrap. Net exercise time between sessions 1 and 10 was compared using a Wilcoxon signed-rank test. Statistical significance was defined as 2-sided $P<.05$, including for Bonferroni-adjusted pairwise comparisons. Clinical analyses were exploratory; multiplicity was adjusted within each longitudinal outcome but not across outcomes or for the exploratory correlation analysis. Exercise metrics and safety outcomes were summarized using counts, proportions, and 95% CIs. Wilson score intervals were used for participant-level proportions, participant-cluster bootstrap intervals for session-level and exercise-item–level proportions, and an exact binomial interval for the session-terminating adverse event proportion. For the questionnaire, no inferential tests were performed, and items 1 - 11 were summarized as normalized mean ratings (0 - 100), calculated as ([mean item rating – 1] / 4)×100.

Ethical Considerations

The study was approved by the Institutional Review Board of Asan Medical Center (2024 - 1159). Written informed consent was obtained from all participants before enrollment after they had received an explanation of the study purpose, procedures, and potential risks. Study data used for analysis were deidentified by removing direct identifiers or replacing them with study-specific codes and were stored in password-protected files on access-restricted institutional systems. Access to the data was limited to the principal investigator and authorized coinvestigators. Each participant received Korean won 100,000 (approximately US $73 based on the exchange rate on August 29, 2026) as compensation for study participation. No study participants are depicted in Figure 1 or Multimedia Appendix 1. The individual shown is a member of the research team from whom separate written consent for publication of the images was obtained.



Results

Participants and Their Characteristics

In total, 26 patients were enrolled, completed the baseline evaluation, and initiated the NFA-based in-bed exergaming program (Figure 2). Of these, 2 participants discontinued before the midpoint evaluation because of hospital discharge or pelvic pain following mild trauma. A total of 24 participants completed the midpoint evaluation and 4 subsequently discontinued before the final evaluation owing to hospital discharge or ICU readmission. Ultimately, 20 patients reached session 10 and completed the final evaluation. All discontinuations were judged unrelated to the intervention. Participant-level details of noncompleters, including the clinical context, number of sessions completed, and investigator-assessed intervention relatedness, are provided in Multimedia Appendix 3. All 26 participants contributed baseline data, whereas subsequent analysis sample sizes varied by outcome and assessment time point.

XSL•FO
RenderX

Figure 2. Study flow diagram for a prospective, single-center feasibility study of posttransplant inpatients after intensive care. Flow diagram showing participant enrollment, completion of baseline, midpoint, and final evaluations, and reasons for discontinuation. The study was conducted at Asan Medical Center, Seoul, Republic of Korea, from October 2024 to October 2025. *Sample sizes varied by outcome and type of analysis. Descriptive summaries used available cases, whereas longitudinal tests used outcome-specific complete cases. Exact sample sizes are reported in the corresponding tables and figures. ICU: intensive care unit.

Baseline demographic and clinical characteristics of all enrolled participants, overall and by intervention completion status, are summarized in Table 1. A total of 23 (88.5%) participants underwent liver transplantation, and 3 (11.5%) underwent bilateral lung transplantation. Mean ICU stay and mechanical ventilation (MV) duration were 24.3 (SD 11.0) days and 21.3 (SD 11.6) days, respectively. The first intervention was initiated a mean of 19.6 (SD 13.6) days after ICU discharge. At study

XSL•FO
RenderX

entry, participants had marked muscle weakness and mobility limitation, with median MRC-SS, ICUMS, and FAC scores of 38.0 (IQR 30.5-42.0), 6.5 (IQR 3.0-8.0), and 0.5 (IQR 0.0 to 1.0), respectively. Although eligibility permitted FAC scores up to 3, a total of 21 (80.8%) participants were at FAC 0‐1, and none had a score above 2. Most of them required ongoing respiratory support at intervention initiation (tracheostomy cannula: 14/26, 53.8%; bilevel positive airway pressure: 8/26, 30.8%; and/or supplemental oxygen: 14/26, 53.8%). Across all participants, usual PT sessions ranged from 0 to 15, with a mean of 8.3 (SD 4.3); completers received 9.6 (SD 3.7) sessions, compared with 3.8 (SD 3.1) among noncompleters. The corresponding ratios of usual PT sessions to delivered NFA sessions were 0.9 (SD 0.4) overall, 1.0 (SD 0.4) among completers, and 0.7 (SD 0.5) among noncompleters.

XSL•FO
RenderX

Table . Baseline demographic and clinical characteristics of the participants. Completers were participants who completed all 10 intervention sessions and the final assessment; noncompleters were those who discontinued before completion.

Characteristic	Enrolled (n=26)	Completer (n=20)	Noncompleter (n=6)

[a]MMSE-K: Korean Version of Mini-Mental State Examination.

[b]ICU: intensive care unit.

[c]MV: mechanical ventilation.

[d]APACHE: Acute Physiology and Chronic Health Evaluation.

[e]MRC-SS: Medical Research Council Sum Score.

[f]ICUMS: Intensive Care Unit Mobility Scale.

[g]FAC: Functional Ambulation Category.

[h]PT: physical therapy.

[i]NFA: Nintendo Ring Fit Adventure.

[j]BiPAP: bilevel positive airway pressure.

[k]LDLT: living donor liver transplantation.

[l]DDLT: deceased donor liver transplantation.

In descriptive comparisons, all 6 noncompleters were liver transplant recipients and had a lower median baseline MRC-SS than completers (33.0, IQR 30.0-36.0 vs 40.0, IQR 34.3-45.0), whereas median FAC was identical (0.5, IQR 0.0-1.0 in both groups) and median ICUMS was higher among noncompleters (7.5, IQR 5.5-8.0 vs 6.0, IQR 3.0-8.0). Mean mechanical ventilation duration was shorter among noncompleters (17.8, SD 9.8 vs 22.4, SD 12.1 d). Other baseline differences are shown in Table 1.

Muscle Strength and Function Measures and HR-QOL

Exploratory clinical outcomes at each time point were summarized using available cases in Table 2, with changes reported as median within-participant differences based on paired observations. Detailed complete-case analyses are provided in Multimedia Appendix 4. The median MRC-SS increased from 38.0 (IQR 30.5-42.0) at baseline to 42.0 (IQR 38.8-48.0) at midpoint and 48.0 (IQR 42.0-48.0) at the final assessment, with a median within-participant change from baseline to final of 8.0 (IQR 2.3-10.3; 95% CI 4.0-10.0). The baseline-to-midpoint and baseline-to-final changes were significant (P=.02 and P=.004, respectively), whereas the midpoint-to-final change was not significant. The median ICUMS increased from 6.5 (IQR 3.0-8.0) to 8.0 (IQR 6.5-8.0) at midpoint and remained at 8.0 (IQR 8.0-9.0) at final, with a median within-participant change from baseline to final of 2.0 (IQR 1.0-4.3; 95% CI 1.0-3.5). ICUMS showed continued within-participant improvement during both the baseline-to-midpoint and midpoint-to-final periods (P=.009 and P=.003). FAC and graded SLR also showed significant within-participant changes during the intervention period, whereas bridge-test change was significant only from baseline to final. HGS increased throughout the intervention period, from 10.5 (IQR 6.8-17.1) kg at baseline to 11.8 (IQR 8.6-18.8) kg at midpoint and 15.1 (IQR 10.8-19.3) kg at final, with a median within-participant change from baseline to final of 3.2 (IQR 1.9-4.9; 95% CI 2.1-4.4) kg; however, the increase reached significance only from midpoint to final and from baseline to final. KES also showed an upward trend, although none of the pairwise comparisons reached significance. The number of usual PT sessions was not significantly correlated with baseline-to-final changes in MRC-SS (Spearman ρ=−0.08, 95% CI −0.56 to 0.43; P=.75) or ICUMS (Spearman ρ=−0.20, 95% CI −0.61 to 0.29; P=.40). Among the 312 scheduled observations included in the missing-data analysis, 35 (11.2%) were missing. The Little test did not reject the hypothesis that the data were missing completely at random (χ^2_{21}=28.45, P=.13).

Regarding the EQ-5D-5L measures of HR-QOL (Table 2), the median EQ-5D-5L index increased from 0.429 (IQR 0.193-0.499) at baseline to 0.519 (IQR 0.252-0.659) at midpoint and 0.622 (IQR 0.349-0.731) at final, with a median within-participant change from baseline to final of 0.138 (IQR −0.050 to 0.328; 95% CI −0.008 to 0.309), although the overall change was not statistically significant. The median EQ-VAS increased from 50.0 (IQR 40.0-70.0) at baseline to 60.0 (IQR 50.0-80.0) at midpoint and 65.0 (IQR 50.0-85.0) at final, corresponding to a median within-participant change from baseline to final of 15.0 (IQR 0.0-30.0; 95% CI 5.0-25.0); the baseline-to-final difference was statistically significant. Among the EQ-5D-5L domains, scores in the mobility domain decreased significantly from midpoint to final and from baseline to final.

Exercise Metrics and Adverse Events

Table 3 summarizes participant retention and session- and exercise-item–level metrics. Of the 26 enrolled participants, 20 completed the final assessment, corresponding to a retention rate of 76.9% (95% CI 57.9%-89%). Across all enrolled participants, 227 of the 260 (87.3%; 95% CI 76.9%-95.8%) protocol-planned sessions were delivered, and 223 were completed, corresponding to 85.8% of all protocol-planned sessions (95% CI 75%-95%). Of these delivered sessions, 223 (98.2%; 95% CI 95.8%-100%) were completed, whereas 4 were interrupted because of fatigue. No session-terminating adverse events (0/227, 0%; 95% CI 0%-1.6%) were observed during 227 delivered sessions. Of the prescribed items, 2103 (97.3%; 95% CI 95.2%-98.9%) were attempted. Among the attempted items, 31 (1.5%; 95% CI 0.7%-2.5%) were interrupted after initiation, primarily because of transient fatigue (n=23), followed by upper-arm pain (n=8). The completion rate was highest for upper-extremity exercises (97.2%), followed by lower-extremity exercises (96.8%), and was lowest for trunk exercises (94.4%). Multimedia Appendix 5 provides detailed distributions of prescribed and completed items and completion rates by target body region and individual exercise type.

Table . Participant retention, intervention delivery, and prescribed exercise-item completion during the 10-session in-bed NFA[a] program among the 26 enrolled participants. Outcomes are presented at the participant, session, and exercise-item levels to characterize retention, intervention delivery, and prescribed exercise-item completion, respectively, together with recorded reasons for interruption and noncompletion. Values at the session and exercise-item levels are aggregated across the participants over the intervention period. Total planned sessions were calculated as 10 sessions for each of the 26 enrolled participants. Body part-specific interruption percentages used the number of attempted items within the corresponding targeted body part.

[c]N/A: not applicable.

Figure 3 presents complete-case data from the 20 participants who completed the final assessment. The aggregate numbers of prescribed and completed exercise items increased during the early sessions and subsequently stabilized, while the failure rate generally decreased over time (Figure 3A). Consistent with Figure 3A, participant-level distributions showed that prescribed exercise-item counts stabilized earlier, whereas completed counts progressively approached them, narrowing the gap across sessions (Multimedia Appendix 6). Median net exercise time increased from 283.0 (IQR 246.5-380.0) seconds in session 1 to 463.0 (IQR 326.0-622.8) seconds in session 10, with a median within-participant increase of 159.0 (IQR 35.5-296.3; 95% CI 81.0-284.0 seconds; $P<.001$; Figure 3B).

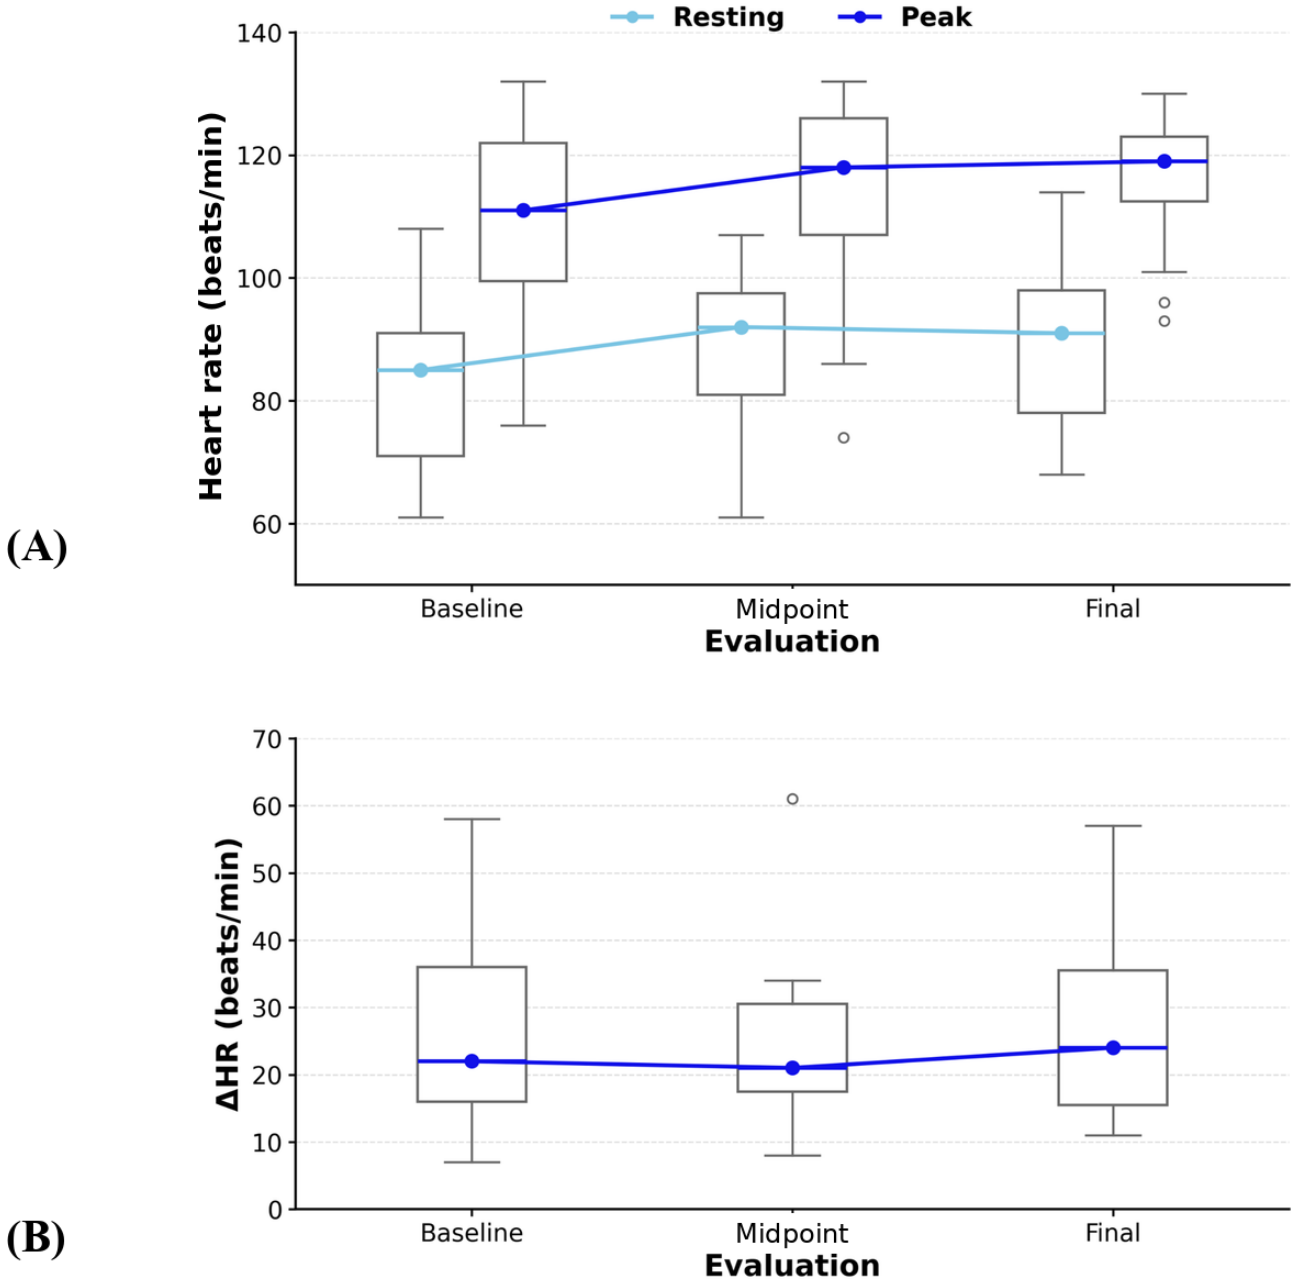

Figure 3. Trends in prescribed and completed exercise items, failure rate, and net exercise time across 10 intervention sessions. Data were obtained from 20 participants who completed all 10 intervention sessions (n=20 per session). (A) Changes in the aggregate number of prescribed and completed exercise items pooled across all participants. The blue line indicates the failure rate (%), defined as the proportion of prescribed exercises that were not completed. Prescribed exercises were classified as not completed if they were not attempted or were interrupted. The gray dashed line indicates the total number of prescribed exercise items, whereas the gray solid line indicates the total number of completed exercise items for each session. (B) Changes in net exercise time (s), defined as the actual duration of exercise performance excluding rest periods. Data are presented as the median (solid line) with IQR (shaded area). Sessions 1 and 10 were compared using a 2-sided Wilcoxon signed-rank test. The net exercise time was significantly higher in session 10 than in session 1 (463.0, IQR 326.0-622.8 vs 283.0, IQR 246.5-380.0 seconds) with a median within-participant increase of 159.0 (IQR 35.5-296.3; 95% CI 81.0-284.0; *P*<.001) seconds.

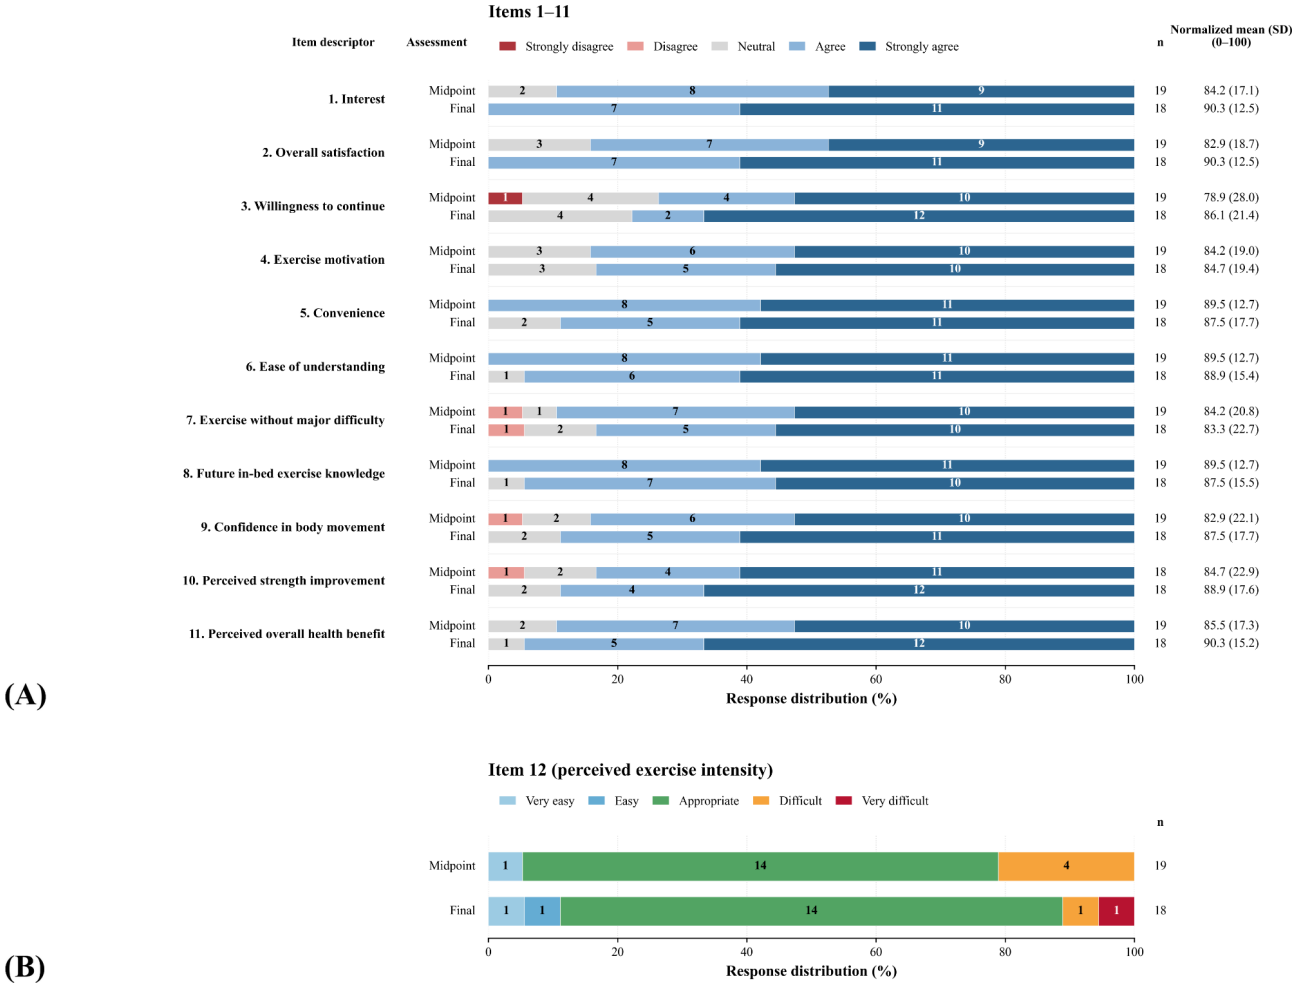
Among the 19 participants with complete HR data at all 3 assessments, neither resting nor peak HR differed significantly across assessments (*P*=.29 and *P*=.10, respectively; Figure 4A), and the highest peak HR recorded across the 3 assessments was 132 beats/min. The median absolute increase from resting to peak HR was 22 (IQR 16-36), 21 (IQR 17.5-30.5), and 24 (IQR 15.5-35.5) beats/min, respectively, with no significant difference across assessments (*P*=.50; Figure 4B).

XSL•FO
RenderX

Figure 4. Heart rate responses across assessments. Box-and-whisker plots show complete-case data from the same 19 participants at baseline, midpoint, and final assessments (n=19 at each assessment). One intervention completer with no peak HR data at any assessment was excluded. Center lines indicate medians, and overlaid lines connect median values to illustrate temporal trends. (A) Resting and peak HR. (B) Peak-resting HR difference (ΔHR), calculated as peak HR minus resting HR. Median (IQR) ΔHR values were 22 (16-36), 21 (17.5 - 30.5), and 24 (15.5 - 35.5) beats/min at baseline, midpoint, and final assessments, respectively (Friedman test, *P*=.50). HR: heart rate.



User Experience and Satisfaction

Questionnaire responses were available from 19 of the 24 (79.2%) participants who completed the midpoint assessment and 18 of the 20 (90%) who completed the final assessment. Responses to items 1 - 11 were concentrated in the "agree" and "strongly agree" categories at both assessments, and all normalized mean item ratings were within the upper quarter of the 0 - 100 scale (Figure 5A). The "willingness to continue" item had the lowest normalized mean rating of 78.9 (SD 28.0) at midpoint, but the rating was higher at 86.1 (SD 21.4) at final. Most respondents rated exercise intensity as "appropriate" at both midpoint (14/19, 73.7%) and final (14/18, 77.8%; Figure 5B). Four (21.1%) respondents rated the intensity as "difficult" at midpoint, whereas only 2 (11.1%) respondents gave ratings above "appropriate" at final.

XSL•FO
RenderX

Figure 5. Item-level response distributions for the study-specific satisfaction questionnaire. Distributions of responses to items 1 - 12 at the midpoint and final assessments. Each 100% stacked horizontal bar shows the distribution of response categories among participants with a nonmissing response to the corresponding item at each assessment. Numbers within bar segments indicate response counts, and n indicates the number of participants with a nonmissing response to the corresponding item at that assessment. (A) Distributions of responses to items 1 - 11. Normalized mean (SD) item rating on a 0 - 100 scale, calculated as ([mean item rating – 1] / 4) ×100. Higher values indicate stronger agreement with the corresponding statement. (B) Distribution of responses to the perceived exercise intensity item.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to evaluate a commercially available exergame on a general ward as an in-bed rehabilitation intervention for posttransplant patients with marked functional impairment after ICU care. Participant retention and delivery of protocol-planned sessions were generally favorable, with high completion among delivered sessions. Most prescribed exercise items were completed, supporting item-level implementation fidelity. No session-terminating adverse events were observed. Questionnaire responses were concentrated in the “agree” and “strongly agree” categories, and all normalized item ratings were in the upper quarter of the scale. Overall, the program showed favorable operational feasibility, with supportive findings for observed short-term safety, tolerability, and acceptability under therapist supervision.

Importantly, the study population comprised high-acuity posttransplant recipients with profound post-ICU functional impairment. Most participants were either nonfunctional ambulators or required continuous physical assistance for ambulation at baseline. Prolonged MV courses and ICU stays [43] were characteristic of the study population, both of which are associated with worse physical function [44,45]. Muscle weakness was similarly pervasive, with most participants meeting the criteria for ICU-AW [46], while Acute Physiology and Chronic Health Evaluation IV scores reflected substantial acute illness severity at ICU admission. This profile differs from those of populations in other exergaming studies, which have largely focused on community-dwelling older adults [33,35], neurologic rehabilitation cohorts [27], or hospitalized older adult patients [34] with relatively preserved function. Even in critical-care–related exergaming studies, functional reserve was generally greater. For example, in a study by Kho et al [32], walking was the highest activity level in half of the participants, and the length of ICU stay was shorter (median 8.5, IQR 2.8-28.8 vs mean 24.3, SD 11.0 d). In Wang et al [25], median baseline MRC-SS scores were 46 - 48; approximately one-third of participants met the criteria for ICU-AW, compared with an MRC-SS of 38.0 (IQR 30.5-42.0) and a higher ICU-AW prevalence in this study. For critical-care and posttransplant inpatients with ICU-AW and severe deconditioning, maintaining adequate physical activity during hospitalization is essential to

XSL•FO
RenderX

support functional recovery and limit the harms of prolonged bed rest [44]. However, ongoing respiratory care needs and other medical complexities may preclude gym-based rehabilitation and shift care toward bedside-only delivery [16,17,47]. Within this setting, however, profound weakness limits patients to a narrow and repetitive range, while fatigue and psychological barriers [10,11,13-15,48] further hinder sustained participation. Introducing exergaming into bedside rehabilitation may help sustain engagement through goal-directed tasks and immediate feedback [19,23,49], particularly when participation is constrained by profound functional impairment or low motivation [11,13,14]. Consistent with this potential mechanism, participants generally gave favorable self-reported ratings on the study-specific questionnaire items assessing interest in exercising with the device and motivation to exercise. Accordingly, this study population represented a particularly challenging clinical context for implementing in-bed exergaming.

As noted above, no session-terminating adverse events were observed despite the substantial deconditioning of the study participants and ongoing respiratory support required by more than half at intervention initiation. Tolerability was also favorable, with infrequent and manageable exercise-related interruptions. Fatigue was the predominant limiting symptom among interrupted exercise items, consistent with another study on exergaming feasibility for early ICU mobilization [50] and with a report that highlighted fatigue as a common issue following solid-organ transplantation [15]. Upper-limb pain was another limiting factor and occurred during both upper-extremity and trunk exercises, which required sustained Ring-Con manipulation and coordinated upper-body movements. These symptoms were predominantly localized to the shoulder or proximal arm, aligning with frequent reports of post-ICU shoulder complications, such as adhesive capsulitis and restricted range of motion [51,52]. However, these transient symptoms were successfully managed with brief rest or task modification without clinical deterioration. Regarding observed short-term safety, although not a definitive safety threshold, the upper HR boundary of 130 beats/min in ICU mobilization criteria provides a conservative reference for the highest peak HR of 132 beats/min observed in this study [53]. This criterion was developed for patients still in the ICU and therefore serves as a conservative benchmark for participants already on general wards. Together with the absence of session-terminating adverse events, these findings indicate that no serious safety concerns were observed during short-term delivery under therapist supervision.

In addition to the overall feasibility findings summarized above, among participants who completed all sessions, median net exercise time increased from session 1 to session 10, an approximately 64% increase in the group median. This pattern suggests that the program could be adjusted as participants tolerated more exercise over time, providing additional evidence of operational feasibility. Regarding participant acceptance, no study discontinuation, session interruption, or exercise-item interruption was attributed to participant refusal. The generally higher item ratings at the final assessment may reflect greater familiarity and acceptance following an initial period of adaptation to the exergame, consistent with the exercise-performance trends. Although good acceptability was also reported in another NFA-based study without individualized prescription [33], the satisfaction and engagement metrics were higher in our study. This difference may relate to the structured nature and personalization of the program, which allowed exercise selection and dosing to be adjusted according to the daily clinical status of each patient, thereby maintaining an appropriate level of challenge. This interpretation is supported by the high exercise-item completion rate and perceived intensity ratings centered on the “appropriate” level. Given the substantial functional and psychological barriers to sustained exercise participation in posttransplant patients with ICU-AW, including helplessness, fear of movement, and low self-efficacy [10,11,14,15], the observed session-level adherence and acceptability results are encouraging.

Among participants who completed the final evaluation, longitudinal trends in completed exercise-item counts and net exercise time paralleled the observed functional changes during the early-to-mid intervention period, particularly through session 6, with initial fluctuations during sessions 1 - 3 possibly reflecting an early familiarization period. This early-to-mid increase coincided with clear within-participant increases at the midpoint, including statistically significant gains in MRC-SS, ICUMS, and graded SLR. The individualized prescription may have supported both early adaptation and subsequent progression by allowing exercise selection and dosing to be adjusted in line with observed improvements in strength and mobility, thereby aligning completed exercise volume with evolving functional capacity. In later sessions, completed exercise-item counts plateaued, whereas the net exercise time increased toward the end of the program, which may have resulted from additional repetitions within selected items, although repetition counts were not recorded. This descriptive temporal alignment provides an exploratory account of how exercise exposure evolved alongside the observed functional changes during the intervention period.

Modern rehabilitation technologies, particularly purpose-built exergaming systems, can provide task-specific practice, multimodal feedback, quantifiable performance targets, and adjustable difficulty, allowing exercise demands to be matched more closely to patient ability [20,21,30]. However, their development and routine implementation can require substantial resources, including acquisition, maintenance, and technical support [54]. Commercially available off-the-shelf exergames are more accessible, but their entertainment-oriented, predetermined movements and fixed progression structures may not adequately accommodate patients’ clinical goals or functional capacity [20,55], a limitation that may be particularly relevant for severely deconditioned, medically complex inpatients. In this study, the NFA custom mode provided a pragmatic compromise, retaining the accessibility of a commercial platform while enabling exercises to be selected, sequenced, and dosed according to each patient’s daily clinical status and functional capacity. Another distinguishing feature of our study was the incorporation of trunk and lower extremity exercises as a substantial component of an in-bed program. Previous in-bed exergaming studies predominantly emphasized

XSL•FO
RenderX

upper extremity training, whereas meaningful lower-limb engagement in other protocols often required standing [30-32,34,50]. Given that proximal stability and lower limb strength are foundational for mobilizing patients with ICU-AW [56,57], extending the exercise repertoire to these regions in a bed-based setting is clinically relevant, particularly for this population with marked functional impairment.

Although the NFA provided a practical compromise between bespoke rehabilitation software and a conventional off-the-shelf exergame, several pragmatic observations and limitations may inform the future development and clinical use of exergames. First, prescribed and completed exercise-item counts plateaued during later sessions despite a modest late increase in net exercise time. The custom mode's 10-item limit may have contributed to this plateau; together with the absence of exercise-specific difficulty adjustment, it may also have limited the systematic application of progressive loading. Exergame platforms incorporating a broader exercise range and adjustable task difficulty may better accommodate progression across changing functional levels. Second, trunk exercises comprised more than half of the study library but had the lowest completion rate. The Back Press and Overhead Side Bend were among the least frequently prescribed. In contrast, the upper- and lower-extremity exercises were prescribed more consistently, and each achieved a completion rate above 95%. Future libraries should include trunk exercises better suited to bed-based delivery while expanding the variety and gradability of limb-focused options. Third, although sessions were planned within a typical 30-minute ward-based therapy window, delivery was occasionally prolonged, mainly by intercurrent bedside care such as suctioning, suggesting that this time window may leave limited flexibility for concurrent clinical care in medically complex inpatients. Finally, resource and workflow implications warrant particular attention. Separate from delays related to intercurrent clinical care, device setup and calibration were required for every session and occasionally contributed to prolonged delivery. Safety monitoring, exercise instruction, and manual assistance remained necessary. In many inpatient settings, staffing constraints and restrictive reimbursement can limit the availability of bedside therapy, leaving severely impaired patients with few opportunities for active movement outside scheduled sessions [12,16-18]. However, given the support required in this study and the absence of formal resource-use or cost evaluation, this approach cannot be assumed to reduce resource use relative to usual bedside PT or to address these constraints; these potential benefits require objective evaluation. Nevertheless, the potential for familiarization with in-bed exergaming to increase activity beyond scheduled therapy [24], together with the preliminary evidence of deliverability and the observed short-term tolerability under monitoring in this study, supports further evaluation of both changes in activity behavior and less resource-intensive delivery models. Future studies should examine whether, after initial familiarization, one-to-one supervision can be reduced or shifted toward one-to-many delivery, and whether this approach can increase patients' activity beyond scheduled therapy and thereby expand exercise opportunities for this population. Addressing these questions will require wearable sensor–based measurement of activity and sedentary time, together with focused implementation outcomes covering device setup and technical failures, staff time and workload, and direct costs, preferably in comparison with conventional bedside exercise.

Limitations

This study had several methodological limitations. First, the single-center, single-arm design without a concurrent comparator and the short intervention period with no postintervention follow-up limited causal inference and assessment of sustained changes. The observed functional changes may reflect natural recovery and concurrent usual PT rather than an independent effect of the NFA-based intervention. Second, attrition and missing data may have affected the longitudinal findings. Although the Little test did not reject the missing completely at random hypothesis, its limited power in this small sample left the missing-data mechanism uncertain. In particular, KES was available for only a subset of participants because reliable measurements were often difficult to obtain in participants with marked weakness, raising the possibility of nonrandom missingness and bias toward stronger participants. Complete-case and completer-only analyses may be affected by selection or attrition bias, while across-session patterns may also reflect therapist learning. Third, physiological responses were characterized using HR measurements obtained only at baseline, midpoint, and final assessments. HR responses may also have been influenced by medication use and altered autonomic or chronotropic function after critical illness and transplantation [58]. Other relevant measures, including oxygen saturation and dyspnea, were not systematically recorded across sessions. Safety outcomes also focused on events meeting the criteria for session termination and may not have captured less severe or transient symptoms. Fourth, this study evaluated selected aspects of operational feasibility rather than the full range of implementation domains. The absence of a screening denominator prevented evaluation of recruitment efficiency, and prespecified feasibility progression thresholds were not established. Technical reliability was not formally evaluated, while item-level completion did not capture repetition counts or the extent of manual assistance. Nonetheless, operational feasibility was quantified at the participant, session, and exercise-item levels. Findings may also not generalize to patients with greater clinical instability or cognitive or sensory limitations that precluded interaction with the exergame, or to other post-ICU populations. The inclusion of both liver and bilateral lung transplant recipients also introduced clinical heterogeneity. The exploratory clinical outcomes may have been affected by unblinded assessment and variation in testing procedures, including manual rather than external stabilization during KES testing. The study-specific SLR and bridge grading systems had not been formally validated, and multiplicity was not adjusted across outcomes. In addition, the satisfaction questionnaire was nonvalidated and nonanonymous, and its wording and administration by treating therapists may have introduced social desirability and response bias. Finally, the small sample limited the precision of feasibility and safety estimates, as reflected by the wide 95% CI for final-assessment retention, and precluded meaningful subgroup analyses.

Conclusions

In conclusion, when delivered under therapist supervision, the individually prescribed in-bed NFA program for posttransplant inpatients after ICU care showed favorable indicators of operational feasibility, including high delivered-session adherence and item-level implementation fidelity. Within the same supervised setting, exercise-item interruptions were infrequent and generally managed through simple modification or substitution of exercise items, and no session-terminating adverse events were observed, suggesting a low apparent short-term risk profile. Participant satisfaction was also generally favorable. By combining the accessibility of a commercial off-the-shelf exergame with individualized exercise prescription, the program extended the application of bedside exergaming to posttransplant inpatients with substantial functional impairment after ICU care who had not achieved independent ambulation. The resulting implementation data and adapted exercise framework may inform the practical application and further evaluation of similar bedside programs. Future controlled studies should determine clinical benefit and broader safety, including less severe or transient exercise-related symptoms, and evaluate how platform and protocol refinements affect the resource requirements and scalability.

Acknowledgments

The authors used generative artificial intelligence (AI) tools, specifically ChatGPT (GPT-5 series; OpenAI) and Gemini (3.1 Pro; Google LLC), for text generation, proofreading, and editing to improve the readability of this paper. ChatGPT (GPT-5.6; OpenAI) was also used for visualization, converting source photographs of exercise movements in Figure 1C and NFA reference images in Multimedia Appendix 1 into illustrations. All AI-assisted content was reviewed and verified by the authors, who take full responsibility for it.

Funding

This study was supported by a National Research Foundation of Korea (NRF) grant funded by the Ministry of Science and ICT (MSIT), Republic of Korea (grant. RS-2024 - 00346048), and grants from the Asan Institute for Life Sciences, Asan Medical Center, Seoul, Republic of Korea (grants. 2024IP0097 and 2024IP0099). All Nintendo hardware and software were commercially purchased by the research team. Nintendo Co., Ltd. provided no equipment, funding, or software support and had no involvement in the study or manuscript preparation.

Data Availability

The datasets generated and analyzed during the current study are not publicly available due to restrictions under local data protection regulations and institutional review board policies regarding patient confidentiality. However, the data are available from the corresponding author upon reasonable request and subject to institutional approval.

Multimedia Appendix 1
In-bed exergaming exercise library and clinical implementation. Detailed overview of the 13 exercise types prescribed in the in-bed exergaming program, categorized by target body region and primary therapeutic focus. For each exercise, an illustration based on a Nintendo Ring Fit Adventure reference image depicting the standard exercise posture is shown alongside a demonstration of the bedside-adapted version. The adaptation retained the primary target body region but was not considered biomechanically equivalent to the standard exercise.

Multimedia Appendix 3
Detailed description of noncompleters.
[PDF File, 106 KB - games_v14i1e95037_app3.pdf]

Multimedia Appendix 4
Statistical analysis of change in muscle strength, functional measures, and health-related quality of life. Unless otherwise specified, statistical analyses were restricted to participants with complete data at all assessment time points (n=20). Statistical significance for overall change was tested using the Friedman test. Post hoc pairwise comparisons were performed only when the overall Friedman test was statistically significant, using 2-sided Wilcoxon signed-rank tests. Pairwise *P* values were Bonferroni-adjusted for the 3 comparisons within each outcome; adjusted *P* values <.05 were considered statistically significant. **P*<.05, ***P*<.01, ****P*<.001. KES was analyzed for participants with complete data (n=12).

Multimedia Appendix 5
Detailed frequency distribution of prescribed and completed exercise items. Exercise item-level outcomes describe the distribution and completion of individualized exercise item prescriptions across target body regions and exercise types. Values are presented as n (%) unless otherwise indicated. Percentages in the prescribed and completed columns were calculated using all prescribed items (N=2161) and all completed items (N=2072), respectively. Exercise-specific completion rates were calculated using the number of prescribed items for the corresponding exercise type as the denominator.
[PDF File, 112 KB - games_v14i1e95037_app5.pdf]

Multimedia Appendix 6
Participant-level frequency distributions of prescribed and completed exercise items across 10 intervention sessions. Data were obtained from 20 participants who completed all 10 intervention sessions (n=20 per session). Each cell indicates the number of participants with the corresponding exercise item count; darker colors indicate a greater number of participants. Blank cells indicate that no participant had the corresponding count. (A) Number of prescribed exercise items per participant at each session. (B) Number of completed exercise items per participant at each session.

Abstract

Background: Ankle mobility and control contribute to balance and everyday movement throughout adulthood, yet are usually assessed through repetitive, abstract tasks that reveal little about movement production. Serious games can make repeated tasks engaging, but most report only end point scores rather than continuous gameplay signals, and few establish system usability. Developing and evaluating such a system in healthy adults is a necessary first step.

Objective: This study aimed to develop Balance Wood, a bilateral ankle-controlled serious game in which seated players tilt a device through ankle flexion-extension to control on-screen play, to describe the system and the signals it records, and to evaluate its usability, safety, and user experience in healthy adults.

Methods: In this two-stage cross-sectional development and usability study, healthy adults without lower-limb injury or balance-affecting neurological or vestibular disorders completed single-session repeated-measures procedures. In stage 1, a total of 40 adults—20 older (mean age 73.0, SD 5.9 y; 10 women) and 20 younger (mean age 28.1, SD 3.2 y; 4 women) adults—completed 3 fixed-order difficulty levels in 1 session (exploratory signal analysis). In stage 2, a total of 18 younger adults (mean age 24.6, SD 3.9 y; 5 women) completed the levels in counterbalanced order. Usability was assessed with the System Usability Scale (0 - 100); use impressions and consciously used body parts with Likert and open-ended items; and device tilt-angle accuracy against a digital goniometer.

Results: The mean System Usability Scale score was 81.5 (SD 11.2; 95% CI 76.0 - 87.1; Cronbach α=.74), above the benchmark of 68, indicating good perceived usability. Mean ratings were 2.11 (SD 1.32) for safety concern (95% CI 1.45 - 2.77) and 1.67 (SD 1.03) for pain (95% CI 1.15 - 2.18). Ankle use was highest at 4.94 (SD 0.24), exceeding knee 2.50 (SD 1.29), hip 2.00 (SD 1.24), and trunk 2.17 (SD 1.15) by Wilcoxon signed-rank tests (P<.001). Device readings agreed closely with the goniometer, with a mean absolute error of 0.66°, an intraclass correlation coefficient of 0.999, and 95% limits of agreement of −0.68 to 1.70°. In stage 1, all measures were computable for the 40 participants, with typical amplitudes of 20.5° to 27.2° and stable speed in both groups. In stage 2, repeated-measures analyses (α=.05) did not detect statistically significant differences across difficulty conditions or presentation positions (all P>.13).

Conclusions: In healthy adults, Balance Wood was usable, well-accepted, low-risk, and provided accurate device-level tilt measurement with predominantly ankle-based control while continuously recording gameplay signals. It is a low-cost, bilateral, ankle-specific control interface with continuous signal capture into 1 easy-to-use device. Its contribution is a reproducible, usability-tested platform with characterized device accuracy, and formally defined candidate measures awaiting validation. Once validated, it could support home- or community-based recording; in the near term, it is a research tool.

Introduction

Ankle and foot motor control contribute to postural adjustment, weight transfer, and everyday movement throughout adulthood [1,2]. This control is graded and dynamic: ankle dorsiflexion force control shows reduced accuracy and greater variability in older than in younger adults [3,4], paralleling age-related declines in ankle proprioceptive acuity [5], and it depends on

XSL•FO
RenderX

feedback about the ongoing movement [6]. Standing, weight transfer, and gait rely on both ankles acting together, yet most paradigms probe ankle control unilaterally, and age-related changes in bilateral force control—evident across effectors [7]—remain comparatively underexplored at the ankle. Characterizing graded, bilateral ankle control therefore calls for tasks that go beyond range of motion or strength alone [8]. Conventional clinical assessments, however, rely on abstract, repetitive tasks and report only maximum thresholds or static holding times, lacking the engaging context needed to capture continuous motor responses; when movement goals are unclear, confidence and the willingness to remain physically active may also decrease [9]. A practical need therefore exists for engaging systems that record interpretable signals of ankle-control behavior.

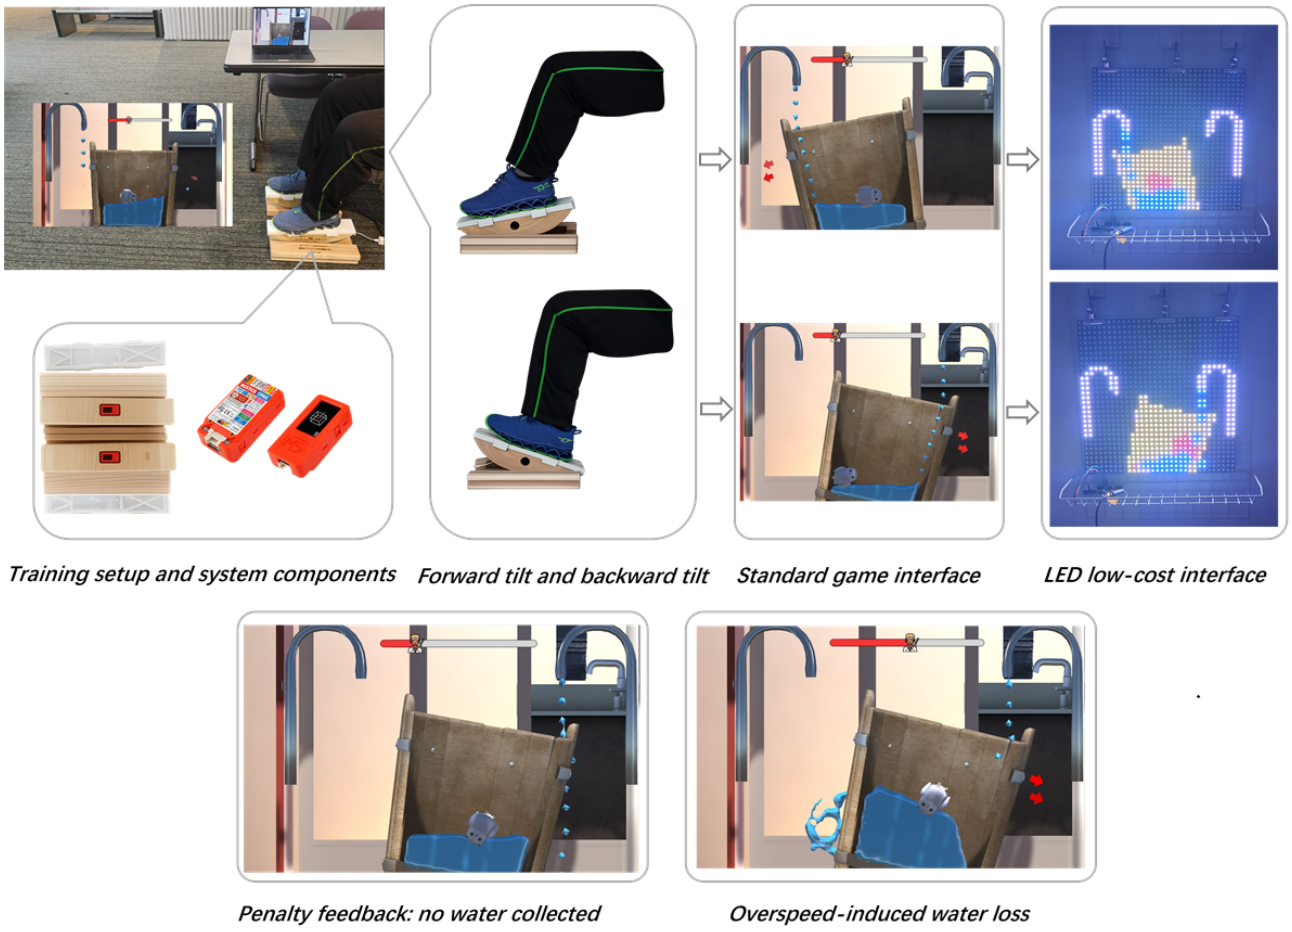
Serious games and exergames offer a promising alternative and appear feasible and acceptable across adult populations, from younger adults [10] to older adults [11-21], though a gap remains. Most existing systems are evaluated through overall training effectiveness, fall-related outcomes, or usability questionnaires, and report only end point scores such as total points or task success rather than the continuous movement signals generated during play. Recent work highlights the value of in-game sensing to capture movement during the task itself [22-24], and some serious games now derive interpretable motor metrics directly from gameplay signals—for example, quantifying movement slowness in Parkinson disease or upper-limb motor performance [25,26]. Such measures nonetheless remain less developed than broad outcome reporting [13,16,19].

This direction also aligns with Moonshot Goal 3, a Japanese government-led research and development initiative on long-term human support through the coevolution of AI and robots in real environments [27,28], within which support systems should accumulate structured behavioral data and capture fine-grained changes in movement patterns over time. We therefore developed Balance Wood, a serious game for the continuous signal recording of bilateral ankle control during gameplay. Participants control the tilt of a virtual wooden tub through slow forward and backward ankle movements, with intuitive physics-based feedback that conveys direction, movement size, and movement pace through changes in the water state.

To characterize the use and signal acquisition properties of Balance Wood, this study was structured as a 2-stage cross-sectional development and usability evaluation in which each participant was assessed in a single session. The aims were twofold: (1) to describe initial system use and signal-derived descriptive characteristics in a broader-age adult sample (stage 1, n=40 healthy adults across two age ranges); and (2) to systematically evaluate the system's behavior under counterbalanced task order and its self-reported usability and user experience in a focused younger-adult sample (stage 2, n=18). A bench-level sensor calibration test of the embedded inertial measurement unit was additionally conducted. This study does not aim to establish measurement validity, demonstrate clinical utility, or test inferential hypotheses about age-related differences. The findings are intended to support future hypothesis-driven and clinical investigations of ankle-controlled serious games.

Methods

Study Design Overview



This 2-stage cross-sectional development and usability study used single-session repeated-measures procedures in both stages. Stage 1 was a fixed-order, within-subjects exploratory data acquisition study with 40 participants (20 older and 20 younger adults), characterizing the time-series signal output of Balance Wood and the descriptive utility of the proposed signal-based measures across trials of varying difficulty. Stage 2 was a counterbalanced supplementary study in an independent sample of 18 younger adults. Reporting of the usability evaluation follows the American Psychological Association Journal Article Reporting Standards for quantitative research, as reflected in the Methods subsection headings below.

Ethical Considerations

Both stages of this study were approved by the Research Ethics Committee of the Hino Campus, Tokyo Metropolitan University (R8-019). All participants in stages 1 and 2 provided written informed consent before participation; the stage 2 procedure (counterbalanced trial-order presentation and questionnaire administration) was covered under the same approved protocol. Before analysis, all recorded data were anonymized by the research team by replacing participant identifiers with numerical codes, and neither the analysis dataset nor this report contains any personally identifiable information. This study was conducted in accordance with the Declaration of Helsinki. Older-adult participants in stage 1 each received JP ¥6000 (approximately US $39, based on an exchange rate of approximately JP ¥153 per US dollar during the October-November 2025 data-collection period) as compensation; younger-adult participants in stage 1 and all stage 2 participants received no financial compensation. All images and videos in this paper and supplementary materials were reviewed to ensure that no study participant can be identified. The individual shown in Figure 1 and in Multimedia Appendices 1 and 2 is an author of this study, who provided written informed consent for the publication of their identifiable image and videos; no other identifiable individual appears in this paper or supplementary materials.

Figure 1. System overview and interface of Balance Wood. Upper left: real-use scenario, with 1 foot on each unit; each unit contains an embedded M5StickC PLUS (M5Stack Technology Co, Ltd) module that senses tilt angle and transmits signals over Wi-Fi. Middle left: forward tilt (top) and backward tilt (bottom) of a unit. Middle right: standard screen-based game interface. Upper right: low-cost LED matrix using the same directional control logic. Lower left: no-water-collected state (insufficient tilt or penalty-related return to neutral). Lower right: water leakage from movement exceeding the angular-velocity threshold. Negative values denote forward tilt and positive values denote backward tilt.

Balance Wood System

Balance Wood is a bilateral system for the tilt-angle signal analysis and continuous signal recording of ankle control during gameplay, converting coordinated foot-tilt input into control signals for an interactive serious game. The system consists of 2 Balance Wood units placed under the feet of the participant, a host computer running the game, and a visual feedback implementation (Figure 1). In the standard configuration, the feedback is presented via a screen-based game. This design follows previous balance-oriented exergame work [11,12,16].

A low-cost alternative based on an LED matrix, operating without a dedicated host computer or display screen, was also developed [29-33]; it was not used in the usability evaluation reported here. Video demonstrations of the screen-based and low-cost LED versions in use are provided in Multimedia Appendices 1 and 2, respectively.

Each Balance Wood unit comprises a tilting wooden device with an embedded M5StickC PLUS (M5Stack Technology Co, Ltd) module mounted at the center. This embedded module simultaneously serves 2 functions: angle sensing and wireless communication. Specifically, each unit measures the respective tilt state and transmits the signal via Wi-Fi. The host system receives the signals from the 2 Balance Wood units through User Datagram Protocol communication. The transmitted value is the roll component of the attitude estimate produced by the module's on-board sensor-fusion routine, which corresponds to the sagittal-plane tilt of the platform. Denoting the left- and right-unit tilt angles at time t as $\theta L(t)$ and $\theta R(t)$, the host computes the combined control angle as their signed sum:

$$\theta c(t)=\theta L(t)+\theta R(t).$$

No other component angle enters the calculation, and no filtering, weighting, or dead band is applied. $\theta c(t)$ is the variable that drives the game and, after the display scaling is reversed, is the variable used for all analyses reported here.

The attitude estimate is derived from the accelerometer and gyroscope signals of the module's embedded inertial measurement unit. As low-cost micro-electro-mechanical-systems inertial sensors carry a fixed mounting and 0-point offset, an initial alignment (zeroing) was performed with the device flat before each session, so that all recorded signals were referenced to 0° [34]. Signals were sampled at approximately 9.5 Hz. Full hardware and signal-acquisition specifications are provided in Multimedia Appendix 3.

As the control variable is the signed sum of the 2 units, same-direction tilts from the 2 feet add, whereas

XSL•FO
RenderX

opposite-direction tilts partially cancel; the interface therefore encourages coordinated bilateral movement. This simplified bilateral design lowers the difficulty of understanding how to operate the game [35-37].

In the recorded tilt-angle signal, forward tilt is represented by negative values and backward tilt by positive values; all main outcomes are described in terms of the forward and backward directions. All recorded signals correspond to the physical inclination of the foot device. For display purposes only, the host system applies a fixed 3/5 scaling factor to the on-screen bucket, so displayed and physical angles are not interchangeable: a displayed angle of 11° corresponds to approximately 18.33° of physical device tilt (Multimedia Appendix 3). The recorded data file stores the display-scaled values; the factor was divided out before analysis, so unless otherwise stated, all angular values reported here are unscaled physical angles.

The recorded signal represents the ankle-controlled tilt angle of the Balance Wood device, generated as participants drove the device through ankle flexion-extension. This device-level angle reflects ankle-driven control behavior rather than a direct anatomical measurement of ankle joint range of motion; the relationship between the device tilt and the underlying ankle joint angle is mediated by the foot-device interface and was not separately calibrated in this study.

Task Interface and Display Implementations

In the standard screen-based implementation, a bucket is displayed in the center of the game interface, with a water source on each side. Water flows randomly from either the left or the right source, and each flow lasts for a randomly selected integer duration between 7 and 12 seconds. Participants are required to tilt the bucket toward the active source to collect the incoming water. Forward tilt corresponds to tilting the bucket to collect water from the left source, whereas backward tilt corresponds to tilting the bucket to collect water from the right source. The interface was designed so that the movement goal could be understood from the visual task outcome rather than from verbal instruction alone. This follows previous exergame work emphasizing intuitive, movement-oriented feedback [13,15,18,38-42].

In both display implementations, successful directional control allows the bucket to collect water from the currently active source; the low-cost version retains the identical bilateral ankle-input structure and directional control principle, consistent with compact wearable and embedded sensing approaches in rehabilitation and functional evaluation [14,31-33,43]. If the bucket is not tilted sufficiently toward the active source, water cannot be collected, and movement that is excessively fast causes water to leak. These 2 visual outcomes let participants judge their own directional accuracy and speed regulation from the state of the game.

Adaptive Challenge-Penalty Mechanism

To elicit sustained, near-maximal excursions rather than passive low-effort movement, the system applies a direction-specific adaptive challenge-penalty rule, tracked independently for the forward and backward directions. This design logic follows broader principles of interactive systems, where a task must balance guidance and challenge to elicit a range of movements from the user [17,19,44-46]. The rule arms for a given direction only once the displayed bucket tilt reaches 11°, a playability threshold determined empirically during development as the lower bound at which the water-flow simulation both engages water collection and retains the collected water; it disarms when the movement returns close to the neutral position. Once armed, maintaining the movement at or above a fixed proportion of the current maximum peak avoids a penalty, whereas failing to do so returns the displayed bucket smoothly toward the midline; sustained performance at that criterion raises the peak threshold for the direction, subject to an observation window that reverts the increase if the criterion is not maintained. The penalty is applied to the displayed bucket angle only: the recorded signal always corresponds to the actual device tilt of the participant and never includes the penalty offset, and no score penalty or change to the water-flow rate is applied. The complete rule set is given in Multimedia Appendix 3, and the numeric value of every parameter is listed in Table S1 in Multimedia Appendix 3.

Study Design

The performance of each participant was examined across 3 consecutive Balance Wood trials, and the resulting time-series signals were described using the proposed exploratory measures. The dataset comprised 40 participants: an older-adult group (n=20) and a younger-adult group (n=20). Including both age groups allowed the system to be exercised across a range of baseline movement capabilities.

The 3 formal trials differed inherently in difficulty, linked directly to the size of the falling water drops: lower difficulty meant larger drops and easier collection. Trial 1 was the easy condition; trial 2 was the medium condition, preset so that completing all water collection required close to 3 minutes, although faster participants could finish 10 to 20 seconds earlier; trial 3 was the high-difficulty condition, intentionally designed so that the task could not be fully completed even with maximal effort, to obtain a complete dataset of ankle behavior under maximal challenge. All 3 conditions ran under the same maximum duration of 180 seconds, and each trial ended at whichever came first: completion of the water-collection target for that condition or expiry of the 180-second limit. As completion requirements differed across trials, raw duration and holding time in seconds were not treated as direct evidence of performance; the analysis instead used the extracted signal-based measures.

Inclusion and Exclusion Criteria

Participants were healthy adults who were able to perform repeated ankle flexion-extension safely and to provide written informed consent. Individuals with any acute or chronic condition that could interfere with safe participation—including lower-limb injury or pain, neurological or vestibular disorders affecting balance, or any contraindication to light physical activity—were excluded. For the older-adult group, participants were community-dwelling older adults; individuals unable to understand the task instructions or to provide informed consent were also excluded.

XSL•FO
RenderX

Sampling Procedures

The younger-adult groups (stages 1 and 2) were recruited by convenience sampling from the Tokyo Metropolitan University community (Hino Campus) and the associated laboratory community, whereas the stage 1 older-adult group was recruited from the general community with support from the JST (Japan Science and Technology Agency) Moonshot Research and Development program (Moonshot Goal 3; JPMJMS2034). Data were collected at the Hino Campus of Tokyo Metropolitan University. In stage 1, the older-adult group was assessed between October and November 2025, and the younger-adult group between February and March 2026; stage 2 was conducted in June 2026.

Sample Size, Power, and Precision

As a development and usability study, the sample sizes were chosen to be appropriate for early-stage usability evaluation rather than for confirmatory hypothesis testing. No formal a priori power analysis was conducted because the study is descriptive and exploratory in nature and is not designed to test inferential hypotheses; accordingly, the reported inferential statistics are interpreted as exploratory and are reported with CIs to convey precision. Stage 1 included 40 participants (20 participants per age group), and stage 2 included 18 younger adults, consistent with sample sizes commonly used in the usability and feasibility studies of serious games.

Participant Characteristics

Only age and sex were collected; no other anthropometric or experience variables were recorded. Characteristics for all 3 groups are summarized in Table 1.

Table . Participant characteristics by study stage and age group (stage 1: single-session exploratory acquisition; stage 2: counterbalanced supplementary study).

	Stage 1, older adults (n=20)	Stage 1, younger adults (n=20)	Stage 2, younger adults (n=18)
Age (years)			
Mean (SD)	73.0 (5.9)	28.1 (3.2)	24.6 (3.9)
Range	60 - 82	23 - 35	21 - 35
Sex, n (%)			
Female	10 (50)	4 (20)	5 (28)
Male	10 (50)	16 (80)	13 (72)

Standardized Setup and Positioning

All sessions used an identical seated setup, standardized by target posture rather than by fixed equipment dimensions. Participants sat upright with the thighs approximately horizontal and both legs directed forward, so that hip flexion was approximately 90°, with the knees flexed to approximately 90°, the shanks hanging vertically, and each foot placed at the center of its Balance Wood unit; in this position, the platform was horizontal and was defined as 0° at session zeroing. Chair height was adjustable from 45 to 60 cm and was set to obtain this posture. Each unit was mounted on a movable wooden base board that permitted rotation in the sagittal plane only, mechanically preventing mediolateral tilt; with the boards in contact, the center-to-center distance between units was 13 cm, widened to approximately 22 cm, or at most 30 cm, for participants requiring a wider stance. All distances were measured directly. Participants wore their own shoes, which were required to be flat-soled, and the feet were not strapped or otherwise fixed to the platforms. Movement outside the ankle was not mechanically constrained; participants were instructed to maintain this seated posture and to control the device with the ankles.

Experimental Procedure

Before the 3 formal trials, participants completed a low-difficulty practice session in which the instructor explained the game content, operating procedure, and precautions while observing performance in real time; formal testing began once the participant was confirmed to have understood the operation. Participants then completed the 3 trials consecutively in a fixed order (trial 1 to trial 2 to trial 3), and the system automatically recorded the tilt-angle signals of the device throughout testing [42,47].

Stage 2 Procedure: Counterbalanced Supplementary Study

Overview

Stage 2 extended the stage 1 protocol in 2 respects. First, the 3 trials were administered in counterbalanced order, separating task difficulty from order effects such as motor learning, adaptation, and fatigue. Second, a standardized usability instrument and a structured feasibility questionnaire were added.

Counterbalanced Balance Wood Trials

Each participant completed the same 3 Balance Wood trials used in stage 1 (trial 1: easy; trial 2: medium; trial 3: high difficulty), but in counterbalanced order following a Latin square design. With 3 trial conditions, the full counterbalancing structure consists of 6 possible orderings (1-2-3, 1-3-2, 2-1-3, 2-3-1, 3-1-2, and 3-2-1). The 18 participants were assigned in equal numbers (3 per ordering) such that all 6 orderings were completed 3 times across the sample. Assignment to ordering followed a prerandomized sequence determined before recruitment.

The task interface, the adaptive challenge-penalty mechanism, and all system parameters were identical to stage 1. As in stage

XSL•FO
RenderX

1, brief practice was provided before the formal trials, and rest periods of at least 1 minute were provided between trials. The near-limit holding threshold used in the holding-proportion measures was defined per participant exactly as in stage 1, preserving within-participant comparability across the 2 stages.

Posttask Questionnaire

Immediately after the Balance Wood trials, participants completed a structured questionnaire in 4 parts (provided in Multimedia Appendix 4); all items were rated on a 5-point Likert scale. Part 1 is the System Usability Scale (SUS) [48,49], scored at 0 to 100. Part 2 is a set of 9 custom feasibility (use-impression) items in 4 dimensions: feedback comprehension, physical burden and safety, enjoyment and adherence, and perceived ankle specificity of movement. Part 3 asks participants to rate the extent to which they consciously used specific joints, muscles, and body regions during the task (3 rating perspectives; see Tables 2-4); this addresses the concern that the recorded combined tilt signal may reflect contributions from body segments other than the ankle. Part 4 provides space for the free-form description of participant experience, perceived difficulty, and any operational changes noticed compared with prior experience. The total stage 2 testing session lasted approximately 30 minutes per participant.

Table . Part 3 consciously used joints in stage 2 (n=18, 5-point Likert). CIs extending beyond the 1 - 5 rating range were truncated to the scale bounds.

	Mean (SD)	95% CI
Ankle joint	4.94 (0.24)	4.83 - 5.00
Toe joints	3.83 (1.20)	3.24 - 4.43
Knee joint	2.50 (1.29)	1.86 - 3.14
Trunk	2.17 (1.15)	1.59 - 2.74
Hip joint	2.00 (1.24)	1.39 - 2.61
Shoulder joint	1.11 (0.32)	1.00 - 1.27

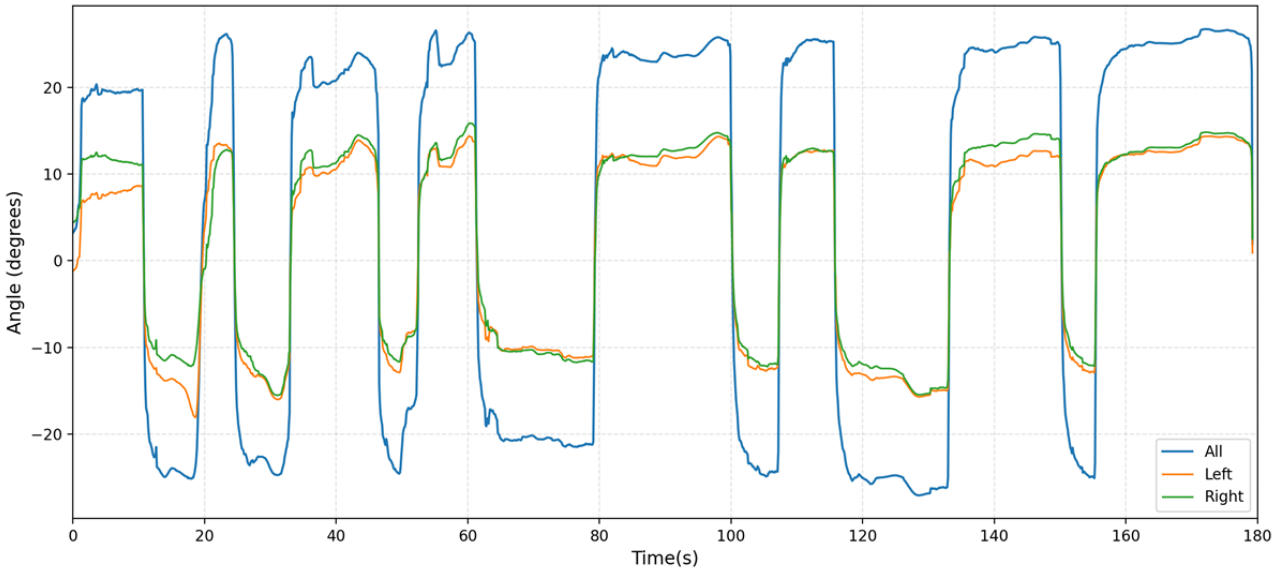
Table . Part 3 consciously used muscles in stage 2 (n=18, 5-point Likert). CIs extending beyond the 1 - 5 rating range were truncated to the scale bounds.

	Mean (SD)	95% CI
Triceps surae	4.78 (0.73)	4.41 - 5.00
Quadriceps femoris	3.28 (1.27)	2.64 - 3.91
Hamstrings	2.94 (1.39)	2.25 - 3.64
Gluteal muscles	2.56 (1.29)	1.91 - 3.20
Trunk muscles	1.94 (1.00)	1.45 - 2.44
Upper limb muscles	1.17 (0.51)	1.00 - 1.42

Table . Part 3 consciously used body regions in stage 2 (n=18, 5-point Likert). CIs extending beyond the 1 - 5 rating range were truncated to the scale bounds.

	Mean (SD)	95% CI
Ankle region	5.00 (0.00)	5.00 - 5.00
Lower leg	4.17 (1.10)	3.62 - 4.71
Toes	4.06 (1.21)	3.45 - 4.66
Knee region	2.89 (1.41)	2.19 - 3.59
Thigh	2.61 (1.38)	1.93 - 3.30
Hip region	2.17 (1.20)	1.57 - 2.76
Trunk/core	1.83 (0.99)	1.34 - 2.32
Upper limb	1.11 (0.32)	1.00 - 1.27

Stage 2: Outcome Measures



In addition to the 5 signal-based outcome measures analyzed for within-group trial effects in stage 1 (see Outcome measures), stage 2 reported the SUS composite score (0 - 100); mean Likert score per part 2 feasibility item and per feasibility dimension; mean Likert ratings of consciously used joints, muscles, and body regions (part 3); and thematic categorization of part 4 open-ended responses.

XSL•FO
RenderX

Representative Example of a Single-Trial Signal

A representative signal from trial 3 of a single participant is displayed (Figure 2), covering the full 180-second trial; each peak corresponds to 1 period of maintained forward or backward ankle movement. Some peaks show an amplitude decrease followed by a rapid rise, reflecting adjustment after the challenge-penalty mechanism was triggered. In many peaks, the latter half reached a greater amplitude than the former half, and peaks later in the trial tended to be larger than the initial ones. Such waveforms illustrate the signal features on which the proposed exploratory measures are computed [47].

Figure 2. Representative time-series from a single balance wood trial, showing the combined control-angle signal together with the individual left- and right-unit signals. Repeated forward and backward peaks appear throughout this trial; some show a decrease followed by rapid recovery, reflecting adjustment to the adaptive challenge-penalty mechanism. Amplitude and effective flexion-extension analyses used peak segmentation, whereas holding analyses used the filtered effective-trial signal with participant-specific directional near-limit thresholds. Negative values denote forward tilt and positive values denote backward tilt.

Acquisition and Definition of Valid Signals

The parameters used in this study fall into 2 categories. System parameters of the adaptive challenge-penalty mechanism—including the 11° displayed-angle minimum valid peak threshold (equivalent to approximately 18.33° physical tilt), the 0.3° threshold increment, the 95% maintenance criterion, the 7-second observation window, and the 4-second penalty cancellation window—were fixed during system development and constitute part of the experimental environment shared by all participants. These parameters shaped the data-generating process and cannot be retrospectively altered without rerunning the experiment. Offline analysis parameters—including the middle 80% peak retention window, the κ=0.8 coefficient for the directional holding threshold, and the second-half-vs-first-half comparison rule for effective flexion-extension classification—were chosen during signal processing and could in principle be varied to evaluate the robustness of derived measures. This distinction is referenced in the Limitations subsection of the Discussion section.

In this study, valid signal acquisition involved 2 complementary levels of processing. First, direction-specific excursions (peaks) were identified for peak-based analyses such as typical directional amplitude and effective flexion-extension proportion. Second, clearly artifactual or nonrepresentative segments were excluded from the continuous trial signal to obtain an effective analyzed signal for time-based outcomes such as directional holding proportion and overspeed proportion.

For peak-based analyses, a peak was defined as a direction-specific excursion bounded by return toward the neutral level, and analysis focused on the stable portion of each excursion: only the middle 80% of each peak was treated as the valid signal region, the first and last 10% being treated as transition periods between forward and backward movement. A symmetric 10% trim was used as a simple operational rule, retaining most of each excursion while reducing the influence of direction-reversal transitions at both ends.

Clearly artifactual or nonrepresentative segments were also excluded, such as isolated initial transitional segments or extreme abnormal segments whose waveform patterns differed markedly from surrounding peaks. Segment exclusion was performed using predefined rules and verified by visual inspection. This operated within each participant's recorded data and did not exclude any participant; no participant-level data were missing.

Outcome Measures

Overview

As sensor-based exergame systems can provide information beyond global scores [23,24,43,50], this study prespecified 7 measures in 4 categories, derived from the device tilt-angle signal: typical forward amplitude, typical backward amplitude, forward holding proportion, backward holding proportion, overspeed proportion, forward effective flexion-extension proportion, and backward effective flexion-extension proportion. Of these, 5 (the 2 typical amplitudes, the 2 directional holding

XSL•FO
RenderX

proportions, and the overspeed proportion) were analyzed for within-group trial effects in stage 1, whereas the 2 directional effective flexion-extension proportions were pooled across all valid excursions and reported descriptively. These measures are exploratory and descriptive: mathematically defined indicators of device-level ankle-control behavior that are not used to assess functional ability, clinical status, or training effects, and whose definition does not establish biomechanical validity.

Typical Flexion-Extension Amplitude

Typical flexion-extension amplitude quantifies the typical displacement produced by ankle flexion-extension in a given direction rather than the single most extreme value. It was calculated separately for forward tilt (negative values) and backward tilt (positive values). For each valid excursion, including both valid forward and valid backward excursions, the maximum angular magnitude in the corresponding direction was extracted. The amplitudes of all valid excursions within a trial were then averaged.

Let Nexc(k) denote the total number of valid excursions in trial k, and let ai(k) denote the amplitude of the i-th valid excursion, expressed as an absolute value. Typical flexion-extension amplitude was defined as

$$Aflex(k)=1Nexc(k)\sum i=1Nexc(k)ai(k).$$

Averaging across excursions makes this measure less sensitive to isolated outlier peaks than a single-trial maximum.

Directional Holding Proportion

Directional holding proportion quantified the proportion of effective trial time during which the participant maintained the control angle within a near-limit region specific to the participant in a given direction. Unlike a peak-count-based definition, this measure was defined as a time proportion over the full analyzed signal after the exclusion of invalid segments.

To improve within-participant comparability across trials, the near-limit threshold for each direction was defined from the typical directional amplitude of the participant in trial 2. Trial 2 was selected as this reference because the easy condition was typically completed too early and the high-difficulty condition could not be completed at all, whereas the medium-difficulty condition was preset to be just completable within the time limit and therefore provided the most representative and stable estimate of each participant's typical directional amplitude. This anchoring was adopted as an early, exploratory choice rather than a validated standard. Specifically, for backward tilt (positive values), the threshold was defined as

$$Tbackward=\kappa Abackward(2),$$

and for forward tilt (negative values), the threshold was defined as

$$Tforward=-\kappa Aforward(2),$$

where $\kappa=0.8$. Thus, the holding region was defined as tilt at or beyond 80% of the participant-specific typical directional amplitude obtained from trial 2. The value $\kappa=0.8$ was used as an operational near-limit threshold, allowing sustained high-amplitude tilt to be captured without restricting the measure to only the brief extreme peak. The same coefficient was applied consistently across participants and trials.

Let Teff(k) denote the total effective analyzed duration in trial k after the exclusion of invalid segments. For backward tilt, let Thold,backward(k) denote the total duration during which the filtered tilt-angle signal of the device remained at or above Tbackward. For forward tilt, let Thold,forward(k) denote the total duration during which the filtered tilt-angle signal of the device remained at or below Tforward. The directional holding proportions were defined as

$$Hbackward(k)=Thold,backward(k)Teff(k),$$

$$Hforward(k)=Thold,forward(k)Teff(k).$$

In addition, for descriptive presentation, a combined holding proportion can be calculated as

$$Hcombined(k)=Hforward(k)+Hbackward(k)=Thold,forward(k)+Thold,backward(k)Teff(k)$$

which represents the proportion of effective trial time spent in either directional near-limit region; the forward and backward proportions were retained separately in the main analysis.

Directional Effective Flexion-Extension Proportion

Directional effective flexion-extension proportion was calculated separately for forward and backward movements to evaluate whether participants demonstrated continued amplitude increase within the valid signal segment. For each valid excursion, that is, the middle 80% of the peak, only the high-amplitude top region was retained. The steep entering and leaving edges of this top region were then trimmed on the basis of local slope, leaving a window intended to represent the plateau-like upper portion of the excursion while excluding rapid rising and falling transitions.

This top window was then divided into a first half and a second half, and the mean amplitude of each half was calculated. If the mean amplitude of the second half was greater than that of the first half, the excursion was classified as an effective excursion. Intuitively, this indicates that during the valid, stable phase of flexion-extension, the participant continued to increase or at least sustain high amplitude rather than allowing the movement to decline.

Let Ntop(k) denote the number of valid excursions analyzed in trial k, and let Neff(k) denote the number of excursions satisfying the criterion that the latter-half amplitude exceeded the former-half amplitude. Effective flexion-extension proportion was defined as

$$E(k)=Neff(k)Ntop(k).$$

When an all-3-trials combined value is reported, it is calculated by pooling all valid excursions across trials 1, 2, and 3 and then recomputing E=Neff/Ntop rather than by averaging the 3 trial-level proportions. Higher values indicate that a larger proportion of valid excursions sustained or increased amplitude during the latter part of the peak.

Overspeed Proportion (Additional Outcome)

Overspeed proportion was included as an additional analysis item and was not treated as a core ankle flexion-extension outcome. The main purpose of this outcome was to examine

XSL•FO
RenderX

the influence of the mechanism of overspeed leakage on the behavior of the participant. Specifically, it quantifies the proportion of analyzed time samples in which angular velocity exceeded a preset threshold. This angular-velocity threshold is a fixed system parameter of the speed-feedback (water-spill) mechanism and is constant across difficulty levels.

Let v(t) denote the instantaneous angular velocity, vthr the preset physical angular-velocity threshold used in the final analysis pipeline, Nall(k) the total number of analyzed samples in trial k, and Nover(k) the number of samples for which |vt|>vthr. Overspeed proportion was defined as

$$O(k)=Nover(k)Nall(k).$$

As the threshold is a fixed feature of the speed-feedback mechanism, this proportion is not interpreted as a measure of motor control.

Statistical Analysis

Stage 1: Statistical Analysis

All stage 1 analyses were conducted separately for the older-adult and younger-adult groups. No between-group inferential tests were performed and no between-group comparisons are reported, because this study was neither designed nor powered for between-group comparison; the 2 stage 1 groups are described separately. No data were missing in stage 1.

For the 5 main trial-level outcomes, descriptive statistics were calculated for each trial. To evaluate within-group trial effects across trials 1, 2, and 3, a 1-factor repeated-measures ANOVA was performed for each outcome. Sphericity was assessed using the Mauchly test, with Greenhouse-Geisser correction applied when violated, and normality using the Shapiro-Wilk test. For each ANOVA, we report *F* test scores, df1, df2, *P* values, and partial eta squared, with 95% CIs for post hoc pairwise mean differences. As 5 outcomes were tested per group, outcome-level multiplicity was addressed using a Bonferroni-corrected threshold of $P<.01$, with uncorrected P values retained. Supplementary Friedman tests were conducted for outcomes showing deviations from normality. Effect sizes were interpreted against conventional benchmarks ($\eta p^2=0.01$, 0.06, and 0.14 for small, medium, and large).

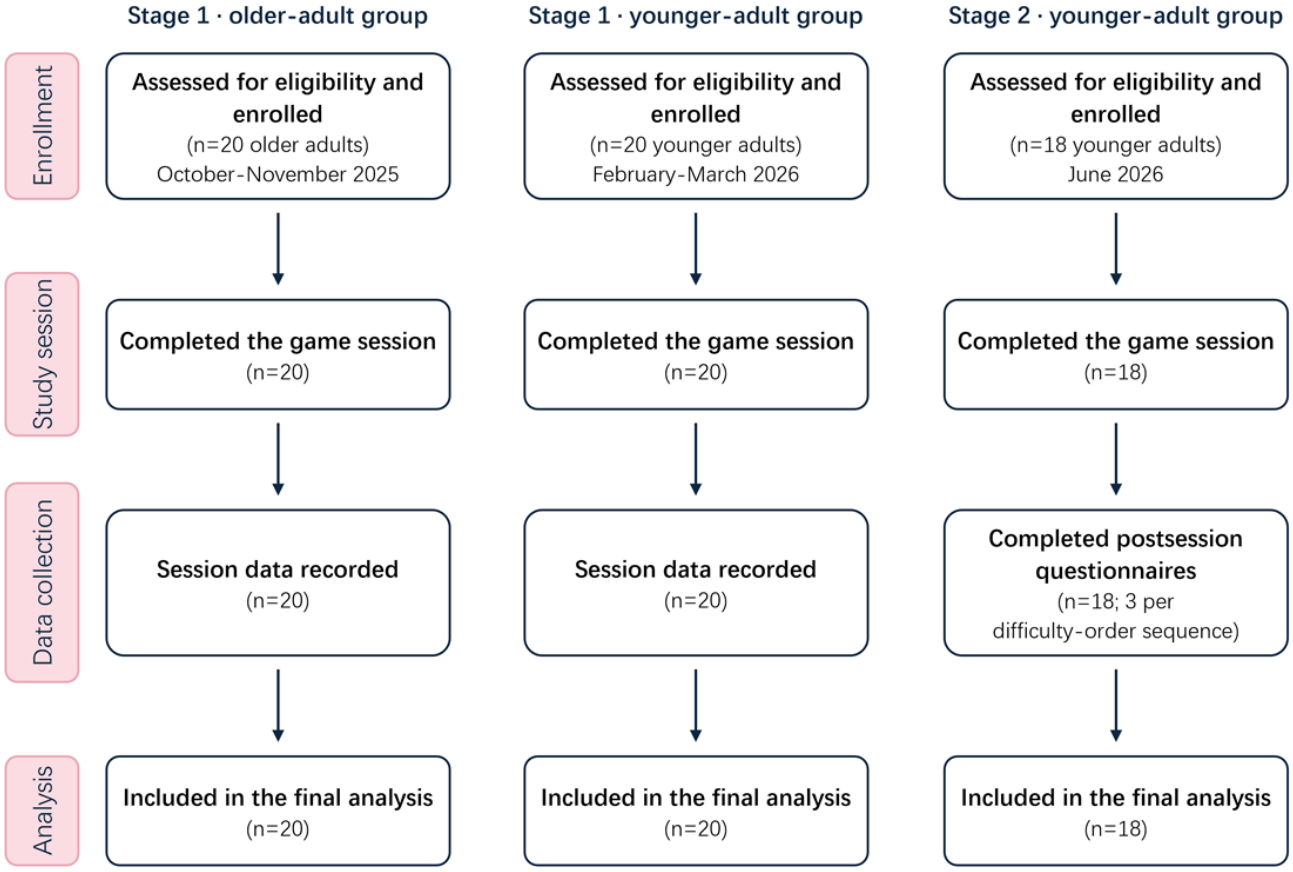
Stage 2: Statistical Analysis

Difficulty and presentation-order effects. For each signal-based measure, differences across the 3 difficulty conditions and, separately, across the 3 presentation positions were examined using repeated-measures ANOVA. As the design was fully counterbalanced, difficulty was decoupled from presentation order; with 3 per ordering, ordering-specific summaries are descriptive only.

Regarding usability and feasibility, the SUS composite score was reported as the mean (SD) with a 95% CI and compared with the conventional 68-point benchmark; internal consistency was summarized using Cronbach α. Part 2 and 3 ratings were reported as means (SDs) with 95% CIs, and part 3 ankle ratings were compared with proximal-segment ratings using Wilcoxon signed-rank tests. Part 4 responses were analyzed using inductive content analysis, with 2 coders independently coding the responses and grouping them into themes through discussion. There were no missing item-level data in the stage 2 questionnaire, and no imputation was required.

Software

All statistical analyses were performed using custom scripts written in Python (version 3.10; Python Software Foundation), with pandas, NumPy, SciPy (version 1.15.3), and Matplotlib (version 3.10.8).



Results

Overview

All 58 enrolled participants (stage 1: 20 older and 20 younger adults; stage 2: 18 younger adults) completed all study procedures and were included in the analysis, with no exclusions or withdrawals (the flow of participants through the 3 groups is shown in Figure 3). In stage 2, all 18 participants provided complete questionnaire responses, with no missing data for the usability outcomes.

XSL•FO
RenderX

Figure 3. Participant flowchart across the 2 study stages, following the American Psychological Association Journal Article Reporting Standards for quantitative research. The 3 groups (stage 1 older adults, stage 1 younger adults, and stage 2 younger adults) were recruited independently—the older adults from the general community with support from the JST (Japan Science and Technology Agency) Moonshot program (JPMJMS2034), and the younger adults by convenience sampling from the Tokyo Metropolitan University community—and all were assessed at the Graduate School of Systems Design, Tokyo Metropolitan University (Hino campus, Tokyo, Japan); no participant took part in more than one group. All enrolled participants completed this study's procedures, with no exclusions or withdrawals.

Older-Adult Group

The descriptive statistics of the main outcomes in the older-adult group are summarized (Table 5). When all 3 trials were combined by pooling valid excursions across the 3 trials, the effective flexion-extension proportion was 0.838 in the forward direction and 0.742 in the backward direction.

XSL•FO
RenderX

Table . Descriptive statistics of the main outcomes in the older-adult group (n=20). Amplitude values are reported on the true physical angle scale. Combined holding proportion was included for descriptive presentation only. Where a per-participant SD was available, 95% CIs (mean ± t(19) × SD/√20) are shown in parentheses; the combined and effective flexion-extension proportions are aggregate ratios with no per-participant SD and are therefore reported as point values only.

	Trial 1	Trial 2	Trial 3

Median (IQR)	0.051 (0.037-0.060)	0.045 (0.041-0.056)	0.051 (0.044-0.057)

The results of the Mauchly test are reported for all 5 outcomes (Table S2 in Multimedia Appendix 3). The sphericity assumption was violated only for the typical backward amplitude (W=0.5432, P=.0041, GG=0.686), therefore, Greenhouse-Geisser corrected results were reported for that outcome. The repeated-measures ANOVA revealed nominally significant trial effects for the typical forward amplitude ($F_{2,38}$=4.169, P=.023, ηp^2=.180), and the typical backward amplitude ($F_{1.33,25.24}$=4.338, P=.036, ηp^2=.186). The forward holding proportion (F2,38=3.122, P=.056, ηp2=.141) and the backward holding proportion (F2,38=2.563, P=.090, ηp2=.119) did not reach nominal significance. The overspeed proportion remained stable across the 3 trials (F2,38=0.416, P=.663, ηp2=.021). Under the Bonferroni-corrected threshold of P<.01, neither amplitude effect reached formal significance, and both should be read as preliminary despite their large effect sizes. Post hoc paired comparisons with Bonferroni correction were conducted for the 2 outcomes demonstrating trial effects. For the typical forward amplitude, no pairwise comparison remained significant after correction, although increases from trial 1 to trials 2 and 3 were observed descriptively. By contrast, for the typical backward amplitude, the increase from trial 1 to trial 2 remained significant after Bonferroni correction (t19=3.518, P=.0023, Padj=.0069, dz=0.787). The increase from trial 1 to trial 3 was additionally retained as a meaningful descriptive change, although it did not remain significant after correction (Table S3 in Multimedia Appendix 3).

Shapiro-Wilk testing indicated approximately normal trial-level distributions apart from the typical backward amplitude in trial 3. A supplementary Friedman test was therefore conducted for that outcome as a sensitivity analysis. It was additionally significant (χ^2_2=9.30, P=.0096, Kendall W=0.233; Table S4 in Multimedia Appendix 3) and did not change the interpretation of the repeated-measures ANOVA result.

XSL•FO
RenderX

Overall, typical amplitudes were higher in the later trials than in trial 1, the clearest pairwise change being the increase in typical backward amplitude from trial 1 to trial 2. The forward holding proportion increased gradually across trials, the backward holding proportion peaked in trial 2 before declining in trial 3, and the overspeed proportion remained stable. The effective flexion-extension proportion suggested a direction-dependent movement pattern rather than a uniform change across both directions.

Younger-Adult Group

The descriptive statistics of the main outcomes in the younger-adult group are summarized (Table 6). When all 3 trials were combined by pooling valid excursions across the 3 trials, the effective flexion-extension proportion was 0.779 in the forward direction and 0.787 in the backward direction.

Table . Descriptive statistics of the main outcomes in the younger-adult group (n=20). Amplitude values are reported on the true physical angle scale. Combined holding proportion was included for descriptive presentation only. Where a per-participant SD was available, 95% CIs (mean ± t(19) × SD/√20) are shown in parentheses; the combined and effective flexion-extension proportions are aggregate ratios with no per-participant SD and are therefore reported as point values only.

Median (IQR)	0.043 (0.037-0.065)	0.049 (0.042-0.057)	0.048 (0.041-0.058)

The results of the Mauchly test are reported for all 5 outcomes (Table S5 in Multimedia Appendix 3). The sphericity assumption was violated only for the typical forward amplitude; therefore, Greenhouse-Geisser corrected results were reported for that outcome. The repeated-measures ANOVA showed no significant trial effect for any of the 5 main inferential outcomes in the younger-adult group, with effect sizes that were small to medium at most (partial ηp^2=0.083 or below). Accordingly, no formal post hoc paired comparisons were performed for the younger-adult group.

Shapiro-Wilk testing indicated that most trial-level distributions in the younger-adult group were approximately normal, although deviations from normality were observed for the typical forward amplitude in all 3 trials and for the overspeed proportion in trial 3. Therefore, supplementary Friedman tests were conducted for these outcomes as sensitivity analyses. These tests were not

XSL•FO
RenderX

significant for the typical forward amplitude (χ22=1.90, P=.3867, Kendall W=0.048) or the overspeed proportion (χ22=1.30, P=.5220, Kendall W=0.033; Table S4 in Multimedia Appendix 3) and thus did not change the overall interpretation of the repeated-measures ANOVA results. Overall, the younger-adult group showed minimal within-session trial-wise change: typical amplitudes, holding proportions, and the overspeed proportion all remained relatively stable across the 3 trials, and the forward and backward effective flexion-extension proportions were similar to one another.

Stage 2 Results: Counterbalanced Supplementary Study

Overview

Consistent with the development-and-usability framing, the usability and feasibility findings are the primary stage 2 outcomes; the signal-derived analyses are reported as secondary, exploratory observations.

Stage 2: Participant Characteristics

Stage 2 enrolled 18 younger adults (mean age 24.6, SD 3.9 y; 5 women), recruited by convenience sampling from the research laboratory community. The 3 difficulty conditions were administered in a fully counterbalanced order: the 6 possible orderings of the easy, medium, and hard conditions (denoted L, M, and H, respectively: LMH, LHM, MLH, MHL, HLM, and HML) were each assigned to 3 participants, yielding a fully balanced Latin square in which each difficulty condition appeared equally often in each presentation position. As participants were drawn from the laboratory community in which Balance Wood was developed, they differed in their degree of prior exposure to the system. Detailed demographic characteristics are summarized in Table 1 alongside the stage 1 participants.

Perceived Usability (SUS)

The mean SUS composite score was 81.5 (SD 11.2; 95% CI 76.0 - 87.1; median 83.75, IQR 78.13-87.50; range 47.5 - 95.0; Cronbach α=0.74, indicating acceptable internal consistency). This score is well above the established benchmark of 68, indicating good perceived usability, although individual variability was present (minimum 47.5). Item-level results are summarized in Table 7: positively worded items received high ratings, and negatively worded items received low ratings, consistent with good usability, and the lowest-scoring positively worded item was Q1 (“I think that I would like to use this system frequently”).

Table . SUS[a] item-level scores in stage 2 (n=18). Odd-numbered items are positively worded, and even-numbered items are negatively worded; values are mean (SD) with 95% CIs on the 1 - 5 response scale. The overall SUS score (0 - 100) was 81.5 (95% CI 76.0 - 87.1).

	Mean (SD)	95% CI
Q1 (+) would like to use frequently	3.33 (0.84)	2.92 - 3.75
Q2 (−) unnecessarily complex	1.83 (0.92)	1.37 - 2.29
Q3 (+) easy to use	4.67 (0.59)	4.37 - 4.96
Q4 (−) need help of a knowledgeable person	1.89 (0.83)	1.47 - 2.30
Q5 (+) functions are well integrated	4.11 (0.83)	3.70 - 4.53
Q6 (−) too much inconsistency	1.72 (0.96)	1.25 - 2.20
Q7 (+) most people would learn quickly	4.61 (0.61)	4.31 - 4.91
Q8 (−) cumbersome to operate	1.44 (0.78)	1.05 - 1.83
Q9 (+) felt confident	4.33 (0.69)	3.99 - 4.67
Q10 (−) needed to learn a lot first	1.56 (0.98)	1.07 - 2.04

[a]SUS: System Usability Scale.

Use Impressions

Item-level results for the 9 part 2 use-impression items are summarized in Table 8. The 2 feedback-comprehension items received high ratings; safety concerns and pain or discomfort were rated low, and participants rated using mainly ankle movement higher than also using nonankle body parts. As part 2 contains both positively and negatively worded items, the items are reported individually rather than as a single composite.

XSL•FO
RenderX

Table . Part 2 use-impression item scores in stage 2 (n=18, 5-point Likert).

	Mean (SD)	95% CI
1. Visual feedback helped me understand the task purpose	4.39 (0.61)	4.09 - 4.69
2. Spill-on-fast-switch feedback helped me adjust speed	4.22 (0.65)	3.90 - 4.54
3. Felt ankle fatigue over the 3 trials	3.61 (1.33)	2.95 - 4.27
4. Concerned about safety during operation	2.11 (1.32)	1.45 - 2.77
5. Experienced pain or discomfort	1.67 (1.03)	1.15 - 2.18
6. Found the game enjoyable	3.78 (0.94)	3.31 - 4.25
7. Willing to use regularly (2 - 3×/wk)	3.61 (0.85)	3.19 - 4.03
8. Mainly used ankle movement	4.28 (0.96)	3.80 - 4.75
9. Additionally used nonankle body parts	2.94 (1.43)	2.23 - 3.66

Consciously Used Body Parts

Part 3 asked participants to rate the extent to which they consciously used specific joints, muscles, and body regions, on 3 rating perspectives (Tables 2-4). Across all 3 perspectives, the ankle and adjacent structures (lower leg and toes) received the highest ratings, and proximal segments received progressively lower ratings. For the joints perspective, Wilcoxon signed-rank tests comparing the ankle joint with the knee, hip, and trunk were all statistically significant (P<.001). This pattern is reported descriptively and is not interpreted as establishing the absence of compensatory movement.

Qualitative Feedback

Twelve of the 18 participants provided free-text responses, which were analyzed using inductive content analysis. Participants generally found the task realistic and engaging and reported clearly feeling the activity at the ankle, which was noted as a strength. The most frequently raised area for improvement was foot slippage: several participants reported that, with some types of footwear, the foot tended to slip or leave the board and requested a fixation or strap. Additional comments noted ankle fatigue at the highest difficulty level and offered suggestions regarding the intuitiveness of the displayed tilt direction.

Device Tilt-Angle Accuracy

To characterize the accuracy of the device tilt-angle output, a bench-level standard-angle test was performed. The Balance Wood platform was tilted to 5 reference angles (0°, 10°, 20°, 30°, and 40°) in both the forward and backward directions, for each of the 2 units, with 3 repetitions per condition (60 measurements in total). At each static position, the reference angle was read with a digital goniometer (SCITOOLS, China; display resolution 0.01°) while the corresponding device tilt-angle value transmitted over User Datagram Protocol was recorded. Agreement was quantified using the metrics listed in Table 9, including the mean absolute error (MAE), root-mean-square error, and the intraclass correlation coefficient (ICC; 2-way mixed, absolute agreement). This is a device-level test of physical tilt-angle measurement and does not assess the anatomical ankle joint angle.

The device output showed close agreement with the goniometer reference, with an MAE of 0.66° (root-mean-square error 0.79°), excellent linearity (R^2=0.998), and excellent agreement (ICC=0.999; Bland-Altman 95% limits of agreement −0.68° to 1.70°). A small systematic bias of +0.51° was observed, and within the operating range observed during gameplay (20°-30°), the MAE was 0.73°. Subdegree agreement is expected when rigid device tilt rather than a human joint angle is measured; joint-angle measurement typically yields errors of several degrees [31,32,43]. Accuracy metrics and per-angle results are summarized in Tables 9 and 10.

XSL•FO
RenderX

Table . Device tilt-angle accuracy against a digital goniometer (SCITOOLS; range 0°-360°, display resolution 0.01°), standard-angle bench test (5 reference angles × 2 directions × 2 units × 3 repetitions = 60 measurements). The test characterizes the physical device tilt angle, not the anatomical ankle joint angle.

	Value
Mean absolute error	0.66°
Root-mean-square error	0.79°
Systematic bias	+0.51°
Intraclass correlation coefficient	0.999
Linear regression (R^2)	0.998
Within-condition SD (repeatability)	0.53°
MAE[a] within operating range (20°-30°)	0.73°
Bland-Altman 95% limits of agreement	−0.68° to 1.70°

[a]MAE: mean absolute error.

Table . Per-angle device tilt-angle accuracy against the digital goniometer (SCITOOLS), standard-angle bench test (n=12 per reference angle: 2 directions × 2 units × 3 repetitions).

	MAE[a]	Bias	Maximum absolute error	n
Reference angle 0°	0.77°	+0.65°	1.80°	12
Reference angle 10°	0.48°	+0.20°	1.00°	12
Reference angle 20°	0.76°	+0.46°	1.40°	12
Reference angle 30°	0.70°	+0.65°	1.50°	12
Reference angle 40°	0.59°	+0.59°	1.30°	12

[a]MAE: mean absolute error.

Counterbalanced Signal-Derived Measures (Additional Exploratory Analysis)

As an additional exploratory analysis, the 7 signal-derived measures defined in stage 1 were recomputed per participant for the stage 2 sample under the counterbalanced design (the combined holding proportion, a derived aggregate, was not included). Differences across the 3 difficulty conditions and across presentation positions were examined using repeated-measures ANOVA. No statistically significant differences were observed across difficulty conditions for any measure (typical forward amplitude: easy 24.8°, 95% CI 23.0 - 26.5; medium 24.2°, 95% CI 23.1 - 25.4; hard 24.0°, 95% CI 22.9 - 25.2; $F_{2,34}$=0.75, P=.48; typical backward amplitude $F_{2,34}$=1.41, P=.26; forward holding proportion $F_{2,34}$=1.31, P=.28; backward holding proportion $F_{2,34}$=1.67, P=.20; forward effective flexion-extension proportion $F_{2,34}$=0.76, P=.48; backward effective flexion-extension proportion $F_{2,34}$=0.41, P=.67; overspeed proportion $F_{2,34}$=1.08, P=.35), and no significant effects of presentation position were observed (all P>.13; the 2 amplitude measures, P=.73 and P=.30). The complete output for both factors is given in Table S6 in Multimedia Appendix 3. These analyses are exploratory, and no inference regarding responsiveness to task difficulty is drawn.

Discussion

Principal Results

This study developed Balance Wood, a bilateral ankle-controlled serious game, and evaluated its usability and the kinds of gameplay-derived signals it records in healthy adults. Across both stages, the system produced continuous tilt-angle signals from which the proposed exploratory measures could be computed.

In stage 1, the proposed measures could be computed for every participant, and each group is described separately. Within the older-adult group, typical directional amplitudes increased across the 3 trials; within the younger-adult group, the measures remained comparatively stable. The overspeed proportion varied little across trials in both groups. Taken separately, they illustrate how continuous signal tracking can characterize movement patterns beyond simple task completion.

In stage 2, under a fully counterbalanced administration in younger adults, the signal-derived measures showed no significant differences across difficulty conditions or presentation positions, and the device tilt angle agreed closely with a digital goniometer at the device level. On the structured questionnaire, perceived usability was good, safety concerns and discomfort were rated low, and participants reported using predominantly the ankle and adjacent structures rather than proximal segments.

XSL•FO
RenderX

Taken together, the 2 stages provide complementary evidence for the signal-derived framework. Stage 1 showed that the measures could be extracted from repeated gameplay and describe within-session patterns. Stage 2 extended the framework to an independent, counterbalanced younger-adult sample, in which all 7 measures were again derived and no statistically significant effects of difficulty or presentation position were detected. The methodological contribution of stage 2 is therefore that the framework remains applicable when difficulty and presentation position are separated by design. Accordingly, stage 1 patterns are best interpreted as descriptions of repeated gameplay rather than effects attributable specifically to task difficulty or order. Stage 2 findings remain exploratory because of the small, younger-adult-only sample and heterogeneous prior exposure.

Comparison With Prior Work

Previous exergame studies and reviews have evaluated usability and acceptability across younger and older adult populations [10,13,20,42]. As usability depends on interaction design and use context, findings from other exergame configurations cannot be assumed to transfer directly to Balance Wood's seated, bilateral, ankle-focused interface. In stage 2, the mean SUS score was 81.5, above the conventional benchmark of 68 [49] and descriptively higher than the score of 70.5 reported for a home-based exergame evaluated in a similarly aged healthy sample [10]. Participants also reported that visual feedback helped them understand the task and adjust their speed, rated safety concern and pain or discomfort low, and indicated predominant reliance on the ankle and adjacent structures. Ratings for enjoyment and willingness to use regularly were 3.78 and 3.61, respectively, on a 5-point scale. These comparisons remain descriptive given the small, younger-adult stage 2 sample and heterogeneous prior exposure to the system.

Controlled laboratory work has characterized bilateral ankle-dorsiflexion force control using customized force-measurement platforms and target-matching tasks [3]. Although informative, this approach was not designed as a serious game and relied on a laboratory-oriented setup. Exergame studies have also quantified movement using 3D motion capture [51] or force-platform center-of-pressure data [52]. Balance Wood instead integrates sensing, visual feedback, and continuous signal recording in a low-cost, seated serious-game interface, deriving direction-specific measures directly from its own bilateral tilt-control signal. Following further validation, this design may facilitate repeated recording in home or community settings.

Finally, prior work has used self-adaptive serious games to adjust task demands during motor learning [53], while related exergame research has examined therapeutic ankle outcomes [54]. In Balance Wood, however, adaptation served a different methodological purpose: rather than primarily targeting motor-learning or therapeutic outcomes, the challenge-penalty mechanism progressively updated the direction-specific peak criterion to encourage repeated, sustained excursions near each participant's current peak, supporting the capture of high-amplitude movement for descriptive signal analysis.

Implications for Research and Practice

Balance Wood provides a compact, relatively low-cost method for collecting continuous bilateral ankle-controlled gameplay signals in 1 session; stage 2 required approximately 30 minutes per participant and no laboratory-grade motion-capture equipment for device-level tilt recording. The platform can support standardized signal acquisition across repeated trials alongside end point outcomes. Favorable usability and feedback comprehension, with low discomfort and safety concerns, support further evaluation in applied settings. Following external validation, the system could be evaluated in community settings, small clinics, or home-based research, potentially lowering the logistical barriers to repeated recording of ankle-controlled behavior. At present, Balance Wood is a research and development platform rather than a clinical assessment or diagnostic instrument. Before independent or unsupervised deployment, future studies should examine biomechanical validity, between-session test-retest reliability, usability, and signal characteristics in older and clinical populations, footwear-related slippage, device fixation, and safety procedures.

Limitations

First, the samples were small (20 per group in stage 1; 18 in stage 2), and several outcomes did not survive multiplicity correction; the results are therefore presented as exploratory and should be read through effect sizes and descriptive patterns rather than *P* values alone. Second, generalizability is limited by the single-site, healthy, and partly younger-adult samples (stage 2 younger adults only, predominantly male, recruited from the university), and between-session test-retest reliability was not assessed. Validation in older and clinical populations is planned as future work.

Third, the signal-derived measures are exploratory descriptors, not validated biomechanical constructs, and may be specific to the Balance Wood task. As the adaptive challenge-penalty mechanism was designed to shape gameplay, its influence on the recorded signals cannot be separated retrospectively; establishing the biomechanical meaning of the measures and systematically varying the mechanism's parameters are left for future work. The near-limit holding threshold was anchored to each participant's own trial 2 amplitude, so the resulting holding proportions should be read as relative to each participant's medium-difficulty performance rather than against an external standard. Fourth, no concurrent validation against gold-standard anatomical measures (eg, goniometry) was performed, so the measures characterize device-level rather than anatomical ankle control; mapping device tilt to the anatomical ankle angle remains for future work.

Conclusions

This study introduced Balance Wood, a low-cost bilateral serious game that converts ankle-controlled device tilt into continuous gameplay signals, and reported its first development-and-usability evaluation in healthy adults. The system showed good perceived usability (above the established SUS benchmark), a positive and low-risk experience, close agreement between its device-level tilt readings and a digital goniometer, and predominantly ankle-based control. Its novelty

XSL•FO
RenderX

lies not in gamification itself but in packaging a low-cost, bilateral, ankle-specific control interface with continuous signal capture into a single, easy-to-use device, which distinguishes it from existing systems that record continuous movement data and are typically laboratory-grade, costly, or oriented toward whole-body or upper-limb movement. Its principal contribution is a reproducible, usability-tested platform with characterized device-level accuracy and formally defined candidate measures. These measures require clinical or biomechanical validation before home- or community-based research; in the near term, the system remains a research tool.

Acknowledgments

The authors thank all participants for their involvement in this study. The authors also thank Yoshitsugu Omori, PhD (Shonan University of Medical Sciences), for his assistance in reviewing and revising this study's questionnaire. The authors declare the use of generative AI in the manuscript preparation and revision process. According to the Generative AI Delegation Taxonomy (GAIDeT) [55], the following tasks were delegated to generative AI tools under full human supervision: proofreading and editing, as well as translation. The generative AI tool used was Claude Opus 4.8 (Anthropic PBC). Responsibility for the final manuscript lies entirely with the authors. Generative AI tools are not listed as authors and do not bear responsibility for the outcomes. This declaration is submitted by YZ on behalf of all authors.

Abstract

Background: Immersive exercise systems may support guided movement practice and physical activity among older adults, but adoption of head-mounted systems cannot be inferred from single-session usability or intention ratings. Older adults must negotiate unfamiliar equipment, movement safety, comfort, perceived control, trust, and perceived benefit. Virtual reality (VR) and mixed reality (MR) are often grouped as extended reality despite different sensory and safety affordances.

Objective: This study examined how older adults' barriers and facilitators evolved during repeated immersive Tai Chi training and how VR and MR delivery appeared to shape immersion, control, trust, safety appraisal, and conditional willingness to continue use.

Methods: We conducted an exploratory, qualitative-dominant longitudinal mixed methods follow-up study in Hunan, China. Community-dwelling adults aged 60 years or older completed guided Tai Chi training in VR or MR while retaining parent-study allocation; comparisons were descriptive and hypothesis-generating. The completed-protocol quantitative sample and the main qualitative denominator each included 34 participants (VR: n=16; MR: n=18). Data sources comprised semistructured interviews, Game Experience Questionnaire dimensions, Virtual Reality Sickness Questionnaire (VRSQ) scores, safety observations, and task performance logs from days 1, 3, and 6. Qualitative data were coded using a Dynamic Barrier Framework–informed codebook and integrated with descriptive quantitative summaries.

Results: Adoption unfolded as a staged process. During entry, unfamiliarity, competence concerns, and mild physical discomfort shaped responses. Initial uncertainty was endorsed by 7 of 16 (43.8%, 95% CI 23.1 - 66.8) VR participants and 6 of 18 (33.3%, 95% CI 16.3 - 56.3) MR participants. During adaptation, participants described practice, feedback, social reinforcement, and environmental experience; accuracy improved from day 1 to day 6 by 0.083 (95% CI 0.024 - 0.142) in VR and 0.103 (95% CI 0.037 - 0.169) in MR. Late-stage willingness remained conditional on comfort, safety, content variety, and usefulness. VR accounts more often emphasized environmental immersion and affective value, whereas MR accounts more often emphasized reality grounding, perceived control, and trust. Standardized VRSQ scores were low overall (VR 8.65 and MR 5.65, on a 0 - 100 scale), with no falls, serious adverse events, or session terminations.

Conclusions: This study combines repeated qualitative accounts with symptom, safety, and performance evidence while holding the Tai Chi content constant across VR and MR delivery. Unlike single-session acceptance studies, broad extended reality comparisons, or endpoint-only evaluations, it shows adoption as a phase-sensitive and conditional process rather than a one-time decision. The Dynamic Barrier Framework explains how entry barriers may soften, persist, or change meaning and how modality-sensitive affordances shape experience without implying device superiority. In practice, immersive exercise should combine gradual orientation, monitored exposure, comfort and safety safeguards, understandable feedback, social support, and modality-sensitive design. Longer community or home follow-up remains necessary before inferring sustained adherence or unsupervised safety.

Introduction

Problem and Description of Research Question

Population aging has increased the need for scalable approaches that support balance, mobility, confidence, and continued physical activity among older adults [1,2]. Falls and fall-related functional decline remain major public health concerns, and exercise-based prevention strategies are consistently recommended for community-dwelling older adults [3,4]. Tai Chi is especially relevant in this context because it combines weight shifting, coordinated postural transitions, attentional focus, and gradual movement control, and evidence continues to support its value for balance-related outcomes in older adults [5,6]. However, conventional Tai Chi training depends on access to instruction, safe practice environments, and repeated attendance. These requirements can be difficult for older adults who face mobility limitations, limited local resources, variable confidence, or practical barriers to sustained participation [7,8].

Review of Relevant Scholarship

Immersive exercise systems have been proposed as one way to extend guided practice beyond conventional rehabilitation and group-class settings. Head-mounted systems can provide structured guidance, immediate feedback, and repeatable practice, and recent syntheses report promising effects on balance and physical activity in older adults [9,10]. However, those reviews also identify heterogeneous interventions, short follow-up, small samples, and unresolved usability issues [9,10]. Evidence that an immersive program can be completed or can improve a physical endpoint therefore does not by itself explain whether older adults will continue to use it, why their judgments change, or what implementation conditions make continued use acceptable. Earlier clinical, home-use, acceptance, virtual reality (VR), and augmented reality (AR) feasibility studies similarly show that readiness depends on usability, context, and age-appropriate implementation [11-16]. Broader medical-VR reviews also show substantial variation in applications and use contexts, reinforcing the need for context-specific adoption evidence [17].

The first gap is temporal. Technology acceptance models, including the technology acceptance model (TAM), the unified theory of acceptance and use of technology (UTAUT), diffusion of innovations, and continuance models, explain usefulness, ease of use, social influence, and intention [18-23], but immersive exercise acceptance is still commonly assessed at a single time point or as a pre-post score. Recent studies show that Chinese older adults can report usefulness and enjoyment after immersive fall-prevention training and that acceptance can remain high after repeated group VR exposure [24,25]. What remains underexplored is how an initial lack of familiarity becomes confidence, trust, conditional willingness, or continued concern during repeated movement practice. This distinction matters because first-session hesitation may be an appropriate appraisal of balance, vision, headset comfort, and task control rather than stable rejection of the technology.

The second gap concerns modality and mechanism. VR typically occludes the physical environment, whereas mixed reality (MR) preserves visual access to the surrounding room through passthrough while overlaying digital training elements [26-28]. A recent preliminary trial suggests that MR exercise can be feasible and beneficial for older adults with sarcopenia [29], but it compared MR with conventional exercise rather than examining VR and MR versions of the same activity. Broad extended reality (XR) categories and endpoint comparisons cannot show how environmental occlusion, visual grounding, immersion, perceived control, and trust are experienced over time. Direct, repeated-exposure evidence on these modality-sensitive processes remains limited.

The third gap is social and contextual. Repeated group VR and remote group–mediated physical activity studies indicate that caregivers, trusted individuals, peers, and group delivery can influence participation and acceptance [25,30]. A recent six-session qualitative study likewise found that older adults could enjoy a VR exercise game while still requesting greater challenge, physical demand, and social engagement [31]. Adoption is therefore coproduced by the device, the exercise task, feedback, supervision, and the community setting; it cannot be reduced to visual immersion or individual intention alone.

A related implementation problem is that short-term attendance is often treated as adherence. A 2026 review found that XR exercise studies for older adults rarely tracked long-term engagement and inconsistently measured exercise intensity and accuracy, with few studies conducted in community settings [32]. This creates a mismatch between claims that a system is acceptable and evidence that it can support sustained, safe, meaningful use. For older adults, the relevant barriers span physical symptoms and fall concerns, technical operation and feedback, psychological control and competence, and social encouragement and support [9,10,32].

We therefore used a Dynamic Barrier Framework (DBF) to organize barriers and facilitators across entry, adaptation, and conditional adoption phases. The DBF follows how a barrier can soften, persist, or change meaning after orientation and repeated supervised exposure. It does not assume a causal pathway and was not used to prove modality superiority. Instead, it structures evidence about unfamiliar equipment, bodily sensations, practice feedback, social reinforcement, perceived control, trust, and future-use conditions. The phase structure was also informed by established distinctions between adoption, maintenance, and stage-based behavior change [33,34].

Accordingly, this study addresses 3 linked gaps: static measurement of a changing acceptance process; limited direct evidence on how VR and MR delivery shape experience when the exercise content is held constant; and insufficient integration of bodily, technical, social, and performance evidence across

XSL•FO
RenderX

repeated sessions. Its contribution is a phase-sensitive, qualitative-dominant explanation of adoption conditions, not a new parametric uncertainty model or a confirmatory comparison of device efficacy.

Study Objectives

No confirmatory hypotheses were specified. The objective of this study was to examine how older adults' barriers and facilitators evolved during repeated immersive Tai Chi training and how VR and MR delivery appeared to shape immersion, control, trust, safety appraisal, and conditional willingness to continue. Specifically, we asked: (1) What entry-stage concerns and facilitators were described during early exposure? (2) How did practice, feedback, social reinforcement, and environmental experience support adaptation? (3) Under what conditions did participants describe willingness to continue use? The study was designed as an exploratory, qualitative-dominant, longitudinal mixed methods follow-up rather than a confirmatory test of VR versus MR superiority.

Methods

Research Design Overview

This was an exploratory, qualitative-dominant longitudinal mixed methods follow-up study of older adults' experiences with VR- and MR-delivered versions of the same immersive Tai Chi exergame. No single philosophical paradigm was prospectively specified. The analysis was pragmatic and interpretive: participant accounts were treated as situated descriptions of experience, while questionnaires, safety observations, and performance logs were used only for descriptive triangulation. In the parent repeated-exposure experiment, participants were allocated 1:1 to VR or MR using a computer-generated sequence. The current follow-up retained that allocation without rerandomization. Because follow-up participation depended on consent, availability, and protocol completion, all VR and MR comparisons are descriptive and hypothesis-generating rather than confirmatory tests of modality superiority [35].

Study Participants or Data Sources

Researcher Description

Qualitative coding was conducted by the first author (XS) and one additional researcher (HQ). Both researchers worked from the same phase-based codebook and excerpt-level matrix, and the first author checked the Chinese-to-English translations used for reporting. No independent third adjudicator was used; disagreements were resolved through discussion and consensus. Reflexive management included coding memos, comparison of coding decisions, codebook revisions, and retention of original Chinese excerpts alongside translations and interpretations.

Researcher-Participant Relationship

Some participants were previously known to members of the research team through community connections, whereas others had no prior relationship with the researchers. Prior familiarity was not used to determine eligibility, group allocation, or coding. Because familiarity could influence willingness to participate or what participants disclosed, the team used the same interview guide, study-code system, phase-based codebook, and consensus procedures across participants and did not treat familiarity as evidence for a preferred interpretation. Sample handling is summarized in Table 1.

Table . Sample handling for the exploratory qualitative-dominant mixed methods follow-up study.

Item	Value
All interview transcripts identified	35 interview transcripts: completed-protocol VR[a] (n=16) and MR[b] (n=18), plus MR37 partial-exposure transcript
Completed-protocol quantitative sample.	34 participants: VR, n=16; MR, n=18
Main completed-protocol qualitative coded evidence	34 participants: VR, n=16; MR, n=18
Partial-exposure qualitative case excluded from main counts	Participant 37 (MR)
Completed-protocol VR interview added to coding matrix	Participant 6 (VR), six author-confirmed paraphrased coding rows; not used as verbatim quotations

[a]VR: virtual reality.

[b]MR: mixed reality.

Participants or Other Data Sources and Participant Characteristics

The completed-protocol analysis used interview evidence, questionnaire responses, safety observations, and session-level performance exports from 34 community-dwelling older adults (VR, n=16; MR, n=18). One additional MR partial-exposure transcript was retained only as a diagnostic case. Participant characteristics relevant to interpretation, including age, sex, balance, exercise, and technology-use indicators, are reported in Table 2.

Cardiopulmonary disease	20 (58.8)	10 (62.5)	10 (55.6)

[a]Values are mean (SD) for continuous variables and n (%) for categorical variables. Percentages are calculated within each column.

[b]VR: virtual reality.

[c]MR: mixed reality.

[d]BBS: Berg Balance Scale.

Inclusion and Exclusion and Participant Selection

Participants were community-dwelling older adults recruited through local community centers and community-based outreach in Hunan, China. Eligibility criteria included age 60 years or older, ability to stand independently, ability to follow guided Tai Chi movements, and willingness to use a head-mounted display under supervision. Exclusion criteria included conditions that could increase risk or compromise safe participation, such as severe vertigo or motion-sickness susceptibility, history of seizure, severe uncorrected visual or auditory impairment, uncontrolled cardiovascular disease, severe musculoskeletal limitations that prevented safe standing movement practice, inability to provide informed consent, or other contraindications identified during screening.

Participant Recruitment

Sampling Procedures and Recruitment Process

The broader research program initially contacted 86 community-dwelling older adults through community-center promotion, on-site outreach, local newspaper advertising, and community contact networks in Hunan, China. After screening, 70 participants completed the initial single-session experiment; 40 of these participants voluntarily entered the repeated-exposure follow-up from which the current interview and session evidence was drawn. The archived follow-up materials contained 35 interview transcripts. For the current analysis, the completed-protocol quantitative and session sample and main qualitative coded sample each included 34 participants (VR, n=16; MR, n=18). Participant 37 was retained only as an MR partial-exposure diagnostic case and excluded from main theme counts. Participant 6 was a completed-protocol VR participant whose author-confirmed paraphrased coding

XSL•FO
RenderX

contributed to participant-level theme counts but was not eligible for use as a verbatim quotation.

Sample Size, Power, and Precision

The sample size was determined by feasibility, participant availability, and the qualitative-dominant purpose of the study. The study was not powered to test VR and MR superiority or causal mechanisms. Quantitative estimates are presented with 95% CIs to describe precision and to support triangulation with qualitative findings. Small denominators, baseline imbalance, and retained allocation are treated as constraints on interpretation rather than as defects that can be overcome through statistical modeling.

Conditions and Design and Training Conditions and Procedure

Both conditions used the same Tai Chi exergame content delivered through a Meta Quest 3 head-mounted display. The VR condition presented a fully virtual environment that occluded the surrounding physical environment. The MR condition used full-color video passthrough with virtual overlays, allowing participants to retain visual access to the real environment. The same application build, task goals, and core settings were used across conditions; delivery mode was the intended difference.

The exergame implemented a simplified 16-form Tai Chi sequence guided by a virtual coach. For each movement, participants aligned the head-mounted display and the left and right controllers with 3 predefined target hotspots. Holding any hotspot within the success window for at least 3 seconds counted as one successful hotspot hold, and 48 successful holds represented one complete 16-movement loop. The sequence restarted when a loop was completed before the session ended. Participants received immediate visual guidance and end-of-session performance summaries. The repeated-exposure protocol comprised 6 sessions delivered across 6 consecutive days, with one session per day; days 1, 3, and 6 were the standardized performance checkpoints used in this analysis.

Masking

Masking was not applicable. Participants and research staff could see whether VR or MR was delivered. The follow-up retained the parent-study allocation, and all comparisons were descriptive.

Measures and Covariates

Instrumentation

Baseline variables included age, sex, education, daily smartphone use duration, Berg Balance Scale (BBS) [36], self-reported exercise intensity, self-reported health status, height, weight, and body mass index. Subjective experience was summarized using a Chinese-adapted 32-item version of the Game Experience Questionnaire (GEQ) core module [37]. Responses were coded on the 0‐4 analytic scale. The standard story-interest item was not administered; therefore, sensory and imaginative immersion was calculated from 5 items rather than the standard 6. The remaining analyzed dimensions were competence, flow, tension and annoyance, challenge, negative affect, and positive affect. Cybersickness was assessed with the 9-item Virtual Reality Sickness Questionnaire (VRSQ) [38]. The oculomotor score was calculated as the sum of items 1, 2, 4, and 5 divided by 12 and multiplied by 100; the disorientation score was calculated as the sum of items 3 and 6‐9 divided by 15 and multiplied by 100. The standardized VRSQ total was the mean of these two subscale scores. Automated game logs provided average accuracy rate and average time spent at standardized checkpoints on days 1, 3, and 6. Average accuracy rate was the proportion of logged frames in which the head and hand hotspots were within the game's tolerance window. Average time spent was recorded in seconds, with lower values indicating faster task performance [39]. Trajectory was retained only as a diagnostic field because its direction and operational definition could not be verified and was therefore excluded from manuscript-ready analyses.

Quality of Measurements

Measurement quality was evaluated using item-level completeness, observed score ranges, floor and ceiling concentrations, and consistency between questionnaire scoring rules and the available item data. Performance-field definitions and units were checked against the available game documentation and prior study records.

Psychometrics

Within-sample Cronbach alpha was reported for analyzed GEQ dimensions and the VRSQ where appropriate. Test-retest reliability was not estimated because repeated administrations represented changing session experiences rather than a stability assessment.

Data Collection

Data Collection Procedures

Semistructured interviews were conducted by the research team across the repeated-exposure follow-up using selected postsession interview modules rather than a single endpoint interview. Interviews were audio recorded and generally lasted approximately 20 minutes. The interview guide prompted participants to describe initial impressions, unfamiliarity, bodily sensations, task difficulty, environmental experience, perceived safety, social reinforcement, perceived learning, trust, and willingness to continue use. Modules were aligned with early contact, adaptation after repeated practice, and later-session evaluation, so later prompts could ask participants to compare current experiences with earlier sessions. This design supported comparability across participants while allowing personally salient barriers and facilitators to be described [40].

Interview material was segmented into analyzable excerpts linked to participant study codes, group membership, DBF phase, theme label, and valence category. The excerpt-level approach was used because a single participant could describe several barriers and facilitators within the same interview. Segmenting these statements allowed the analysis to retain complexity while summarizing unique-participant theme endorsement at the phase level.

Recording and Data Transformation

Initial Chinese-language transcripts were generated from the audio recordings using a Qwen-based automated transcription

XSL•FO
RenderX

tool. Participant names and direct identifiers were replaced with study codes in the analytic matrix. The original Chinese transcripts were retained as the primary textual evidence, and Chinese-to-English translations used for analysis and reporting were checked by the first author. Quotations retained in the paper were checked against the corresponding Chinese transcript and shortened, where necessary, by removing repeated fillers or unclear fragments rather than silently reconstructing them. Author-confirmed summaries from participant 6 were used for coding and participant-level counts but not as direct quotations.

Analysis

Data-Analytic Strategies

Qualitative analysis followed thematic analysis and framework-oriented procedures [41-43]. A DBF-informed codebook combined phase tags (entry, adaptation, and conditional adoption) with theme labels for barriers and facilitators. Initial codes were developed from the interview guide, DBF phases, and repeated reading of excerpts. Codes were then refined to distinguish conceptually adjacent themes such as Initial Uncertainty, Physical Discomfort, Skill Adaptation, Environmental Immersion, Trust Development, and Conditional Adoption.

To improve coding transparency, the analytic matrix retained the original excerpt, English translation, DBF phase, theme label, valence, and a short coding memo. For example, comments about headset heaviness, eye discomfort, or dizziness were coded as Physical Discomfort or Motion Discomfort, depending on the specific symptom. Comments about discussing strategies, comparing scores, or sharing ways to improve were coded as Social Reinforcement. Comments that expressed willingness only if equipment comfort, floor safety, content variety, or session duration improved were coded as Conditional Adoption or Adoption With Safety Measures. A codebook excerpt and representative coding examples are provided in Multimedia Appendix 1.

Two researchers (XS and HQ) participated in coding, compared coding decisions, and resolved disagreements through discussion and consensus. Coding memos and codebook revisions were retained to support an audit trail. Thematic saturation was not treated as a statistical threshold; operationally, thematic sufficiency was judged to have been reached because later transcripts primarily elaborated existing phase-level categories, such as uncertainty, physical discomfort, immersion, social reinforcement, trust, and conditional adoption, rather than generating new dominant phase-level themes [44,45]. Theme counts represent unique participants endorsing a theme within the completed-protocol qualitative sample and are interpreted as descriptive evidence coverage rather than prevalence estimates.

Methodological Integrity

Methodological integrity was supported through 4 linked procedures. Adequacy was addressed by using repeated-phase prompts across the completed-protocol qualitative sample and by retaining discrepant as well as convergent accounts. Researcher perspectives were managed through the shared interview guide, explicit phase and valence fields, coding memos, comparison of coding decisions, and consensus discussion. Groundedness was supported by retaining original Chinese excerpts, linking every coded statement to a participant and session phase, and presenting representative quotations. Meaningfulness and coherence were examined through integration with questionnaire, safety, and performance evidence without forcing convergence when data sources diverged. No participant member checking was conducted, and this absence is treated as a limitation rather than implied as a completed procedure.

Mixed Methods Integration

Integration occurred at three levels. First, qualitative themes were quantified as unique-participant endorsements within each DBF phase. Second, theme endorsement was linked descriptively to GEQ, VRSQ, and performance summaries. Third, discrepant and illustrative cases were examined to clarify how adoption could proceed despite early uncertainty, mild symptoms, or conditional reservations. This integration strategy was intended to connect experience, performance, and interpretation without converting the study into a confirmatory quantitative comparison [46,47].

The integration priority was explanation rather than convergence alone. When interview themes, questionnaire profiles, and performance logs pointed in the same direction, they were used to strengthen interpretation. When they diverged, the qualitative account was used to clarify why a participant could improve technically while remaining cautious about comfort, safety, or future use.

Analytic Strategy and Quantitative Analysis

Baseline characteristics were summarized using means and SDs for continuous variables and counts and percentages for categorical variables. Standardized mean differences and absolute proportion differences were used to describe baseline imbalance. Item-level completeness, Cronbach alpha, observed score ranges, and floor and ceiling concentrations were examined for each GEQ dimension and the VRSQ. Performance was summarized at days 1, 3, and 6 for average accuracy rate and average time spent (seconds), and day 1 to day 6 change was presented with 95% CIs. Trajectory was excluded from manuscript-ready performance results because its definition and direction could not be verified. GEQ and VRSQ profiles were interpreted descriptively. No *P* values or confirmatory between-group superiority tests were reported because the study was exploratory and quasi-experimental.

Data Diagnostics

Data diagnostics included item completeness, observed ranges, floor and ceiling concentrations, session availability, and verification of performance-field definitions. No outlier exclusions, transformations, or imputations were used. Trajectory was excluded because its direction and operational definition could not be verified.

Missing Data

The completed-protocol quantitative dataset and main qualitative coded dataset each included 34 participants (VR, n=16; MR, n=18). The partial-exposure MR transcript was retained only

XSL•FO
RenderX

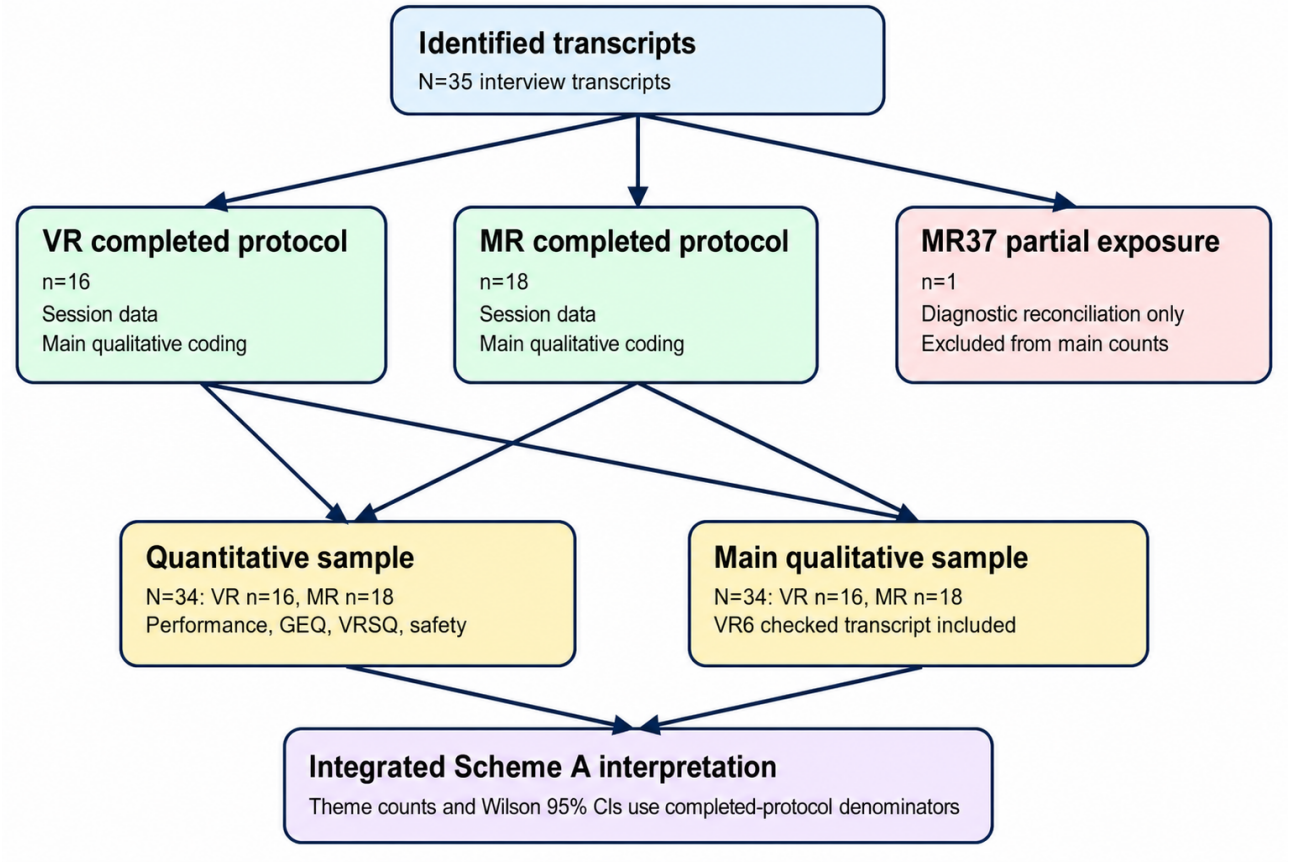
for diagnostic reconciliation and excluded from main theme counts. One completed-protocol VR transcript was checked and added to the coding matrix using verified coding rows. Given the small sample size and the nonconfirmatory design, analyses used complete-case summaries by data source, and missingness was reported descriptively rather than modeled with imputation. A formal missing completely at random test and multiple imputation were not conducted because the study did not make confirmatory estimates.

Safety Monitoring

All sessions were supervised by the research team. Participants received orientation before headset use, assistance with equipment fitting, and reminders that they could pause, rest, or stop at any point. A researcher remained nearby to monitor movement safety, dizziness, fatigue, discomfort, headset pressure, anxiety, and potential fall risk. Predefined stopping criteria included participant request to stop, visible instability, worsening dizziness or nausea, marked fatigue, anxiety, headset discomfort that did not resolve after adjustment, or any researcher concern that continued movement could increase fall risk. Monitoring procedures included presession orientation, in-session observation, symptom checks during pauses or after reported discomfort, immediate rest or headset removal when needed, and postsession confirmation that symptoms had resolved or remained mild. The training area was arranged to reduce obstacles and allow researcher assistance if needed. No falls, serious adverse events, or session terminations were recorded.

Ethical Considerations

The study received institutional approval from the Institute of Visual Informatics, Universiti Kebangsaan Malaysia, following assessment by selected institutional examiner panels on July 2, 2024 (official institutional approval reference: UKM.IVI.600-4/6/P130610). The current repeated-exposure follow-up used data collected under this approved research program. All participants received an explanation of the study purpose and procedures and provided written informed consent before participation. Study data were deidentified for analysis, participant identifiers were replaced with study codes, and no identifiable participant images are included in the study or Multimedia Appendices. No cash or performance-based financial compensation was provided. Participants received small noncash souvenirs as tokens of appreciation at predefined milestones.



Results

Participant Flow and Participant Characteristics

Thirty-five interview transcripts were identified. The main completed-protocol analysis included 34 participants for quantitative data (VR, n=16; MR, n=18) and 34 participants for qualitative coded evidence (VR, n=16; MR, n=18). Participant 37 was an MR partial-exposure case and was excluded from main theme counts. Participant 6 was a completed-protocol VR participant whose author-confirmed paraphrased coding was added to the qualitative coding matrix for participant-level counts but not for direct quotation. This handling creates a single denominator for the main completed-protocol interpretation. Participant disposition and analytic inclusion are summarized in Figure 1.

XSL•FO
RenderX

Figure 1. Participant flow diagram for the qualitative-dominant mixed methods follow-up study of immersive Tai Chi training among older adults in Hunan, China.

The flow diagram summarizes 35 identified interview transcripts, the exclusion of MR37 from the main theme counts, and the inclusion of completed-protocol VR6 coding in the main qualitative denominator. The complete quantitative sample had a mean age of 69.38 (SD 8.80; 95% CI 64.69 - 74.06) years in VR and 68.00 (SD 7.17; 95% CI 64.43 - 71.57) years in MR. BMI was 22.92 (SD 2.82; 95% CI 21.42 - 24.43) kg/m^2 in VR and 23.73 (SD 3.19; 95% CI 22.14 - 25.32) kg/m^2 in MR. BBS scores were high in both groups: 53.81 (SD 5.06; 95% CI 51.12 - 56.51) in VR and 55.06 (SD 2.26; 95% CI 53.93 - 56.18) in MR. Baseline standardized mean differences were 0.17 for age, –0.27 for BMI, and –0.32 for BBS. The groups also differed descriptively in sex distribution, smartphone use, education, and self-reported exercise intensity. These imbalances may have influenced engagement, technology confidence, safety appraisal, and trust development.

The broader recruitment pathway and participant flow are reported above. Exact calendar dates for recruitment and repeated follow-up were not available in the archived analytic files used for this revision.

Statistics and Data Analysis

All 34 participants had complete GEQ and VRSQ item data. Reliability was good for GEQ competence (α=0.834), flow (α=0.801), and positive affect (α=0.837), acceptable for the 5-item adapted sensory and imaginative immersion dimension (α=0.711), and acceptable for the standardized VRSQ total (α=0.740). GEQ challenge was questionable (α=0.657) and was interpreted cautiously. GEQ tension and annoyance showed severe floor concentration and zero-variance items, while GEQ negative affect showed inconsistent item covariance (α=–0.442); neither was treated as a reliable composite for substantive interpretation. The standardized VRSQ total was 8.65 (SD 8.89) in VR and 5.65 (SD 7.67) in MR. These questionnaire findings provide descriptive context only and do not establish modality superiority (Table 3).

RenderX

Table . Questionnaire reliability and descriptive profiles by delivery group[a].

Scale	Items	Cronbach α	Reliability and caution	VR[b] (n=16), mean (SD)	MR[c] (n=18), mean (SD)
GEQ[d] competence	5	0.834	Good	3.41 (0.69)	3.24 (0.82)
GEQ sensory and imaginative immersion (5-item adapted)	5	0.711	Acceptable for descriptive triangulation	3.69 (0.47)	2.64 (0.58)
GEQ flow	5	0.801	Good	3.83 (0.41)	2.57 (0.70)
GEQ tension and annoyance	3	0	Not interpretable: severe floor and zero variance	0.08 (0.33)	0.00 (0.00)
GEQ challenge	5	0.657	Questionable; interpret cautiously	1.30 (0.44)	1.20 (0.73)
GEQ negative affect	4	−0.442	Inconsistent item covariance; do not use as a reliable scale	0.41 (0.40)	0.33 (0.33)
GEQ positive affect	5	0.837	Good	3.74 (0.47)	3.53 (0.61)
VRSQ[e] total (standard 0 - 100 score)	9	0.740	Acceptable for descriptive triangulation	8.65 (8.89)	5.65 (7.67)

[a]GEQ dimensions are reported on the 0-4 analytic scale. The VRSQ total uses the standard 0-100 score. Reliability and distribution diagnostics are used to delimit interpretation, not to select favorable outcomes.

[d]GEQ:

[e]VRSQ: Virtual Reality Sickness Questionnaire.

Performance Across Repeated Sessions

Both groups showed practice-related changes in system-recorded performance across supervised sessions. Average accuracy rate increased from 0.812 (SD 0.134) on day 1 to 0.895 (SD 0.088) on day 6 in VR and from 0.817 (SD 0.174) to 0.920 (SD 0.081) in MR. Day 1 to day 6 accuracy change was 0.083 (95% CI 0.024-0.142) in VR and 0.103 (95% CI 0.037-0.169) in MR. Average time spent decreased from 5.99 (SD 2.49) seconds to 5.14 (SD 0.97) seconds in VR and from 5.26 (SD 0.94) seconds to 4.75 (SD 0.60) seconds in MR. Average time spent change was −0.856 (95% CI −1.754 to 0.042) seconds in VR and −0.506 (95% CI −0.802 to −0.209) seconds in MR. These within-sample descriptive changes are compatible with increasing task familiarity and performance adjustment, but they do not establish causal learning or modality superiority (Table 4).

Table . Performance at days 1, 3, and 6 and descriptive day 1 to day 6 change.

Metric[a]	Group	Day 1, mean (SD)	Day 3, mean (SD)	Day 6, mean (SD)	Day 1 to day 6 change (95% CI)
Accuracy	VR[b]	0.812 (0.134)	0.864 (0.100)	0.895 (0.088)	0.083 (0.024 to 0.142)
Accuracy	MR[c]	0.817 (0.174)	0.858 (0.199)	0.920 (0.081)	0.103 (0.037 to 0.169)
Average time spent (in seconds)	VR	5.99 (2.49)	5.54 (1.37)	5.14 (0.97)	−0.856 (−1.754 to 0.042)
Average time spent (in seconds)	MR	5.26 (0.94)	4.99 (0.86)	4.75 (0.60)	−0.506 (−0.802 to −0.209)

[a]Average accuracy rate is the system-recorded proportion of logged frames in which the head and hand hotspots were within the game's tolerance window. Average time spent is reported in seconds; lower values indicate faster task performance. 95% CIs are descriptive; no *P* values or between-group superiority tests were performed.

Findings

Phase 1: Entry, Uncertainty, and Mild Physical Discomfort

Entry-stage responses were characterized by unfamiliarity, uncertainty, and bodily adjustment. Initial Uncertainty was endorsed by 7 of 16 participants (43.8%; 95% CI 23.1% - 66.8%) in VR and 6 of 18 participants (33.3%; 95% CI 16.3% - 56.3%) in MR. Physical Discomfort was endorsed by 4 of 16 participants (25.0%; 95% CI 10.2% - 49.5%) in VR and 3 of 18 participants (16.7%; 95% CI 5.8% - 39.2%) in MR. Initial Adaptation was endorsed by 1 of 16 participants (6.2%; 95% CI 1.1% - 28.3%) in VR and 5 of 18 participants (27.8%; 95% CI 12.5% - 50.9%) in MR. These findings indicate that early resistance was not reducible to physiological discomfort alone. Participants also described unfamiliar equipment, uncertainty about whether they could operate the system, and concern about performing movements correctly.

A VR participant stated, “I was a little worried.” An MR participant described the first five minutes as “It felt very difficult.” These transcript-grounded excerpts illustrate competence and task uncertainty rather than physical intolerance alone. Other participants described novelty and curiosity, suggesting that unfamiliarity could operate as both a barrier and a facilitator depending on whether orientation and reassurance were sufficient.

This entry pattern has practical importance because it suggests that support should begin before performance feedback. Older adults who worried about operating the system or performing incorrectly needed clear orientation, slow-paced familiarization, and visible researcher support. Early adoption was also a response to whether participants felt that errors, pauses, and bodily sensations could be managed safely.

Phase 2: Adaptation, Immersion, and Social Reinforcement

During adaptation, participants increasingly described the training in relation to perceived improvement, environmental experience, and encouragement from others. Environmental Immersion was endorsed by 9 of 16 participants (56.2%; 95% CI 33.2% - 76.9%) in VR and 8 of 18 participants (44.4%; 95% CI 24.6% - 66.3%) in MR. Social Reinforcement was endorsed by 7 of 16 participants (43.8%; 95% CI 23.1% - 66.8%) in VR and 9 of 18 participants (50.0%; 95% CI 29.0% - 71.0%) in MR. Skill Adaptation was endorsed by 6 of 16 participants (37.5%; 95% CI 18.5% - 61.4%) in VR and 9 of 18 participants (50.0%; 95% CI 29.0% - 71.0%) in MR. Emotional Engagement was endorsed by 1 of 16 participants (6.2%; 95% CI 1.1% - 28.3%) in VR and 6 of 18 participants (33.3%; 95% CI 16.3% - 56.3%) in MR.

VR accounts often connected engagement to scenery, music, and emotional comfort. One VR participant explained, “I preferred the openness of nature, the boundless mountains...it felt as though I was immersed in nature.” MR accounts more often connected adaptation to remaining oriented to the real environment while learning the movement sequence; one participant stated, “I think I could get better the more I played.” Social reinforcement appeared in both groups. A VR participant described strategy sharing directly: “I wanted to share my method with them so that they could also achieve higher scores.” These accounts show that peer comparison and shared problem solving operated alongside immersive scenery and system feedback.

GEQ profiles supported this interpretation descriptively: VR had higher sensory and imaginative immersion (3.69; SD 0.47) and flow (3.83; SD 0.41) than MR (2.64; SD 0.58 and 2.57; SD 0.70), respectively. These questionnaire summaries are used only to contextualize qualitative interpretation, not to test modality superiority.

Phase 3: Trust Development and Conditional Adoption

Late-stage adoption was conditional rather than unconditional. Conditional willingness with improvements was endorsed by 6 of 16 participants (37.5%; 95% CI 18.5% - 61.4%) in VR and 1 of 18 participants (5.6%; 95% CI 1.0% - 25.8%) in MR. Conditional willingness was endorsed by 2 of 16 participants (12.5%; 95% CI 3.5% - 36.0%) in VR and 4 of 18 participants (22.2%; 95% CI 9.0% - 45.2%) in MR. Trust Development was endorsed by 0 in VR and 5 of 18 participants (27.8%; 95% CI 12.5% - 50.9%) in MR, while Trust and conditional willingness was endorsed by 5 of 16 participants (31.2%; 95% CI 14.2% - 55.6%) in VR and 3 of 18 participants (16.7%; 95% CI 5.8% - 39.2%) in MR. These patterns should be interpreted cautiously because baseline and follow-up conditions differed descriptively, but they suggest different experiential emphases.

Some participants expressed willingness to continue immersive Tai Chi if safety, headset comfort, session duration, content variety, and the physical setting were improved. An MR participant answered “I trusted it” and later described the equipment as “it felt reliable.” A VR participant described a possible place in the daily routine: “I could dance for exercise in the morning and play this in the afternoon; that would be quite good.” Another linked willingness to a practical environmental safeguard: “Just put down a thin carpet.then I would not be worried.” These accounts support conditional adoption rather than evidence of long-term unsupervised adherence.

Conditional adoption was therefore not a weak form of acceptance; it was the dominant form of late-stage evaluation in this supervised setting. Participants did not simply accept or reject the system. They specified conditions under which continued use would be reasonable, such as shorter sessions, more comfortable headset fitting, safer space arrangement, clearer guidance, or richer content (Table 5).

[d]MR: mixed reality.

Mixed Methods Integration and Safety Findings

Triangulation across interviews, questionnaires, and performance logs supported a phase-sensitive interpretation. Accuracy improved in both groups, but participants interpreted improvement through different experiential frames. VR accounts often connected engagement to environmental immersion and affective value, whereas MR accounts more often emphasized reality grounding, perceived control, and trust. The same performance pattern could be interpreted differently depending on comfort, flow, sickness symptoms, and perceived control. Figure 2 synthesizes how entry uncertainty and physical discomfort gave way to practice-supported adaptation and then to trust or conditional willingness; the arrows organize the interpretation and do not represent tested causal effects. The map is a qualitative-dominant visual synthesis.

XSL•FO
RenderX

Figure 2. Thematic map of dynamic barriers and facilitators across Dynamic Barrier Framework phases in repeated immersive Tai Chi training.

Safety-related interview content included dizziness, fatigue, eye discomfort, headset pressure, and concern about falling. Strict safety and discomfort themes were present in 7/16 (43.8%) of VR participants and 11/18 (61.1%) of MR participants. No falls, serious adverse events, or session terminations were recorded. These mild symptoms nevertheless shaped conditional adoption because participants evaluated continued use in relation to whether the system felt safe, manageable, and worthwhile (Table 6).

Discussion

Support of Original Hypotheses and Principal Findings

No confirmatory hypotheses were specified; findings were evaluated against the stated objectives and research questions. This exploratory, qualitative-dominant longitudinal mixed methods follow-up study addressed how older adults' barriers and facilitators evolved during repeated immersive Tai Chi training and how VR and MR delivery appeared to shape that process. Adoption unfolded from entry uncertainty and bodily adjustment, through practice- and socially supported adaptation, toward trust and conditional willingness based on comfort, perceived safety, content value, and implementation support. System logs showed higher average accuracy rate and lower average time spent over repeated supervised sessions, which is consistent with task familiarization but does not by itself demonstrate durable motor learning. Questionnaire evidence contextualized immersion, flow, and sickness without establishing modality superiority. Together, these findings answer the stated aims by showing that adoption was a changing, embodied, and socially situated evaluation rather than a single intention score or simple device preference.

Similarity of Results: Dynamic Adoption Beyond Static Acceptance Models

The findings extend technology acceptance and continuance research by showing why repeated exposure matters for movement-based immersive systems. Existing models emphasize usefulness, ease of use, social influence, facilitating conditions, and continuance intention [18-23]. Recent older-adult studies have also documented favorable acceptance after immersive training or repeated group exposure [24,25].

XSL•FO
RenderX

This study adds a temporal and bodily explanation: usefulness and ease of use were not fixed beliefs but judgments revised as participants learned headset fitting, interpreted movement feedback, managed symptoms, compared performance, and tested whether stopping or asking for help was acceptable. The DBF therefore complements established acceptance models by specifying when and how barriers changed during supervised use. In this process, feedback-supported competence is consistent with self-efficacy theory [48], while confidence in system feedback and stopping procedures is better understood as calibrated trust than unqualified acceptance [49].

Early uncertainty had at least four forms. Procedural uncertainty concerned how to wear and operate unfamiliar equipment; performance uncertainty concerned whether movements were correct or tasks could be completed; embodied uncertainty concerned dizziness, fatigue, headset pressure, and balance; and environmental uncertainty concerned awareness of the physical room while moving. These concerns resemble recent reports that older adults need age-appropriate adaptation, clear support, suitable challenge, and socially meaningful use [24,31,32]. In this study, orientation addressed procedural uncertainty, repeated practice and feedback addressed performance uncertainty, symptom monitoring addressed embodied uncertainty, and supervision or passthrough visibility addressed environmental uncertainty. Hesitation should therefore not be equated automatically with nonacceptance; it can be a rational safety appraisal that changes when uncertainty becomes manageable.

Interpretation: VR and MR as Differentiated but not Superior Pathways

The VR and MR comparison should be interpreted cautiously. Recent reviews support the potential of immersive training to improve balance and physical activity outcomes in older adults [9,10], and a preliminary randomized trial reported promising findings for MR-based exercise in older women with sarcopenia [29]. Those studies establish clinical and implementation plausibility, but they do not determine whether VR or MR is superior for the present Tai Chi application. Our qualitative evidence instead identifies different experiential emphases: VR accounts foregrounded scenery, absorption, and affective value, whereas MR accounts more often foregrounded visual grounding, control, and trust. These are design hypotheses rather than causal modality effects. Alternative explanations remain plausible because baseline imbalance, prior technology experience, novelty, supervised delivery, community familiarity, and individual preference can shape immersive-system responses [11-16,50]. Preserving access to the physical room may support orientation for some users but reduce absorption, whereas full visual immersion may enhance engagement while increasing uncertainty for others [26-28,50]. Future comparisons should therefore manipulate occlusion, feedback, and supervision directly rather than treating the present group pattern as a stable property of either modality.

Social reinforcement deserves separate emphasis. Participants described discussing strategies, comparing scores, sharing methods, and wanting multiplayer or encouragement features. This is consistent with recent group and remote VR studies in which trusted facilitators, peer connection, and group delivery shaped acceptance and engagement [25,30], and with qualitative evidence that older users wanted stronger social engagement in VR exercise games [31]. For community programs, social support is therefore not an accessory to the headset. It is part of the intervention mechanism and may remain motivational after technological novelty declines.

Safety, Comfort, and Conditional Adoption

Safety concerns were not peripheral; they were part of the adoption process. Average VRSQ scores were low, and no falls, serious adverse events, or session terminations were recorded, but interviews still documented dizziness, fatigue, eye discomfort, headset pressure, and concern about falling. This combination is consistent with reviews describing generally feasible immersive exercise alongside persistent usability and tolerability concerns [9,10,50]. Symptom averages can therefore understate the importance of episodic discomfort for an individual's decision to continue. Short initial sessions, stable layouts, headset-fit checks, visible stopping procedures, symptom monitoring, and instructor support serve both risk control and trust formation [9,10,50]. The absence of serious adverse events in supervised sessions is not evidence of safety for unsupervised community or home use because supervision, equipment setup, and immediate assistance were part of the conditions under which participants evaluated the system. Recent adherence research likewise notes that XR exercise evidence is dominated by short, supported programs and rarely includes long-term community follow-up [32]. Any transfer to home use should therefore be preceded by explicit risk assessment, an orientation protocol, clear stopping rules, and a plan for technical or caregiver support [32,51-53].

Implications for Practice

For community and home implementation, immersive Tai Chi should be delivered as a phase-sensitive service rather than a stand-alone product. Entry support should reduce procedural, performance, bodily, and environmental uncertainty through orientation, simple controls, fit checks, visible safety precautions, and permission to pause. Adaptation support should combine understandable performance feedback, progressive challenge, peer comparison, and encouragement. Conditional adoption requires lighter and easier-to-fit equipment, meaningful content variety, transparent safety procedures, and realistic access to instructor, caregiver, or technical support. These priorities align with calls for age-appropriate challenge, social engagement, and service continuity in XR exercise [31,32] and with broader evidence that older adults' health-technology engagement depends on usability, perceived value, support, and fit with daily life [51-53]. For VR delivery, the priority is to preserve the motivational value of immersive scenery while reducing disorientation, headset burden, and uncertainty about the surrounding space [9,10,50]. For MR delivery, environmental visibility should be paired with clear virtual guidance, trustworthy feedback, and sufficient content richness; recent MR exercise evidence also supports supervised, adaptive task progression rather than unassisted exposure [29]. For both modalities, community programs should plan staff training, safe layouts, symptom checks, and gradual progression before considering independent home use [32,51-53].

XSL•FO
RenderX

Limitations and Generalizability

Several limitations should be considered. First, the follow-up retained the parent study allocation and was not rerandomized; the VR and MR comparison is exploratory. Second, the small community sample from Hunan, China limits transferability. Third, one MR partial-exposure case was excluded from main theme counts, and participant 6 contributed author-confirmed paraphrased coding rather than direct quotations. Fourth, baseline differences in sex distribution, smartphone use, exercise intensity, and BBS may have influenced engagement and trust. Fifth, some participants were previously known through community connections, which may have affected participation or disclosure despite standardized procedures. Sixth, automated transcription may contain recognition errors; quotations were therefore shortened to transcript-grounded excerpts and should remain subject to final source-audio checking before submission. Seventh, six supervised sessions do not demonstrate long-term adherence or unsupervised safety. Eighth, the system-defined average accuracy rate and average time spent quantify game-task performance rather than validated biomechanical technique; the backend's numeric spatial-tolerance threshold was not preserved in the available export, and trajectory direction and definition were unverifiable. Performance findings were therefore restricted to directly reproducible descriptive fields, and trajectory was excluded. Finally, theme counts indicate evidence coverage within this qualitative sample, not population prevalence.

Future Directions

Future research should prospectively register larger and more balanced trials, predefine adverse-event and stopping procedures, and preserve backend metric specifications, including spatial-tolerance thresholds, before data collection. Repeated-measures designs should distinguish short-term task familiarization from retained motor learning and should test whether phase-tailored orientation, feedback, social support, and symptom management improve adherence. VR and MR comparisons should hold exercise content constant while manipulating environmental visibility and feedback, and they should include longer community or home follow-up. This agenda is consistent with current evidence calling for multidimensional adherence measurement, long-term tracking, and direct evaluation of age-sensitive XR service design [9,29,32].

Conclusion

This exploratory, qualitative-dominant longitudinal mixed methods follow-up study is innovative in combining repeated qualitative accounts with symptom, safety, and performance evidence while holding the Tai Chi content constant across VR and MR delivery. Unlike single-session acceptance studies, broad XR comparisons, or endpoint-only evaluations, it shows that older adults repeatedly evaluate whether an immersive system is understandable, physically manageable, socially supported, and worth continuing. The DBF-informed account contributes a phase-sensitive explanation of how entry barriers may soften, persist, or change meaning and how VR and MR affordances can shape experience without establishing device superiority. The real-world implication is that immersive exercise should be implemented as an age-friendly service rather than a stand-alone headset: programs need gradual orientation, monitored exposure, comfort and safety safeguards, understandable feedback, meaningful challenge, social support, and modality-sensitive design [9,10,29,31,32,51-53]. Longer community or home follow-up remains necessary before inferring sustained adherence or unsupervised safety.

Acknowledgments

The authors declare the use of generative AI tools during research documentation, data analysis support, and manuscript preparation. A Qwen-based artificial intelligence transcription tool was used to produce initial Chinese-language transcripts from interview recordings. OpenAI ChatGPT and Codex, using GPT-family models whose specific model identifiers varied across sessions, were used iteratively to assist with literature search and organization, generation and debugging of R code for descriptive analysis and visualization, Chinese-English translation, manuscript structuring, text drafting and rephrasing, summarization, proofreading and language editing, identification of limitations, and preparation of responses to reviewers. Because this assistance occurred iteratively across multiple stages, individual uses could not always be assigned to a single isolated manuscript section. Generative artificial intelligence was not treated as an author, an independent qualitative coder, or an autonomous scientific decision-maker. Two human researchers retained responsibility for qualitative coding and interpretation. The authors retained responsibility for reviewing translations, executing and inspecting the statistical analyses, verifying cited sources, checking retained quotations against source materials, and critically reviewing and approving all interpretations, conclusions, and final manuscript text. Responsibility for the accuracy, integrity, and final content lies entirely with the authors. Generative AI tools are not listed as authors and bear no responsibility for the final work. This declaration is submitted under the collective responsibility of the authors.

Abstract

Background: Physical activity is one of the preferred interventions for mild cognitive impairment (MCI); however, the physical activity levels and adherence of older adults with MCI are particularly limited. Exergames are expected to be a key strategy to address these issues. However, existing exergames lack usability among the older adult population.

Objective: We aimed to design and develop an MCI-centered exergame for older adults and test its usability.

Methods: We used a cross-sectional, convergent mixed methods study with a single-group observational design, comprising a user-centered design phase (part 1) and a usability evaluation phase (part 2). In part 1, the "Lehuo Pingpang" virtual reality (VR) table tennis exergame prototype was designed and developed using Unity3D (Unity Technologies) and a PICO 4 Pro system. In part 2, a total of 12 older adults (aged ≥60 years) with MCI were recruited via convenience sampling from community, home-based, and institutional care settings in Changsha, Hunan. Usability was evaluated using a convergent mixed methods approach. Immediately after a supervised, independent gaming session, quantitative usability was measured using the System Usability Scale, while qualitative feedback regarding user experiences and barriers was gathered concurrently through face-to-face semistructured interviews. Data integration occurred at the interpretive level to synthesize the quantitative metrics with qualitative themes.

Results: In part 1, an original design framework for MCI exergames was constructed. Group discussions selected table tennis as the core activity and PICO 4 Pro as the hardware platform based on clarity and physical comfort. A multidisciplinary expert meeting (n=8) optimized the preliminary plan across six dimensions, resulting in the final prototype Lehuo Pingpang. In part 2, 12 participants (mean age 69.08, SD 6.08 y) evaluated the prototype. The mean System Usability Scale score was 79.38 (SD 12.89; 95% CI 71.19 - 87.57), indicating acceptable and reliable usability. Qualitative interviews (data saturation achieved at the 9th interview, with 12 completed) identified 2 main themes and 7 subthemes categorized into positive experiences and deficiencies. Mixed methods integration demonstrated that quantitative usability and learnability indicators strongly converged with qualitative praise for simple operation and safety functions, though complemented by learning friction from controller button complexity and VR unfamiliarity, as well as minor user interface flaws (small buttons). Crucially, while quantitative confidence was high, long-term frequent-use intentions were moderate. Qualitative findings revealed that this was driven by physical discomfort (eg, VR dizziness and facial pressure).

Conclusions: Guided by an original evidence-based design framework, this study successfully developed and evaluated a customized MCI-specific VR exergame. Unlike existing research, this work highlights how multidisciplinary co-design and culturally familiar sport themes can optimize digital rehabilitation. It brings to the field of gerontechnology a replicable development workflow and vital mixed methods insights regarding the paradox between quantitative acceptability and qualitative physical discomfort driven by novelty.

KEYWORDS

mild cognitive impairment; older adults; exergames; physical activity; user-centered design; usability

Introduction

Mild cognitive impairment (MCI) represents a transitional pathological state between cognitive decline associated with normal aging and dementia [1]. It is reported that 42% of the worldwide population aged older than 60 years is affected by MCI [2]. Moreover, the prevalence of MCI increases with advancing age, and its incidence and rate of progression to dementia are projected to continue rising, primarily due to global increases in life expectancy and sedentary lifestyles [3-8]. Therefore, older adults with MCI represent a critical window for preventing and treating dementia, and interventions should prioritize addressing sedentary lifestyle behaviors.

Physical activity is the preferred intervention for MCI, and it is also an effective and economical nonpharmacological approach to reducing the risk of dementia [9,10]. Physical activity can significantly improve cognitive function, physical function, and quality of life in patients with MCI [11,12]. However, the physical activity levels and adherence of older adults with MCI are particularly limited due to disease-related motor and cognitive changes. A systematic review of older adults with MCI and dementia found that the adherence rate to physical activity interventions was as low as 16% [13]. Therefore, while physical activity is the preferred intervention for MCI, older adults with MCI still face problems of insufficient physical activity levels and poor adherence.

Exergaming, an emerging form of physical activity, has the potential to achieve this goal. Exergames are a combination of exercise and games, also known as active video games, which incorporate physical activity into a video game environment through body-controlled movements [14]. Soltani et al [15] described exergaming as a tool to combat sedentary lifestyles. Exergaming can improve exercise adherence and participation by enhancing motivational drive and satisfaction [16], which in turn may exert positive effects on cognitive function improvement [17]. The American College of Sports Medicine has even defined exergaming as the future of physical activity [18]. Thus, as an emerging mode of exercise, exergaming holds promise as a key strategy to enhance physical activity levels and adherence among older adults with MCI.

Despite their potential, existing exergames endure notable limitations. Ongoing reviews of current evidence indicate that many studies rely on outdated and commercially discontinued game systems, such as the Nintendo Wii, Xbox Kinect (Microsoft Corp), or Sony PlayStation [19,20]. Crucially, these commercial systems were never specifically designed for therapeutic or rehabilitation cohorts [19]. Previous studies have shown that existing exergames primarily target young people, and the design of related exergames (eg, Wii and Kinect) is not suitable for older adults. These games often feature colorful and visually busy game interactions, inappropriate music, and highly demanding user interface (UI) navigation [21]. Meanwhile, their design in the physical activity and/or cognitive domains is overly complex and difficult [22,23]. Moreover, most existing exergames are designed for entertainment and recreation rather than based on exercise principles [21]. Therefore, most existing exergames lack usability among older adults. Development should be based on the fundamental principles of exercise and tailored to the specific needs of different target users.

Within the broad field of eHealth system development, user-centered design (UCD) [24] has consistently been the most commonly applied framework [25]. Rooted in the usability requirements of the target population, it holds promise for resolving the identified issues in existing exergames. UCD refers to a series of activities throughout the product development process, including collecting user needs, analyzing user tasks, and conducting iterative rapid prototyping and usability testing to optimize the UI for maximum usability [26]. This approach ensures that products incorporate functions meeting user needs and provide interfaces matching users' experience and capabilities to support efficient task completion [27]. Usability testing within UCD is a critical precursor to formal intervention, as technological usability is a prerequisite for improving health outcomes [28]. Furthermore, user feedback can be leveraged to identify issues [29], facilitating technical refinement and optimization for better adaptation to target users. Therefore, the UCD process is expected to yield a highly usable product.

In the current methodology, the Multidisciplinary Iterative Design of Exergames (MIDE) framework adopts a multidisciplinary research approach and an iterative method to ensure that each exergame meets the necessary health goals while providing an engaging and easy-to-understand design for its target population [30]. It was proposed by Canadian systems design engineer Yirou Li [30]. It is currently the only exergame design framework that targets older adults and covers the entire lifecycle of exergame design, development, and evaluation, aiming to provide guidelines and considerations related to these processes [30]. This framework includes a three-stage methodology: (1) conducting contextual research to understand the needs of users and therapists through direct interaction and literature reviews; (2) a design and development phase requiring collaboration between therapists and users to cocreate and customize game content; and (3) evaluating the device's effectiveness, usability, and user acceptance. Guided by this framework, the design of the exergame in this study systematically encompasses these three stages—contextual research (design needs analysis), game design and development, and system evaluation—by using the UCD approach and integrating the feedback of various stakeholders. Consequently, adopting a UCD methodology guided by the MIDE framework to explore user preferences and motivational factors is imperative [21]. As digital technologies evolve rapidly, older adults—particularly those with MCI—face increasingly significant digital barriers. Therefore, there is an urgent need for usability research specifically tailored to this vulnerable population. Therefore, there is an urgent need to conduct usability research on technologies among older populations, particularly in individuals with MCI. Accordingly, guided by the MIDE framework, this study aims to (1) design and develop

XSL•FO
RenderX

an exergame centered on older adults with MCI and (2) test its usability among older adults with MCI.

Methods

Overview

This study consists of two parts: one is to design and develop an exergame prototype (part 1) based on the research results [31] of the team's previous analysis of the needs of older adults with MCI for exergames, and the other is to test the usability of the exergame prototype among older adults with MCI (part 2).

Part 1: Design and Development of an Exergame Centered on Older Adults With MCI

Phase 1: Early-Stage Preparations

A multidisciplinary team of 12 researchers was established, comprising experts in geriatric nursing, sports rehabilitation, medical robotics, virtual reality (VR), and human-computer interaction technology, alongside graduate students. Their primary task was to translate design concepts into a tangible product. The target user group was defined as older adults aged ≥60 years with MCI. To accommodate the diverse care landscape in China, the exergames were designed for adaptability across community, institutional, and home-based care settings.

Phase 2: Needs Analysis and Group Discussion

First, based on our previous research [31], we clarified the specific requirements of older adults with MCI. These include the need for age-friendly design, scientific validity and safety during exercise, a good gaming experience, simultaneous physical and cognitive training, and the provision of support and training. Based on these identified needs, we proposed an original design framework for exergames targeting older adults with MCI as a primary contribution of this paper. Second, the multidisciplinary team convened for a group discussion to translate this newly developed framework into specific, actionable design strategies. Finally, by integrating the core components of the framework with the outcomes of the discussion, the "Preliminary Design Plan for Exergames Targeting Older Adults With MCI" was formulated.

Phase 3: Expert Meeting

While our previous needs analysis (phase 2) extensively involved patients with MCI, they were not directly included in this preliminary design validation phase. The primary reason is that older adults with MCI experience cognitive decline, particularly in domains such as abstract thinking and executive function. Evaluating noninteractive, low-fidelity materials (eg, conceptual PowerPoint [Microsoft Corp] slides or UI wireframes) may pose significant cognitive challenges for them, as it requires a high degree of abstract visualization to conceptualize interactive experiences. Therefore, following established inclusive design practices for cognitively impaired populations, we tailored the traditional UCD process by using a multidisciplinary expert team to bridge this gap. The goal was to rapidly translate abstract requirements into a tangible, high-fidelity prototype that MCI users could actually comprehend and evaluate during the subsequent usability testing.

First, the expert team was selected. To recruit independent, external specialists who were entirely separate from our core research and development team, a purposive sampling method was used. Potential candidates were identified through the authors' academic networks, affiliated clinical institutions, and professional associations, and were initially contacted via email or telephone to present this study's objectives and scope. Experts participated voluntarily. The inclusion criteria for experts were (1) those engaged in multidisciplinary research, rehabilitation medicine, sports medicine, geriatrics, geriatric nursing, computer software development, ergonomics, human-computer interaction, VR game development, community medical work, etc; (2) those holding a master's degree or above; and (3) those with an intermediate professional title or above, or with 10 years or more of specialized work or research experience.

Second, a multidisciplinary expert meeting was convened to evaluate the preliminary design. To ensure quality, comprehensive materials were distributed two weeks in advance to allow for preparation. The session began with a presentation of the research context, objectives, preliminary design plan, and interface designs via PowerPoint, followed by a structured discussion on potential revisions to reach a consensus on the optimization strategies. All feedback and agreed revisions were documented through audio recordings and field notes.

To analyze these collected data, the research team reviewed the audio recordings and field notes postmeeting to systematically extract and categorize the experts' suggestions into thematic design optimization dimensions. Based on these categorized suggestions, the research team adjusted and modified the preliminary exergame design plan to formulate a revised version. This revised plan was returned to the experts for verification and confirmation to ensure their input was accurately interpreted and implemented. After no further revisions were needed, the final version of the exergame design plan was formed.

Phase 4: Development of the Exergame Prototype

Development Steps of the Exergame

First, based on the final exergame design plan and combined with development objectives and principles, the interface content, interaction modes, logical processes, etc, of the exergame were clarified. Next, software development was carried out by technical personnel; meanwhile, the first author closely collaborated throughout the process, deeply participated, and completed multiple rounds of operation testing and debugging together with technical personnel, ultimately developing the exergame prototype.

Development of the Software End

The development strictly followed the UCD approach, closely aligning with the needs of older adults with MCI to transform the design plan into a physical product. As involving older adults with MCI in testing unstable, raw software builds during the programming phase poses excessive cognitive load and potential safety risks, the first author acted as a surrogate evaluator (user proxy) representing the target users. To implement this approach

XSL•FO
RenderX

during the coding process, the technical team directly translated the structured modules, interaction logics, and technical specifications outlined in the final design plan—which were grounded in actual user requirements (phase 2)—into concrete C# code in Unity3D. Throughout this software development phase, rather than using a linear coding process, we used an iterative "code-test-refine" cycle. The first author regularly playtested the evolving builds against the user-centered specifications in the final design plan, identified usability hurdles, and collaborated with technical personnel to make immediate code adjustments before the next milestone.

Code writing and functional implementation were carried out according to the game design plan, with project development based on the PC-oriented Unity3D engine. The development used C# language, used Microsoft Visual Studio as the compilation platform, ran on the Windows 11 (Microsoft Corp) OS, and was supported by hardware including an Intel Core i5 CPU and a high-performance PC workstation.

Part 2: Usability Evaluation With Targeted Users

Mixed Methods Research Design Overview

Tuena et al [32] proposed that in usability studies targeting older adults, the mixed research method combining quantitative and qualitative research is the preferred approach, as it can ensure the completeness and interpretability of research results. Thus, to achieve a comprehensive usability evaluation, a cross-sectional, convergent mixed methods design (incorporating a nonexperimental, single-group observational quantitative strand and a descriptive qualitative strand) was used. This study has been reported in line with the GRAMMS (Good Reporting of a Mixed Methods Study) checklist [33]. In this design, quantitative and qualitative data were collected concurrently, analyzed separately, and integrated during the interpretation phase [34]. There were no missing data in this study; all 12 participants completed the required assessments. The flow of participants through each stage of the current study is visually detailed in the participant flowchart (Figure 1).

XSL•FO
RenderX

Figure 1. Participant flowchart illustrating the enrollment, usability testing, mixed methods data collection, and data analysis stages for older adults with mild cognitive impairment.

XSL•FO
RenderX

Quantitative Method

Inclusion and Exclusion Criteria

Inclusion criteria: aged ≥60 years; met Petersen's MCI criteria [35], including self-reported or informant-reported memory decline, Montreal Cognitive Assessment (MoCA) scores [36] (≤13 points for illiterate individuals, ≤19 points for those with primary school education, and ≤24 points for those with junior high school education or above), Activities of Daily Living Scale score ≤23, and no clinical diagnosis of dementia. Exclusion criteria were cardiovascular diseases, visual impairments, orthopedic or neurological diseases affecting participation in exergames; cancer; severe obesity (BMI >40 kg/m²); mental disorders or other conditions severely impairing communication; and participation in other health-related studies. No restrictions were placed on recruitment based on demographic characteristics such as sex or ethnicity.

Participant Characteristics

Overview

Older adults with MCI were recruited in this study. This study's sample consisted of 12 older adults with MCI. Their major demographic characteristics (including age, sex, and educational background) and important topic-specific characteristics (MoCA scores) are detailed in the Results section.

Sampling Procedures

A convenience sampling method was used to recruit participants from community, home, and institutional care settings in Changsha, Hunan, China, between February and March 2024. To identify potential participants, the research team actively collaborated with community health care workers and facility administrators to conduct an initial records-based prescreening of registries. Eligible older adults who met the baseline age and diagnostic records were contacted via telephone or face-to-face visits. The researchers clearly explained the study's background, objectives, and voluntary participation nature. For those who expressed interest, a face-to-face evaluation session was conducted by the first author in a quiet room to perform the MoCA screening and verify study eligibility. Written informed consent was formally obtained from each eligible individual before enrollment, and they were informed of their right to withdraw at any stage of the usability testing without any negative consequences. No monetary payments or agreements were made to the participants. Out of all eligible individuals who met the prescreening criteria and completed the initial evaluation, 100% participated in the usability testing session.

Sample Size, Power, and Precision

Regarding sample size, Macefield [37] suggests a reasonable baseline range for identifying usability issues is 5‐10 participants, while comparative studies aiming for statistically significant results should include 10‐12 participants. Additionally, usability study guidelines indicate that the optimal sample size is 10±2 participants [38]. Thus, to achieve adequate precision and representation, the sample size for the quantitative phase of this study was determined to be 12 participants. No power analysis was performed as no inferential hypothesis testing was planned. No stopping rules or interim analyses were used.

Measures and Covariates

The primary outcome measure was usability. Immediately postsession, a self-developed questionnaire collected demographic data, while the System Usability Scale (SUS) [39] assessed the exergame's usability. The SUS is a scientifically validated, reliable scale (eg, ω=0.91 [40]) that is easy to administer [39,41] and frequently used in game research [19,42-45]. It consists of 10 items covering effectiveness (learnability), efficiency (usability), and satisfaction [46], rated on a 5-point Likert scale (1="strongly disagree," 5="strongly agree") [39,41]. Scores are calculated using a specific algorithm: raw scores for odd-numbered items are subtracted by 1, and for even-numbered items are subtracted from 5. The sum is multiplied by 2.5 to yield a final score (0‐100). Scores ≥70 are considered "acceptable," with 50‐70 as "marginally acceptable," and <50 as "unacceptable" [47]. Secondary measures and covariates included demographic data (age, sex, and educational level). All measures collected in this study are included in this report.

Data Collection

Before this study, the first author (XC) briefed participants on the research objectives and prototype functions, provided a demonstration, and obtained consent for audio recording. Participants selected their preferred testing location (home, community center, or care facility) and performed a mandatory 10-minute safety warm-up. To ensure an authentic experience, participants used the prototype independently under XC's safety supervision (Figure 2). The quantitative data collection occurred immediately after this session.

XSL•FO
RenderX

Figure 2. An older adult participant with mild cognitive impairment (MCI) wearing a virtual reality (VR) headset to experience the "Lehuo Pingpang" exergame prototype.

Conditions and Design

This quantitative component of this study used a cross-sectional, nonexperimental, single-group observational design.

Data Analysis

For quantitative research, valid questionnaires were numbered, and research data were double-entered into Excel (Microsoft Corp) spreadsheets. Quantitative data were analyzed using SPSS (version 26; IBM) software. First, P-P plots were used for normality testing of quantitative data. When quantitative data followed a normal distribution, descriptive statistics were performed using mean and SD; when quantitative data did not follow a normal distribution, median, IQR, minimum, and maximum values were used for descriptive statistics. Frequencies and constituent ratios were used to describe categorical data.

XSL•FO
RenderX

Qualitative Method

Research Design Overview (Qualitative)

The qualitative strand of this study used a descriptive qualitative approach using face-to-face semistructured interviews. This design was chosen to capture participants' subjective usability experiences, emotional responses, and specific suggestions for prototype refinement. The reporting of qualitative data adhered to the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [48].

Study Participants or Data Sources

The qualitative phase included the same 12 older adults with MCI who completed the quantitative usability phase, ensuring complete integration of the datasets. The interviews were conducted immediately following the quantitative data collection between February and March 2024.

Participant Recruitment

Participants were recruited concurrently with the quantitative phase. After completing the physical exergame play session and the quantitative questionnaires, participants were immediately invited by the researchers to participate in a follow-up interview. Written informed consent for both the interview and audio recording was confirmed once more before the start of the qualitative session.

Data Collection (Qualitative)

Face-to-face semistructured interviews (lasting 30 - 45 min) were conducted by trained researchers (XC and HN) in a private room at the participants' testing locations to explore experiences and identify usability issues. The interview guide, developed based on our research objectives, included three open-ended questions: (1) What was your overall experience and how did you feel after using the exergame prototype? (2) Which aspects of the exergame prototype require improvement or optimization? (3) Do you have any additional feedback or suggestions? Audio recordings were transcribed verbatim within 24 hours by the same researchers, supplemented by field notes for analysis.

Qualitative Data Analysis

Qualitative data were managed via NVivo (version 12; Lumivero) and analyzed concurrently with collection using thematic analysis [49], which is a highly appropriate method for identifying usability patterns and user experiences. To capture the participants' experiences directly, a purely inductive coding approach was used, allowing codes and themes to emerge directly from the raw transcript data. This systematic 6-phase process [50] included the following: (1) regarding familiarization, two researchers (XC and HN) independently read the transcripts; (2) regarding generating initial codes and the codebook, the two researchers (XC and HN) independently coded a subset of the transcripts, and then met to compare their open codes, resolve discrepancies through discussion, and establish a preliminary coding scheme (initial codebook); (3) regarding searching for themes, the remaining transcripts were coded in NVivo (version 12) using this preliminary codebook, and related codes were clustered to identify broader candidate subthemes and themes; and (4) reviewing themes, (5) defining and naming themes, and (6) producing the report. Disputed areas in coding or theme interpretation were discussed by the two research team members and resolved through consensus, with consultation from a qualitative research expert (HF).

Methodological Integrity

The principal investigator and interviewer (XC) is a doctoral researcher in geriatric nursing and digital health. She has received systematic training in qualitative methodologies and completed a six-month collaborative research residency within the Sports Rehabilitation and Medical Robotics team at the Ningbo Institute of Materials Technology and Engineering. This interdisciplinary background spanning clinical care and medical robotics significantly enhanced the depth of data collection and enriched the interpretation of human-computer interaction nuances during the interviews. The coauthors (HN and HF) are established experts in geriatric nursing, digital health, qualitative methods, and nursing informatics. This collective expertise served to enhance the rigor of qualitative interpretation. Throughout the research process, researchers XC and HN maintained reflexive journals to critically monitor personal assumptions, and the team held regular reflexivity meetings to ensure that all analytical outputs remained strictly grounded in the raw data.

To ensure deep allegiance to the authentic experiences of older adults with MCI, several measures were taken. First, the interviews were conducted immediately following the exergame playing session, ensuring that participants' recall of usability friction and emotional experiences was fresh and vivid. Second, all interviews were conducted face-to-face in the ecological environments where participants had just completed the gameplay, minimizing cognitive displacement. Finally, raw verbatim transcripts and extensive field notes were continuously cross-checked to ensure that the developed codes fully captured the nuances of the participants' voices.

To ensure that the qualitative findings directly served our research goal of optimizing the exergame prototype, we focused on actionable utility. The inductive codes were systematically synthesized into distinct optimization categories, which directly mapped onto the design modules for software revision. Triangulation with a qualitative research expert (HF) was conducted to verify that the final themes and subthemes provided concrete, practical design recommendations rather than generic descriptions.

The trustworthiness of this study was evaluated according to four criteria by Lincoln and Guba [51]: (1) credibility, (2) dependability, (3) confirmability, and (4) transferability. A variety of methods were used to ensure trustworthiness. These included taking reflective notes, triangulating data from multiple perspectives (researcher triangulation), conducting research team meetings, reporting on this study in detail, and using verbatim quotes to support themes. In addition, the final themes and results were sent to participants for validation and approval.

Mixed Methods Integration

Integration occurred at the interpretation level to identify convergence, divergence, and complementarity between the two datasets. Specifically, a joint display was used to systematically compare the quantitative SUS dimension scores

XSL•FO
RenderX

with the corresponding qualitative themes and verbatim quotes. While the quantitative SUS scores established a baseline measurement of general usability, the qualitative findings were integrated to explicitly explain the underlying reasons (the "why") behind these scores and the specific user pain points, thereby generating comprehensive meta-inferences that extend the understanding of the statistical patterns [52].

Ethical Considerations

This study was approved by the ethics review committee of Nursing and Behavioral Medicine Research, School of Nursing, Central South University (E202397). All participants provided written informed consent before enrollment, acknowledging their right to withdraw at any time without explanation, and were advised that such withdrawal would not affect future services or opportunities. To ensure participant privacy, all collected data were systematically deidentified. Specifically, participants were assigned unique alphanumeric codes upon enrollment, which were used to label all demographic questionnaires, usability scales, and qualitative transcripts. During the verbatim transcription of the qualitative interviews, any potential identifying information mentioned by the participants was removed and replaced with generalized placeholders. Furthermore, all digital files were stored on a password-protected and encrypted storage system accessible exclusively to the core research team. No compensation was offered to the participants. Furthermore, no individual participants or users can be identified in any images included in the manuscript or supplementary material.

Results

The Findings of Phase 2 in Part 1

While our prior qualitative research [31] identified the specific exergame requirements of older adults with MCI, the current manuscript proposes an original, structured design framework based on those requirements. As a primary contribution of this paper, this original framework was constructed to guide the subsequent development process. See details in Table 1.

XSL•FO
RenderX

Table . Design framework for exergames tailored to older adults with mild cognitive impairment.

Theme and subtheme	Module	Category
Design older people-friendly exergames		
Appropriate game rhythm and speed	Adaptive difficulty adjustment	• N/A[a]
Simple and easy-to-understand game operations	Error tolerance design	• N/A
Simple and easy-to-understand game operations	Game interface design	• Color, font, layout, aesthetics, operation
Can be played both sitting and standing	Movement posture	• Standing and sitting postures
Ensure scientific validity and safety in the process of sports		
Specify precautions	Safety design	• Target users • Exercise precautions
Exercise intensity and duration reminder	Safety design	• Exercise intensity indication
Exercise intensity and duration reminder	Exercise prescription	• Exercise frequency • Exercise duration • Exercise duration • Exercise progression
Provide a good gaming experience		
Link to real life	Game scene	• Location, character, costume, prop, ground, background music, sound effects, eye protection mode
Diversified choices	Randomness	• N/A
Diversified choices	Game scene	• Location, character, costume, prop, ground, background music, sound effects, eye protection mode
Exercise physical and cognitive functions		
Achieve personalization	Adaptive difficulty adjustment	• N/A
Exercise physical function	Before and after game assessment	• N/A
Exercise cognitive function	Data monitoring	• N/A
Exercise cognitive function	Training goals	• Daily goals, weekly goals
Exercise cognitive function	Exercise data	• Exercise report exercise records
Provide support and training		
Providing feedback and motivation in the game	Feedback mechanism	• N/A
Providing feedback and motivation in the game	Reward mechanism	• Text and voice encouragement, game score, reward stars, badges
Game usage training	Game modes	• Single/double player mode • One-handed/two-handed mode • Training/competition mode

[a]N/A: not applicable.

The group discussion established the goal of developing a user-centered, immersive, and culturally relevant exergame. Table tennis was selected as the primary sport activity for three reasons: (1) its familiarity among Chinese older adults minimizes the learning curve and cognitive load; (2) its competitive nature effectively motivates physical engagement [53,54]; and (3) racket sports are the sports most conducive to health and longevity [55]. Furthermore, to accommodate the

XSL•FO
RenderX

cognitive limitations of older adults with MCI, the design prioritizes simplified tasks over complex narratives to minimize frustration and ensure training continuity.

Finally, the group discussion selected the PICO 4 Pro (Figure 3) based on two critical metrics: clarity and comfort. Regarding clarity, the device offers 4K+ resolution and a high refresh rate, meeting the requirements for high-quality software streaming. Regarding comfort, it excels in three aspects: (1) supporting interpupillary distance adjustment and allowing users to wear prescription glasses; (2) combining a lightweight body (597 g) with a rear-mounted battery design to achieve front-rear balance; and (3) using a breathable face mask to prevent excessive perspiration during exercise.

Figure 3. Front view of PICO 4 Pro [56].

Based on the above results, the "Preliminary Design Plan for Exergames Targeting Older Adults With MCI" has been formulated, as detailed in Table 2.

XSL•FO
RenderX

Table . Preliminary Design Plan for Exergames Targeting Older Adults with Mild Cognitive Impairment. This game uses virtual reality equipment and interacts with the exergame via controllers, eliminating the need for gesture-based interaction. As such, it does not involve the "use of appropriate gestures" principle in exergame development. Concerning the "avoidance of small objects" principle, compared to other table tennis exergames, this game has appropriately increased the size of the table tennis ball and reduced its speed. Different ball sizes and speeds are also set according to varying game difficulties and stages.

Module and category	Content
Game name	
N/A[a]	Lehuo Pingpang
Game rules	
N/A	11-point system
Game modes	
Single/double player mode	Play alone or with another person
One-hand/two-hand mode	Allows using either hand to play the exergame
Training/competition mode	Training mode for learning, competition mode for matches
Pre- and postgame assessment	
N/A	Physical and cognitive functions are assessed through a smart health management system for older adults developed by the research team, which shares data with the exergame
Exercise prescription	
Exercise frequency	At least 2 exercise sessions per week
Exercise time	25 to 60 minutes of daily exercise, with a maximum daily exercise duration of 1 hour
Exercise intensity	At least moderate-intensity exercise, reaching at least 60% of the maximum heart rate
Exercise progression	First increase daily exercise time, then exercise frequency
Exercise postures	
Standing/sitting posture	Use either standing or sitting posture to play the exergame, and switch between them at any time
Game scenario	
Venue, characters, costumes, props, floor, background music, sound effects, eye protection mode	Venue: table tennis stadium; original Chinese animated character designs and costumes with consistent style; game props with contrasting colors; floor free of distractions; background music featuring simple rhythms preferred by older adults; sound effects including ball hitting sounds, cheers, and applause; eye protection mode enabled by default
Adaptive difficulty adjustment	
N/A	Adjust difficulty based on game scores. Increase difficulty in the next round for good performance; otherwise, decrease it. Difficulty levels correspond to specific game stages
Data monitoring	
N/A	Heart rate, exercise time, calorie consumption, etc, displayed on the game interface
Feedback mechanism	
N/A	Real-time feedback through text, voice, static images, and dynamic animations
Reward mechanism	
Text and verbal motivation	Positive reinforcement through text and verbal cues
Game scoring	Display game scores on the game interface
Stars and badges	Reward stars, which can be redeemed for corresponding badges when a certain number is accumulated
Safety design	

XSL•FO
RenderX

Module and category	Content
Suitable users	Specify the range of suitable users
Exercise precautions	Display safety reminders on the interface before starting the game
Exercise intensity prompt	Provide prompts when exercise intensity is excessive
Fault tolerance design	
N/A	No restrictions on hitting height, angle, or position; hitting within a general range is sufficient
Training goals	
Daily and weekly goals	Provide suggestions for daily and weekly goals before starting the game, but completion is not mandatory
Exercise data	
Exercise report	Include scores, exercise time, heart rate, calorie consumption, equivalent to xx steps, etc
Exercise records	Record day xx, session xx of exercise, etc
Game interface design	
Color, font, layout, aesthetics, operation	Clear color contrast between text and images, simple colors for the interface or background; use simplified Chinese with large font, avoid professional terms; layout from left to right and top to bottom, with important information centered; provide realistic graphic visuals and sound effects to create an aesthetic environment through sensory stimulation; simplify operation steps and minimize hierarchical settings
Randomness	
N/A	Include random values for table tennis size and speed

[a]N/A: not applicable.

The Findings of Phase 3 in Part 1

Basic Information of Experts

A total of 8 experts from relevant disciplines were invited to the expert meeting (Table 3).

Table . Basic information of experts.

Number	Sex	Educational background	Professional title	Discipline/specialty
1	Female	Doctor	Professor	Geriatric care
2	Male	Master	Chief therapist	Sports medicine, rehabilitation medicine
3	Male	Doctor	Senior engineer	Mechanical engineering, sports rehabilitation, and medical robotics technology
4	Male	Doctor	N/A[a]	Company director specializing in AI and computer vision
5	Female	Doctor	Professor	Clinical medicine expert
6	Female	Master	Chief rehabilitation therapist	Rehabilitation therapy expert
7	Female	Doctor	Professor	Geriatric care
8	Female	Master	N/A	Virtual reality, human-computer interaction

XSL•FO
RenderX

Content to Be Modified in the "Preliminary Design Plan for Exergames Targeting Older Adults With MCI"

Overall, while the experts affirmed the scientific validity and feasibility of the preliminary design, they proposed specific optimizations across six dimensions. Regarding game rules, they recommended refining the 11-point system to include side-changing service (a standard table tennis rule where players alternate the right to serve every two points) and adding an automatic service function (an accessibility feature where the system serves the ball automatically if the player fails to react within a set timeframe) to accommodate older adults' slower reactions. For incentives, they suggested incorporating leaderboards to align with standard gaming conventions and boost motivation. In terms of safety, they emphasized the necessity of emergency measures specifically for fall risks. Furthermore, experts advised extending adaptive difficulty adjustments to the two-player mode and enhancing social connectivity features beyond basic multiplayer interaction.

Final Design Plan for Exergames Targeting Older Adults With MCI

Based on the above research findings, the "Preliminary Design Plan for Exergames Targeting Older Adults With MCI" was revised by the development team after discussions, while ensuring that its core elements remained unchanged. This process resulted in the "Final Design Plan for Exergames Targeting Older Adults with MCI," as detailed in Table 4.

XSL•FO
RenderX

Table . Final design plan for exergames targeting older adults with MCI.

Module and category	Content
Game name	
N/A[a]	Lehuo Pingpang
Game rules	
Competition rules	11-point system
Service rules	A 5-second countdown will start when serving. If the player fails to serve within the time limit, the system will serve automatically
Side-changing service rules	Players shall switch serving sides after serving twice consecutively. When reaching match point, each player shall serve once alternately
Game modes	
Single/double player mode	Play alone or with another person
One-hand/two-hand mode	Allows using either hand to play the exergame
Training/competition mode	Training mode for learning, competition mode for matches
Pre- and postgame assessment	
N/A	Physical and cognitive functions are assessed through a smart health management system for older adults developed by the research team, which shares data with the exergame
Exercise prescription	
Exercise frequency	At least 2 exercise sessions per week
Exercise time	25 to 60 minutes of daily exercise, with a maximum daily exercise duration of 1 hour
Exercise intensity	At least moderate-intensity exercise, reaching at least 60% of the maximum heart rate
Exercise progression	First increase daily exercise time, then exercise frequency
Exercise postures	
Standing/sitting posture	Use either standing or sitting posture to play the exergame, and switch between them at any time
Game scenario	
Venue, characters, costumes, props, floor, background music, sound effects, eye protection mode	Venue: table tennis stadium; original Chinese animated character designs and costumes with consistent style; game props with contrasting colors; floor free of distractions; background music featuring simple rhythms preferred by older adults; sound effects including ball hitting sounds, cheers, and applause; eye protection mode enabled by default
Adaptive difficulty adjustment	
N/A	In single-player mode, the difficulty is adjusted based on game scores: the difficulty of the next round is increased for good performance, and decreased otherwise. Difficulty levels correspond one-to-one with stages. In two-player mode, if the game scores of both sides differ greatly, the size of the table tennis ball for the loser is increased, or the speed of the table tennis ball is slowed down, and the opposite applies to the winner
Data monitoring	
N/A	Heart rate, exercise time, calorie consumption, etc, displayed on the game interface
Feedback mechanism	
N/A	Real-time feedback through text, voice, static images, and dynamic animations
Reward mechanism	
Text and verbal motivation	Positive reinforcement through text and verbal cues
Game scoring	Display game scores on the game interface

XSL•FO
RenderX

Module and category	Content
Stars and badges	Reward stars, which can be redeemed for corresponding badges when a certain number is accumulated
Leaderboard	After each game round, a leaderboard is displayed
Safety design	
Suitable users	Specify the range of suitable users
Exercise precautions	Display safety reminders on the interface before starting the game
Fall detection	Real-time fall detection: an alarm is triggered when a fall occurs (to ensure clinical reliability and prevent false alarms during intense gameplay, the real-time fall detection algorithm in “Lehuo Pingpang” operates on a 0.1 ms evaluation cycle using the PICO 4 Pro’s tracking data. The software continuously acquires the real-time headset height ( ) and calculates the first-order difference between consecutive heights to approximate vertical velocity. A fall alarm is triggered only when two conditions are met simultaneously: (1) the height remains below 1.3 m (below normal standing height) for three consecutive cycles; and (2) the calculated height difference (velocity) exceeds 0.8 m/s for three consecutive cycles)
Exercise intensity prompt	Provide prompts when exercise intensity is excessive
Fault tolerance design	
N/A	No restrictions on hitting height, angle, or position; hitting within a general range is sufficient
Training goals	
Daily and weekly goals	Provide suggestions for daily and weekly goals before starting the game, but completion is not mandatory

The Findings of Phase 4 in Part 1

The research and development result is a VR exergame prototype titled Lehuo Pingpang, as shown in Figure 4.

XSL•FO
RenderX

Figure 4. Initial running interface of the Lehuo Pingpang Exergame prototype.

The Findings of Part 2

General Information of Participants

This study included a total of 12 participants, including 7 female and 5 male participants, with a mean age of 69.08 (SD 6.08; 95% CI 65.22 - 72.94; range 61 - 82) years, as shown in Table 5.

XSL•FO
RenderX

Table . General information of participants (N=12).

Group	Values
Age (years), mean (SD)	
—[a]	69.08 (6.08)
Sex, n (%)	
Female	7 (58.3）
Male	4 (41.7）
Educational level, n (%)	
Primary school	4 (33.3）
Junior high school	6 (50）
Senior high school	1 (8.3）
Junior college	1 (8.3）
BMI, mean (SD)	
—	23.53 (2.45)
MoCA[b] scores, mean (SD)	
—	18.75 (2.30)

[a]Not applicable.

[b]MoCA: Montreal Cognitive Assessment.

SUS Results

The mean SUS score of the Lehuo Pingpang exergame prototype was 79.38 (SD 12.89; 95% CI 71.19 - 87.57) points (range 55.00 - 97.50, n=12), indicating that the usability of this exergame prototype among older adults with MCI is "acceptable," that is, it is usable. The narrow margin of this CI, with its lower bound (71.19) remaining comfortably above the established acceptability threshold of 70, indicates a highly precise and reliable conclusion that the exergame prototype has acceptable usability in the target population (Table 6).

Results of Semistructured Interviews

Overview

When the 9th interview was conducted, data saturation was reached. To ensure no new themes emerged, we conducted 3 additional interviews. Therefore, a total of 12 interviews were conducted in this study. Through in-depth analysis of the interview data and induction of categories, themes, and subthemes, a total of 2 themes and 7 subthemes were identified (Figure 5). The older adults with MCI who participated in the interviews were denoted and ordered using the English letter “P.”

XSL•FO
RenderX

Figure 5. Thematic map illustrating the conceptual network, dynamic interconnections, and analytical relationships between the core usability evaluation focus, the two main themes, and the seven subthemes derived from the reflexive thematic analysis of older adults with mild cognitive impairment.

Theme 1: The Experience of Using the Exergame Prototype Is Relatively Positive

Subtheme 1: Simple and Convenient Operation

Some older adults with MCI stated that the game operations, including turning the game on and off, were very simple.

> ***P2:*** *Just press the button on the glasses, and you can turn it on or off—just like a phone. That's really convenient.*
>
> ***P8:*** *The operation is so simple. Anyone who's played games or used a phone can learn it. It's even easier than the ones I've played before—way simpler, really.*

Subtheme 2: Beautiful and Realistic Design

Some older adults with MCI indicated that the colors in the game interface are beautiful and comfortable, and the overall game design is realistic.

> ***P4:*** *Wow, everything looks so clear once you put on the glasses. It feels clearer than what I see with my own eyes, just like watching TV or a movie.*
>
> ***P5:*** *This game is exactly like the real thing—totally identical. It's high-tech stuff.*
>
> ***P7:*** *The colors in this game are really nice. They look comfortable, easy to get used to.*

Subtheme 3: Professional and Interesting Content

Some older adults with MCI stated that the game content is professional and consistent with actual rules and norms. In addition, the exergame is highly interesting and can arouse the interest of older adults with MCI.

> ***P4:*** *This game is pretty fun, y'know? I really like it. Once I get used to having a good time with it, I'll keep playing nonstop.*
>
> ***P5:*** *The rules for playing in the game are the same as real table tennis rules—really standard. I'm a pro at this, I know what I'm talking about, haha.*
>
> ***P6:*** *I really like this. I'm quite interested in it.*
>
> ***P7:*** *No matter how many days I play or how long, these goals are basically achievable. They're all perfect for us older adults.*

Subtheme 4: Practical and Reasonable Functions

Some older adults with MCI mentioned that function settings such as the selection of controllers, game feedback, and safety settings in the game are both practical and reasonable.

> ***P2:*** *You can use one racket or two—this function is great. Choose whatever you want, either way works.*
>
> ***P3:*** *There's a reminder if you swing too early or too late. That's really good. I can learn from it and get better and better.*
>
> ***P5:*** *I love the function that sets a safety zone. Step out of the zone, and you can see real things outside; stay in it, and you only see what's in the glasses. It makes you feel really secure.*

XSL•FO
RenderX

Theme 2: Deficiencies in the Exergame Prototype

Subtheme 1: Deficiencies in Game Design

Some older adults with MCI stated that the exergame prototype has deficiencies in design, such as font size and clarity.

> ***P1:*** *The 'confirm' and 'exit' buttons need to be bigger. They're too small—I can never point to them right. Also, they're way too far apart. After tapping one, I have to turn my head to tap the other. Can't they be put together?*
>
> ***P6:*** *Everything else is fine, but the characters are a bit blurry. I couldn′t even make out the character′ball′). Its strokes aren′t clear—it looks like it′s blocked by the people in the game.*
>
> ***P8:*** *The space between the ping-pong table and the wall here is too narrow. The people in the game can't move around freely. It doesn't make sense.*

Subtheme 2: Deficiencies in Gaming Experience

For example, older adults with MCI have poor gaming experience due to their lack of relevant experience, such as using exergames; second, older adults with MCI may experience discomfort when wearing VR headsets; in addition, there are insufficient types of exergames, etc.

> ***P1:*** *I've never used anything like this before. It just feels awkward to use.*
>
> ***P3:*** *I don't have other issues, but wearing the glasses for too long makes my head a bit dizzy. Not super dizzy—just that uncomfortable feeling of not being used to it.*
>
> ***P7:*** *It doesn't feel very comfortable. It's pinching my face, and that pinch feels unpleasant.*
>
> ***P5:*** *The light inside the glasses is pretty bright. Wearing them for a long time makes my eyes feel strained.*
>
> ***P9:*** *There aren't enough games here. Add some more, and it'll be even more fun.*

Subtheme 3: Deficiencies in the External Environment

Some older adults with MCI mentioned that the exergame prototype has deficiencies in terms of the external environment, as it is affected by factors such as network and external hardware environment.

> ***P1:*** *Is this affected by the network? The Wi-Fi signal at my place isn't great, and it feels like the stuff in the glasses lags.*
>
> ***P2:*** *I just think there are a bit too many buttons. I can't remember which one to press when. If there were fewer, it'd be better.*
>
> ***P4:*** *It's just my feeling—maybe I'm not using it right, but I feel like I'm standing really high up, higher than the ping-pong table. It's weird. Shouldn't the game fix this on its own? I should be placed on the floor by the ping-pong table instead.*

Integration of Quantitative and Qualitative Findings

Following the convergent mixed methods design, the quantitative SUS scores and qualitative themes were integrated using a joint display (Table 7) to generate comprehensive meta-inferences. Based on established usability evaluation frameworks [46], the 10 SUS items were structured into three core dimensions: learnability (items 4, 5, and 10), usability (items 2, 3, 7, and 8), and user satisfaction (items 1, 6, and 9). These quantitative dimensions and their raw item-level scores were mapped directly against the corresponding qualitative themes, subthemes, and illustrative participant quotes to explore convergence and complementarity.

XSL•FO
RenderX

Table . Joint display of quantitative SUS[a] scores and qualitative interview themes.

Usability dimension	Mean score (SD; 95% CI)	Corresponding qualitative theme and subtheme	Illustrative quotes	Integration findings (meta-inferences)
1. Learnability	• Question 4: 2.50 (SD 1.24; 1.71 - 3.29) • Question 5: 4.83 (SD 0.39; 4.58 - 5.08) • Question 10: 2.83 (SD 1.40; 1.94 - 3.72)	1. Theme 1: the experience of using the exergame prototype is relatively positive • Subtheme 4: practical and reasonable functions 2. Theme 2: deficiencies in the exergame prototype • Subtheme 2: deficiencies in gaming experience • Subtheme 3: deficiencies in the external environment	• P5 (theme 1): “I love the function that sets a safety zone... It makes you feel really secure.” • P1 (theme 2): “I’ve never used anything like this before. It just feels awkward to use.“ • P2 (theme 2): “I just think there are a bit too many buttons. I can’t remember which one to press.”	Convergence and complementarity: excellent quantitative functional integration (question 5=4.83) strongly converges with users’ praise for the integrated safety zone function. However, the moderate scores on learning costs and need for support (question 10=2.83, question 4=2.50) are complemented by qualitative findings. Unfamiliarity with VR[b] hardware (P1) and controller button complexity (P2) created learning friction, explaining the quantitative learning curve.
2. Usability	• Question 2: 1.50 (SD 0.52; 1.17 - 1.83) • Question 3: 4.50 (SD 0.67; 4.07 - 4.93) • Question 7: 4.25 (SD 0.75; 3.77 - 4.73) • Question 8: 1.42 (SD 0.51; 1.10 - 1.74)	1. Theme 1: the experience of using the exergame prototype is relatively positive • Subtheme 1: simple and convenient operation 2. Theme 2: deficiencies in the exergame prototype • Subtheme 1: deficiencies in game design	• P2 (theme 1): “Just press the button on the glasses, and you can turn it on or off... really convenient.” • P8 (theme 1): “The operation is so simple... Anyone who’s played games can learn it.” • P1 (theme 2): “The ‘confirm’ and ‘exit’ buttons need to be bigger. They’re too small.”	Convergence and complementarity: quantitative usability indicators are exceptionally strong, evidenced by high ease of use (question 3=4.50, question 7=4.25) and very low perceived complexity and difficulty (question 2=1.50, question 8=1.42). This strongly converges with qualitative reports of simple, phone-like operations. However, specific UI[c] design flaws (eg, small “confirm/exit” buttons, P1) complement these scores, highlighting target areas for iterative refinement.

XSL•FO
RenderX

Usability dimension	Mean score (SD; 95% CI)	Corresponding qualitative theme and subtheme	Illustrative quotes	Integration findings (meta-inferences)
3. User satisfaction	• Question 1: 3.58 (SD 1.01; 2.94 - 4.22) • Question 6: 1.08 (SD 0.29; 0.90 - 1.26) • Question 9: 4.25 (SD 0.75; 3.77 - 4.73)	1. Theme 1: the experience of using the exergame prototype is relatively positive • Subtheme 2: beautiful and realistic design • Subtheme 3: professional and interesting content 2. Theme 2: deficiencies in the exergame prototype • Subtheme 2: deficiencies in gaming experience	• P5 (theme 1): “The rules for playing in the game are the same as real table tennis rules—really standard.” • P7 (theme 1): "The colors in this game are really nice. They look comfortable, easy to get used to.” • P3 (theme 2): “I don’t have other issues, but wearing the glasses for too long makes my head a bit dizzy. Not super dizzy—just that uncomfortable feeling of not being used to it.”	Discrepancy and expansion: quantitative scores show high confidence in use (question 9=4.25) and low perceived inconsistency (question 6=1.08), converging with praise for standard tennis rules and comfortable visual designs. However, the relatively moderate score on the intention to use frequently (question 1=3.58) contrasts with this high confidence. Qualitative findings reveal that this discrepancy is driven by significant physical barriers (VR dizziness/facial pinching) and is linked to a potential novelty effect and social desirability bias (which initially inflated question 9 and question 6 scores), subsequently exposed and balanced by candid qualitative interviews. This confirms how physical experience limits sustained, long-term satisfaction (question 1=3.58).

[a]SUS: System Usability Scale.

[b]VR: virtual reality.

[c]UI: user interface.

Discussion

Principal Findings

This study successfully designed, developed, and evaluated an immersive VR exergame prototype tailored to older adults with MCI. Guided by the three-stage MIDE framework, we successfully developed “Lehuo Pingpang,” translating the target population’s requirements into an aging-appropriate and safe VR exergame prototype. Furthermore, our convergent mixed methods usability evaluation confirmed that the exergame prototype is safe and generally acceptable. By integrating our quantitative SUS scores and qualitative interview themes into three core dimensions—usability, learnability, and user satisfaction—we derived comprehensive insights regarding the prototype’s performance. Collectively, these integrated findings demonstrate that while the exergame prototype is highly viable and acceptable, the identified challenges provide essential, user-driven empirical guidance for subsequent iterative optimizations.

System Usability: Quantitative Comparison With Prior Work

The average SUS score in this study was higher than the 70-point threshold required for an acceptable game [47], indicating that the usability of the exergame prototype among older adult individuals with MCI is acceptable. These results are consistent with the findings of Altorfer et al [57] and Shah et al [58], who reported even higher average SUS scores. Altorfer et al [57] explored the feasibility and effectiveness of a cognitive-motor dual-task training exergame in 39 older adult inpatients through a pilot randomized controlled trial, testing its usability with the SUS scale. The results showed an average SUS score of 83.60 (SD 13.72), indicating high usability among older adult inpatients. Shah et al [58] co-designed and developed a VR-based exergame with older adults living in or previously living in rehabilitation centers and physical therapists, using a mixed methods approach to evaluate its usability. Among 14 participants, the quantitative part yielded an SUS score of 83.75 (SD 13.3), confirming acceptable usability. The higher SUS scores in these two studies may be attributed to the fact that participants in this study experienced the exergame prototype fewer times and for a shorter duration, whereas the usability studies mentioned above measured SUS scores after multiple long-term exposures, allowing participants to become more familiar with and accepting of the exergame, thus achieving higher usability levels.

However, this study’s results are inconsistent with those of Thalmann et al [59], who conducted a usability study on their newly developed VITAAL exergame among 13 older adults with mobility impairments, reporting an average SUS score of 58.3 (SD 16.5), lower than this study’s findings. Possible reasons include two aspects: on the one hand, the participants in this study had a younger average age, and research by Bangor et al [60] showed a significant correlation between age and SUS

XSL•FO
RenderX

scores, meaning older age may negatively impact SUS scores, which could explain why this study's results were higher. On the other hand, the study by Thalmann et al [59] included older adults with mobility impairments, while the 12 participants in this study had no mobility limitations. Thus, compared to the sample from the study by Thalmann et al [59], this study's participants may have been more suited to using exergames.

Multidimensional Mixed Methods Integration: Usability, Learnability, and Satisfaction

In the usability dimension, the low perceived complexity and high ease of use demonstrated by the quantitative analysis strongly converged with the "simple and convenient operation" reported by participants in the qualitative evaluation. Participants generally appreciated the system's intuitive physical layout and convenient operational experience. This success is primarily attributed to the strict adherence to age-appropriate interface design principles during system development. To accommodate age-related degenerative changes, the prototype incorporated appropriate error tolerance rather than overemphasizing precise manipulation [61]; concurrently, interface elements were arranged in a regular and simplified manner to reduce the attentional burden on older adults [61]; and sufficient reaction time was provided to bolster their confidence [62]. Furthermore, to assist older adults with MCI in processing information rapidly, the interface used large fonts and icons while avoiding complex technical jargon [61]; the layout adhered to visual movement rules of left-to-right and top-to-bottom, presenting crucial prompt information in the center to guide the user's line of sight [62]; meanwhile, the system integrated multichannel feedback modes, such as audio-visual synchronization and dynamic graphics, to satisfy the information readability needs of older adults [63]. This series of design practices aligns with the design principles of Bogza et al [64] for a web-based decision aid tailored to older adults with MCI, which similarly emphasized simplifying design, using clear and easy-to-understand phrasing, and using pictograms as visual reminders to aid user memory. Moreover, qualitative interviews played a critical complementary role to the aforementioned positive ratings. Under the subtheme of "deficiencies in game design," some participants pointed out that the "confirm" and "exit" buttons were too small. This complementary finding reveals minor shortcomings in the actual execution of centering and sizing guidelines within the interface layout, thereby providing a precise, user-experience-driven direction for subsequent iterative UI designs.

In the learnability dimension, the prototype received moderate ratings, indicating that some participants faced a distinct learning curve. On one hand, the quantitative high functional integration of the system strongly converged with the qualitative appreciation for the practical safety boundary function, with participants stating that the customizable safety zone provided a profound sense of security. This is scientifically supported by the system's built-in safety boundary setup: the VR headset first displays the real-world scene through pass-through video, and only presents the virtual world scene after the user has autonomously designated a safe range; when the user exits the safety zone, the device issues a prompt and automatically switches back to the real-world scene, ensuring safety during exercise. Furthermore, to prevent overexertion and injury, sufficient time was allocated between high-intensity exercises for older adults to relax and recover [65]. On the other hand, the higher learning costs and moderate need for technical support shown in the quantitative analysis were critically complemented by qualitative interviews—participants generally mentioned their lack of prior VR experience and expressed confusion regarding the complex controller button layout. The study by Tuena et al [32] pointed out that handheld controllers can be complex for some older adults, particularly those with dementia or MCI; this is consistent with the findings of Malinowski et al [66], who revealed that older adults with MCI face greater difficulties in using technology than those without any cognitive impairments. Additionally, Gerling et al [67] emphasized that providing a technology-based training system capable of building technological confidence is of paramount importance, enabling a better gaming experience and more successful training. Multiple prior studies have similarly confirmed the importance of age-appropriate design and robust technical functionality to the usability of exergames [44,68,69]. Regarding learning costs, Thalmann et al [59] also pointed out that a brief period of familiarization and learning is required during the first training session of an exergame. Collectively, these findings highlight the necessity in future clinical applications of providing structured preuse training, allowing sufficient adaptation time, and designing simplified, tactile controllers customized specifically for older populations.

In the user satisfaction dimension, quantitative indicators exhibited high subjective confidence and extremely low perceived system inconsistency, which strongly converged with the qualitative approval of the prototype's "beautiful and realistic design" and "professional and interesting content." A plausible explanation is that table tennis is a highly familiar sport and leisure element in the daily lives of most Chinese older adults, which is crucial for enhancing game acceptance [70] and consequently boosting their confidence to participate. The validation of the prototype's "beautiful and realistic design" stemmed from the aesthetic sensory stimulation provided by its realistic visual graphics and audio effects [71]; the endorsement of its "professional and interesting content" is consistent with the findings of Shah et al [58], which confirmed through semistructured interviews that older adults find VR-based exergames highly engaging and interesting. The "professionalism" of the system is chiefly reflected in its multidisciplinary, collaborative design philosophy: the development process deeply integrated opinions from various experts across hospitals, universities, research institutes, and technology enterprises, covering four key domains—geriatric nursing, clinical medicine, rehabilitation medicine, and AI; moreover, the entire design scheme was fully evidence-based, strictly adhering to the guiding principles in the "Guidelines for Designing Exergames to Enhance Physical and Social Activity of Older Adults" [61].

However, a prominent methodological discrepancy and contradiction emerged between the exceptionally high subjective confidence and the relatively moderate intention to use the system frequently. Qualitative interviews expanded on this paradox, revealing that participants' long-term willingness to

XSL•FO
RenderX

use the game was likely constrained by immediate physical discomforts such as VR motion sickness (dizziness), eye fatigue, facial pressure, and physical fatigue. These feedback reports of physiological discomfort were validated by the systematic review of clinical and research applications of VR in older adults by Tuena et al [32], which also identified usability issues including discomfort and motion sickness. In addition, research by Stanney et al [72] and Sharples et al [73] pointed out that eye strain is one of the most frequently reported symptoms during the use of VR technology. This concern is further supported by similar exergame research; for instance, in a study by Song et al [74] evaluating the usability and feasibility of VR and mixed reality Tai Chi exergames for community-dwelling older adults, although the physiological comfort of the screened sample was acceptable and severity levels were low, they initially excluded 18.6% of participants due to VR discomfort. Prior studies have emphasized that VR cybersickness is a common but frequently underestimated barrier that can lead to user abandonment [75,76], which explains the underlying reason why participants in our study held reservations regarding long-term, frequent use.

From a deeper perspective, this paradox of high scale scores coexisting with physical discomfort can be explained by the "novelty effect" commonly observed in usability testing with older populations. The enjoyment of the experience stemmed largely from the "novelty" brought by the game [70]. The highly immersive nature of VR was an unprecedented experience for most first-time participants with MCI, and the intense freshness and excitement of the initial trial temporarily masked or diluted their physical discomfort when filling out the quantitative assessments. This key contradiction underscores the indispensable value of the convergent mixed methods design used in this study: the quantitative survey established a positive baseline of general acceptability, while the qualitative interviews successfully unmasked the true physical barriers and technical friction, thereby ensuring a balanced and objective evaluation.

Iterative Optimization and Future Design Considerations

In response to the usability issues, an iterative design scheme for the exergame prototype is proposed. First, in terms of game design, the "confirm" and "exit" buttons should be enlarged, and the distance between them shortened; text in the game scene should be prevented from being obscured; and the distance between the table tennis table and the gymnasium walls in the virtual scene should be adjusted to a reasonable range.

Studies have shown that compared with nonimmersive devices such as desktop computers and projectors, the use of head-mounted displays is more likely to cause head pressure, eye fatigue, physical fatigue, and cybersickness symptoms [77]. For standalone devices such as the PICO 4 Pro, these symptoms are often influenced by software optimization. The technical specifications of our prototype's Unity (Unity Technologies) build target a 90 Hz screen refresh rate, a rendering resolution of 1920×1920 per eye, and an end-to-end latency of 12 ms. To address issues such as strong light inside the glasses, eye strain from prolonged use, discomfort from the VR headset feeling tight on the face, and dizziness, future software optimizations will focus on several critical avenues. First, we will implement Application SpaceWarp to significantly reduce rendering latency and improve performance, allowing the application to render at half the actual screen refresh rate without affecting display quality [78]. Second, we will enable Adaptive Resolution to automatically scale the viewport resolution based on the current GPU workload—decreasing it during high GPU loads and increasing it when resources are sufficient—maximizing GPU resources to enhance image quality without dropping frame rates [79]. Third, adopting the Universal Render Pipeline will optimize PICO's GPU capability and improve rendering performance specifically for XR [80]. While software optimization remains our primary pathway, for users who still experience persistent discomfort, we will consider using a surface television instead of a head-mounted display in future studies to reduce the aforementioned discomfort while maintaining a sense of immersion.

To tackle the problem of limited game types, we will continue to enrich the variety of games in future research to provide more options for older adults. In addition, older adults with MCI require sufficient time to learn, understand, and adapt to the exergame, as well as adequate preuse training, and sufficient support during use. Finally, regarding hardware-related issues of the game, such as a slightly excessive number of controller buttons, susceptibility to network influences during use, and the lack of reminders or guidance for older adults to adjust the relative height between the controller and the ground, continuous improvement and optimization will be made in subsequent processes.

Methodological and Design Implications for MCI-Centered Exergames

Based on our design and development experience, several key recommendations are proposed for future exergame designs tailored to older adults with MCI. First, ensuring safety during exercise is paramount, which requires adopting a UCD approach throughout the design and development process in close collaboration with stakeholders such as older users and health care professionals. To maximize physical accessibility, the interface must be simple and easy to understand, comfortably accommodating both standing and sitting postures alongside single- or two-handed gameplay. Second, cognitive load should be minimized by incorporating widely familiar elements, providing high error tolerance, and offering sufficient reaction times during play to prevent user frustration. Furthermore, exergames should prioritize health benefits and focus on individual differences, dynamically balancing user abilities and game difficulty through adaptive difficulty adjustments. Finally, to foster long-term engagement, designers should offer diverse task scenarios, use positive incentive strategies while avoiding negative reinforcement, integrate social support functions to enhance social connections, and deliver multichannel feedback with real-time prompts and responses.

Limitations

Some limitations of this study need to be acknowledged. First, regarding the design and development phase, this study only designed and developed one game scenario and one exergame. Second, there was a lack of direct end user (patients with MCI)

XSL•FO
RenderX

participatory co-design during the intermediate preliminary design validation (phase 3). While this tailored UCD approach was considered because the cognitive decline and potential difficulties in abstract thinking in patients with MCI may make it challenging for them to evaluate noninteractive, low-fidelity UI mock-ups, it deviated from a strict UCD cycle. Relying solely on multidisciplinary experts at this stage meant that certain UI issues, such as inappropriate button sizes and spacing, were only identified after the high-fidelity prototype was fully developed. Nevertheless, these identified UI issues served as empirical, user-driven data that directly informed the concrete, multidimensional iterative design scheme proposed in the Iterative Optimization and Future Design Considerations section for subsequent optimization. Future iterations will explore adapted co-design methods with end users earlier in the process, using simplified but interactive mock-ups to prevent such UI failures.

Regarding the usability evaluation phase, several limitations must be noted. First, the sample size of participants was relatively small, and all participants were from the same region, which may lead to selection bias. Additionally, this study only explored the usability of the exergame prototype from the perspective of older adults with MCI, without investigating this issue from the perspectives of other stakeholders (such as caregivers, medical staff, etc). Notably, although the sample size of 12 participants aligns with usability testing guidelines for identifying usability issues, the high SD in the SUS scores (12.89) indicates significant individual differences among older adults with MCI. Future research should involve a larger and more diverse sample size to better account for this variance and to further validate the system's usability across a broader user group. Finally, the duration of the usability study is relatively short, which may not be able to fully explore the existing usability issues.

Conclusions

This study successfully designed, developed, and evaluated "Lehuo Pingpang," a tailored VR table tennis exergame prototype for older adults with MCI. The innovation of this work lies in the formulation of an original, evidence-based design framework that systematically translates the complex cognitive-motor requirements of MCI users into safe, immersive physical-digital interactions. Furthermore, this study contributes to the field of gerontechnology a replicable, multistage development workflow and critical mixed methods methodological insights, unmasking the paradox where high quantitative usability scores can temporarily mask qualitative physical discomfort (eg, VR dizziness and facial pressure) due to novelty effects. In the real world, this prototype provides a highly viable, safe, and motivating dual-task rehabilitation tool. It can be easily deployed across community, institutional, and home-based care settings, ultimately enhancing cognitive-motor capacity, lowering barriers to digital interventions, and promoting active, healthy aging among cognitively vulnerable older populations.

Acknowledgments

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (2025; Generative Artificial Intelligence Delegation Taxonomy), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing. The GenAI tool used was Gemini 3 Pro Preview (Google LLC). GenAI tools are not listed as authors and do not bear responsibility for the outcomes. Declaration submitted by the authors. AI (Gemini 3 Pro Preview) was used for minor language refinement and editing, specifically to improve grammar, spelling, verb tense, sentence flow, and English idiomatic expression. All outputs were reviewed and modified by the authors, and the authors take full responsibility for the final content.

Abstract

Background: Adolescents with mild intellectual disabilities often exhibit deficits in motor proficiency and neurocognitive processing, which can limit their functional independence. Although virtual reality (VR) exergames provide a motivating platform for physical activity, objective data quantifying their impact on standardized motor scales remain scarce, particularly when implemented through structured pedagogical frameworks. Earlier research established the WISH (warm-up, imitation, settings, half-hour) and WON (warm-up, objective evaluation, no problem!) protocols to facilitate gameplay independence in this population. However, the extent to which this systematic approach translates into measurable clinical motor and reaction time gains requires further investigation.

Objective: This study evaluated the effectiveness of a 16-session structured VR exergame intervention, using the WISH and WON protocols, in enhancing motor proficiency and shortening simple reaction time among adolescents with mild intellectual disability.

Methods: A multisession, single-group pretest and posttest pilot design was used. A convenience sample of 8 adolescents (3 males, 5 females; mean age 17.63, SD 1.77, range 15 - 20 years) was recruited from a special school complex in Poland. The intervention was conducted over an 8-month period (October 2023 to May 2024), consisting of 16 sessions conducted once every 2 weeks. The rhythmic fitness game “OhShape!” (Odders Lab) was played on the Meta Quest 2 system. Motor proficiency was assessed with the Bruininks-Oseretsky Test of Motor Proficiency short form, and simple reaction time to visual and auditory stimuli was measured using a standardized Alfa-Electronics meter. Statistical analysis was performed using the Wilcoxon signed-rank test (α=.05).

Results: Total Bruininks-Oseretsky Test of Motor Proficiency scores significantly improved from a baseline mean of 69.25 (SD 6.80; 95% CI 63.56 - 74.94) to 80.50 (SD 5.50; 95% CI 75.90 - 85.10) at the posttest (P=.01; r=0.74). Based on the standardized 5-point proficiency scale, the group mean rose from 1.88 (SD .64; 95% CI 1.34 - 2.42) at baseline to 2.88 (SD .35; 95% CI 2.59 - 3.17) postintervention (P=.008; r=0.89). Furthermore, the mean simple reaction time decreased from 426.50 (SD 52.3; 95% CI 382.78 - 470.22) ms to 392.10 (SD 38.4; 95% CI 359.98 - 424.22) ms at the final assessment (P=.02; r=0.72).

Conclusions: This pilot study suggests structured VR exergaming may address motor deficits in adolescents with mild intellectual disability. Promoting autonomy via protocols was associated with measurable motor gains within this cohort. Although the absence of a control group limits causal claims, immersive VR may offer a supportive tool for neuro-motor adaptations in special education, warranting validation in larger controlled trials.

Introduction

Background and Rationale

Intellectual disability (ID) is characterized by significant limitations in intellectual functioning and adaptive behavior [1]. Children and adolescents with ID are more vulnerable to obesity and secondary metabolic health issues than typically developing children [2,3]. Beyond cardiovascular and metabolic concerns, individuals with mild ID frequently exhibit impaired motor proficiency, including delays in gross motor movements, bilateral coordination, and postural stability [4-6]. Consequently, this population often presents with strikingly low health-related physical fitness levels [7], and their physical inactivity is a major contributor to poor health and reduced quality of life [8]. While traditional sports games and structured athletic programs have been shown to effectively improve motor skills, coordination, and overall physical fitness in youth with ID [9], immersive virtual reality (VR) exergames have emerged as a transformative, complementary solution. These digital platforms offer distraction-free environments that foster higher exercise intensities and greater persistence [10,11]. However, a significant problem persists: despite the potential of VR, many interventions focus primarily on participation metrics rather than objective clinical outcomes [12,13]. Relying solely on subjective engagement metrics or in-game scores is insufficient to confirm real-world functional transfer. Therefore, using rigorous, standardized clinical assessments is critically needed to scientifically validate whether digital gameplay translates into genuine neuro-motor adaptations and tangible developmental progress for the ID population.

Review of Relevant Scholarship

Recent advancements suggest that immersive serious games act as holistic educational environments, facilitating the training of meta-skills, cognitive, emotional, and behavioral, which are crucial for functional adaptation [14]. Specifically, gamified interventions have demonstrated a significant positive impact on problem-solving abilities and concept development in students with ID, bridging the gap between digital play and cognitive growth [15]. Educational and inclusive environments have also been shown to further support these developments, positively influencing fine motor skills and attention levels [16]. Furthermore, recent meta-analyses indicate that the benefits of digital technology-based interventions for neuro-cognitive efficiency are not universally consistent, often depending on the specific cognitive domains targeted, the clinical characteristics of the population [17-19], as well as the recruitment settings and delivery contexts used [20].

However, individuals with ID demonstrate significant learning curves and adaptive gains in digital environments, suggesting that immersive VR can facilitate real-world skill transfer if properly structured [21,22]. This is supported by findings that while VR exergaming effectively improves locomotor skills in children with developmental disabilities, it is insufficient on its own to significantly enhance object control skills or overall physical activity levels, indicating that VR must be mixed with reality-based programs [23]. Crucially, the latest longitudinal evidence strongly confirms that while fully immersive VR enhances cognitive-motor skills during gameplay, their transfer to specific real-world tasks and generalized response times remains critically limited without integration into practical, structured training frameworks [24]. To maintain long-term adherence and intrinsic motivation, serious games must incorporate optimal challenges and be matched to the player's behavior [25]. Furthermore, recent qualitative research highlights that carefully calibrated immersive VR environments, when combined with facilitative, nondirective professional support, serve as psychologically safe platforms that can strengthen self-determination, autonomy, and action-control beliefs in adults with ID [26]. The lack of structured instructional protocols has been a significant barrier to the effective application of VR in this population. Evidence from various motor skill interventions [27], including object control skills training [28], highlights the importance of systematically designed, error-reduced approaches. Previous work addressed this by establishing the WISH (warm-up, imitation, settings, half-hour) and WON (warm-up, objective evaluation, no problem!) training protocols, which facilitate gameplay independence [29]. Recent innovations in telehealth and mHealth support systems further demonstrate that remote, technology-aided interventions can effectively stimulate physical activity, leisure engagement, and mobility for individuals with ID and related mobility disabilities [30-32]. While earlier reports suggest these protocols are effective for fostering autonomy [29], the current report differs by shifting the focus from subjective independence metrics to the evaluation of objective clinical outcomes. Evaluating the efficacy of immersive therapeutic interventions [33] requires accurately measuring functional gains. Therefore, this study relies on standardized clinical tools, specifically the Bruininks-Oseretsky Test of Motor Proficiency (BOT-2), whose validity and reliability for detecting genuine neuro-motor adaptations in youth with IDs are strongly supported by recent methodological literature [34,35].

Hypothesis, Aims, and Objectives

The primary aim of this pilot study was to evaluate the feasibility and preliminary effectiveness of a 16-session VR exergame intervention, governed by the WISH and WON protocols, in improving objective motor proficiency and shortening simple reaction time (SRT) in adolescents with mild ID. To foster intrinsic motivation and ensure sustained engagement, the core expectations and instructional frameworks were derived from Self-Determination Theory. This theory emphasizes that teachers' motivational behaviors, specifically providing autonomy support and competence-building feedback, are vital for pupils' persistence and internal satisfaction during technology-mediated learning [36].

Given the pilot nature of this study, the hypotheses were formulated to explore preliminary trends and directional changes rather than definitive clinical efficacy. Specifically, this study evaluated the following hypotheses:

- Primary hypothesis: the structured VR intervention was expected to elicit positive shifts in global motor proficiency, as measured by the BOT-2 short form (SF) total point score.
- Secondary hypothesis: the intervention was hypothesized to enhance central cognitive efficiency, which would be

XSL•FO
RenderX

reflected in a trend toward shortened SRT to visual and auditory stimuli.

Additionally, secondary exploratory analyses were preplanned to evaluate whether raw numerical point gains on the BOT-2 translated into meaningful qualitative shifts across clinical descriptive categories (eg, moving from "Well Below Average" to "Below Average" or "Average"), and whether the intervention improved intra-individual neuro-cognitive response stability over time.

To appropriately address these objectives, a single-group pretest and posttest pilot design was selected. This specific design relates directly to the exploratory nature of the study by using a within-subject comparison to minimize the confounding impact of high interindividual variability in motor and cognitive baselines, a common characteristic of the ID population. This approach allows for the safe and targeted exploration of potential developmental trends under identical environmental conditions before moving toward larger controlled trials.

Methods

Inclusion and Exclusion

Eligibility was determined based on a comprehensive set of criteria to ensure safety and data reliability. To be included, individuals were required to have a formal diagnosis of mild ID and no prior experience with immersive VR technology. Participants had to be current pupils of a special education school, within the age range of 8 to 25 years. Methodological requirements specified that candidates must be efficiently handed (both right and left), not be taking psychotropic medications, and be free from chronic or acute physical injuries. A documented statement from the school psychologist and physical education (PE) instructor was mandatory to confirm that each student possessed sufficient physical and mental health for participation. Students requiring vision correction were eligible provided they used specialized overlays for glasses within the VR headset.

Conversely, individuals were excluded if they had previous exposure to VR environments or did not meet the diagnostic criteria for mild ID. Other exclusion factors included being over 25 years of age, a history of ophthalmic surgery, or current use of psychotropic drugs. History of fresh or long-term injuries also led to disqualification. Finally, candidates were excluded if school staff determined their health status was below the threshold necessary for standard participation in PE lessons.

Participant Characteristics

A total of 10 eligible students were identified and approached for participation. Of those approached, 100% (8/8) of the individuals and their legal guardians provided informed consent to enroll in the study. Consequently, 10 participants commenced the intervention. However, two participants dropped out during the course of the study due to personal reasons and withdrawal from the school. In accordance with established reporting standards, recruitment was officially closed upon exhausting the available pool of eligible students within the facility for the current academic year, which served as the predefined stopping rule establishing the final cohort size. Thus, the final analytical sample consisted of 8 adolescents (3 males and 5 females). Participant age ranged from 15 to 20 years, with a mean age of 17.63 (SD 1.77) years. The group was considered relatively homogeneous, sharing a formal diagnosis of mild ID. At the developmental stage of late adolescence, participants demonstrated similar baseline motor proficiency levels, as evidenced by their pretest BOT-2 scores.

Ethical Considerations

The study was approved by the Institutional Review Board at the Karol Marcinkowski Medical University in Poznań (No. 684/23). All procedures adhered to ethical standards, ensuring voluntary participation. No payments or monetary incentives were made to participants. Informed consent was obtained from parents or legal guardians, and verbal assent was secured from the students. All collected data were strictly anonymized, and confidentiality measures were implemented to protect participants' privacy throughout the research process. To ensure complete nonidentifiability in the visual materials, facial features of the participants were obscured using the PicDefacer image anonymization tool (Barakin Digital). Furthermore, explicit written informed consent was obtained from the parents or legal guardians specifically granting permission for the publication of these anonymized photographs.

Sample Size, Power, and Precision

As this was a pilot study focusing on the initial efficacy of a structured pedagogical framework in a specialized setting, a formal a priori power analysis was not conducted. The sample size (n=8) was determined by the total available cohort of students at the participating facility who met all eligibility criteria during the study period. Precision of parameter estimates was evaluated through the reporting of 95% CI for all primary motor and cognitive outcomes.

Measures and Covariates

The primary measures defined and evaluated in this study included global motor proficiency and SRT to visual and auditory stimuli (pooled average across both modalities).

Data Collection

The intervention used the Meta Quest 2 standalone VR system featuring a wireless head-mounted display (1832 x 1920 pixels per eye; 60 - 90 Hz refresh rate) and two 6 degrees of freedom hand controllers. Participants played "OhShape!" (Meta Quest 2; Odders Lab), a rhythmic VR fitness game requiring full-body synchronization with an incoming musical stream within a 2.0 ×2.0 meter safe zone. Core mechanics involved matching precision silhouettes for bilateral coordination, smashing red obstacles with boxing-style punches for upper-limb reaction speed, and performing squats or lateral "step-and-reach" shifts to avoid barriers, thereby training dynamic stability and core strength. To ensure an optimal challenge tailored to the unique learning curves of individuals with ID, difficulty levels were dynamically adjusted based on a 5-star performance system, while treatment fidelity was maintained by monitoring the participant's real-time perspective via a linked smartphone application.

XSL•FO
RenderX

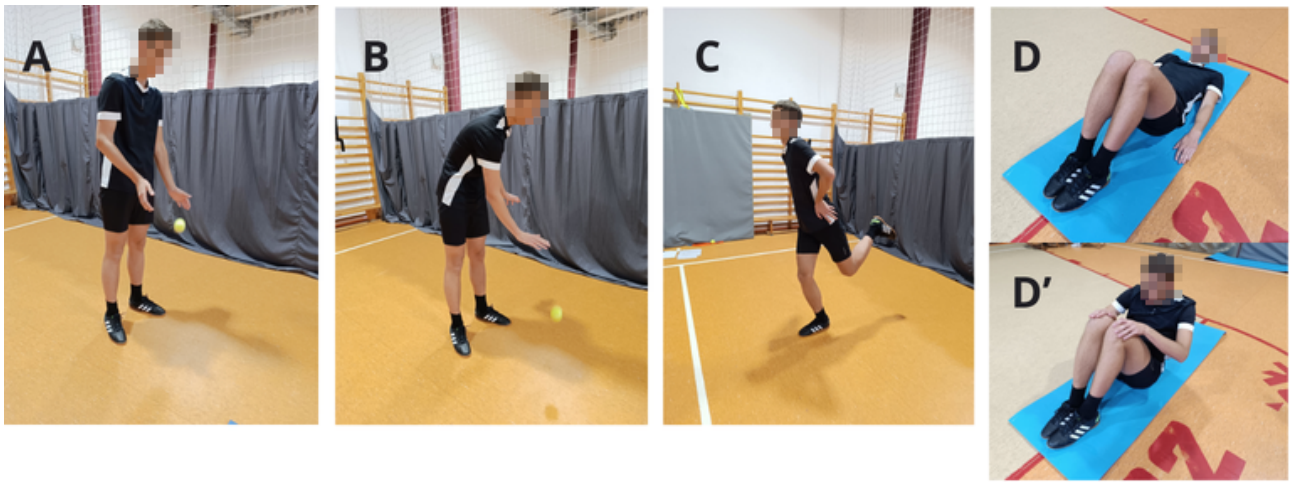
The sessions were integrated into regular PE classes and supervised by a trained instructor. The 16 sessions were divided into 2 phases based on previously established protocols:

- WISH phase (sessions 1‐4): focused on movement technique, technology familiarization, and reducing anxiety.
- WON phase (sessions 5‐16): focused on individual progress, increasing difficulty levels, and fostering gameplay autonomy.

To ensure sustained engagement, instructor behaviors were operationalized based on the SDT-based classification [26,36]. This involved providing autonomy support by gradually shifting gameplay control to the participant during the WON phase, supporting competence through optimal challenges and structured feedback, and fostering relatedness through supportive instructor involvement and emotional encouragement throughout all sessions.

Quality of Measurements

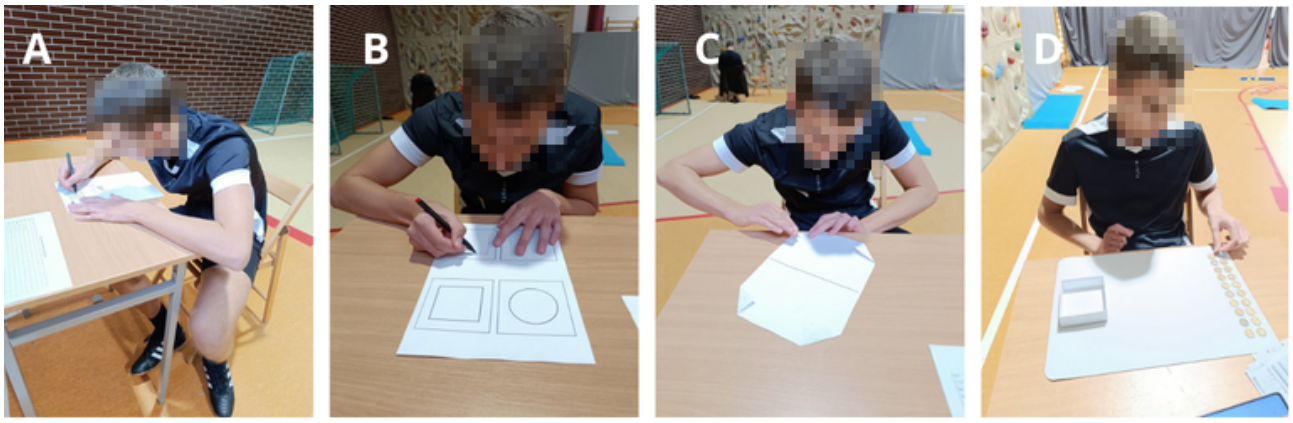
To enhance the quality of measurements and ensure methodological rigor, all pretest and posttest assessments were strictly standardized, occurring under identical environmental conditions (same room, time of day, and examiners) using validated instruments. Specifically, the SRT test was performed three times for each participant during each assessment series to enhance measurement reliability, maximize data stability, and minimize intraindividual performance fluctuations.



Instrumentation

Motor Proficiency (BOT-2 SF)

Motor proficiency was assessed using the BOT-2 SF [37]. This standardized instrument is highly effective for populations with developmental challenges, demonstrating excellent internal consistency and superior test-retest reliability specifically in individuals with IDs [38]. The SF version was specifically selected for this study due to its high psychometric efficiency and its strong correlation with the complete form (r=0.80-0.87) [39,40].



Crucially, the abbreviated administration time of 15‐20 minutes mitigates the risk of cognitive fatigue and limited attention spans common in youth with mild ID [39,40]. Furthermore, the inclusion of visual supports and photographs in the administration easel minimizes language demands, making the assessment more accessible for participants with receptive language deficits [37,41]. Recent evidence confirms that the BOT-2 is a responsive tool for monitoring psychomotor progress following technological and game-based interventions [41,42]. By using benchmarks such as the minimal detectable change, the BOT-2 serves as an essential resource for monitoring the effectiveness of clinical rehabilitation in children with disabilities [38,42]. The standardized administration of the subtests, conducted in a controlled school environment to ensure ecological validity, is illustrated in Figures 1 and 2.

Figure 1. Evaluation of gross motor skills: selected coordination and strength tasks from the Bruininks-Oseretsky Test of Motor Proficiency (BOT-2) Short Form in adolescents with mild intellectual disabilities (n=8) at a special school in Poland (October 2023 to May 2024). Subitems illustrated include: (A) upper-limb coordination (catching a tossed ball); (B) upper-limb coordination (dribbling a ball with an open palm); (C) bilateral coordination (one-leg stationary hop); (D) strength (sit-up initiation phase); and (D') strength (sit-up completion phase).

Figure 2. Evaluation of fine motor skills: selected precision, integration, and manual dexterity tasks from the Bruininks-Oseretsky Test of Motor Proficiency (BOT-2) Short Form in adolescents with mild intellectual disabilities (n=8) at a special school in Poland (October 2023 to May 2024). Subitems illustrated include: (A) fine motor precision (drawing lines); (B) fine motor integration (copying shapes); (C) manual dexterity (paper folding); and (D) manual dexterity (transferring pennies).

Simple Reaction Time (SRT)

Cognitive efficiency was quantified using the Alfa-Electronics (Ustrzyki Dolne) standardized reaction time meter [43-46]. This hardware-based measurement provided an objective record of the latency (in ms) between a randomized stimulus and the participant's motor response [43,44]. The SRT test serves as a fundamental metric for evaluating the efficiency of the central nervous system and sensorimotor coordination [17,47,48]. The device presented visual and auditory stimuli in a randomized, alternating order, and the participant was instructed to react as quickly as possible to either modality. The final SRT value represents the combined average latency across all randomized stimuli. The measurement procedure, featuring a participant performing the SRT test using the specialized apparatus, is illustrated in Figure 3. In alignment with previous research, this measurement protocol and the Alfa-Electronics apparatus have been validated, showing high internal consistency with a Cronbach α of 0.958 and a split-half reliability coefficient of 0.818 (P<.001) [49].

XSL•FO
RenderX

Masking

Due to the nature of the immersive VR intervention, complete blinding of the participants and the PE instructor delivering the sessions was not feasible. However, to minimize assessment bias, a single-blind protocol was implemented for outcome evaluations. The pretest and posttest assessments (BOT-2 and SRT) were conducted by an independent examiner who was not involved in the execution of the 16-session VR intervention and remained unaware of the study's specific intermediary training hypotheses. Furthermore, a single-blind procedure was maintained during data diagnostics, as all participant datasets were completely anonymized and coded prior to statistical analysis, ensuring the investigator remained masked to identity during processing.

Psychometrics

The BOT-2 SF [37] is a standardized instrument, and also highly effective for populations with developmental challenges, demonstrating excellent internal consistency and superior test-retest reliability specifically in individuals with IDs [38]. The SF version was specifically selected for this study due to its high psychometric efficiency and its strong correlation with the complete form (r=0.80-0.87) [39,40].

Cognitive efficiency was quantified using the Alfa-Electronics (Ustrzyki Dolne, Poland) standardized reaction time meter [43-46]. This measurement protocol and the Alfa-Electronics apparatus have been validated, showing high internal consistency with a Cronbach α of 0.958 and a split-half reliability coefficient of 0.818 (P<.001) [49].

Conditions and Design

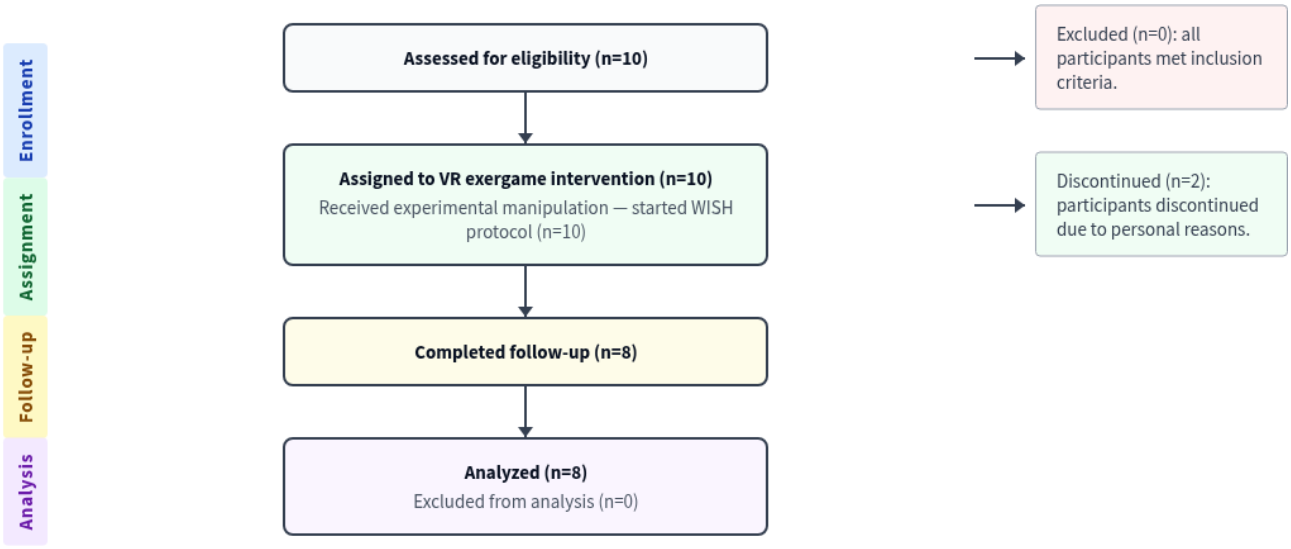
The research followed a nonrandomized, single-group pretest and posttest pilot design involving a structured experimental manipulation. This specific design was selected to evaluate the initial feasibility and efficacy of the WISH and WON protocols within a naturalistic special education environment, where randomization into a control group was not practically feasible due to the limited total cohort of eligible students. To address concerns regarding the internal consistency of results in a small-scale study, a within-subject comparison was used. This approach effectively minimizes the confounding impact of high interindividual variability in motor and cognitive baselines, a common characteristic of the ID population, by using each participant as their own control. To ensure methodological rigor, all pretest and posttest assessments were strictly standardized, occurring under identical environmental conditions (same room, time of day, and examiners) using validated instruments. Furthermore, the 8-month duration of the 16-session intervention was strategically planned to facilitate the observation of stable neuro-motor adaptations, ensuring that the results reflect genuine developmental shifts toward normative thresholds rather than temporary performance fluctuations or novelty effects.

Data Diagnostics

Planned data diagnostics included the exclusion of anticipatory errors in SRT measurements. Latencies shorter than 100 ms were defined as statistical outliers and excluded from the final analysis. Mean values were calculated from stable trials across the three measurement series to ensure data reliability. There were no missing data in this study (0%). All 8 participants completed all pretest and posttest assessments, which precluded the need for missing data imputation or the Missing Completely at Random test.

Analytic Strategy

Statistical analysis was performed using Statistica 13.0 (TIBCO Software Inc.). Descriptive statistics, including the mean, median, and SD, were calculated for both motor proficiency and reaction time parameters. Due to the small sample size (n=8), nonparametric statistical methods were used to ensure the robustness of the findings. The Wilcoxon signed-rank test was used to compare pretest and posttest outcomes. The level of statistical significance was set at P<.05. To determine the magnitude of the intervention's impact, effect sizes were calculated using the formula r=Z/√ N. Effect sizes were interpreted according to Cohen criteria: 0.1 for a small effect, 0.3 for a medium effect, and 0.5 for a large effect.



Results

Participant Flow

As illustrated in the participant flowchart (Figure 4), a total of 10 eligible students from the special school complex were initially assigned to the VR exergame intervention and commenced the training framework. Following the completion of the foundational WISH phase, 2 participants discontinued their participation due to personal reasons. The remaining 8 participants successfully proceeded to the WON phase, demonstrated 100% adherence, and completed all 16 scheduled training sessions. Consequently, the final analytical sample tracked from assignment through to the final posttest series consisted of 8 individuals.

XSL•FO
RenderX

Figure 4. Flowchart of participants through the stages of the 16-session VR exergame intervention in adolescents with mild intellectual disabilities (n=8) at a special school in Poland (October 2023 to May 2024). VR: virtual reality; WISH: warm-up, imitation, settings, half-hour.

Sampling Procedures

Participants were recruited through a convenience sampling strategy at a single institutional setting (a special school complex in Poland). Out of the initial pool of eligible students approached within the facility, a 100% enrollment rate was achieved, resulting in 10 active participants entering the training framework. Data collection and empirical tracking were comprehensively conducted over an 8-month period from October 2023 to May 2024, ultimately yielding a final analytical sample of 8 adolescents after accounting for procedural attrition during the initial phase of the intervention.

Statistic and Data Analysis

Missing Data

There were no missing data encountered at any assessment stage of this study (0% missing data frequency). All 8 participants included in the final cohort completed both the pretest and posttest measurement series in their entirety. Therefore, data imputation procedures were unnecessary, and missing completely at random data testing was precluded.

Statistical Assumptions and Software

Due to the exploratory nature and small size of the final analytical cohort (n=8), data distributions were assumed to be nonnormal, and nonparametric statistical procedures were used to maintain mathematical rigor. All inferential and descriptive computations were conducted using Statistica 13.0 software. The level of statistical significance for all corresponding hypothesis tests was set a priori at $P<.05$. Treatment fidelity was high, with 100% protocol adherence among the final sample under the uniform guidance of a single trained instructor.

Baseline Data

Baseline demographic and clinical characteristics for the final analytical sample (n=8) are summarized in Table 1. At the onset of the study (session 0), the participants exhibited significant motor proficiency deficits, with a group mean qualitative standing categorized as ’below average’ (mean 1.88, SD 0.64). All participants were efficiently handed and had no prior exposure to immersive VR environments.

RenderX

Table . Baseline demographic and clinical characteristics of adolescents with mild intellectual disabilities (n=8) at a special school in Poland (October 2023).

Characteristic	Value (n=8)
Demographics	
Age (years), mean (SD; range)	17.63 (1.77; 15-20)
Sex, n (%)	
Male	3 (37.5)
Female	5 (62.5)
Clinical status, n (%)	
Diagnosis (mild intellectual disability)	8 (100)
Prior VR[a] experience (none)	8 (100)
Baseline performance (pretest)	
BOT-2[b] total point score, mean (SD; 95% CI)	69.25 (6.80; 63.56 - 74.94)
BOT-2[b] qualitative category, mean (SD)	1.88 (0.64)
SRT[c] (ms), mean (SD; 95% CI)	426.50 (52.3; 382.78 - 470.22)

[a]VR: virtual reality.

[b]BOT-2: Bruininks-Oseretsky Test of Motor Proficiency

[c]SRT: simple reaction time.

Primary Hypothesis: Motor Proficiency

The primary hypothesis assumed that the 16-session VR intervention would significantly improve global motor proficiency (BOT-2 total score). The Wilcoxon signed-rank test confirmed a statistically significant postintervention increase. The group's mean total BOT-2 score rose from 69.25 (SD 6.80; 95% CI 63.56 - 74.94; range 55 - 74) to a posttest mean of 80.50 (SD 5.50; 95% CI 75.90 - 85.10; range 72 - 88). This change was statistically significant (P=.01; r=0.74) according to the Wilcoxon signed-rank test [Table 2].

Table . Pretest and posttest motor proficiency (BOT-2)[a] outcomes in adolescents with mild intellectual disabilities (n=8) following a 16-session virtual reality (VR) intervention (October 2023–May 2024).

	Pretest (session 0), mean (SD; 95% CI)	Posttest (after session 16), mean (SD; 95% CI)	Difference, mean (P value)
BOT-2 total score (points)	69.25 (6.80; 63.56-74.94)	80.50 (5.50; 75.90-85.10)	+11.25 (.01)
BOT-2 qualitative category[b]	1.88 (0.64; 1.34-2.42)	2.88 (0.35; 2.59-3.17)	+1.00 (.008)
SRT[c] (ms)	426.50 (52.3; 382.78-470.22)	392.10 (38.4; 359.98-424.22)	−34.40 (.02)

[a]BOT-2: Bruininks-Oseretsky Test of Motor Proficiency, Second Edition (Short Form). Total point score range: 0 - 88.

[b]Descriptive categories mapped to a 5-point Likert scale: 1: well below average; 2: below average; 3: average (normative parity); 4: above average; 5: well above average. For individuals with intellectual disabilities, reaching Category 3 (average) represents the achievement of functional parity with typically developing peers.

[c]SRT:simple reaction time.

Secondary Hypothesis: Cognitive Efficiency (Reaction Time)

Objective measurements of neuro-cognitive efficiency (combined visual and auditory SRT) revealed a statistically significant improvement in response speed. The mean SRT shortened by 34.40 ms, decreasing from a baseline of 426.50 (SD 52.3; 95% CI 382.78 - 470.22) ms to 392.10 (SD 38.4; 95% CI 359.98 - 424.22) ms at the final assessment (P=.02) (Table 2). Beyond the improvement in average response speed across both visual and auditory modalities, participants demonstrated enhanced neuro-cognitive stability. This was evidenced by a reduction in response variability and a narrowed range between minimum and maximum reaction times compared to the initial measurements.

Exploratory Hypotheses and Estimates

The first exploratory analysis investigated whether the numerical increase in BOT-2 point scores translated into a meaningful clinical shift in the participants' descriptive motor categories (eg, moving from a "below average" classification to an "average" classification). Analysis of the 5-point standardized qualitative proficiency scale revealed a significant upward shift. The group mean increased by exactly one full descriptive category, rising from 1.88 (SD 0.64; 95% CI 1.34 - 2.42) at baseline to 2.88 (SD 0.35; 95% CI 2.59 - 3.17) postintervention

XSL•FO
RenderX

(P=.008, r=0.89). Practically, this indicates that 75% of the participants (6 out of 8 individuals) successfully transitioned from a "below average" motor standing to "average" functional parity, reaching the normative motor levels expected for their typically developing peers.

The second exploratory analysis examined whether the VR training framework improved the consistency of the participants' focus and reaction times, rather than just their raw speed. In individuals with IDs, high variability between the fastest and slowest reactions often indicates attention deficits or executive dysfunction. Posttest evaluations of the SRT data revealed a marked reduction in this variability. Specifically, the statistical range, the gap between the individual's minimum (fastest) and maximum (slowest) response latencies across the measurement trials, was substantially constricted compared to the initial baseline metrics. This narrowing of the response range indicates that following the intervention, the participants not only reacted faster but also executed the cognitive tasks with greater neurological stability, consistency, and sustained attention.

Discussion

Principal Findings

The primary objective of this pilot study was to evaluate the feasibility and preliminary effectiveness of a structured VR exergame intervention, governed by the WISH and WON protocols, in enhancing motor proficiency and cognitive processing speed in adolescents with mild ID. The findings provide encouraging support for both the primary and secondary hypotheses, indicating that a systematically guided digital intervention can elicit positive shifts in global motor coordination and balance while accelerating simple reaction times to sensory stimuli [50]. Furthermore, exploratory analyses revealed an enhanced stability in neuro-cognitive responses and a qualitative migration of participants toward normative parity, suggesting that technology-driven frameworks can successfully support stable sensorimotor adaptations and reduce intra-individual variability in youth with neurodevelopmental conditions [50].

Comparison With Prior Work

These outcomes strongly contribute to the growing consensus regarding the clinical utility of immersive environments in special education and neurorehabilitation [33]. When compared to traditional, long-term sports programs, such as hockey, basketball, or swimming, which often require extensive multimonth timelines or trigger high attrition rates due to social isolation, the intensive digital framework evaluated here offers a highly motivating and time-efficient alternative [9,51,52]. The observed trends in postintervention coordination approached established western developmental benchmarks [53] and compared favorably against regional normative data reported for youth with ID [6].

However, this study observed broader global motor improvements than those reported in nonimmersive digital interventions [13], potentially due to the highly rhythmic, full-body immersive nature of the chosen exergame [32]. While some earlier studies suggested that 12-month programs might be necessary for individuals with severe ID [51], our preliminary data corroborate emerging evidence that shorter, intensive game-based interventions can effectively elicit measurable neurocognitive and proprioceptive changes in mild ID cohorts [17,54]. Additionally, the structured protocol used here offers a promising, time-efficient alternative to longer traditional sports interventions [52]. Such results highlight VR active games and digital exergames as noninvasive, accessible tools that can enhance physical literacy domains and movement skills while encouraging broader participation in physical activities [55,56].

A critical insight from this study lies in the interaction between immersive interfaces and motor skill acquisition. Prior work demonstrated that while stationary bike-based VR exergames improve locomotor skills, they fail to enhance object control or ball skills because basic body redirection or hand controllers do not provide sufficient sensorimotor feedback for complex manipulation [23]. Similarly, recent longitudinal evidence indicates that unguided fully immersive VR training yields limited skill transfer to real-world tasks or generalized reaction times [24]. This study directly addresses these challenges by incorporating the WISH and WON protocols to provide structured instructional guidance [29]. By scaffolding the user's experience, these protocols appeared to facilitate superior motor control and response quickness, aligning with recent clinical trials which show that task-oriented VR active games systematically enhance predictive internal modeling and visuomotor adaptation in children with developmental coordination challenges [55,57]. Although updating internal models often involves persistent compensatory errors and motor variability [57], the combination of immersive stereoscopic visualization and structured pedagogical scaffolding appears to minimize cognitive load, helping users form and generalize more accurate predictive motor plans [4,5,57].

Mechanistically, combining computerized cognitive training with motion-based digital interactions provides a highly effective multisensory environment that substantially promotes visual-motor integration and global motor functions in individuals with intellectual challenges [58]. By leveraging adaptive technology, such integrated cognitive-motor interventions expand the complexity of the perceptually enriched world users interact with, actively accelerating general visual perception, visual-motor speed, and spatial relations [58].

Furthermore, immersive therapeutic role-playing setups have been verified to yield statistically significant improvements in concentration scores and active engagement, highlighting the profound clinical value of tailored hand-eye coordination training in game-based environments [59].

The positive changes in motor independence and cognitive engagement observed in this study reinforce the theoretical foundations of Self-Determination Theory within digital learning [36]. Recent qualitative evidence demonstrates that when immersive VR programs are paired with facilitative, nondirective professional support, they function as psychologically safe environments that significantly bolster self-determination, personal agency, and action-control beliefs [26]. While such agency-building effects have primarily been documented in aging adults with ID [26], this study extends

XSL•FO
RenderX

this novelty to an adolescent cohort, confirming that providing autonomy support and structured containment can successfully foster autonomous gameplay and perceived competence in younger populations [26,29,36]. This is highly consistent with contemporary findings from international special education initiatives, which emphasize that structured VR-based motor skill programming yields high usability, robust pedagogical effectiveness, and an emotionally secure student experience [60]. Similarly, the incorporation of interactive mobile architectures and augmented reality in physical education has been shown to alleviate cognitive friction, thereby accelerating gross motor skill mastery in elementary and secondary school environments [51,61,62].

To address the crucial "so what?" question regarding the real-world value of this project, the simultaneous improvements documented in motor proficiency and visual-motor speed carry profound practical benefits for the daily independent living and personal safety of adolescents with mild ID. Translating laboratory-derived metrics into concrete functional autonomy means that these adolescents can navigate their everyday physical environments with greater security. Specifically, the significant acceleration in SRTs directly translates into enhanced pedestrian safety, allowing individuals to react faster to sudden real-world hazards, such as an oncoming vehicle when crossing a street. At the level of daily routines, the refinement of fine and gross motor mastery directly supports the performance of essential activities of daily living, such as handwriting, object manipulation, or tying shoes [58]. Crucially, contemporary locomotor evidence underscores that VR protocols incorporating enriched sensory feedback and progressive task difficulty possess high ecological validity, proving that behavioral modifications learned while stepping in place in a virtual setting successfully transfer to actual walking behaviors in a real environment [63]. By fine-tuning movement patterns and reducing spatial margins without increasing the danger of physical contact, this structured training diminishes the real-world risk of accidental tripping and catastrophic falls [63,64]. This protective mechanism is further reinforced by target-oriented exergaming frameworks which demonstrate that digital sensorimotor tracking significantly enhances shoulder joint position sense and lower-extremity neuromuscular functionality during functional sit-to-stand activities [54]. By stabilizing postural control and peripheral proprioceptive awareness, such interventions directly address the core integration deficits typical of neurodevelopmental conditions [54].

However, long-term follow-up models in adapted physical activity warn that while structured interventions markedly accelerate motor milestones, these acquired motor adaptations significantly regress if continuous participation is discontinued, yielding a substantial loss of the acquired gains specifically in vital domains like bilateral coordination and balance [65]. This clinical reality underscores the absolute necessity of transitioning this VR protocol into a continuous, long-term institutional routine rather than a transient laboratory experiment [65].

From an institutional implementation standpoint, this structured exergaming intervention provides a highly practical, standardized, and scalable solution for special education frameworks and therapeutic workflows. Special schools frequently struggle with compromised student motivation and high attrition rates in traditional PE sessions, where conventional exercises are often perceived as monotonous, overly rigorous, or exclusionary. This intervention directly overcomes this motivational barrier by offering an attractive alternative to boring PE, using the inherent appeal of gamification, child-friendly characters, and multimodal reward structures to secure a safe and emotionally supportive environment [58]. Indeed, recent pediatric exercise data confirm that integrating novel exergaming guided by objective, real-time physiological metrics, such as visually targeted heart rate zones, yields flawless compliance, keeping children deeply physically challenged and intrinsically motivated without experiencing technological boredom [66].

For educational specialists and oligophrenopedagogues, this structured digital design represents a ready-to-use asset. The system offers ease of replication, high safety standards, and robust engagement metrics [66]. The specific deployment of the WISH and WON instructional scaffolds directly mitigates operational risks; spatial safety mapping indicates that under unguided conditions, virtual collisions occur predominantly on the "trailing" or backward-facing side of the user's body due to localized visual-spatial gaps [63]. By providing structured containment, our protocols ensure whole-body sensory recalibration and comprehensive motor planning.

Nevertheless, school-based deployment strategies must remain flexible; multitask sensorimotor evidence reveals that while active digital systems trigger substantial functional gains, neurodivergent cohorts frequently display a "high-gain yet unstable" learning curve, characterized by significant intragroup and trial-by-trial performance volatility [67]. By leveraging these structured pedagogical scaffolds, special education professionals can successfully compensate for these psychomotor fluctuations, stabilizing long-term motor skill acquisition over time [67].

Limitations

Several limitations must be acknowledged to contextualize the generalizability and external validity of these exploratory findings.

First, as a pilot investigation, the small sample size restricts statistical power and limits immediate generalizability to the broader population of adolescents with ID.

Second, the single-group pretest and posttest architecture lacks a parallel control group, which inherently limits the ability to draw definitive causal claims regarding the standalone efficacy of the VR exergame independent of natural maturation or external factors.

Third, the wide chronological age bracket encompassing late adolescence involves varying degrees of biological and neuromuscular maturation, which may have acted as a confounding variable influencing individual motor trainability [4,53].

Fourth, while the BOT-2 SF is highly sensitive for identifying motor delays, its lower specificity for mapping advanced athletic

XSL•FO
RenderX

developments implies that the observed changes primarily reflect the closing of developmental gaps rather than high-tier athletic skill acquisition [37-40]. In consideration of reporting guidelines regarding the precision of measurement protocols, it should be noted that the streamlined design of this abbreviated tool focuses primarily on broad functional changes rather than highly granular, microlevel adjustments. While this SF protocol is exceptionally efficient and well-validated for capturing macrolevel developmental shifts in youth with ID [37-40], its structural brevity means it might not register minor, step-by-step psychomotor fluctuations, thus presenting a highly stable and conservative estimate of the participants' actual motor progress.

Fifth, although the intervention demonstrated robust psychometric gains, this study did not directly evaluate the long-term ecological transfer of these motor skills to unstructured, real-world daily living activities, a limitation that mirrors ongoing transfer challenges highlighted in recent neurodevelopmental literature [24,26].

Finally, because immersive technology was a novelty in the local educational setting, the long-term retention of these sensorimotor improvements remains uncertain once the initial novelty effect subsides, a phenomenon frequently cited as a barrier in digital health feasibility models, crossover setups, and scoping reviews of exergaming compliance [56,68,69].

Conclusions

In conclusion, this pilot study provides valuable preliminary evidence that structured pedagogical frameworks, such as the WISH and WON protocols, can successfully transform commercial immersive exergames into effective clinical and educational assets for addressing motor and cognitive delays in adolescents with mild ID. These findings indicate that integrating autonomy-supportive digital environments into physical education curricula offers a motivating, stigma-free avenue to improve physical literacy and cognitive processing stability [36,56]. While these early-stage results are highly encouraging, further research using larger, randomized controlled trials with multicenter recruitment and long-term longitudinal follow-ups is strictly necessary to validate these trends and establish standardized guidelines for digital health interventions in special education [68,69].

Acknowledgments

The authors declare the use of generative AI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GAI tools under full human supervision: visualization; proofreading and editing; translation; identification of limitations; recommendations. The GAI tool used was: Gemini 1.5 Pro (by Google). Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes. The tasks were delegated by the primary author, JC, who was responsible for the original draft and visualization, with the knowledge and approval of all co-authors (JM, AR, AW). JC delegated the tasks as follows: Gemini 1.5 Pro (by Google) was utilized for text-related tasks, including language translation, proofreading, stylistic editing, and structuring the responses to the reviewers' and editor's comments (assisting in recommendations and identifying study limitations). The AI tool NanoBanana was used strictly to generate the Table of Contents (TOC) image. The AI-powered tool Picdefacer was used purely for ethical data protection and participant de-identification; it utilizes client-side neural network AI for automated face detection and blurring directly within the browser, ensuring sensitive images were never uploaded to external servers. Additionally, Picdefacer was used to automatically strip EXIF metadata (such as GPS coordinates and dates) from the photographs to guarantee absolute privacy. No AI was used for data collection, statistical analysis, or drawing primary scientific conclusions. All co-authors reviewed and approved this allocation of tasks.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Authors' Contributions

JC: writing—original draft, visualization, methodology, investigation, formal analysis, data curation, conceptualization.
JM: writing—review & editing, supervision, project administration.
AR: writing—review & editing, methodology, investigation (PE and oligophrenopedagogy expert oversight).
AW: writing—review & editing, methodology, validation (external research protocol verification).
All authors (JC, JM, AR, AW) reviewed and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Physical activity plays a central role in the course and progression of chronic conditions in older adults. However, individuals within this population tend to have an inactive lifestyle. Exergaming, which is defined as the integration of physical activity with game-based elements, offers a promising approach to promote physical activity in individuals with chronic conditions. Despite its potential, limited evidence exists on how specific game elements influence behavioral and psychological outcomes in this population.

Objective: The aim of this study is to explore the behavioral and psychological change techniques experienced by individuals with chronic conditions using a walking-based mobile exergame, called Heart Farming.

Methods: A cross-sectional qualitative design was used based on a gamification framework, using data from semistructured interviews with 14 participants aged 67 to 92 years who used the Heart Farming exergame for 3 months. Participants with chronic conditions, including heart failure, Parkinson disease, type 2 diabetes, stroke, or rheumatic disease, were recruited from 2 ongoing studies. Data were analyzed using deductive content analysis and presented based on the gamification framework.

Results: The data analysis revealed increased motivation to walk, which was facilitated by game elements such as goals, rewards, feedback, and planning. Participants valued not only the sense of progression and achievement within the game but also the real-world benefits, such as spending time in nature or feeling a sense of community with others. Exergaming was integrated into daily routines by supporting the planning and structuring of daily activities. It was also perceived as enjoyable, especially due to its farming theme and visual design. Behavioral change techniques such as goal setting, feedback, and social support were commonly experienced, whereas focus on past success (as described in the gamification framework) was not used as a technique by the exergame. Psychological techniques, including self-monitoring and stress management, were mentioned. A feeling of discomfort due to playing in public was reported, and participants varied in terms of the levels of digital literacy. Social interaction features were not adequately used, even though some participants created informal support groups to exergame.

Conclusions: This study contributes to the exergaming literature by examining behavioral and psychological change techniques from the perspective of individuals with chronic conditions. Exergaming incorporates a variety of behavioral and psychological change techniques, which were experienced by the participants in various ways. Individuals' previous knowledge of exergaming, interests, and illness progression were mentioned as factors that can influence their experiences of exergaming. By increasing the understanding of how game elements are experienced and how they influence health-related behavior, the findings of this study may inform the development of exergames that are better tailored to users' needs. Further research is needed to refine behavioral change techniques and assess condition-specific adaptations to maximize engagement and health outcomes.

Introduction

Background

Approximately one-third of adults worldwide are living with at least 1 chronic condition [1]. Being physically active can have a positive impact on the course and progression of different chronic conditions, such as chronic heart failure [2], stroke [3], or Parkinson disease [4]. However, despite the significance of being physically active, individuals with chronic conditions tend to have an inactive lifestyle. This is characterized by low levels of physical activity and sedentary behavior like sitting or lying down [5].

Gamification is a well-known and widely used approach to increase motivation and user engagement by implementing game design elements in nongame contexts [6], including health care and behavioral change [7]. Gamification emphasizes identifiable behavioral and psychological change techniques, such as goal setting, feedback, and self-monitoring, from which psychological and behavioral change can emerge [8]. Although these techniques can be layered onto existing activities or systems, they can also be part of a unified game structure as a *serious game*. Serious games are games with a primary nonentertainment objective, such as promoting learning, health, or behavioral change, that fundamentally shape the design and function of a game [9]. In their book on serious games, Dörner et al [9] introduced the term "characterizing goal" to describe these primary nonentertainment objectives of serious games. When the characterizing goal refers to exercises or other physical activities, the game is typically called an *exergame*.

Exergaming, which combines gameplay with physical activity in real life, is a relatively new approach to increasing physical activity for individuals with chronic conditions. Exergames are serious games for health that can possibly increase motivation to physical activity [10] and improve physical function, balance, exercise capacity, and energy expenditure [2,11,12]. Although many traditional exergames are designed for indoor use in front of a screen, some individuals might prefer outdoor exergames rather than being confined to screen-based play indoors [13-15]. Mobile exergaming is a suitable option for remote physical activity interventions, particularly when in-person meetings with health care professionals are not possible. Smartphones are equipped with built-in technologies, such as accelerometers, cameras, and sensors [16].

Mobile exergames employ a range of technologies to support and motivate physical activity, including indoor, outdoor, and hybrid solutions. GPS is a technology that relies on satellite positioning to track movement over larger areas. GPS is used in location-based exergames that are primarily suited for outdoor use [17,18]. An example of a game that uses this technology is Pokémon Go [19]. However, location-based exergames, including Pokémon Go, have previously been criticized as inappropriate or even dangerous. Pokémon Go has been shown to contribute to accidents caused by players' inattention to their surroundings while walking or even driving [20,21]. In contrast, augmented reality is a technology that integrates digital content with the real-world environment using cameras and sensors, enabling interactive and context-aware experiences that can be used both indoors and outdoors, while also supporting precise movement and spatial tracking [16].

Exergames use various techniques that aim to achieve behavioral change and can thus be useful in establishing healthy behaviors in individuals with chronic conditions [22]. The combination of key elements (eg, reward, challenge, feedback, information, goals, and planning) with the main aims of rehabilitation programs, such as motor skills learning, long-term retention, and transfer of skills, makes exergaming a valuable tool for health care professionals [23,24]. Although the physiological component (ie, the physical activity) is important for an exergame to be effective, it is also important to keep the psychological attractiveness (ie, the "fun") of exergames in mind [25,26]. The attractive nature of exergames might enhance individuals' motivation to engage in physical activity, which may in turn lead to positive outcomes in terms of dose response, adherence to, and long-term effectiveness of the rehabilitation programs. Although exergaming can help distract from unpleasant feelings like pain, there is a negative correlation between perceived exertion and enjoyment [27,28], and it is important to adapt the intensity of the exercise to avoid feelings of overexertion.

There are several previous studies indicating the health benefits of exergaming in individuals with chronic conditions. A recent randomized controlled trial (RCT) on the home-based and tailored exergaming interventions has shown them to be feasible and safe for individuals with movement disorders, with adjustable difficulty levels, real-time feedback, and balance-focused tasks being particularly important for addressing gait and postural control in Parkinson disease [29]. Findings from studies conducted on people with heart failure demonstrate that exergaming, alongside other exercise modalities such as yoga, can positively influence exercise capacity as well as physical and mental health, highlighting the importance of designing exergames that are safe, motivating, and adaptable to varying functional abilities to support sustained participation among older adults with chronic conditions [30]. In addition, the findings of a systematic review show that exergaming can improve quality of life, physical functioning, and psychological well-being among people living with a wide range of chronic conditions [22]. Gamification-based interventions have also been found to enhance self-management, motivation, and long-term engagement in chronic disease care, further supporting the potential of exergames as a complementary tool in chronic condition management [31].

Study Objectives

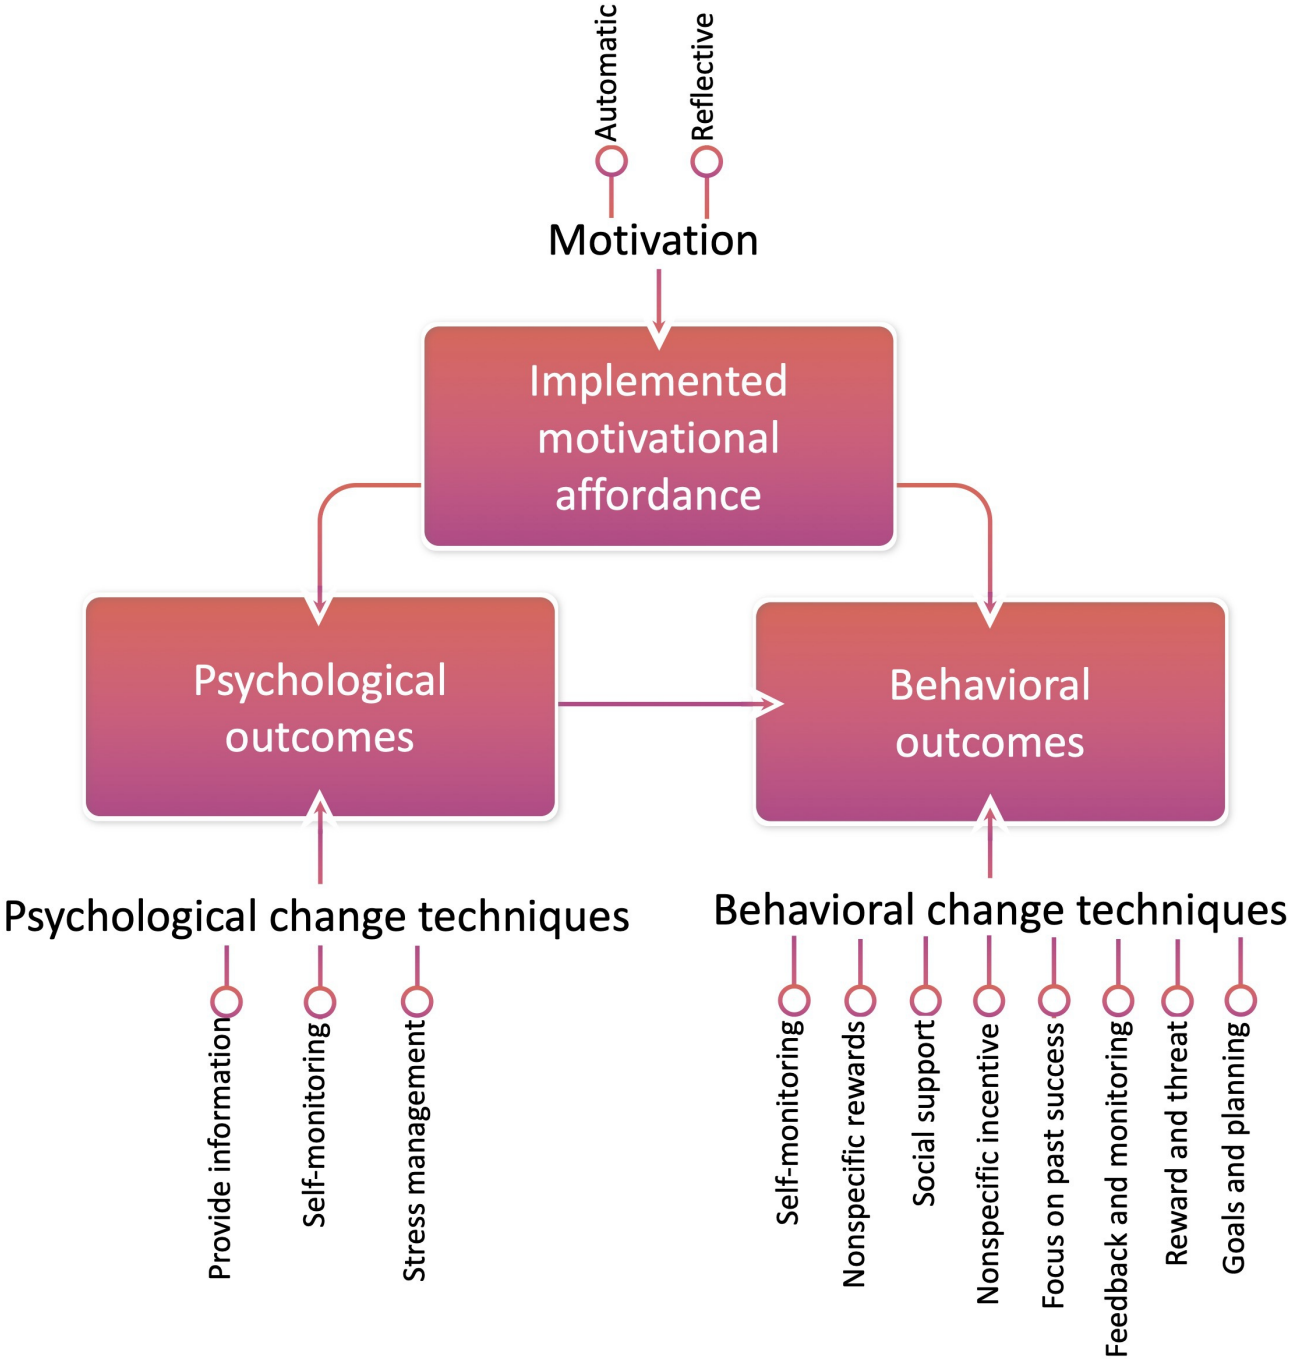
Although there is much research to support the potential health benefits of exergaming, there is a gap in evidence regarding the game elements that impact health behavior and how individuals experience them. To fully understand the potential of exergames as a tool to increase physical activity in people with chronic conditions, further exploration of this population's experiences of exergaming is required. By gaining insight into how gamification techniques are experienced, researchers and developers may be able to better tailor and adapt exergaming interventions to the user's needs. Therefore, the purpose of this study is to explore the experienced behavioral and psychological

XSL•FO
RenderX

change techniques in individuals with heart failure, Parkinson disease, type 2 diabetes, stroke, or rheumatic disease when using a walking-based mobile exergame.

Methods

Research Design Overview



This study adopted a qualitative descriptive cross-sectional study design and was conducted within the Heart-eXergame (Heart-eXg) study, which is an international RCT, and the Heart Farming Chronic Conditions (HF-CC) study. The study was reported in accordance with the Journal Article Reporting Standards for Qualitative Research guidelines [32].

The Gamification Framework

Gamification may be used in exergaming to maintain behavioral change and encourage physical exercise [33]. Gamification is defined as the use of game elements in a nongaming context, for example, behavioral change [6]. Gamification consists of 3 main components (Figure 1): implemented motivational affordances (properties of the gamified system that allow the user to experience competence, relatedness, and autonomy), psychological outcomes (induced by motivational affordance and psychological change techniques), and behavioral outcomes (induced by motivational affordances, psychological outcomes, and behavioral change techniques) [8]. The psychological change techniques are *providing information*, *self-monitoring*, and *stress management*, while the included behavioral change techniques are *self-monitoring*, *nonspecific rewards*, *social support*, *nonspecific incentives*, *focus on past success*, *feedback and monitoring*, *reward and threat*, and *goals and planning*.

XSL•FO
RenderX

Figure 1. The gamification framework for exergaming by Berglund et al [8], showcasing how behavioral and psychological change techniques influence psychological and behavioral outcomes (reproduced from Berglund et al [8], with permission from the authors under the CC BY-NC 4.0 license).

Specific game elements used to impact health behaviors can also be sorted as different principles of gamification [8]. These principles state that the gamified system should provide *meaningful purpose* by aligning goals with the user's goal or interest, include *meaningful choice* by giving users agency over how they reach the goals, *support player archetypes* by leveraging individual characteristics of the user, clearly communicate *feedback* on how the user's actions affect their progress, and provide *visibility* over the user's progress. These principles can be used to sort specific game elements according to their purpose. For example, digital rewards and game levels can be used to communicate progress (visibility) and which actions cause progression (feedback).

The Heart Farming Exergame

The mobile exergame Heart Farming used in this study was developed by a research team of game developers and health care professionals [16,34]. It was developed using the gamification framework described earlier [8], with the characterizing goal of motivating individuals with heart failure to walk 10 minutes more per day [16].

The exergame uses walking as the main interaction to drive the game forward. To allow for precise tracking both outside and inside, the exergame uses augmented reality technology to track the phone's, and therefore the player's, movements by analyzing the view from the mobile phone's camera [16]. The theme of the exergame is a farm where the player can buy fields and

XSL•FO
RenderX

manage them by sowing, watering, and harvesting crops. All actions in the game have a set number of meters the player must walk in real life to complete the action. The distance needed to complete actions is based on the player's individual walking goals to balance the effort needed for people with different abilities.

To progress in the exergame, the player must create a plan with actions to perform and walk until all tasks are completed. The exergame also included an option called "autoplay," where a plan is created automatically, allowing the player to walk without actively planning their actions. The created plan will yield random crops and is not as effective in progressing in the game as actively planning. Multiple gamification elements are also used in the exergame as displayed in Table 1.

Table . Descriptions of key game elements in the Heart Farming walking–based exergame and how they utilize the gamification elements described by Berglund et al [8].

Gamification element	Game elements in Heart Farming
Leaderboards	A leaderboard displays the 3 players who gained the most experience points the previous day.
Levels of achievements or ranks	Levels are based on the player's experience points, and leveling up will also give access to new game contents.
Score systems	The number of meters the player has walked is used to reach their daily goal, set to how many meters would be needed for that player to walk for 10 minutes.
Experience points reward systems	All actions performed in the game are associated with a number of experience points the player earns when completing them. The amount of experience points earned for an action is the same for all players, even though the meters needed is determined by each player's own walking ability.
Item-granting system rewards	Players receive a gift each day when they open the exergame. The gift contains a random crop they can sell or store to use later.
Resources	Crops can be sold for money or stored to use for specific achievements, for example, to fulfill requirements for unlocking an animal or a neighbor. The money is used to buy new fields to sow new types of crops and expand the farm and progress in the game.
Achievement systems	Heart Farming has a mission book with animals that can be unlocked and placed on the farm by doing all the tasks specified by that animal. There are also neighboring houses placed on the farm that request certain crops, and selling the requested crops fills up a series of hearts that resets at the start of every week. If all hearts are filled before the end of the week, the player gains a decorative item on that neighbor's house.
Feedback messages	Sound effects are used to communicate completion of tasks and plans while the player is walking, as well as let the player know if the game is registering walking or not. Animations are used when achieving goals, such as a trophy appearing when reaching the daily goal or a heart expanding to show a new item when completing the requests from a neighbor.
Unlocking mechanisms	The crops the player can grow are limited by their current level and are unlocked when leveling up. Leveling up also unlocks some available actions in the game, such as being able to fish in the river or do squat exercises for extra crops.
Social or peer pressure	Players can send messages to other players in the form of emojis and can help each other by sending crops from their own farm.

Study Participants

The Heart-eXg study is registered on clinicaltrials.gov NCT05641662. In the Heart-eXg study, participants had to be diagnosed with heart failure by a physician, while participants in the HF-CC study had to self-report at least one of the following chronic conditions: heart failure, Parkinson disease, type 2 diabetes, stroke, or rheumatic disease. In both studies, participants had to be older than 18 years of age and in a stable condition. Participants who were unable to perform a 6-minute walk test or unwilling to use a smartphone to exergame were not included. Further exclusion criteria were severe cognitive dysfunction, anticipated short-term survival, or difficulties in understanding or reading the Swedish language. All participants provided informed consent before participating in the study. Participants in the intervention group of the Heart-eXg study and the participants in the HF-CC study were advised to walk 10 minutes more every day for 3 months using a mobile exergame. For further information, see the Heart-eXg study website [35].

All participants were introduced to the exergame during introductory sessions in the university, outpatient clinics, or offices of the patient organizations, where members of the research team provided oral instructions and assistance to install

XSL•FO
RenderX

the exergame on their mobile phones. When needed, the research team offered individual help to participants, including more detailed explanations or providing practical assistance with the exergame. In addition, participants were given step-by-step written instructions (manual) with QR codes to short instructional videos. The manual was provided in Swedish with simple vocabulary and illustrations of the exergame to facilitate the understanding of the different functions/steps in the exergame. During the first month of the intervention, participants also received follow-up calls weekly, where they could also raise questions or issues regarding the exergame. Participants in the intervention group of the Heart-eXg study and the participants in the HF-CC study were all advised to walk 10 minutes more every day for 3 months using a mobile exergame called Heart Farming. Interviews were conducted at the 3-month follow-up.

A purposeful sampling strategy was used to recruit participants with variation in their playing patterns (eg, participants who played extensively and others who primarily used the autoplay function), symptoms, age, and sex. This strategy was chosen to ensure variability within the sample and to capture rich, information-dense data that could illuminate different experiences relevant to the study aim.

Data Collection

The semistructured interviews were conducted by 3 researchers: one of the authors of this paper (HO), who was actively involved in the exergame's development as a game developer, and 2 health care professionals (a nurse and an occupational therapist) who were not involved as authors in the study. To mitigate bias, the interviewers did not have any pre-established relationship with study participants. If, for instance, one interviewer conducted follow-up phone calls, another researcher was assigned to perform the interview to maintain objectivity. Participants were not informed of HO's involvement in the development of the game to minimize the risk of response bias. To further minimize potential bias related to HO's involvement in developing the exergame, interviews were conducted using a semistructured guide, and reflexive discussions were held within the research team throughout data collection and analysis. In addition, data analysis involved multiple researchers who were not involved in the game's development, ensuring analytical triangulation and critical appraisal of interpretations.

The interview guide was divided into 3 different components, including the participants' experiences of playing the Heart Farming exergame, its influence on daily life and habits, and its different game elements. The development of the interview guide was based on the gamification framework developed by Berglund et al [8] to focus on how the gamification elements were experienced by the participants. The interview guide was also informed by Klompstra et al [13] to include the overall experience of using the Heart Farming exergame, including daily life and habits. The interview started with an introductory question ("Can you tell me about your experiences with playing this game for the last 3 months?") and continued with more specific questions about the exergame. Probing questions, such as "Could you elaborate?" "Could you provide an example?" or "What do you mean by saying that?" were used to facilitate the conversation and provide more accurate descriptions and rich information. A translated version of the interview guide is attached as Multimedia Appendix 1.

A pilot interview was first conducted with a participant to assess the clarity of the questions. After discussions with the research team, no further modifications were needed to the interview guide, based on this pilot interview. Due to the relevance of the information, the pilot interview was included in the data analysis. No field notes were kept by the interviewers. After conducting 12 interviews, information power was achieved because of clear redundancy with repetition of patterns in the data without novel additions [36]. To confirm this, 2 additional interviews were conducted. No additional new information came from the last 2 interviews.

The interviews took place at the participants' homes, one of the university campuses, or over the telephone, depending on the participants' preferences and the feasibility of traveling to and from the interview. In 2 phone interviews, the participants' spouses were present during the interview. During the analysis, the researchers made sure not to include any of the spouses' comments during the analysis, and only the answers from the participants were included. The interviews were recorded and transcribed for analysis, with the participants' consent. The length of the interviews varied between 18 and 69 minutes, with an average length of 35 (SD 15) minutes. All interviews were conducted in Swedish, which is the native language of both the participants and the interviewers.

Data Analysis

The data analysis was performed after the completion of data collection. A deductive content analysis following the steps suggested by Elo and Kyngäs [37] was applied. The framework introduced by Berglund et al [8] was used in a descriptive way to structure the analysis. A categorization matrix was developed based on the behavioral and psychological change techniques introduced in the framework and visualized in Figure 1.

During the preparation phase, all authors read through the transcribed interviews to familiarize themselves with the data and gain an in-depth understanding of the content. In the organization phase, the first 3 interviews were analyzed in parallel by 4 of the authors (MA, HO, LK, and AB), and the meaning units were allocated to the categorization matrix based on the gamification framework for exergaming. Thereafter, the remaining interviews were independently analyzed by the first 2 authors (MA and HO), who equally divided the work. To facilitate the coding process, the NVivo 15 (Lumivero) software was used. Finally, in the reporting phase, the findings were presented in alignment with the structured categories in a way that ensured clarity.

Methodological rigor was ensured by following the guidelines established for qualitative studies, introduced by Guba and Lincoln [38]. Analysis of triangulation was ensured through regular discussions between the authors, aiming at reaching a consensus considering the categorization of the data. The interviews were read multiple times to get an overall understanding of the content, and the parts of the interviews were constantly compared with the whole. Authentic quotations

XSL•FO
RenderX

were translated into English and presented as part of the results to increase the trustworthiness of the findings. The translation of the quotations was performed by the 2 first authors (MA and HO), and another researcher (LK) verified the accuracy of the translations.

Researcher Reflexivity

Two female researchers (MA and HO) conducted the biggest part of the data analysis presented in this paper. Both were PhD students employed at Linköping University. MA had a background in occupational therapy with a master's education, and HO was a game developer with a master's education as well. Their personal presumptions were that physical activity can be promoted by the Heart Farming exergame and that it can motivate participants to walk more on a daily basis. Both presumed that exergaming can influence daily life and habits.

Their contribution to developing the interview guide was equal. MA did not participate in data collection, while HO performed the interviews with 2 other health care professionals. The transcription of the interviews and the data analysis were mainly performed by MA and HO. To mitigate biases, part of the data analysis was performed by LK and AB, and a discussion took place considering the data analysis. All the authors gained closeness to the data by repeatedly reading the interview transcripts and listening to the original interview recordings. Reflexive discussions with co-authors AB, EB, AS, TJ, and LK supported MA and HO in enacting researcher reflexivity. AB and EB had a background in game development, AS and TJ had a nursing background, and LK had a background in public health. They were all experienced researchers in the field of exergaming and individuals with chronic conditions.

Ethical Considerations

The study is registered on clinicaltrials.gov with the ID NCT05641662. The Heart-eXg study and the HF-CC study were conducted in line with the Declaration of Helsinki. The Heart-eXg received ethical approval from the Regional Ethical Review Board in Linköping (Dnr 2021 - 03314), as did the HF-CC study (Dnr 2023-06398-01). Participants received written and verbal information about the study's aim before providing written informed consent to participate.

Participant privacy and confidentiality were carefully protected throughout the study. All collected data were anonymized prior to analysis, and any potentially identifiable information was removed from the transcribed interviews. The anonymized data were stored securely in a separate folder, accessible only to the research team. No financial or other forms of compensation were provided to the participants in this study. The manuscript and all supplementary materials do not include images or other content that could enable the identification of individual participants. As such, additional consent for publication of identifiable materials was not required.

Due to the sensitive nature of personal data and study materials, data cannot be made freely available. However, by contacting the corresponding author, procedures for sharing data, analytic methods, and study materials for reproducing the results or replicating the procedure can be arranged in accordance with Swedish legislation.

Results

Participant Details

A total of 14 participants were included in this study. Study participants were individuals with chronic conditions who had access to exergaming in the Heart-eXg or the HFCC study for 3 months. There were 8 (57.1%) women and 6 (42.9%) men with ages ranging from 67 to 92 (mean age 75.3, SD 8.9) years. Five (35.7%) participants were diagnosed with heart failure, 4 (28.6%) with Parkinson disease, 4 (28.6%) with rheumatic disease, and 1 (7.1%) with stroke.

Deductive Analysis

The data were structured based on the gamification framework by Berglund et al [8], which was partly confirmed by the data from the participants. Regarding the behavioral change techniques, 5 out of 8 could be fully confirmed in the data. The technique "focus on past success" was not used in the design of the exergame, and therefore, participants did not mention it. Participants experienced rewards but not threats as described in "Rewards and threats." "Nonspecific rewards" was also not used as a technique in the exergame, but participants experienced the social aspects of exergaming, and thus, it is described under social support. "Self-monitoring" could be found but was experienced as psychological rather than behavioral and was thus only included under the psychological change techniques.

Behavioral Change Techniques

Overview

These techniques have been identified as crucial to changing the behavioral outcomes of users in real life. Following the framework, behavioral change techniques include goals and planning, reward and threat, feedback and monitoring, focus on past success, nonspecific incentive, social support, nonspecific reward, and self-monitoring [8]. The exergame used multiple gamification elements, which could be mapped to the techniques according to Table 2. The analysis of the interviews revealed additional experiences connected to behavioral techniques. Although these experiences were not linked to specific gamification elements and are not included in the table, they are discussed further in the text.

XSL•FO
RenderX

Table . The behavioral change techniques experienced by people with chronic conditions after playing the Heart Farming walking–based exergame for 3 months and the gamification elements facilitating the techniques based on the deductive analysis using the gamification framework by Berglund et al [8].

Behavioral change techniques as described in the framework	Heart Farming gamification elements
Goals and planning	The daily goal, one of the exergame's *score systems*, gave participants a goal to reach and plan around. This assisted in structuring daily life and developing a gaming strategy.
Reward and threat	The *experience points*, *reward system*, and a*chievement systems* (eg, collecting animals) worked as rewards that motivated participants to walk more. No threats were mentioned by the participants.
Feedback and monitoring	*Feedback messages* assisted in planning their walk (walking progress) and motivated participants to continue walking to finish their plans (audio feedback).
Focus on past success	Not used as a technique and not mentioned.
Nonspecific incentive	The graphics and farming theme increased motivation.
Social support	The *leaderboard* was used to compare scores with the top 3 players.
Nonspecific rewards	*Social or peer pressure* (via the experience of an exergame community) is described under social support.
Self-monitoring	This was experienced as a psychological, not behavioral, technique.

Goals and Planning

Participants described how exergaming assisted in planning and structuring their daily routine. Participants preferred to exergame in the mornings, and they mentioned that they usually have coffee and breakfast directly afterward, as a form of reward for accomplishing their daily goal, which is one of the exergame's reward systems. Participants also combined their everyday activities such as visiting the doctor or doing grocery shopping with exergaming. Sometimes participants played inside the house, especially when the weather did not allow them to play outside.

> *I use it every time I go to the health care center and when I get a blood test, and I also use it when I go to my children and my grandchildren.* [67-year-old man]

They also mentioned the gaming strategy they used while exergaming and the use of the option to autoplay. Participants who used the game emphasized that they chose to prepare their plan for the game at home, so they did not have to interrupt their walking during the journey. The variety of options within the game provided was appreciated, and participants mentioned that they chose to harvest the farm and collect animals. Autoplay was used when participants wanted a simpler option or they did not want to interrupt their walking.

Reward and Threat

Participants mentioned that the digital rewards they received motivated them to walk more. Collecting animals was considered enjoyable, and players chose what actions to take in the exergame according to what was required (eg, harvest 3 fields) to get that animal.

> *And then I look at what I am missing, for example, do I need to get a new dog, horse or elephant? Then I work towards gaining them.* [67-year-old man]

Sometimes participants expressed the need to receive more rewards and money when selling to neighbors and more points when they walked further (after having achieved their daily goal). They mentioned that receiving more money for selling to neighbors might increase their motivation. They felt that if they wanted to walk more daily after achieving their daily goal, that would lead to more rewards.

Feedback and Monitoring

The feedback provided from the game assisted the participants in monitoring their behavior. Participants mentioned that knowing how much they walked during the day helped them in planning their walk for the rest of the day.

Participants generally liked the sound and noted that the sound effects helped to understand what happened in the game and made the process more interactive. The footsteps and farming sounds helped confirm if the camera was tracking the distance and that the sounds for reaching a goal or the end of a plan acted as both notification and reward.

> *You heard gravel when you walked and it also because a bit of a whip [referencing the expression "carrot and stick," in Swedish literally "carrot and whip"], and a little carrot as well, to have it there and know that it checks how much you walk.* [80-year-old woman]

If participants continued exergaming 3 times more after having reached their daily goal, which was 10 minutes of walking daily, the game reminded them to rest. Participants adhered to this suggestion.

Nonspecific Incentive

Increased physical activity and perceived improved health were considered motivating factors to continue exergaming. Participants mentioned that they noticed an increase in their walking speed, endurance, and the number of daily steps. Some even mentioned that they noticed weight loss because of increased physical activity, and thus, they felt more motivated to exergame.

XSL•FO
RenderX

> *It was not that I was a big fan of this specific game but measuring the daily physical activity and comparing it with how improved I felt [regarding physical activity level], that was what I liked.* [77-year-old man]

Participants highlighted that exergaming not only motivated them to walk more but also increased their appetite to go outside and enjoy nature. Exergaming provided them with the "little push," as mentioned by a 71-year-old woman, and thus, it gave them a purpose to go out and walk with the game, instead of being physically inactive inside.

Participants liked the graphics used in the game. A 68-year-old woman stated that "it's nice with these fields and the barns in the middle of it all." They also mentioned that they liked the option provided by the exergame to do squats instead of walking as an alternative that provided some variation. Participants also thought that the graphics were clear and made the game easier to understand, providing an incentive to continue with exergaming. However, participants also mentioned that the graphics were too childish. A 71-year-old man characterized the exergaming as "a game for children."

Participants generally liked the farming theme of the game. They referred to a sense of nostalgia while exergaming, and specifically, a 68-year-old woman mentioned "[It] can be fun to have a farm in your imagination." Participants mentioned that they liked this particular exergame, despite a lack of general interest in games, due to its graphics.

> *I don't have any interest in [games] but this, when I saw that auto-walking man out and walking, that I thought was a little fun, so I was immediately hooked on that.* [85-year-old man]

Social Support

Even though playing with others was an option within the exergame, some participants were not that interested in this function, while others did not have anyone to play with or did not know how to use this function.

Participants were interested in using the leaderboard as a form of competition by comparing their own scores with the top 3 players displayed on the leaderboard. They also suggested ways to make it easier to see your own score compared to those of the other players, as they did not always make it to the top 3.

> *Yeah or end up in the top three on the leaderboard. It could maybe be a top ten list. So, you could see roughly where you are—or yeah, if you're not even in the top ten, then depending on how many individuals are playing, maybe you'd feel like making an effort, or not?* [67-year-old man]

Socializing and creating a community around exergaming was a nondigital reward mentioned during the interviews. Some participants who met during the introduction session reported that they took the initiative to organize group lunch meetings to discuss the game and walk together.

> *I think it has been very fun and therefore I think that the other ladies will also continue exergaming, and then I thought we could maybe go for a walk. We can walk, and after we can go and have a coffee, and the ones who can't walk that fast can rest more often.* [71-year-old woman]

Psychological Change Techniques

Overview

These techniques in the exergame aim to change the psychological outcomes of the users in real life. According to the framework, psychological change techniques include providing information, self-monitoring, and stress management. Even though the exergame was not designed to use the technique to provide information, participants experienced different levels of understanding of the exergame based on the information they received from the research team. Self-monitoring was used by the exergame and was thus mentioned by the participants. Stress management was not used in the design of the exergame; however, participants still mentioned stress and pain relief from getting immersed in the exergame. The gamification elements used in the exergame can be mapped to the techniques according to Table 3.

Table . The psychological change techniques experienced by people with chronic conditions after playing the Heart Farming walking–based exergame for 3 months and the gamification elements facilitating the techniques based on the deductive analysis using the gamification framework by Berglund et al [8].

Psychological change techniques as described in the framework	Heart Farming gamification elements
Provide information	The exergame did not use this technique. However, different levels of familiarity with the exergame were reported as an important factor in the experience of the exergame.
Self-monitoring	*Levels of achievements or ranks* increased motivation to progress in the exergame.
Stress management	Although stress management was not used as a technique, participants reported experiencing stress relief when exergaming. Some factors (eg, exergaming in public) unintentionally created stress for the participants.

Provide Information

The exergame did not use a technique to provide any health information, nor was this mentioned by the participants. However, different levels of understanding of the exergame were reported as a factor affecting their exergame experience and are thus presented under this section. Participants with previous experience with games found the exergame to be

XSL•FO
RenderX

intuitive and easy to get into, while participants who were less familiar with technology found it to be complicated and hard to understand. A participant referred to her old age as a possible reason for not understanding the exergame.

Self-Monitoring

Participants found enjoyment in making progress in the game. The different levels they could reach in the game served as motivation and a goal to reach when playing.

> *I probably like these different levels the best, it has been the most fun to go after them.* [77-year-old man]

Participants also liked receiving a trophy for reaching their daily goals. Participants mentioned sometimes reaching their daily goal 2 or 3 times.

> *Yes, I remember, it has happened a few times maybe that I have gotten many of these flags like when I have walked far now and then, and then I feel "wow, that was many of those flags.*" [80-year-old woman]

Stress Management

The exergame did not use a technique to aid in stress management. However, playing the exergame could serve as stress relief, and specifically, an 80-year-old woman mentioned that "*it's a relaxation at the same time that I need it.*" Participants highlighted the role of exergaming in relieving pain, as immersion in the exergame made it easier to distract from pain.

> *I absolutely feel like it has only felt good, and then it can also be good if you have a day with a lot of pain, then you also forget a little, when you are like busy with these animals […] then I actually forget the rest a bit.* [77-year-old man]

Participants also reported factors that unintentionally led to increased stress. Sometimes they thought that the game did not accurately measure how far they walked or that the exergame did not react to finger presses. Some worries were also expressed about what other individuals thought when they were exergaming in public.

> *So, I have to walk like this, and then I have gotten the question "are you recording me?" from individuals nearby.* [68-year-old woman]

Discussion

Main Contributions

This study aimed to explore the experiences of behavioral and psychological change techniques used by a walking-based exergame. Principal findings indicated that exergaming provided motivation to walk by using goals and rewards, and participants found value not only by progressing and getting rewarded in the exergame but also through experiences of getting out in nature or finding community with others. Participants found that exergaming assisted them in planning and structuring their daily routines, often playing in the mornings and integrating it with activities, such as visiting the doctor or grocery shopping. Several challenges were mentioned, including holding the phone and handling the camera or playing in public. Participants appreciated having support from the research team when being introduced to the exergame. Health-related impairments, such as knee problems, influenced the experience of exergaming. However, exergaming could also provide a distraction from pain.

Individuals' capacities can influence their experience with exergaming, which includes their attitude toward exergaming, exergaming skills, and health-related impairments [27]. This was emphasized by the participants in our study, as they believed that their old age might have affected their capacity for exergaming. Previous qualitative studies indicated that exergaming can be experienced as a fun, engaging, and enjoyable activity for individuals with chronic conditions [13,39,40]. Participants in our study also enjoyed exergaming, although some were not as interested in exergaming and reported limited experiences with games prior to participating in this study. For an exergame to be experienced as an enjoyable activity, the skills and previous knowledge of participants should be evaluated [41]. Participants' level of knowledge and skills with technology should be taken into consideration, since familiarization with technology can differ greatly for older adults [41]. For example, individuals may worry about their ability to play if they find the technology to be very advanced [14,41,42]. To overcome this challenge, individuals in our study received a structured familiarization with the exergame, including an introductory session and follow-up calls from the members of the research team who aimed to provide sufficient support, instruction, and feedback. Similar findings have been reported in other studies, highlighting the importance of familiarization when introducing exergames to older adults [27].

Social connection is a strong motivator for physical activity, especially in older adults [42-45], and could provide motivation to increase physical activity [41]. The exergame in our study included some support for social interaction within the exergame, where players could send emojis and crops to each other. However, participants in our study did not use the social functions in the exergame due to a lack of interest, difficulty understanding these functions, or not having anyone to play with. A previous study found a positive correlation between the number of messages players send to each other and their physical activity, highlighting the potential of social interaction within an exergame [46].

Participants in our study created social groups outside of the exergame where they walked together using the exergame but did not use the social interaction within the exergame. In another study, they also found that observing each other while exergaming can motivate players to play, even when playing single-player exergames [40]. Culture could also have an impact on how socialization affects exergame opportunities, as individualistic cultures are less likely to feel embarrassed, while older adults in other countries might experience discomfort from feeling judged by others [27]. In our study, there were also participants who stated that they are not interested in playing with others, as well as participants who expressed discomfort from playing the exergame in public, where other individuals could see them. This should also be considered when designing an exergame.

XSL•FO
RenderX

The participants of our study emphasized that exergaming is easy to incorporate into their daily lives, and they could combine daily activities, such as grocery shopping or doctor visits, with exergaming. In addition to walking 10 minutes more each day, study participants also mentioned that they integrated their daily activities with exergaming. Creating new routines is associated with increased adherence to exergaming [13]. To avoid interrupting their daily activities by stopping to play on the phone, participants of our study preferred to complete all their planning before they started walking and to handle all their rewards at the end of the walk. This indicates a preference for separating exercise from gameplay, which other exergames for older adults have utilized before [47].

Having the opportunity to exergame outdoors was considered an asset by the participants in our study. Exergaming motivated participants to go outside and engage with nature, exploring their surroundings instead of remaining inactive at home. However, individuals whose hands were unsteady or shaking while holding the phone could cause inaccurate measurements. Although participants in our study were offered armbands that could hold their phones without blocking the camera, this was not seen as ideal, and participants expressed a desire for another solution that would allow them to keep the phone in their pocket while walking, something that was not possible, as the technology used requires the phone's camera. The alternative solution of using GPS instead introduces the issue of imprecise tracking in indoor environments, especially when walking short distances [16]. As participants used the exergame indoors under certain circumstances, for example, during bad weather, the ability to do so should still be considered when deciding what technology to use for this type of exergame.

Health-related impairments can impact individuals' experience of exergaming [27]. The participants in our study were diagnosed with different chronic conditions (including stroke, chronic heart failure, Parkinson disease, and rheumatic disease) and varied in terms of symptom severity and disease progression. In our study, exergaming was considered an effective distraction from pain. This finding aligns with previous studies that have highlighted the significant role of exergaming in distracting from physical exertion and everyday life [10,27,38]. An RCT that compared brisk walking with exergaming in older adults also indicated that exergaming produced a lower level of perceived exertion, possibly due to distractions provided through exergame graphics or sound effects [47].

The results of our study show that future exergame design for individuals with chronic conditions should prioritize accessibility, adaptability, and meaningful integration into daily life. A systematic review by Cugusi et al [22] shows that exergames combining physical activity with cognitive engagement can enhance physical, cognitive, and mental health outcomes in older adults and people with chronic diseases while also supporting motivation and adherence. Tailored exergaming solutions that can be played at home, with adjustable difficulty levels and clear, intuitive feedback, are particularly relevant for addressing mobility, balance, and long-term engagement needs in clinical populations such as those with heart failure or dementia [30,48]. In line with these findings, it is essential to assess individuals' skills and prior experience before developing or implementing exergames. Designing exergames that are safe, person-centered, and adaptable to varying functional abilities is crucial for supporting sustained participation among individuals living with chronic conditions [34].

Strengths and Limitations

The strengths and limitations of this study ought to be taken into consideration when interpreting the results. The target sample included individuals with diverse chronic conditions, which differ in terms of symptom severity and illness progression. This provides a deeper understanding of the topic under investigation. In terms of transferability, the results may mirror the Swedish older population with certain chronic conditions, but there may be cultural differences, age differences, and differences if the game were to be used in other chronic conditions. Future studies are required to determine whether condition-specific exergames should be developed.

The use of this gamification framework assisted in structuring the analysis of the data. However, its use might have led to the absence of some important aspects discussed during the interviews. A few parts of the framework were not confirmed by the data, including the focus on past success, nonspecific rewards, threats, and self-monitoring as behavioral techniques. Although this framework underpinned the development of the Heart Farming exergame, it can be considered a broad, overarching model for game design. Therefore, it is understandable that not all the techniques described in this framework are employed in the Heart Farming exergame. It is also important to consider that the interviews were conducted by one of the game developers, which might have introduced potential biases. However, the data analysis was conducted by researchers with diverse academic backgrounds and clinical experience, which may have strengthened the trustworthiness of the findings.

While participants made promising statements regarding the effect the exergame had on their health, this study did not collect or analyze any potential health effects. To draw any conclusions about the actual health benefits of this type of exergame, future studies should include quantitative data on measurable health indicators to analyze how they are affected by exergaming.

Conclusions and Implications

This study contributes to the exergaming literature by examining behavioral and psychological change techniques from the perspective of individuals with chronic conditions. To our knowledge, this is the first qualitative study to apply this gamification framework within this population. Considering the results of this study in combination with previous findings, exergaming can be a promising approach to improving physical activity and achieving behavioral change in individuals with chronic conditions. Considering individuals' needs, previous knowledge of exergaming, interests, and illness progression is critical when developing and using exergames in health care. By increasing understanding of how game elements are experienced and how they influence health-related behavior, the findings of this study may inform the development of exergames that are better tailored to users' needs.

XSL•FO
RenderX

Looking ahead, future studies with more diverse populations and larger sample sizes should focus on the evaluation of the impact of behavior-change techniques used in exergames to maximize the positive effects of exergaming in individuals with chronic conditions. It would also be valuable to explore whether different behavior-change techniques are required depending on the symptoms of diverse chronic conditions.

Acknowledgments

According to the GAIDeT (Generative AI Delegation Taxonomy; 2025) [49], the following tasks were delegated to generative artificial intelligence (GAI) tools under full human supervision: proofreading and editing. The GAI tool used was Grammarly. Responsibility for the final manuscript lies entirely with the authors. The authors would like to thank everyone who participated in this study.

Abstract

Background: Patients with chronic stroke commonly experience motor and cognitive impairments, with diminished quality of life. Their participation in rehabilitation is often limited by long travel distances and low motivation. Given the health benefits of multimodal exercise, with the accessibility and engagement offered by interactive exergames, delivering such interventions in a remote format may help overcome common barriers, and enhance health outcomes.

Objective: This study aimed to assess the content validity and feasibility of a prototype home-based multimodal exergame for patients with chronic stroke.

Methods: This study comprised a cross-sectional study for content validity and preliminary usability evaluation (part 1), and a prospective single-arm feasibility study with blinded assessors (part 2). In part 1, the content validity of a prototype home-based multimodal exergame was evaluated by 5 experts. Moreover, 5 patients with chronic stroke were enrolled to evaluate the preliminary usage of the game prototype. Enjoyment, rating of perceived exertion, user feedback, satisfaction, and safety were assessed. In part 2, 9 patients with chronic stroke were enrolled to evaluate the feasibility of home-based multimodal exergame (mean age 53.67, SD 11.70 years, and mean time post stroke onset 75.00, SD 101.99 months). Participants performed the intervention for 60 min/day, 3 days/week, for 6 weeks. Feasibility outcomes, including adherence, adverse events, motor function, cognitive function, and enjoyment of the program, were determined.

Results: In part 1, the content validity index for the overall program was 0.82. The average total enjoyment score was 47.80 out of 56 (SD 7.50), the rating of perceived exertion was 13.40 out of 20 (SD 0.55), the satisfaction score was 8.60 out of 10 (SD 1.34), and no adverse events were reported. In part 2, after the 6-week intervention, positive changes were observed in global cognition (mean difference=−3.44, 95% CI −5.66 to −1.23; *P*=.007) and executive function (mean difference=38.43, 95% CI 3.78-73.08; *P*=.03) compared with baseline. Participants reported a consistently high level of exercise enjoyment throughout the training period. The average exercise adherence rate was 85.19%, and no adverse events were reported throughout the training.

Conclusions: These findings suggest that the prototype home-based multimodal exergame was a valid, enjoyable, accessible, and user-friendly rehabilitation approach. Unlike conventional home exercise programs, this multimodal exergame integrates physical and cognitive training into an interactive remote rehabilitation platform for individuals with chronic stroke. The intervention showed potential benefits for cognitive outcomes, maintained enjoyment, and promoted exercise adherence, and reported no adverse events throughout the intervention period. These findings provide preliminary evidence that home-based multimodal exergame may support long-term rehabilitation participation. Importantly, the program may address barriers to stroke rehabilitation, including transportation limitations, restricted access to rehabilitation services, and low long-term adherence, particularly among individuals living in underserved or remote areas.

Introduction

Globally, stroke is recognized as a leading cause of mortality and a major contributor to the burden on public health systems [1]. Findings from the Global Burden of Disease database revealed that disability-adjusted life years due to stroke increased by 32% from 1990 to 2019, reaching approximately 140 million [2]. Additionally, approximately 30% - 40% of survivors of stroke experience cognitive or motor impairments that contribute to long-term disability [3]. These poststroke impairments have been shown to adversely affect quality of life and functional independence, increase dependence in activities of daily living, and limit social participation [3,4]. Therefore, comprehensive rehabilitation strategies are essential to address multiple domains of recovery and improve health outcomes in survivors of stroke.

It has been well-established that poststroke rehabilitation and multimodal exercise are essential in improving health outcomes and reducing long-term complications [5,6]. Several studies have demonstrated that multimodal or multicomponent exercise programs incorporating balance, coordination, resistance, and aerobic training can enhance various aspects of physical function and activities of daily living [7-9]. Although the health benefits of physical activity and exercise are well-recognized, several survivors of stroke are physically inactive [10]. A prospective longitudinal cohort study reported that nearly 40% of participants were physically inactive at the 1-year follow-up after stroke [11]. Additionally, adherence to rehabilitation programs tends to decline over time, particularly in long-term interventions in survivors of stroke [12]. The limitation of engagement in physical activity and rehabilitation among patients with stroke is partly due to long travel distances, limited transportation access, shortages of health care providers, and low motivation [13,14]. These barriers can substantially limit long-term rehabilitation participation, underscoring the need for interventions that are accessible, engaging, and effective in promoting motivation and adherence. To address these challenges, particularly the need for long-term engagement, the integration of augmented feedback has emerged as a crucial strategy for improving both motor outcomes and motivation in individuals with cerebrovascular injury [15-17]. Clinical studies in patients with stroke have also indicated that training with augmented feedback improved walking speed and distance [18-20]. Therefore, multimodal exercise that is accessible, safe, enjoyable, and provides augmented feedback may promote health benefits and improve adherence to regular physical activity among patients with chronic stroke.

Technology-based interventions (eg, exergame) have been incorporated into medical treatments, offering accessible and motivating rehabilitation strategies [15,21-23]. Research evidence demonstrated that exergaming has positive impacts on balance and functional mobility in patients with chronic stroke [15]. Apart from the beneficial effects of exergaming on physical health, its interactive characteristics promote motivation among users, leading to greater adherence compared with regular exercise [21,22], and making it enjoyable and effective for patients with stroke [24]. Previous studies demonstrated that home-based exergame improved physical outcomes and health-related quality of life in older adults [5] and patients with stroke [25,26]. A recent study by our research group demonstrated that home-based interactive physical-cognitive exergame via a computer vision-based platform was usable and enjoyable for older adults both with and without cognitive impairment [23]. Despite these promising findings, evidence regarding home-based multimodal exergame interventions specifically designed for individuals with chronic stroke remains limited. Existing rehabilitation studies in survivors of stroke have largely focused on physical exercise interventions [9] and clinic-based rehabilitation programs [9,27]. Furthermore, recent evidence has highlighted the importance of developing strategies that promote long-term exercise persistence and adherence among survivors of stroke [28]. To the best of our knowledge, studies investigating multimodal exercise delivered via an exergame platform for patients with chronic stroke in home-based or remote settings remain limited. Therefore, this study aimed to evaluate the content validity and feasibility of a novel home-based multimodal exergame integrating physical-cognitive exercise, gamification, augmented feedback, and computer vision-based monitoring for individuals with chronic stroke. Given the well-established health benefits of multimodal exercise and the increasing accessibility of technology-based interventions, it is hypothesized that a home-based multimodal exergame would be valid and feasible for individuals with chronic stroke.

Methods

Study Design

This study consists of two parts: (1) the evaluation of the content validity index and the preliminary usage of a prototype home-based multimodal exergame using a cross-sectional study design, and (2) the evaluation of the feasibility of the home-based multimodal exergame for patients with chronic stroke using a prospective single-group study design.

Inclusion and Exclusion Criteria

The inclusion criteria were (1) diagnosis of ischemic or hemorrhagic stroke at least 6 months before enrollment; (2) age between 20 and 80 years; (3) normal cognitive function, as determined by the Mental State Examination T10 score [29,30]; and (4) ability to see a notebook monitor screen from a distance of at least 60 cm, with or without corrective lenses. The exclusion criteria were (1) severe spasticity (Modified Ashworth Scale ≥3), (2) neglect or impaired communication, and (3) any comorbidity or complication that precluded participation in the training program.

Participant Characteristics and Sampling Procedures

The study participants consisted of 2 groups involved in different phases of the study: expert reviewers in study part 1 and patients with stroke in study parts 1 and 2. The expert panel was recruited to evaluate the content validity of the prototype home-based multimodal exergame. Moreover, 5 experts with experience in game and web-application design, health innovation, stroke rehabilitation, neurocognition, and physical-cognitive training participated in the content validation process.

XSL•FO
RenderX

For the preliminary usability evaluation and feasibility study, demographic characteristics of the participants, including age, sex, time post onset, paretic side, and education level, were recorded. Patients with chronic stroke were recruited using convenience sampling through online and offline advertising to local communities, hospitals, rehabilitation centers, and social media advertisements. Participant screening and outcome assessments were conducted by blinded assessors.

Sample Size, Power, and Precision

As this study was designed as a preliminary usability and feasibility study, a formal power analysis was not performed. The intended and achieved sample sizes were 5 participants with chronic stroke for the preliminary usability evaluation and 9 participants for the feasibility study. Sample sizes were determined pragmatically based on feasibility and the exploratory nature of the study. No interim analyses or stopping rules were applied.

Procedure

A novel home-based multimodal exergame was developed specifically for patients with chronic stroke by integrating the existing evidence from the literature [31,32] and adapted from our previous studies [33,34]. Additionally, a human-centered design methodology was applied to the development of the game-based exercise prototype [35], incorporating brainstorming sessions with the research team. Based on the synthesized evidence, a multimodal exergame-based intervention was applied to promote health performance, especially physical and cognitive aspects, among patients with stroke. The prototype of the multimodal exergame consists of physical exercises combined with cognitive training, including seated exercises, sit-to-stand training, proprioceptive neuromuscular facilitation (PNF) pattern-based exercises, balance training, aerobic exercise, and cognitive training targeting attention, memory, and executive function. Overall movements in multimodal exercise included shoulder flexion and extension, shoulder horizontal abduction and adduction, elbow flexion and extension, scapular protraction, lateral trunk flexion, hip flexion with knee flexion, hip abduction and adduction with knee flexion, knee flexion and extension, ankle dorsiflexion and plantarflexion. Gamification principles were integrated into the exergame to enhance user engagement, motivation, and adherence during exercise sessions. The overall structure and features of the game, including its objectives, gameplay mechanics, and graphical user interface, were systematically integrated and refined based on practical considerations to develop a functional prototype of the game-based training system. The exergame incorporated gamification features, including goal setting, rewards, interactive elements, and cognitive engagement, along with augmented feedback delivered through visual and auditory cues. Visual feedback (eg, on-screen movement tracking and progress bars) and auditory feedback (eg, sounds indicating success or errors) were integrated into the game-based design. Game-based concepts were applied to develop the digital exercise prototype using the Unity 3D game engine, incorporating computer vision techniques based on BlazePose for real-time pose estimation and user-system interaction. The system operates on a standard personal computer or notebook equipped with a webcam, without requiring additional wearable sensors. The system is semiautomated, enabling motion tracking and feedback without continuous therapist input. User-system interaction and feedback are achieved through real-time tracking of user movements, with feedback provided during gameplay as well as performance outcomes (eg, scores and errors) at the end of each game. The summary of the design and characteristics of home-based multimodal exergame is presented in Figure 1. Moreover, the novel home-based multimodal exergame includes a camera feature that displays participants' movements, which can be monitored remotely through software such as Zoom (Zoom Communications) meetings. This functionality enables health care providers to remotely observe and assess the rehabilitation progress of patients with stroke at home or in remote locations, as illustrated in Figure 2.

The content validity of the developed intervention was assessed to determine whether its components accurately represent the intended construct for a specific clinical or research purpose. This evaluation was conducted by a panel of experts who rated each item based on its relevance and representativeness within the content domain. The content validity of the program was assessed by 5 experts who have expertise in the game and web-application design, innovation for health, stroke rehabilitation, neurocognition, and physical-cognitive training using the item-objective congruence (IOC) method. An overall IOC score greater than 0.75 for the intervention program was considered an acceptable content validity [36].

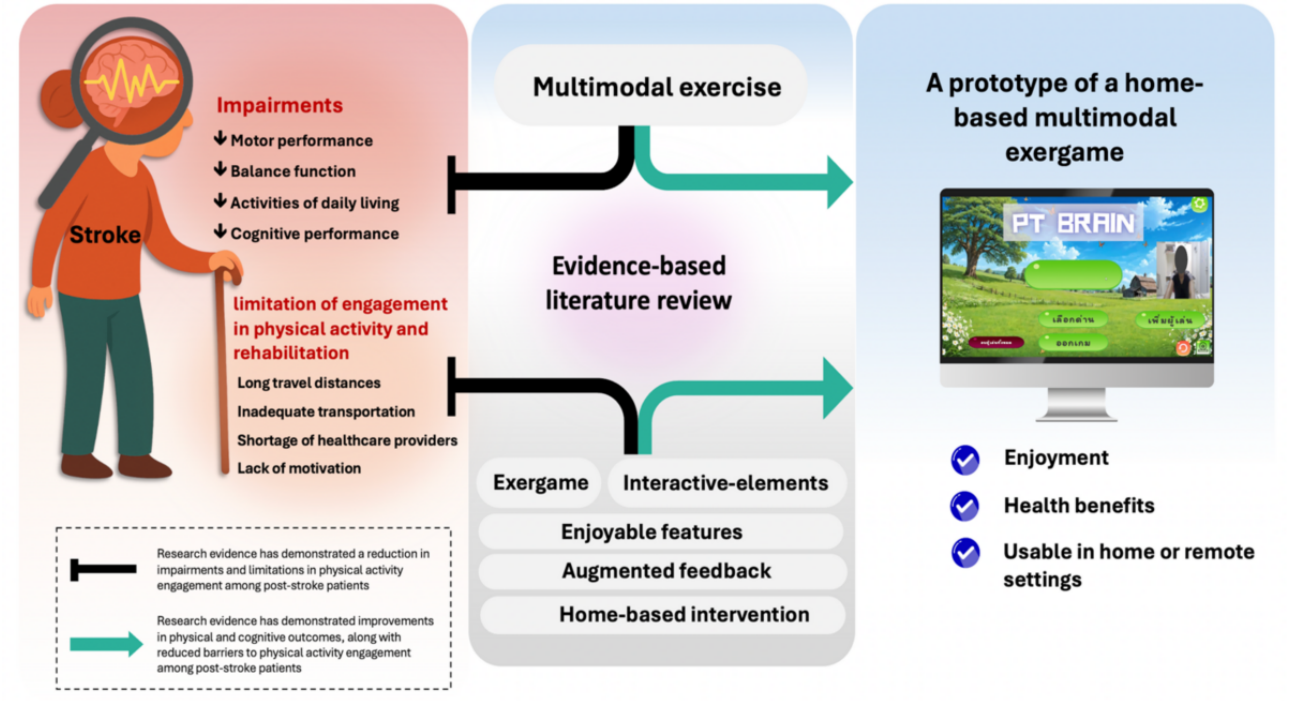
For the preliminary usability evaluation, written informed consent was obtained from all eligible participants before study participation. Demographic characteristics of participants, including age, sex, time post onset, paretic side, and education level, were recorded. A total of 5 patients with chronic stroke were enrolled to evaluate the preliminary usage of the game prototype. Participants meeting the eligibility criteria performed multimodal exergame. The multimodal exergame included a 10-minute warm-up and cool-down period, and 50 minutes of exercise. Participants were instructed to attend 2 sessions in a single visit to the research center. In session 1, participants were familiarized with the exergame via an in-game tutorial that provided detailed instructions on the correct performance of each exercise program. Following the tutorial, participants practiced a short sample of the exergame under the supervision of a physiotherapist. After the familiarization session, all participants were asked to rest until their perceived fatigue returned to baseline levels. In session 2, participants performed the multimodal exergame in the training room under the supervision of physiotherapists who remotely monitored them from the monitoring room. During exercise, participants were instructed to share their exergame desktop screen with the therapist via the Zoom meeting application. Additionally, the camera feature and computer vision-based system in the developed multimodal exergame allowed therapists to monitor exercise accuracy and safety.

After evaluating the content validity index and the preliminary usage of prototype home-based multimodal exergame, consensus from the expert and research team on the concept and design, along with comments and feedback, was used to refine the final

XSL•FO
RenderX

version of the home-based multimodal exergame. The finalized version of the home-based multimodal exergame was used to evaluate the feasibility of the program in part 2 of the study.

Figure 1. The summary of the design and characteristics of home-based multimodal exergame for patients with chronic stroke.



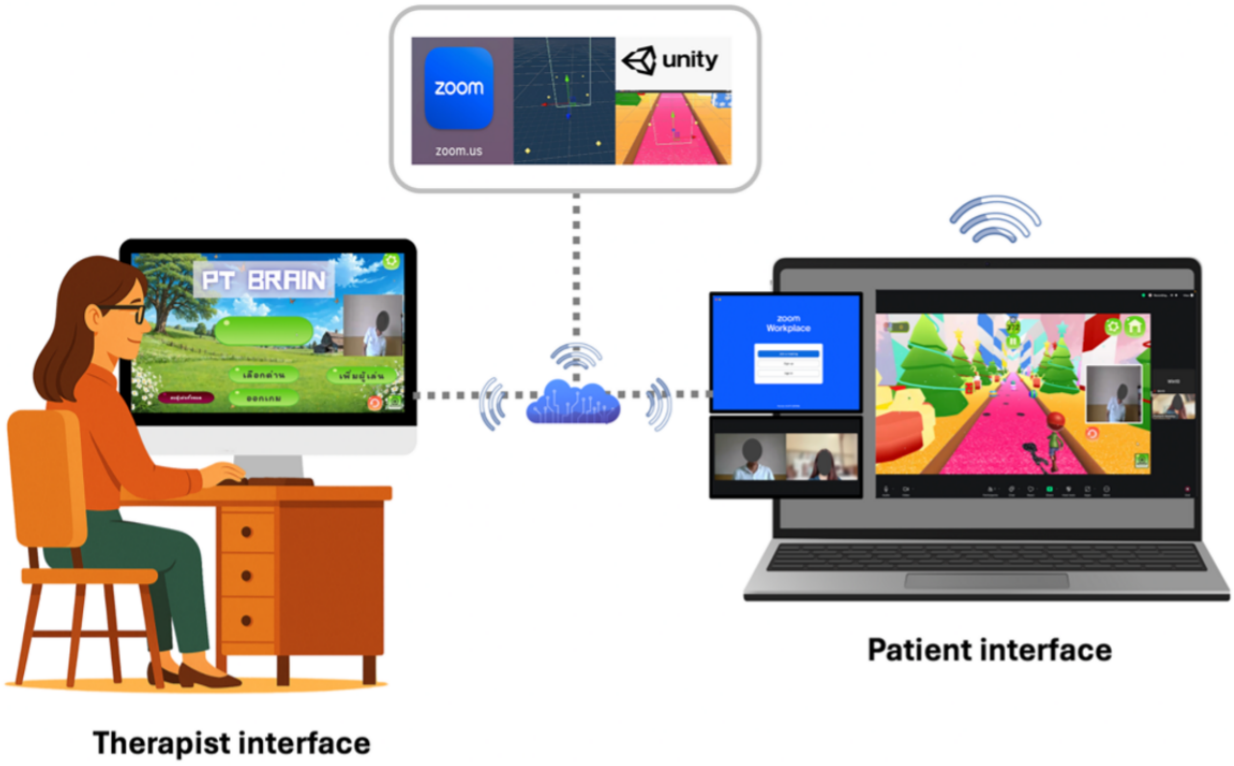


Figure 2. A framework of home-based multimodal exergame for patients with chronic stroke at home or in remote locations.

For the evaluation of the feasibility of the home-based multimodal exergame, written informed consent was obtained from all eligible participants before participation in the study. This feasibility study was a prospective single-arm trial with blinded assessors conducted over a 6-week home-based intervention. A total of 9 patients with chronic stroke were recruited using convenience sampling to evaluate the feasibility of the exergame, applying the same inclusion and exclusion

XSL•FO
RenderX

criteria as in part 1. Participants who met the eligibility criteria performed the intervention for 60 min/day, 3 days/week for 6 weeks. The home-based multimodal exergame is designed to be performed primarily in a seated position, with progression to functional tasks. The intervention comprises seated exercises, sit-to-stand training, PNF pattern-based exercises, balance training, aerobic exercise, and cognitive training. The multimodal exercise incorporates a range of joint movements and motor patterns involving the upper extremities, lower extremities, and trunk, with an emphasis on coordinated and functional movements such as alternating upper and lower limb movements, multidirectional reaching, weight shifting, trunk control, and sit-to-stand transitions. All exercises were performed for 5 repetitions per set for 2 sets, followed by 2 combined exercise sets (COMBO-SETs). The first COMBO-SET comprised alternating arm and leg lifts combined with forward arm and leg extensions, performed for 1 minute in level 1 and 2 minutes in level 2. The second COMBO-SET consisted of alternating boxing movements combined with alternating heel-toe tap steps, performed for 40 seconds in level 1 and 80 seconds in level 2. In addition, preparatory sit-to-stand training and sit-to-stand training were performed for 5 repetitions per set for 2 sets in level 1 and 3 sets in level 2. Cognitive tasks are embedded within the exergame to simultaneously engage attention, memory, and executive function. A summary of the home-based multimodal exergame is presented in Table 1. Before the home-based training, participants were asked to practice with a researcher to ensure they could perform the intervention correctly and safely. During the home-based intervention, participants were instructed to self-monitor their vital signs (eg, heart rate), rating of perceived exertion (RPE), and any adverse events. Participants were educated to recognize warning signs such as dizziness, loss of balance, or unusual symptoms, and were instructed to immediately stop exercising and notify the research team if such symptoms occurred. A researcher (PN) met with the participants via Zoom at the end of weeks 1, 2, and 4 to monitor their training. Each participant was assigned a unique Zoom ID, and all sessions were conducted on a one-to-one basis to ensure privacy and confidentiality. During the monitoring sessions, participants were instructed to share their screens with the researcher. In addition, the integrated camera function and computer vision-based system enabled real-time monitoring of exercise performance, allowing the researcher to assess movement accuracy and safety. The training sessions were recorded with participants' consent. In addition, all recorded and collected data were anonymized and securely stored. Family members were permitted to stand beside participants during exercises at home.

Table . A summary of the consensus features of exergame prototype (characteristics and descriptions of the exergame prototype) for patients with chronic stroke.

Characteristics	Descriptions
Overall features	
Program topic	• Prototype of a home-based multimodal exergame
Targeted users	• Patients with chronic stroke
Core components	• A multimodal exergame designed for home-based or remote use, consisting of (1) warm-up and cool-down phases (10 min), (2) main exercise phase (50 min) including seated exercises, sit-to-stand training, PNF[a] pattern-based exercises, balance training, aerobic exercise, and cognitive training. Two levels of difficulty (level 1 and level 2) are available, adjustable based on individual ability
Procedure used	• Designed to enhance both physical and cognitive health outcomes by promoting user engagement through online videos and interactive elements
Game type	• Health promotion game involving multimodal exercise
Game characteristics	
Physical components	• Game 1: to enhance physical activity in upper and lower extremities • Game 2 - 5: to enhance upper extremities and trunk movement
Cognitive components	• Game 1: to enhance attention domain • Game 2: to enhance working memory, attention, and visuospatial ability • Game 3: to enhance executive function, interference inhibition, and attention domains • Game 4: to enhance cognitive flexibility and attention domains • Game 5: to enhance executive function, working memory, visuospatial ability, and attention domains

XSL•FO
RenderX

Characteristics	Descriptions
Overall features	
Rules and levels	 • Game 1: follow movement guidelines in online videos. Exercises: seated exercises, sit-to-stand training, PNF pattern-based exercises, balance, and aerobic exercise Level 1: 5 repetitions/set, 2 sets of exercise with combined exercise sets (alternating arm and leg lifts combined with forward arm and leg extensions: 1 min; alternating boxing movements combined with alternating heel-toe tap steps: 40 s). Level 2: 5 repetitions/set, 2 sets of exercise with combined exercise sets (alternating arm and leg lifts combined with forward arm and leg extensions: 2 min; alternating boxing movements combined with alternating heel-toe tap steps: 80 s, preparatory sit-to-stand training and sit-to-stand training for 5 repetitions/set for 3 sets) • Game 2: memorize a sequence of numbers displayed on a clock (eg, 5-11-3) and perform corresponding movements by directing their trunk and arm toward each number in the memorized order (eg, move to 5, then 11, and 3) Level 1: 3 Question; Level 2: 4 Question • Game 3: memorize fruit and vegetable images within a given time and then collect the corresponding images they remembered, alternating with collecting coins. Level 1: Remember 5 pictures in 10 s, 2 nonrelevant pictures Level 2: Remember 5 pictures in 8 s, 5 nonrelevant pictures • Game 4: move as quickly as possible to respond to the target based on the image criteria (eg, move toward the target when a mole appears; remain still when a bomb appears) Level 1: Conditions of cognitive stimuli are mole and bombs; the rate of presented cognitive stimuli is 0.2 Level 2: Conditions of cognitive stimuli are mole, mole with hat, and bombs; the rate of presented cognitive stimuli is 0.4 • Game 5: remember the characteristics of the ball within a given time, solve mathematical puzzle questions displayed on the screen, and alternate with collecting the balls that matched the ones they had memorized Level 1: 7 Questions (12 s/question), rate of presented stimuli is 0.2 Level 2: 7 Questions (8 s/question), rate of presented stimuli is 0.4

XSL•FO
RenderX

Characteristics	Descriptions
Overall features	

Game mechanics	• The program incorporates gamification to support engagement and adherence:
	  • Goal setting: clear exercise goals to encourage consistency and motivation
	  • Progress bar: visual progress bars help participants monitor their performance
	  • Scoring system: real-time performance feedback boosts motivation and supports cognitive engagement
	  • Visual and auditory feedback: on-screen cues and sounds provide immediate feedback on performance, reinforcing learning and motivation
	  • Interactive elements and cognitive engagement: cognitively engaging tasks and interactive elements are purposefully designed to sustain attention and encourage continuous participation throughout the intervention period

Setting	• Indoor space with a plain white background, approximately 3×2 meters in area.
Device	• Computer or notebook
Sensor and system	• Computer vision-based system
Play time	• 60 min

[a]PNF: proprioceptive neuromuscular facilitation.

Outcome Measures

Study Part 1

The usability parameters assessed included enjoyment, RPE, user feedback, satisfaction, and safety. Enjoyment during participation in the multimodal exergame was measured using the Physical Activity Enjoyment Scale (PACES) [37,38]. The PACES comprises 8 items that evaluate enjoyment on a 7-point Likert scale ranging from 1 (strongly disagree) to 7 (strongly agree). Total enjoyment scores were calculated, with higher scores indicating greater enjoyment [37]. For RPE assessment, perceived exertion was measured using the Borg 6 - 20 scale [39,40], and ratings of perceived exertion during the exercise session were recorded. Both positive and negative feedback including functionality, software, exercise components, program design, game rules, and difficulty level were recorded and documented to inform program refinement. For satisfaction, participants were instructed to rate their overall satisfaction after using the multimodal exergame on a scale from 1 (very dissatisfied) to 10 (very satisfied). Additionally, safety outcomes were monitored and evaluated through the reporting of adverse events. Any adverse events or incidents occurring during exercise (eg, fatigue, falls, increased muscle tone, and dizziness) or any exercise-related harm were documented and evaluated.

Study Part 2

The outcome measures for the feasibility of the home-based multimodal exergame in patients with chronic stroke included physical and cognitive outcomes, enjoyment, adherence, and adverse events. Motor function was assessed using the Short Physical Performance Battery (SPPB) [41]. The battery consists of 3 subtests—standing balance, gait speed, and chair-stand. A total SPPB score was calculated by summing the scores of the subtests, with higher scores indicating better motor function [41]. Functional mobility was measured using the Timed Up and Go test (TUG) [42,43]. Participants were asked to stand up from a chair and move at their maximum but safe pace for 3 meters, then turn and walk back to the seat and sit down. A faster time in the TUG test indicates better functional performance. For cognitive function, global cognition, executive function, and memory were measured using the Montreal Cognitive Assessment (MoCA) test [44], Trail Making Test (TMT A and B) [45], and Digit Span test [46], respectively. Higher scores on the MoCA and Digit Span Test indicate better global cognitive and memory performance, respectively. A smaller difference in completion time between TMT A and B indicates better executive function. Enjoyment was measured using the PACES [37,38]. Additionally, adherence and adverse events were also recorded.

Data Collection

For study part 1, usability outcomes and adverse events were collected immediately after the exergame session. For study part 2, physical and cognitive outcomes were assessed before and after the 6-week intervention. Program enjoyment was evaluated after 1 week and at the completion of the 6-week training period. Adherence and adverse events were also recorded throughout the study.

Blinding

Due to the nature of the intervention, participants and researchers administering the intervention were aware of the study procedures. However, outcome assessments were

XSL•FO
RenderX

conducted by blinded assessors (CS for cognitive assessment and PE for physical assessment) who were not involved in the intervention delivery.

Data Diagnostics

All participants completed the study protocol and all outcome assessments, with no missing data or postdata collection exclusions.

Statistical Analyses

All analyses and statistical calculations were performed using SPSS software (version 25.0, IBM Corporation). The content validity index of the program was determined using the IOC, with an IOC value greater than 0.75 indicating an acceptable level of validity. Descriptive statistics were used to describe the characteristics of participants and usability outcomes. The normality of the data was tested using the Shapiro-Wilk test. Paired sample *t* tests were used to compare the difference in outcome measures between pre- and post–6-week training. Mean differences were calculated, with 95% CIs reported. All data were presented as mean (SD) or n (%). A significant level was set at $P<.05$.

Ethical Considerations

The study protocol was approved by the Ethics Committee of the Faculty of Associated Medical Sciences, Chiang Mai University (approval AMSEC-67EX-023). All participants provided written informed consent before participation in the study. All collected data were deidentified and handled in accordance with applicable ethical guidelines and data protection regulations to protect participant privacy and confidentiality. Participants received transportation reimbursement of 500 Thai Baht (THB; approximately US $15) in accordance with institutional research regulations. No identifiable personal information or participant images are included in this manuscript.

Results

Part 1: Content Validity Index, Features of the Exergame Prototype, and Preliminary Program Usage

Overview

The content validity index for each game, based on the average IOC for objectives and level of difficulty, was 1.00 for game 1, 0.90 for game 2, 0.80 for game 3, 0.90 for game 4, and 0.50 for game 5. The overall content validity index was 0.82, indicating an acceptable level of validity. The lower IOC value for game 5 was related to expert feedback indicating that the sequence and arrangement of answer choices on the screen could be confusing and might increase task difficulty beyond the intended objectives of the game. Based on the expert feedback, the design and presentation sequence of game 5 were revised to enhance clarity and usability before inclusion in the final prototype.

The multimodal exergame comprised 5 exergame modes, designed to enhance both physical and cognitive function of individuals with stroke. Each exergame had 2 levels of difficulty, with complexity progressing through an increased number of repetitions and exercise steps, variations in movement direction, extended training duration, increased cognitive load and attentional demands, and reduced resting periods. Additionally, gamification elements such as real-time feedback, scoring systems, performance levels, rewards, and visual and auditory cues were integrated to enhance user motivation, engagement, and adherence to the training regimen. A summary of the consensus features of the home-based multimodal exergame is presented in Table 1.

Participant Characteristics

A total of 5 patients with chronic stroke were enrolled in study part 1 to determine the program usage. The mean age of participants was 56.40 (SD 11.37) years, time since stroke onset was 39.40 (SD 33.34) months, the average number of medications was 1.80 (SD 1.64), and BMI was 24.85 (SD 4.36) kg/m^2. All participants were male, with 2 diagnosed with hemorrhagic stroke and 3 with ischemic stroke. Most participants (4/5, 80%) had left-side paresis. None of the participants had previous experience using exergames. The demographic characteristics of participants are presented in Table 2.

[a]MSET10: Mental State Examination T10

Preliminary Usage Outcomes

The average total enjoyment score after exercise as measured by PACES was 47.80 (SD 7.50). The average score for each item was 5.97 (SD 0.94), with subitem averages ranging from 5.60 to 6.40 (Table 3). For the ratings of perceived exertion, 3 participants reported a score of 13, and 2 participants reported a score of 14 (Table 4). The average perceived exertion rating was 13.40 (SD 0.55; Table 4). Regarding satisfaction, the average score was 8.60 (SD 1.34), with scores ranging from 7 to 10 (Table 4). Overall feedback indicated that most participants found the functionality of the multimodal exergame user-friendly and easy to understand. Most participants also reported that the exergame software was generally well-designed to provide an optimal level of difficulty (neither too difficult nor too simple), and that the game featured clear illustrations and vibrant cartoon graphics. All participants reported that all game levels are well-designed and provide an appropriate challenge. As for the negative feedback, two participants reported that the sensor occasionally responded slowly and that the fruit images in the game were difficult to see clearly. Additionally, 1 participant noted that some exercise movements (eg, alternating between toe taps and heel taps) were too complicated, while another mentioned that the game rule instructions were confusing when playing for the first time. User feedback and suggestions, including both positive and negative aspects, are summarized in Table 5. Importantly, no musculoskeletal complaints, injuries, falls, or adverse events were reported during the multimodal exergame training.

Part 2: Feasibility of the Home-Based Multimodal Exergame

Participant Characteristics

A total of 9 patients with chronic stroke were enrolled in study part 2. The mean age of participants was 53.67 (SD 11.70, range 39-68) years, time post stroke onset was 75.00 (SD 101.99, range 6-264) months, number of medications was 1.56 (SD 1.51, range 0-4), and the level of education was 13.33 (SD 4.33, range 6-21) years. Of the 9 participants, 7 were male and 2 were female; 4 were diagnosed with hemorrhagic stroke, while 5 were diagnosed with ischemic stroke. Moreover, 5 participants presented with left-side paresis, and 4 with right-side paresis. The demographic characteristics of the participants are summarized in Table 6.

Feasibility Outcomes, Adherence, and Adverse Events

Results indicated that improvements in the MoCA score (mean difference=−3.44, 95% CI −5.66 to−1.23; *P*=.007), TMT B completion time (mean difference=38.75, 95% CI 8.27-69.22; *P*=.02), and TMT B-A (mean difference=38.43, 95% CI 3.78-73.08; *P*=.03) were observed from pretest to posttest (Table 7). No significant changes were observed in the SPPB score, time in TUG, time to complete the TMT A, digit span sum score, and PACES sum score posttest compared with pretest (mean difference=−0.22, 95% CI −1.22 to 0.78; *P*=.62; mean difference=2.31, 95% CI −1.53 to 6.15; *P*=.20; mean difference=0.32, 95% CI −14.14 to 14.77; *P*=.96; mean difference=−0.22, 95% CI −1.80 to 1.35; *P*=.75; and mean difference=−1.78, 95% CI −6.99 to 3.43; *P*=.45, respectively; Table 7). Additionally, the average exercise adherence rate was 85.19%. Throughout the 6-week training period, no adverse events, injuries, or falls were reported.

Discussion

Principal Findings

To the best of our knowledge, this intervention is the first prototype of an interactive, multimodal exercise program incorporating gamification and augmented feedback, specifically designed to target both cognitive and physical outcomes in individuals with chronic stroke residing at home or in remote areas. Findings from this study demonstrated that the preliminary use of the developed exergame prototype showed high content validity (IOC=0.82) and was enjoyable, easily accessible, user-friendly, and safe for patients with chronic stroke. Feasibility outcomes further support the implementation of this program, as reflected by a high adherence rate, absence of adverse events, and sustained enjoyment throughout the training period. Collectively, these findings suggest that the multimodal exergame is both safe and feasible for use in individuals with chronic stroke and may offer potential benefits for cognitive outcomes following 6 weeks of training.

Stroke rehabilitation interventions and poststroke exercise programs frequently encounter challenges, such as long travel distances, a lack of available health care providers, high dropout rates, and low motivation [13,14], all of which contribute to physical inactivity [11]. To mitigate rehabilitation barriers, this study developed and implemented a gamified physical-cognitive exercise program delivered through practical and accessible formats, including online videos and home-based training. Based on a synthesis of existing evidence [33,34,47,48] and a development brainstorming process, both physical and cognitive interventions for stroke rehabilitation were developed. All essential exercises for stroke rehabilitation were incorporated into the multimodal exercise program. Findings demonstrated that the content validity index of the overall program was high, indicating that the content of the home-based multimodal exergame is appropriate for individuals with chronic stroke. Additionally, interactive game-based training has emerged as a promising strategy to enhance user engagement, potentially leading to improved adherence and more favorable intervention outcomes [15,21,22]. The program in this study was designed according to gamification principles to promote user engagement and enjoyment. This study revealed that all participants reported high satisfaction and enjoyment with the program. The average score on PACES for each item was 5.97 ranged from 5.60 to 6.40, reflecting positive emotional responses and enjoyment during the combined physical and cognitive activities. The use of gamification elements may enhance enjoyment and promote long-term participation by aligning physical and cognitive challenges with game-like experiences [34,49,50]. These findings align with previous research demonstrating that gamification elements, such as goals, rules, and rewards, improved intrinsic motivation, satisfaction, and enjoyment in exercise programs [34,49-51]. Furthermore, the use of augmented feedback may provide extrinsic information during training sessions and plays a crucial role in enhancing motivation in individuals with stroke [18].

Usability feedback from 5 patients with chronic stroke indicated the multimodal exergame was easy to use, appropriately challenging, and included exercise movements that were suitable and easy to follow. The results were in line with the previous study [34,52] and suggested that the positive feedback from users unfamiliar with new technologies may be due to the user-friendly interface and appropriately challenging task levels incorporated into the intervention design. However, some users reported occasional delays in game graphics and sensor detection; exercise movements, such as alternating between toe

XSL•FO
RenderX

taps and heel taps, were too complicated, and some instructions were unclear. In response to negative feedback from participants, technical adjustments were implemented to enhance sensor performance and reduce system latency. Additionally, minor revisions to graphics and certain instructions were made based on consensus from the expert panel and research team. The finalized version of the intervention program was developed through a rigorous process. Consequently, the preliminary prototype of the multimodal exergame demonstrated satisfactory scientific validity, aligning with constructs relevant to specific clinical and research objectives in poststroke rehabilitation.

The American Stroke Association demonstrated that encouraging physical activity among survivors of stroke should focus on moderate-intensity of exercises and managing risk factors to prevent secondary stroke and improve cardiovascular health [6]. To confirm exercise intensity, this study used the Borg scale for subjective assessment [53]. It has been documented that the RPE is a simple and practical method that does not require special equipment to measure an individual's subjective level of exertion and is used to ensure that exercise intensity remains within tolerable limits [6,53]. The results of this study showed that the average perceived exertion rating during exercise was 13.40, indicating moderate-intensity exercise. Previous studies showed that exercise at moderate intensity promoted health benefits in patients with stroke [54,55]. Thus, the prototype of multicomponent exercise at moderate intensity could provide opportunities to support stroke recovery. Additionally, integrating objective measures (eg, heart rate monitoring via wearable devices) would further enhance the precision of intensity monitoring and enable more personalized and adaptive progression of the exercise program. Furthermore, combining perceived exertion with heart rate–based targets may facilitate automated adjustment of exercise intensity across sessions.

Emerging evidence suggests that multimodal interventions integrating physical and cognitive components may confer broader benefits than single-domain training in older adults [56,57]. In addition, research evidence has demonstrated that multimodal exercise improved health outcomes in older adult patients with stroke and frailty [7] and older adults with dementia [8]. In this feasibility study, participants demonstrated improvements in global cognition and executive function following a 6-week home-based multimodal exergame. However, these findings should be interpreted with caution due to the small sample size and the absence of a control group, which limit causal inference and increase the risk of overestimating intervention effects.

The observed trends in cognitive outcomes may be partly explained by the design of the intervention. Specifically, the exergame tasks were structured to engage multiple domains of cognition, with a particular emphasis on executive processes such as attention, inhibition, and cognitive flexibility. In contrast, memory-related tasks were less frequently represented and primarily limited to working memory components. In addition, the progression from lower to higher difficulty levels incorporated increased cognitive load, shorter response times, and greater exposure to distracting stimuli. These features likely required maintained attention and adaptive control, which may preferentially stimulate executive function [58,59]. Nevertheless, given the exploratory nature of this study, these mechanistic interpretations remain speculative and should be confirmed in controlled trials.

In contrast to the cognitive findings, motor performance, as assessed by the SPPB and TUG, did not show significant changes following the intervention. This lack of improvement may be related to several characteristics of the training program. To prioritize the safety of home-based and remote training, the intervention primarily emphasized seated activities and sit-to-stand exercises, with limited incorporation of dynamic balance, gait training, or higher-intensity lower extremity tasks. As a result, the stimulus may not have been sufficiently specific or intense to elicit measurable improvements in functional mobility outcomes that require integrated components of balance, walking speed, and transitional movements. Furthermore, the outcome measures themselves may have influenced the findings. Both SPPB and TUG capture complex, whole-body functional performance, including gait and dynamic balance [41-43], which were not extensively targeted in the intervention. Therefore, the transfer of training effects to these measures may have been limited. It is also possible that the relatively short intervention duration and limited sample size reduced the statistical power to detect changes in both motor performance and memory outcomes. Importantly, no adverse events were reported during training with the home-based multimodal exergame. After evaluating the feasibility of the program, the total PACES score was maintained over the training period, and a high adherence rate was presented. This finding highlights the safety and feasibility of remote, technology-assisted interventions for individuals with chronic stroke. Additionally, participants were able to engage consistently with the exergame protocol in remote areas and their home environments.

Taken together, while the findings support the feasibility of a home-based multimodal exergame intervention and suggest potential cognitive benefits, they should be interpreted as preliminary. Future studies using randomized controlled designs, larger sample sizes, and longer intervention periods are needed to establish efficacy. Additionally, incorporating more task-specific and higher-intensity motor components, as well as selecting outcome measures that are closely aligned with the training stimuli, may help clarify the extent to which such interventions can improve both cognitive and motor function in individuals with chronic stroke.

Limitations

This study has several limitations that should be acknowledged. All participants demonstrated normal range of cognitive function, as determined by a screening tool. In addition, most participants had an educational background of high-school level or higher. Therefore, the findings primarily reflect the experiences of this specific group and may not capture the perspectives of individuals with different cognitive profiles or those with lower educational attainment. Although RPE is well-documented as a practical method for measuring an individual's subjective level of exertion during exercise, incorporating objective measurements (eg, polar heart rate

XSL•FO
RenderX

monitors) would provide a more precise and comprehensive assessment of exercise intensity, while enabling personalized intensity adjustment in future studies. Furthermore, participants' technology literacy was not formally assessed and may have influenced the study outcomes, particularly usability, satisfaction, and adherence. As this study primarily assessed the content validity, usability, and feasibility of the intervention program in patients with chronic stroke, the effectiveness of the system and program requires further investigation through large-scale, methodologically rigorous clinical trials to establish definitive clinical outcomes.

Conclusions

The home-based multimodal exergame demonstrated acceptable content validity, usability, and feasibility in individuals with stroke. Unlike conventional home exercise programs, this multimodal exergame integrates both physical and cognitive training into an interactive home-based and remote rehabilitation platform for patients with chronic stroke. The intervention was found to be enjoyable, accessible, user-friendly, and safe, while showing potential benefits for cognitive outcomes, maintaining exercise enjoyment, and promoting exercise adherence throughout the training period. This preliminary evaluation suggests that the home-based multimodal exergame is a promising rehabilitation tool that may enhance patient engagement, support long-term rehabilitation participation, and help address barriers to stroke rehabilitation, particularly for individuals living in underserved or remote areas.

Acknowledgments

The authors gratefully acknowledge the contributions of all participants for their time and cooperation. The authors declare the use of generative artificial intelligence (GAI) in the writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GAI tools under full human supervision: proofreading and editing. The GAI tool used was ChatGPT (GPT-5.3-mini). Abstract

Background: Educators are exploring new methods to educate beyond the classroom as global concerns about students' cognitive, emotional, and social well-being grow. Physical education (PE) has been demonstrated to boost cognitive and psychological outcomes in several studies. Most research has neglected the benefits of gamification and artificial intelligence (AI)–based feedback in PE, focusing instead on conventional PE formats. The impacts of technologically enhanced PE settings on students' cognitive performance through feedback and reward mechanisms remain understudied.

Objective: This study aimed to investigate how intrinsic motivation and AI-based feedback moderated the effects of gamified PE on students' cognitive performance.

Methods: The study used a cross-sectional design. In Beijing, Shanghai, Chengdu, and Guangzhou, a total of 1029 public high school students completed a standardized questionnaire. Students in secondary school (male: n=490, 47.6% and female: n=539, 52.4%) aged 10-18 years, were recruited from urban, suburban, and rural locales. Participants were sourced from public, private, and semigovernment schools, reflecting a range of academic achievement levels and access to technology. Students participating in standard PE sessions were included, whereas those with medical conditions that restricted physical exercise were excluded. Data were gathered via standardized questionnaires during designated PE sessions. Gamified PE, cognitive performance, intrinsic motivation, teacher support, collaboration, and AI feedback were examined using standardized instruments. Trained facilitators helped younger participants understand and follow ethical norms. The study used maximum likelihood estimation for structural equation modeling. Bootstrapping was used to analyze mediation and moderation effects at a 5% significance level (α=.05).

Results: According to structural equation modeling, gamified PE highly predicts cognitive performance (β=.34; *P*<.001). Other significant factors were teacher support (β=.31; *P*<.001), physical exercise enjoyment (β=.28; *P*<.001), and teamwork (β=.26; *P*<.001). AI-based feedback strengthened the link between gamified PE and cognitive performance under moderation analysis (β=.18; *P*<.001). Mediation analysis indicated that intrinsic motivation partially mediated the relationship, resulting in a significant indirect effect (β=.21, 95% CI 0.12-0.31; SE=0.05).

Conclusions: This research integrates gamified PE with AI-based feedback mechanisms to evaluate students' cognitive outcomes, a domain that has been rarely investigated experimentally. This study highlights the combined effect of intrinsic motivation and AI-generated feedback in a technology-enhanced PE context, in contrast to previous research that primarily focuses on traditional PE methods or isolated gamification elements. The findings enhance the field by demonstrating that student-centered, feedback-rich PE environments may improve cognitive abilities through social interaction, enjoyment, and instructor support. AI-assisted, gamified PE programs may enhance learning outcomes and academic performance among secondary school students.

Introduction

Background of Research

In the 21st century, multimodal techniques that integrate physical, cognitive, emotional, and technical components have become more important in education [1]. Contemporary research suggests that physical and intellectual education must be integrated, even though traditional schools generally divide them [2,3]. Physical education (PE) can change children's lives by enhancing their emotional, cognitive, and academic performance [4]. Concerns about student inactivity and cognitive overload have led to the development of gamified PE, an innovative teaching approach. This strategy uses game-design principles to make exercise more enjoyable, goal-oriented, and cognitively demanding [5]. Gaming methods combined with physical exercise have been shown to enhance motivation, teamwork, and self-control—essential for both mental and physical well-being [6].

Gamification incorporates features such as points, competition, prizes, badges, levels, and leaderboards into nongame contexts to motivate and engage users. Gamification, which originated in marketing and business, is now being used in classrooms to engage students [7]. This type of PE transforms static exercises into game-like cooperative learning settings where students work together to achieve goals. Research suggests that gamified methods improve students' engagement, enjoyment, and academic success [8]. Teenagers often find PE uninteresting or irrelevant; therefore, these strategies have been effective in capturing their attention. Gamified PE promotes active participation and cognitive engagement by allowing students to make choices, solve problems, and reflect on outcomes in real time [9].

Cognitive performance, encompassing attention, memory, reasoning, and problem-solving, has been extensively studied in educational psychology about physical well-being [10,11]. Regular exercise improves working memory, executive function, and information processing speed. Neurobiological mechanisms, including increased cerebral blood flow, reduced cortisol levels, and the release of brain-derived neurotrophic factor, may explain this connection [12]. Gamified PE may directly stimulate cognitive brain networks through rule-following, decision-making, instruction, memory, and strategy adjustment [13]. China's rapidly changing educational system is a fascinating environment for studying these dynamics. China has put student well-being alongside academic success in recent years to address excessive academic pressure, mental health issues, and physical inactivity in school-age children and adolescents [14]. National educational reforms aim to provide students with a "quality education" that nurtures their emotional, physical, and cognitive potential [15]. Chinese schools are experimenting with gamified teaching, notably in PE, to achieve this goal [16]. Despite well-defined policy aims, empirical research on the implementation processes and outcomes of these innovations is lacking. Understanding the impact of gamified PE on cognitive development and academic achievement in Chinese children requires considering psychological factors, such as motivation, and external factors, such as technology use.

Intrinsic motivation links gamified PE to cognitive performance. This is the desire to do something because it is fun, fascinating, or valuable. Ryan and Deci's [17] self-determination theory states that intrinsic motivation is driven by autonomy, competence, and relatedness. Gamified situations provide autonomy, competence, and relatedness. Gamified aspects in PE may help students understand and connect with physical exercise by making repetitive tasks more interesting [18]. Intrinsic motivation enables students to self-regulate their participation, thereby improving cognitive functioning and task performance [19]. The mediating role of intrinsic motivation is crucial in understanding how gamified PE may impact cognitive outcomes. Gamified PE may be enhanced or mitigated by technology, particularly artificial intelligence (AI)–powered feedback systems. Many progressive schools worldwide use smart wearables, mobility trackers, and digital dashboards, with AI being increasingly integrated [20,21]. These technologies enhance training efficiency by offering adaptive learning environments, personalized feedback, and real-time performance monitoring. AI may transform PE by enabling real-time monitoring of students' and teachers' efficiency, speed, endurance, and progress [22]. By acknowledging effort, fostering reflection, and driving self-improvement, such technologies may increase student engagement when gamified. Student receptivity to technology, teacher implementation skills, and institutional resources can all impact their effectiveness. Thus, AI-based feedback may moderate the relationship between gamified PE and cognitive performance sufficiently to change its direction.

In addition to these core concepts, contextual considerations should also be addressed. In China, a collectivist culture that values group cohesiveness and cooperative learning, peer collaboration is important. Gamified PE involves collaborative, communicative, and goal-oriented teamwork [23]. This may improve relationships and higher-order thinking via collaborative problem-solving and strategy building. Teacher support also affects student engagement in gamified contexts. When teachers model healthy exercise habits, provide constructive feedback, and encourage autonomy, they may motivate and engage students. Instructor behavior and gamified content delivery are crucial factors in assessing the effectiveness of an intervention [24]. Another key component in China's educational background is the variety of school settings, from public to private and urban to rural. The accessibility of gamification and AI technologies may vary. In Shanghai and Beijing, schools have smart classrooms and instructors who use technology to make learning an engaging experience [25]. Rural or low-resource schools often struggle with outdated technology, a shortage of qualified personnel, and resistance to innovative

XSL•FO
RenderX

teaching methods. Demographics and institutional characteristics may help explain differences in student cognitive performance. Confucian values, including diligence, self-control, and academic achievement, also shape Chinese educational perspectives [26]. These principles influence students' perceptions of gamification and other innovative teaching methods. Gamified PE may be invigorating for some students but too limited for others. Thus, cultural perception is a subtle yet powerful factor that may influence new teaching approaches [27]. To achieve cognitive and motivational advantages, gamified PE may need culturally relevant values and communication strategies.

This study should be viewed from the perspective of modern educational research, which increasingly promotes interdisciplinary collaboration. Motivation theory, PE, educational technology, and cognitive science must collaborate to understand student learning. Gamified PE combines movement studies, behavioral psychology, and technology. These cross-domain interactions are seldom studied, particularly in China's sociocultural context. Gamification in academic fields such as mathematics or language learning has garnered the greatest attention [28], whereas most research has focused on the cognitive advantages of physical exercise [29]. Technical, motivational, and cognitive studies on gamified PE as a core intervention are lacking.

This study is theoretically and practically important for Chinese educational innovation and student growth. Gamifying PE programs can improve children's health and engagement, a trend that is becoming increasingly significant in schools worldwide [30]. Gamified PE may increase physical activity and cognitive function in China, where academic achievement often takes precedence over emotional and physical growth [31]. Studying the mediating role of intrinsic motivation reveals the psychological underpinnings behind student learning and engagement. While educational technology shapes learning settings, AI-based feedback serves as a moderating component that addresses this tendency. This study's results contribute to the global discussion on educational reform, technology-enhanced learning, and student motivation, as it is one of the first to systematically analyze these factors within the Chinese secondary school system. New technologies help school administrators, policymakers, and educators develop more engaging, productive, and intellectually stimulating PE programs.

Today's educational studies must grasp how PE, cognitive development, and motivational psychology interact, particularly in rapidly modernizing nations such as China. Given the growing use of gamified methods and AI in education, research on their influence on key learning outcomes is urgently needed. Over the past 20 years, research on the cognitive benefits of exercise has evolved. Still, the impact of 2 modern pedagogical innovations, namely gamification and AI-based feedback, on this area remains unknown. This study emphasizes gamified PE, intrinsic motivation, AI-based feedback, and cognitive performance. The 3subsections of the review conclude with a hypothesis to guide empirical research.

Gamified PE and Physical Activity Enjoyment With Cognitive Performance

Several studies have demonstrated that gamified PE enhances children's learning and brain development [30,32]. Rule-based, competitive, and strategic games boost students' attention, engagement, and decision-making in gamified PE [33]. Gamified learning activities have been shown to improve task completion and working memory. Gamified physical activities compel students to solve problems, devise strategies, and assess their progress in real time, which promotes higher-order thinking. These benefits stem from PE games and competitions that keep children moving and engaged in critical-thinking activities [34]. Gamified PE lessons improved content retention and self-regulated learning. It is widely recognized that exercise enhances cognitive function. Students who like exercising are more likely to persist with it. This aids brain growth and executive function [35,36]. A meta-analysis found that children who were happier while exercising performed better on cognitive flexibility and memory tests. Engaging and pleasant activities promote academic learning, critical dual-task performance, and prefrontal brain activity. Despite a lack of scientific data, gamification is gaining popularity in China as a teaching method [37,38]. Gamified PE treatments in Shanghai, China, have improved students' memory and attention. Gamified PE increased mental rotation exercises and digit span recall. These results support the premise that engaging and interesting physical exercise promotes both physical and psychological health. Gamification's novelty must be managed carefully to keep users interested and minimize cognitive fatigue [39,40].

Peer Collaboration and Teacher Support to Cognitive Performance

Working together in class has long been shown to boost students' social and cognitive development. Collaborative learning plays a key role in intellectual growth. Teamwork and collaboration in PE foster effective communication, critical analysis, and perspective-taking [41,42]. Students who worked together on physical activities performed better on reflective thinking and adaptation exams. Peer contact in PE improves strategic thinking and decision-making, particularly when participants must collaborate to solve challenges or reach a consensus [43,44]. Coordinated peer collaboration in PE enhances cognitive engagement. This was especially evident when students discussed approaches and reflected on their outcomes. Cognitive benefits have been observed in teaching games for understanding models, which rely heavily on peer interactions [45,46]. These models improve foresight, planning, and problem-solving. Collectivist principles that promote group cohesiveness and shared accomplishment make peer collaboration meaningful in Chinese education. Chinese students who took PE programs with a partner performed better on executive functioning assessments. Peer collaboration and teacher support help influence students' cognitive involvement [47]. Teachers who foster autonomy and provide clear feedback help pupils build intrinsic motivation and learning perseverance. PE teachers' primary duties include engaging students and making the classroom exciting. Scaffolding, encouragement, and feedback improve cognitive performance [48,49]. Physical ability and academic success were higher in Chinese students

XSL•FO
RenderX

who were more encouraged by their PE teachers. Formative assessments and motivational signals reduced cognitive load and increased self-reflection in PE students [50]. Gamified PE highlighted the need for psychologically safe spaces where children can experiment, fail, and learn, which is essential for cognitive development [51]. Instructors remain crucial to PE courses that use AI to support students in understanding digital feedback and to foster metacognition [52]. These findings suggest that students need to collaborate and have their teachers' support to increase cognitive performance, particularly in dynamic and game-based learning environments.

Mediating Role of Intrinsic Motivation and Moderating Effect of AI-Based Feedback

Intrinsic motivation, which is the drive to do something for its own sake, has been linked to scholastic and cognitive success. Gamified learning settings make students feel more connected, competent, and independent [53]. Motivation to study enhances students' use of deeper cognitive techniques, sustained attention, and effort. Genuinely driven PE students performed better and persevered longer in motor learning tasks. Enjoyment and perceived competence during PE influenced the relationship between PE involvement and academic success [54,55]. Inner motivation mediated the relationship between physical activity and math performance in Chinese middle schools. A recent study suggests that gamified PE motivates students to enhance their executive functioning and facilitate learning transfer [56,57]. These findings support the cognitive benefits of gamified PE, including increased intrinsic motivation, perceived competence, and a sense of control. In contrast, AI has enhanced PE by providing students with real-time performance statistics. Smart wristbands equipped with AI-powered motion sensors facilitate reflective thinking and personalized learning. AI-based feedback enhanced students' metacognitive awareness and adaptive learning strategies [58,59]. This input may reinforce learning loops, give immediate incentives, and drive persistent participation in gamified contexts. Students who received AI-enhanced PE courses performed better on spatial thinking and problem-solving examinations than those who received conventional instructor feedback. AI's moderating influence is not always positive. Students may become excessively dependent on external validation or overwhelmed by AI technology, depending on deployment and preparation [60,61]. Thus, its effectiveness may vary depending on the situation. AI-enhanced PE pilot programs in China have shown promising outcomes, with improved engagement and physical literacy [62]; however, concerns remain regarding unequal access and teacher training. When paired with AI-based feedback, gamified PE may improve cognitive function, particularly depending on the quality of feedback, engagement, and customization.

Research Gaps and Contribution of the Study

There is growing evidence that PE is important for cognitive development; however, the impact of gamified PE interventions on cognitive outcomes remains unclear, particularly in the Chinese educational and cultural context. Exercise has been shown to improve attention, memory, and executive functioning in several studies [63,64]. These studies have primarily examined aerobic or endurance activities, rather than PE programs that use games to enhance these areas. Gkintoni et al [65] found that motor skill memorization in conventional PE improves mental agility, while gamified activities that require flexibility, strategy, and decision-making in the present engage students' brains more effectively.

Another topic with limited research is the impact of PE on cognitive functioning and its underlying mechanisms. Self-determination theory has been applied in motivation research; however, few studies have examined intrinsic motivation as a moderator in gamified PE [66,67]. Sañudo et al [68] observed that gamification boosts physical activity, but their models do not account for the psychological relationship between intrinsic motivation, internal pleasure, and mental performance. To develop educational interventions that are both physically and psychologically beneficial, it is essential to understand the driving factors of gamified learning.

Research on the cognitive effects of gamified PE using AI-based feedback is seldom conducted. Although AI is becoming increasingly widespread in developing or transitional education systems, such as China's, academics have given less attention to its applications in PE. AI research in education has focused on academic learning platforms or disregarded pedagogy. Zha et al [69] study shows that AI-enhanced feedback tools may assist students in learning PE technical skills, but they do not link them to cognitive progress. In addition, there is limited knowledge about how technological tools affect motivational psychology. AI feedback in gamified PE has not been studied to determine whether it enhances self-awareness and metacognitive processing or merely motivates.

The literature on physically interactive, game-based learning environments does not address multilevel classroom dynamics, including student-teacher collaboration and instructor support. The social aspect of PE is often overlooked in empirical models that combine gamification and cognitive findings. Iglesias and Fernandez-Rio [70] conducted a comparative study. Students may be more engaged in collaborative PE. The research does not examine how these interactions increase cognition or how teacher scaffolding affects it. Comprehensive frameworks must incorporate instructional strategies, motivating factors, technological upgrades, and student interaction patterns, which affect cognitive performance.

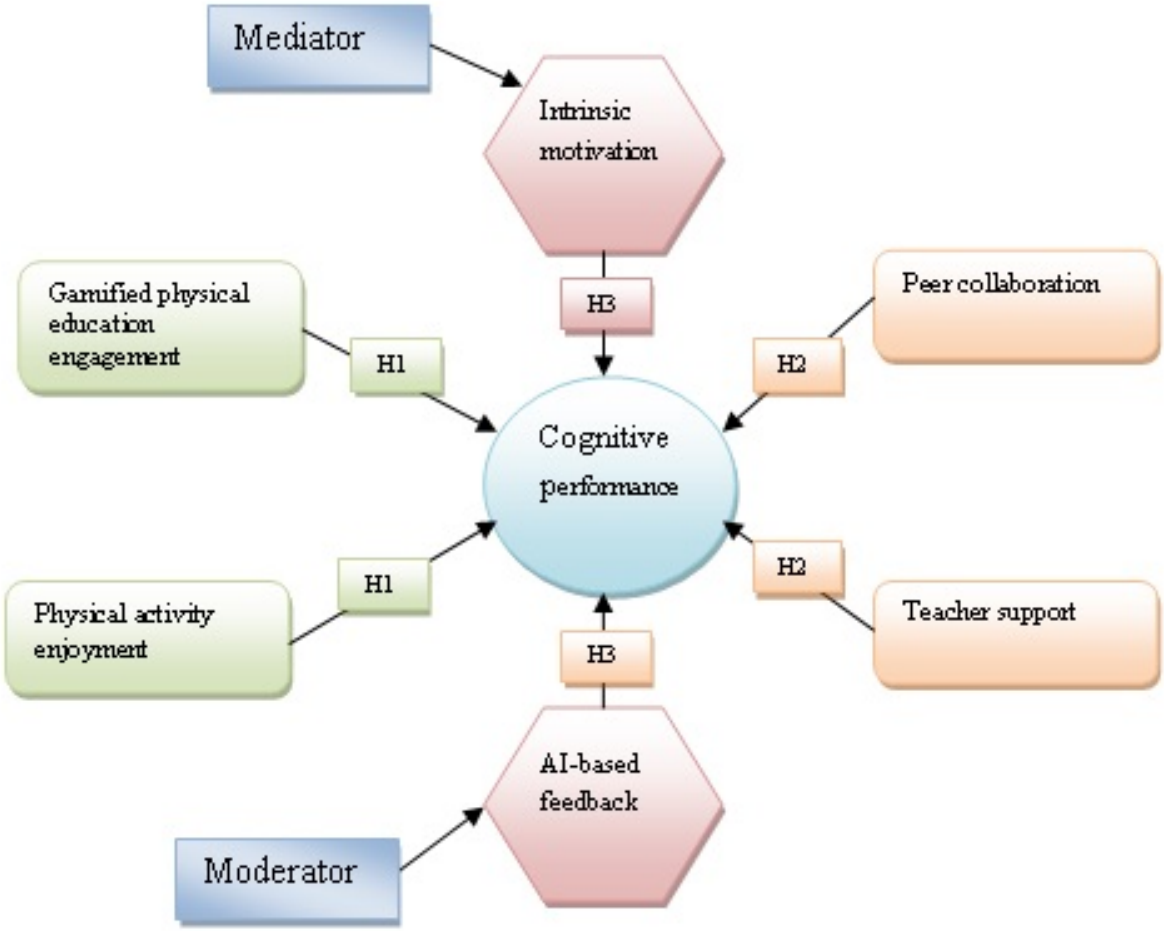
This study examines how gamified PE, physical activity enjoyment, peer cooperation, and teacher support impact students' cognitive performance in China's unique educational system, aiming to fill these complex gaps. This study integrates pedagogical and psychological perspectives to better understand how innovative PE methods can enhance cognitive performance. The research incorporates both technology and physical exercise, unlike previous investigations. The study uses intrinsic motivation as a mediating component to enhance the theoretical understanding of internal motivational processes in gamified scenarios. It also examines how AI-based feedback moderates the effects of digital technology on learning in interactive, collaborative classrooms. The study suggests that secondary school PE programs facilitate students' cognitive and developmental progress by providing data to inform curriculum development, teacher professional development, and the

XSL•FO
RenderX

effective use of educational technology. It can help Chinese and other school administrators develop balanced, tech-integrated, and student-centered PE curricula to achieve 21st-century learning goals.

Research has linked gamified PE with an intrinsic desire to exercise and improved cognitive function to form the following research hypotheses:

- H1: Gamified physical education and physical activity enjoyment have a significant positive effect on students' cognitive performance.
- H2: Peer collaboration and teacher support have a significant positive effect on students' cognitive performance.
- H3: Intrinsic motivation mediates, and AI-based feedback moderates, the relationship between gamified physical education and cognitive performance.



Methods

Theoretical Framework

This study is based on cognitive load theory (CLT) and self-determination theory (SDT), with contextual support from Constructivist Learning Theory. Deci and Ryan's [71] self-determination theory explains how students' sense of enjoyment in connectivity, autonomy, and competence motivates them to pursue diverse activities. SDT is helpful for this study because it shows how intrinsic motivation moderates the relationship between gamified PE and cognitive function. Gamification elements, such as points, challenges, levels, and social engagement, help PE programs fulfill students' psychological needs and encourage enthusiastic participation. As gamified PE becomes more engaging and personalized, students' cognitive engagement, memory, and problem-solving abilities are expected to improve [72]. CLT suggests that gamification and other instructional methods may increase working memory and decrease cognitive load, particularly when combined with real-time AI-based feedback [73]. Such feedback may help students focus, repair mistakes quickly, and learn more via adaptive responses by strengthening the gamified PE-cognition link. According to Constructivist Learning Theory, teachers can direct students' exploration, social interaction, and feedback, while students can also help themselves through peer collaboration and instructor support [74]. Teamwork and teacher facilitation are highly effective in promoting engagement and the application of cognitive skills in PE.

These theoretical frameworks create the study's expected variable relationships (refer to Figure 1).

Figure 1. Conceptual framework showing hypothesized relationships among explanatory variables, mediator, moderator, and dependent variable (cognitive performance) with hypotheses H1–H3. Data from 1029 high school students in Beijing, Shanghai, Chengdu, and Guangzhou, 2025. Source: author's work. AI: artificial intelligence.

XSL•FO
RenderX

The first hypothesis (H1) states that gamified PE and physical activity enjoyment will enhance students' cognitive performance. Physically active classrooms boost students' physical health, mental clarity, memory, and problem-solving skills. H2, which builds on H1, suggests that teacher and peer interaction enhances students' cognitive performance by focusing on the social and pedagogical aspects of learning. These factors make the classroom a friendly yet challenging environment for students to learn through hands-on experiences, collaborate, and receive constructive feedback. H3, the technological and psychological components, reveals that intrinsic motivation mediates the relationship between gamified PE and cognitive performance and that AI-based feedback moderates this relationship. Intrinsically motivated students are more likely to focus, continue the course, and actively engage in learning using AI feedback systems, which improves outcomes. This paradigm encompasses motivation, instruction, technology, and cognition, and when combined, these elements demonstrate how gamified PE can support learning in today's classrooms.

Population, Sample, and Research Design

The study investigated the influence of intrinsic motivation and AI-based feedback on the relationship between gamified PE and students' cognitive performance in China's unique cultural and educational context. The research includes secondary school PE students from various regions in China. The sample included urban, suburban, and rural schools from Beijing, Shanghai, Chengdu, and Guangzhou municipalities. These regions were selected because they participate in national education innovation projects and have various degrees of classroom technology integration. The study used quantitative, cross-sectional surveys and structured questionnaires to obtain participant data. The 1029 completed and valid responses from 1175 surveys issued to 10- to 18-year-olds yielded an 87.6% response rate. Based on Cochran sample size calculation approach, which accounts for a 95% CI and a 3% margin of error, a sample of desired respondents was required. Multivariate statistical analysis, including structural equation modeling (SEM), can be reliably performed with the given sample.

Demographic Profile

The study collected demographic data to understand the participants' contextual profiles and ensure diversity across crucial parameters. High, moderate, and low achievers were categorized based on their academic achievement. The demographic component of the questionnaire inquired about school type (public, private, or semigovernment), location (urban, suburban, or rural), and access to technology (high, moderate, or low). The study cross-tabulated these factors to ensure consistency among student demographics and institutional settings.

Measurement Scales

This survey included key factors from theoretical and empirical investigations (refer to Table 1). Cognitive performance was assessed using a Cognitive Functioning Scale item derived from the Woodcock-Johnson Tests. The item includes: "*My memory has improved due to gamified PE*."A cognitive development study has validated this scale [75]. The first independent variable, gamified physical education engagement, was assessed using the game-based learning engagement scale. The item was *"I feel more engaged in gamified PE*," followed by Hamari et al [76]. The second independent variable, physical activity enjoyment, was assessed using the physical activity enjoyment scale with a representative item, "*I feel energetic after physical activity*," as suggested by Kendzierski and DeCarlo [77]. The third independent variable, examined by the collaborative learning scale, was "*Team-based PE helps me learn more*," as used by Laal and Ghodsi [78] for instrumentation. Belmont et al [79] used the scale and representative items, including "*My teacher helps me reflect on progress*," to score instructor support, the fourth independent variable, on the Teacher as Social Context Questionnaire–Autonomy Support subscale. The mediating variable, intrinsic motivation, was operationalized using the intrinsic motivation inventory-interest and enjoyment subscale. One key item is "*I feel accomplished after PE*." Deci and Ryan's [71] theoretical model and psychometric validation by McAuley et al [80] provided support for this instrument. AI-based feedback was measured using a sample item from the smart education technology–enhanced feedback scale, supporting Ifenthaler et al [81] and Caspari-Sadeghi et al [82]. The study used a 5-point Likert scale for all items, with 1 indicating "strongly disagree" and 5 indicating "strongly agree."

XSL•FO
RenderX

Table 1. Measurement scales and sample items for studied variables, based on responses from 1029 high school students in 4 Chinese cities, 2025.

Constructs	Measurement scale	Sample item from questionnaire	Literature support
Cognitive performance (DV[a])	Cognitive Functioning Scale (adapted from Woodcock-Johnson Tests)	I can concentrate better during lessons after gamified PE[b].	[75]
Gamified physical education engagement (IV1[c])	Game-Based Learning Engagement Scale	I enjoy gamified PE classes.	[76]
Physical activity enjoyment (IV2[d])	Physical Activity Enjoyment Scale (PACES)	Physical activities are fun for me.	[77]
Peer collaboration (IV3[e])	Collaborative Learning Scale	I work better in teams during PE.	[78]
Teacher support (IV4[f])	Teacher as Social Context Questionnaire–Autonomy Support subscale	My PE teacher gives helpful feedback.	[79]
Intrinsic motivation (mediator)	Intrinsic Motivation Inventory (IMI): interest and enjoyment subscale	I participate in PE because I enjoy it.	[71,80]
[g]AI-based feedback (moderator)	Technology-Enhanced Feedback Scale	AI-based feedback helps me improve my physical skills.	[81,82]

[a]DV: dependent variable.

[b]PE: physical education.

[c]IV1: independent variable 1.

[d]IV2: independent variable 2.

[e]IV3: independent variable 3.

[f]IV4: independent variable 4.

[g]AI: artificial intelligence.

Pilot Study and Diagnostic Tests

A pilot study evaluated the validity, reliability, and clarity of content and timing of the research instrument with 50 students from similar backgrounds in the different groups of research participants, aged 10-18 years. After conducting reliability analysis using Cronbach , all questionnaire components had coefficients above 0.70, indicating strong internal consistency. The dimensionality of each scale was assessed using exploratory factor analysis, and construct validity, including convergent and discriminant validity, was examined using confirmatory factor analysis (CFA) with using SPSS AMOS software (IBM Corp). The scale's average variance extracted (AVE) and composite reliability (CR) values were within the acceptable range for all structures, proving its validity. Variance inflation factor multicollinearity tests verified the dataset's suitability for regression-based modeling. These tests showed that the independent variables were not highly correlated.

Reporting Standards

This study followed the APA Journal Article Reporting Standards for Studies Using Structural Equation Modeling to provide comprehensive documentation of model construction, estimation methods, model fit indices, and mediation and moderation studies [83].

SEM was used to test the study's hypotheses (H1, H2, and H3) and to estimate the direct and indirect correlations among variables for further statistical analysis. Furthermore, a moderated-mediation analysis was also performed for robust inferences. The study applied bootstrapping with 5000 resamples to establish the relevance of the indirect effects; the study accordingly performed the analysis. An interaction term was tested to assess whether AI-based feedback moderates the connection between gamified PE and cognitive performance. The relationship's intensity and direction were considered. Model fit indices, including comparative fit index (CFI), Tucker-Lewis Index (TLI), root-mean-square error of approximation (RMSEA), and standardized root-mean-square residual, were within acceptable bounds, demonstrating model robustness. The relationships were exhaustively analyzed using SPSS Statistics version 26 (IBM Corp) and AMOS version 24 (IBM Corp) for all statistical methods.

Finally, this research relies on reliable statistical methods, measurement instruments, and rigorous sampling. By incorporating both technical and psychological components into educational interventions, such as gamified PE, Chinese secondary school students can gain a multifaceted understanding of how modern pedagogical strategies impact cognitive development. The stratified sample, high response rate, and advanced SEM methodologies make the findings reliable and accessible to a large audience.

Ethical Considerations

This study was approved by the Research Ethics Committee of Kyonggi University, Suwon-si, Republic of Korea (Institutional Review Board no 12416). All procedures were conducted in accordance with institutional and national ethical guidelines. Written informed consent was obtained from all participants before data collection. For participants younger than18 years, written and oral consent was obtained from their parents or legal guardians. Trained facilitators assisted younger participants to ensure they clearly understood the survey items and participated voluntarily. All data were anonymized at the time of collection; no personal identifiers were recorded, and participants were

XSL•FO
RenderX

assigned unique numeric codes for data handling and analysis. No images or other identifying materials of individual participants were collected or included in the paper. Therefore, no identifiable participant information is disclosed, and no additional consent was required for images.

Results

Stratified random sampling was used to recruit students from various schools across the 3provinces, categorized by school type and geographic location. The study initially categorized schools by geography. Each stratum's students were randomly selected. The study carefully balanced gender and grade levels for equitable sampling. PE instructors distributed questionnaires during class time with the support of administrators. Participation was voluntary, and students were given anonymity and confidentiality, which enhanced the legitimacy of the responses. School coordinators and field supervisors collaborated to gather data using standardized instruments over 2 months. Given the wide age range of participants, methodological and ethical adjustments were implemented for children in the 10- to 12-year age group, who may experience developmental difficulties in recalling intricate survey questionnaires. For this age group, the questionnaire was read aloud by trained facilitators in a structured manner. The facilitators read questions to the students individually, provided simplified explanations, and ensured that the students responded voluntarily without asking leading questions. This approach ensured the validity, accuracy, and adherence to ethical guidelines when using young respondents in psychological and educational research. The 13- to 18-year-old respondents were able to complete the questionnaire independently.

Table 2 provides the demographics of respondents to illuminate the study's sample composition and contextualize the results. The sample comprised 1029 students from various educational institutions throughout China, ensuring a broad representation of student opinions and learning conditions. Male students comprised 47.60% (n=490) of the sample, while female students comprised 52.40% (n=539). The findings are more generalizable due to a gender-diverse participant pool and relatively equal distribution. Three age groups of students were 10-12, 13-15, and 16-18 years. The students included 438 (42.60%) aged 13-15 years, 310 (30.10%) aged 10-12 years, and 281 (27.30%) aged 16-18 years. This age group encompasses a broad range of developmental periods in middle and upper elementary and secondary school, making it crucial for gamified learning and cognitive growth. The survey found that 479 (46.60%) students assessed their academic performance as moderate, 305 (29.67%) as excellent, and 245 (23.83%) as low achievers. These distributions show how students from diverse academic backgrounds use gamified PE and AI-based feedback. Public schools educated 428 (41.60%) students, private schools 311 (30.20%), and semigovernment schools 290 (28.20%). This indicates a balanced representation across institutional types, as educational systems and funding may affect the integration of gamified PE and AI. The respondents were drawn from a variety of areas, including urban (366/1029, 35.60%), suburban (360/1029, 35%), and rural (303/1029, 29.40%) locations. Geographic diversity is considered when assessing the impact of educational infrastructure and technological accessibility on cognitive performance outcomes. As a result, the study also reveals regional variations in teaching and educational resources. Finally, 400 (38.90%) students reported high access to digital tools and platforms, 451 (43.90%) reported moderate access, and 178 (17.30%) reported limited access, a significant variable given this study's focus on AI-based feedback. These results suggest that students' technological readiness may influence or moderate the effectiveness of gamified learning approaches. Given the relatively high percentages of students with moderate to high technology access, most students appeared to have participated meaningfully using digital and AI-driven teaching resources.

Table 3 provides descriptive statistics, validity indicators, and internal reliability and stability for each of the study's major latent variables, assessing the stability and internal consistency of the structural model's constructs.

XSL•FO
RenderX

Table 2. Demographic characteristics of 1029 high school student respondents across Beijing, Shanghai, Chengdu, and Guangzhou, 2025.

Demographic variable and category	Value, n (%)
Sex	
Male	490 (47.60)
Female	539 (52.40)
Age group	
10-12 years	310 (30.10)
13-15 years	438 (42.60)
16-18 years	281 (27.30)
Academic performance	
High achiever	305 (29.60)
Moderate achiever	479 (46.60)
Low achiever	245 (23.80)
School type	
Public	428 (41.60)
Private	311 (30.20)
Semigovernment	290 (28.20)
Geographic location	
Urban	366 (35.60)
Suburban	360 (35)
Rural	303 (29.40)
Technology access level	
High	400 (38.90)
Moderate	451 (43.80)
Low	178 (17.30)

Table 3. Descriptive statistics, reliability, composite reliability, and average variance extracted for all study constructs based on 1029 student responses, 2025.

Variables	Value, mean (SD)	Cronbach α	CR[a]	AVE[b]
Cognitive performance	4.18 (0.72)	0.89	0.91	0.66
Gamified PE[c] engagement	4.25 (0.68)	0.92	0.93	0.70
Physical activity enjoyment	4.12 (0.75)	0.87	0.89	0.64
Peer collaboration	4.05 (0.81)	0.86	0.88	0.61
Teacher support	4.1 (0.70)	0.91	0.92	0.69
Intrinsic motivation	4.21 (0.65)	0.90	0.91	0.68
AI[d]-based feedback	3.89 (0.79)	0.88	0.90	0.65

[a]CR: composite reliability.

[b]AVE: average variance extracted.

[c]PE: physical education.

[d]AI: artificial intelligence.

Cognitive performance, the study's primary dependent measure, had a mean score of 4.18 (SD 0.72). With modest fluctuation, participants reported strong cognitive engagement and outcomes. The scale's Cronbach of 0.89 indicated high internal consistency. The CR was 0.91, and the AVE was 0.66, both exceeding the convergent validity criteria of 0.50. Scale elements adequately explained the hidden component. Gamified PE Engagement, a major independent variable, had the highest mean score (mean 4.25, SD 0.68), reflecting positive participant views of PE gamification. Cronbach of 0.92, CR of 0.93, and

XSL•FO
RenderX

AVE of 0.70 indicate the reliability of this scale. These statistics demonstrate that the gamified engagement measurement model is statistically valid and substantively relevant due to its strong internal cohesion. Another independent variable with a high mean score of 4.12 (SD 0.75) supported favorable participant attitudes toward PE. AVE 0.64, Cronbach 0.87, and CR 0.89 all exceeded acceptable norms, indicating the construct's internal reliability. Gamified activities motivated and engaged participants in PE. Peer collaboration also had strong psychometric features, with a mean of 4.05 (SD 0.81), CR=0.88, AVE=0.61, and Cronbach α=0.86. These findings support the favorable benefits of collaborative learning on academic success and demonstrate that the instrument effectively captures the social dynamics and cooperative learning aspects of PE. Teacher support was another major independent variable with high reliability and validity. A mean of 4.10 (SD 0.70), Cronbach of 0.91, CR of 0.92, and AVE of 0.69 indicated a robust construct. These statistics highlight the role of instructors in designing, guiding, and supporting gamified education and physical learning, as well as cognitive outcomes and participant motivation. Most participants were motivated and self-driven in gamified learning contexts, with an average Intrinsic Motivation score of 4.21 (SD 0.65). This construct had an AVE of 0.68, a CR of 0.91, and a Cronbach of 0.90. Self-determination theory suggests that intrinsic motivation is crucial for academic achievement, and these values support the statistical validity of the motivation construct. Finally, AI-based feedback had a lower mean of 3.89 (SD 0.79), suggesting a wider range of responses. However, Cronbach scores of 0.88, CR 0.90, and AVE 0.65 indicate strong construct validity and internal consistency. Although experiences with AI feedback varied (possibly due to familiarity or availability), participants generally reported that it improved engagement and performance. Table 4 shows the item-level standardized loadings and metric invariance estimates.

XSL•FO
RenderX

Variable and item	λ (standardized loading)	Cross-loading (max)	Mandarin translation ΔCFI[a]
AIF5	0.84	0.10	0.003

[a]CFI: comparative fit index.

[b]PE: physical education.

[c]AI: artificial intelligence.

The study looked at item-level standardized loadings (λ) and cross-loadings for all latent constructs to ensure the study instrument was reliable and valid (refer to Table 5). The standardized loadings for each item were 0.75-0.88, indicating robust construct representation, while the cross-loadings were less than 0.12, indicating discriminant validity. The translation into Mandarin was tested for metric invariance, and all constructs had ΔCFI values <0.01, which indicates that the translated items perform the same as the original instrument. Table 5 provides a comparison of original CF and higher-order CFA models, which helps determine whether the measurement model in this research is legitimate.

Table 5. Comparison of original confirmatory factor analysis (CFA) and higher-order CFA models, including model fit indices, for constructs measured in 1029 high school students in Beijing, Shanghai, Chengdu, and Guangzhou, 2025.

Model	CFI[a]	TLI[b]	RMSEA[c]	SRMR[d]	χ^2 (*df*)	AIC[e]	BIC[f]
Original CFA[g]	0.961	0.953	0.042	0.038	2.85 (532)	2180.45	2245.67
Higher-order CFA (reduced model)	0.954	0.946	0.043	0.040	2.87 (534)	2145.32	2210.58

[a]CFI: comparative fit index.

[b]TLI: Tucker-Lewis Index.

[c]RMSEA: root-mean-square error of approximation.

[d]SRMR: standardized root-mean-square residual.

[e]AIC: Akaike information criterion

[f]BIC: Bayesian information criterion

[g]CFA: confirmatory factor analysis.

In a higher-order structural factor analysis (CFA), the study combined 2latent factors: intrinsic motivation and enjoyment of physical exercise, and cognitive performance and teamwork. Having a χ^2/df ratio of 2.87 and good fit indices (CFI=0.954, TLI=0.946, RMSEA=0.043, and standardized root-mean-square residual=0.040), the higher-order model effectively fit the measurement model. The higher-order CFA has lower AIC (2145.32) and BIC (2210.58) than the original CFA, indicating that the reduced model is more parsimonious without losing theoretical or empirical validity. These results suggest that the dual-framework model (SDT + CLT) may retain construct validity and conceptual coherence with fewer latent variables.

The Fornell-Larcker criterion and the heterotrait-monotrait (HTMT) ratio of correlations were used to assess the discriminant validity of SEM. Table 6 provides their results.

Table 6. Fornell-Larcker criteria and the heterotrait-monotrait (HTMT) ratio assessing the discriminant validity of all constructs in 1029 high school students, 2025.

Constructs	Fornell-Larcker diagonal	HTMT[a] ratios (max)
Cognitive performance	0.81	0.82
Gamified PE[b]	0.84	0.79
PE[b] enjoyment	0.80	0.76
Peer collaboration	0.78	0.74
Teacher support	0.83	0.77
Motivation	0.82	0.81
AI[c] feedback	0.81	0.80

[a]HTMT: heterotrait-monotrait.

[b]PE: physical education.

[c]AI: artificial intelligence.

The diagonal line shows the square root of each construct's AVE compared to the interconstruct correlations, using Fornell-Larcker criteria. This method demonstrates discriminant validity when the square root of a concept's AVE is greater than its highest correlation with any other construct. Cognitive performance's Fornell-Larcker diagonal value of 0.81 is greater

XSL•FO
RenderX

than its connections with gamified PE, motivation, and AI feedback. AI feedback (0.81), gamified PE (0.84), PE enjoyment (0.80), peer collaboration (0.78), teacher support (0.83), motivation (0.82), and AI Support (0.83) all have top diagonal values, indicating that each construct's items are more strongly related to their latent variable than to any other. The HTMT ratio was used to enhance this investigation. PLS-SEM applies HTMT for a more sensitive and reliable discriminant validity test. Discriminant validity is good when HTMT values are <0.85. All HTMT scores in the results were between 0.74 and 0.82. For cognitive performance, none of the constructs has an HTMT ratio >0.82, which is sufficient. AI feedback (0.80), gamified PE (0.79), PE enjoyment (0.76), peer collaboration (0.74), teacher support (0.77), motivation (0.81), and AI support (0.79) all fall below the threshold, supporting the premise that each latent concept is empirically distinct. Table 7 shows the estimates of Harman single-factor and latent common method variance.

Table 7. Harman single-factor and latent common method variance (CMV) tests to evaluate potential survey bias in 1029 high school student responses, 2025.

Test type	No of factors extracted	Variance explained by first factor (%)	Total variance explained (%)	ΔCFI[a] (with CMV[b] factor)	$\Delta\chi^2$[c] (*df*)	*P* value	Conclusion
Harman single-factor test	7	28.6	72.4	—	—	—	No CMV concern (first factor<40%)
Latent common method factor test	7 + CMV	26.9	74.1	0.006	21.38 (1)	.09	No significant CMV effect (ΔCFI<0.01)

[a]CFI: common method variance.

[b]CMV: common method variance.

[c]$\Delta\chi^2$: change in chi-square value.

Harman single-factor test and the latent CMV factor test were used to assess for self-reported data-related CMV. The unrotated factor analysis found 7 variables, although the first accounted for 28.6% of the variance (vs 40%). This indicates that no factor dominated the item-level covariance structure. This finding was confirmed by adding a latent CMV component to the measurement model. The model fit comparison showed no significant reduction in fit, even after controlling for method effects (ΔCFI=0.006 and $\Delta\chi^2_1$=21.38; *P*=.09). These findings strongly suggest that common method bias does not threaten the study's validity and that discriminant integrity of latent constructs is preserved.

Table 8 provides the SEM findings, which strongly support the research's theoretical approach. There is a positive relationship between gamified PE and students' cognitive performance. Gamified PE may enhance students' concentration, memory, and information-processing skills [84]. According to the engagement-learning paradigm, students learn meaningfully when they are emotionally, behaviorally, and cognitively involved [85]. Game elements, such as goal-setting, fast feedback, and reward systems, in PE sessions, may help children learn more effectively and improve cognitively [86]. Chaiyarat [87] and Aibar-Almazán et al [88] reported that gamification can make the classroom more dynamic and engaging, thereby enhancing students' problem-solving and critical-thinking skills.

Table 8. Structural equation modeling (SEM) path estimates showing relationships among studied factors with standardized beta coefficients and significance levels, based on 1029 students, 2025.

Path	Estimates (β)	SE	*t* statistic	*P* value
Gamified PE[a] → cognitive performance	.34[b]	0.05	6.80	<.001
Enjoyment → cognitive performance	.28[b]	0.06	4.67	<.001
Collaboration → cognitive performance	.26[b]	0.07	3.71	<.001
Teacher support → cognitive performance	.31[b]	0.06	5.17	<.001

[a]PE: physical education.

[b]*P*<.001 (1% significance level).

Teacher support is the second strongest predictor of students' cognitive performance. This suggests that instructors must understand how to positively impact students' cognitive growth through effective lesson preparation, positive reinforcement, and constructive feedback. Gamified and AI-feedback classrooms require teacher facilitation [89]. Teachers should motivate students by establishing a psychologically safe classroom, helping them grasp and implement challenging feedback, and scaffolding their learning to support their growth and development [90]. Cha et al [91] found that students feel more confident, engaged, and cognitively involved in classroom tasks, especially in active and digitally mediated settings, when they view their teachers as accessible, attentive, and helpful.

There is a positive relationship between physical activity enjoyment and students' cognitive performance, which suggests that students who enjoy PE may focus better, experience lower cognitive stress, and feel emotionally good, which helps them

XSL•FO
RenderX

learn. According to SDT, individuals are more engaged and learn more when they have a personal interest in the result [92]. Chen [93] found that children who enjoy physical activities are more willing to participate and better able to harness the psychological benefits of exercise, leading to improved classroom concentration, memory, and performance. Enjoyment enhances cognition in gamified environments by reducing performance anxiety and boosting self-confidence.

Peer collaboration and cognitive performance were significantly positively associated. Collaborating with peers during gamified PE classes boosts cognitive development. The focus on idea-sharing, collaborative problem-solving, and social and emotional support in peer learning enhances understanding and mental agility. This result is supported by Vygotsky's sociocultural theory, which emphasizes the role of social interaction in internalizing information [94]. Qi and Derakhshan [95] found that physically active educational activities help students develop social and cognitive skills for academic success. Collaboration, negotiation, and peer feedback improve metacognition and learning.

The study analyzed cluster effects in Beijing, Shanghai, Chengdu, and Guangzhou using intraclass correlation coefficients (ρ) and design effects for each latent construct. The intraclass correlation coefficients ranged from 0.02 to 0.06, resulting in design effects of 7.18 to 19.90 with an average cluster size of 310 respondents per city (Table 9). After achieving the threshold (ρ>0.05), a multilevel structural equation model with random intercepts was used to review cognitive performance and AI-based feedback. There were minor differences in explained variance (ΔR^2= +0.02 to +0.05) and standardized path coefficients (Δβ<.02) between single-level and multilevel estimations. The findings reveal that provincial clustering did not significantly affect gamified PE engagement, intrinsic motivation, and cognitive performance. Therefore, the estimation technique does not influence structural model robustness.

Table 9. Cluster diagnostics and multilevel structural equation modeling (SEM) robustness checks verifying the stability of results across school clusters in 1029 high school students, 2025.

Construct	Number of clusters (cities)	Average cluster size (n^-)	ICC[a] (ρ)	Design effect=1+(n^-−1)ρ	Single-level β (gamified PE → cognitive performance)	Multilevel β (random intercept model)	Δβ[b] (bias)	ΔR^2 (change in explained variance)
Cognitive performance (CP)	4 (Beijing, Shanghai, Chengdu, and Guangzhou)	310	0.05	16.45	.45	.43	−.02	0.04
Gamified PE[c] engagement	4	310	0.04	13.36	.34	.33	−.01	0.03
Intrinsic motivation	4	310	0.03	10.27	.21 (indirect κ^2=0.16)	.20	−.01	0.02
AI[d]-based feedback	4	310	0.06	19.9	.18 (interaction β)	.17	−.01	0.05
Teacher support	4	310	0.02	7.18	.31	.30	−.01	0.02
Peer collaboration	4	310	0.03	10.27	.26	.25	−.01	0.02

[a]ICC: intraclass correlation coefficient.

[b]Δβ: change in bias.

[c]PE: physical education.

[d]AI: artificial intelligence.

Table 10 assessed the impact of AI-based feedback on the model using effect-size indices (κ^2 and PM), conditional effects at ±1 SD, and ΔR^2. The mediation study revealed a medium-to-large effect size (κ^2=0.19) and PM=0.36, suggesting that intrinsic motivation indirectly accounts for36% of the connection. Intrinsic motivation substantially influenced the link between gamified PE and cognitive performance (β=.23; *P*<.001). A moderated analysis indicated that AI-based feedback increased the positive correlation between gamified PE and cognitive performance (β=.17; *P*<.001). The correlation between AI feedback and gamified learning gains increased with complexity, with β=.13 at low levels (–1 SD), β=.20 at medium, and β=.28 at high levels (+1 SD). The inclusion of the interaction term raised the model's explanatory power from R^2=0.47 to R^2=0.55, resulting in a ΔR^2 of 0.08, indicating that AI-based feedback explained an additional 8% of the variance in students' cognitive performance.

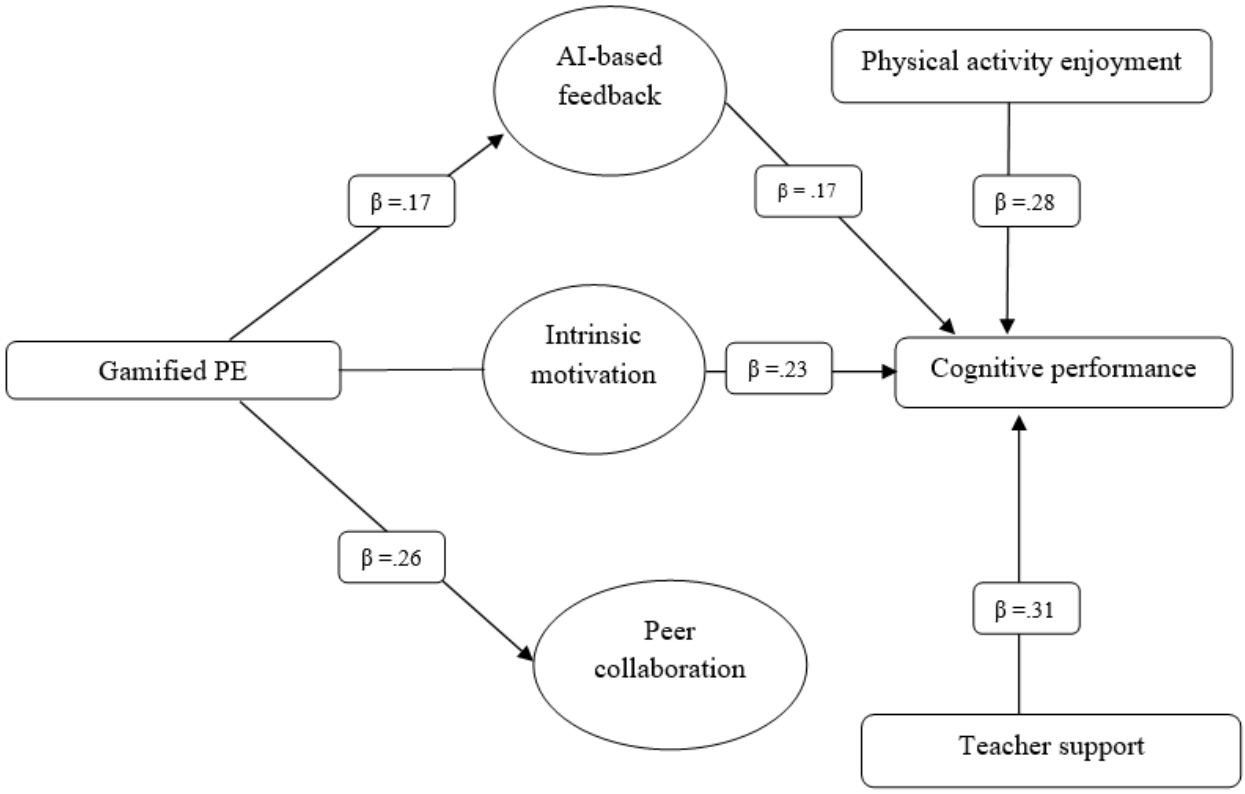
[e]Conditional effects: changes in the slope of gamified PE → cognitive performance at low (–1 SD), mean, and high (+1 SD) levels of artificial intelligence (AI)–based feedback.

[f]ΔR^2: 0.08, indicating an 8% increase in explained variance after counting the moderation term.

[g]*indicates a 1% significance level.



The quantity of AI feedback in gamified PE sessions affects student engagement and cognitive performance. Gamified PE improves cognitive function, and AI-based feedback enhances this impact. Children who participate in gamified PE and receive continuous, real-time AI-powered feedback are more likely to experience enhanced cognitive outcomes, including improved memory recall, attention, problem-solving, and mental engagement [96]. Feedback intervention theory suggests that timely and personalized feedback helps learners concentrate on task-related goals, self-regulate, and engage cognitively [97]. It may be challenging to obtain adaptive, data-driven insights in traditional PE settings, but AI-powered feedback is immediate, objective, and tailored. These systems, integrated into a gamified framework, make learning more engaging and challenging for students, providing explicit guidance on how to improve, which in turn fosters deeper thinking. According to Suresh Babu and Dhakshina Moorthy [98], gamification alone can boost student engagement. However, intelligent feedback systems can amplify these effects on cognition by influencing learner behavior and performance in real-time. The study's findings support the use of technology-enhanced, customized learning environments in modern school design. Gamified education uses AI feedback as a cognitive support system to help students recall and apply what they have learned via hands-on, interactive activities [99]. CLT suggests that real-time AI feedback, which optimizes task difficulty and decreases ambiguity, helps learners focus on important cognitive activities. The moderating impact also affects curriculum and educational policy, suggesting that complex feedback systems are needed for gamified physical instruction to maximize cognitive outcomes. For gamified learning to be most effective, schools and instructors should use or invest in AI-powered solutions that tailor insights and feedback to each student's unique profile and cognitive capabilities.

Gamified PE improves cognitive function, and intrinsic motivation is a crucial psychological factor. Gamified PE enhances intrinsic motivation, leading to improved cognitive performance. The indirect effect explains most of the variance in cognitive performance, confirming that gamification's structure and qualities are significant, but what counts most are learners' psychological moods. Self-determination theory emphasizes relatedness, competence, and autonomy as components of intrinsic motivation, which is reflected in this mediation effect. Gamified learning environments enhance intrinsic interest and satisfaction by fostering autonomy through choice, competence through manageable tasks, and relatedness through peer collaboration [53]. Students who are genuinely motivated to study are more likely to use metacognitive skills, pay attention, and learn more deeply. Shalgimbekova et al [100] suggest that motivation moderates the link between instructional

XSL•FO
RenderX

design and learning outcomes. This result highlights the role of motivation in mediating the pedagogical efficacy of innovative teaching methods. Even if gamified PE is fun and structured, internalizing values and desires drives cognitive growth. This study supports the idea that the motivating processes of instructional inputs are as essential as the inputs themselves in cognitive performance [101]. Gamification sets the scene, but intrinsic motivation propels cognitive functioning. This mediation strengthens Hypothesis H3, which states that intrinsic motivation mediates the relationship between gamified PE and cognitive performance. Gamification alone is ineffective; however, students' natural incentive to participate and accomplish tasks substantially enhances outcomes, as evidenced by the considerable indirect path. This means that instructional designers, policymakers, and instructors should support children's intrinsic drive to learn and incorporate engaging aspects into PE interventions to enhance academic cognition. Figure 2 shows the structural model with standardized path coefficients.

Figure 2. Structural model displaying standardized path coefficients for all hypothesized relationships among studied factors in 1029 high school students, 2025. Source: Author's estimate.AI: artificial intelligence; PE: physical education.

The significant first-order factor loadings (λ=0.65-0.88; *P*<.001) indicate high correlations between observable indicators and their latent components (refer to Table 11). The substantial second-order factor loadings (λ=0.71-0.84; *P*<.001) suggest that SDT and CLT collaborate to create a more sophisticated integrative model. The complete model suited the specified conceptual framework well, with CFI=0.957, TLI=0.949, and RMSEA=0.041.

XSL•FO
RenderX

Table 11. Structural equation modeling (SEM) results for the dual-framework model with standardized path coefficients in 1029 students, 2025.

Analysis	Statistic	*P* value
Second-order CFA[a]	Factor loadings: λ=0.65-0.88 (1st-order) and λ=0.71-0.84 (2nd-order)	<.001

Covariance	Covariance=0.42	<.001
Cross-loading check	Max cross-loading=0.25	—[e]
Latent interaction test	$\Delta\chi^2$=4.12[f]	.04

[a]CFA: confirmatory factor analysis.

[b]CFI: comparative fit index.

[c]TLI: Tucker-Lewis Index.

[d]RMSEA: root-mean-square error of approximation.

[e]Not available.

[f]Indicates a 5% significance level.

Further, a significant association (covariance=0.42; *P*<.001) was found between intrinsic motivation and AI-based feedback, using a covariance approach. While preserving discriminant validity, this study supports the significant link between these factors. The measurement model was tested, and cross-loadings indicated that cognitive performance, intrinsic motivation, and AI-based feedback are empirically independent, supporting the structural coherence of the dual-framework SEM.

To determine whether AI-based feedback has context-specific effects, the study conducted multigroup moderation tests by level of technology access (high, moderate, and low) and location (urban vs rural; refer to Table 12).

Table 12. Multigroup moderation analysis examining differences in study relationships by urban vs rural location and technology access in 1029 high school students across 4 cities, 2025.

Path	Group	Sample size (n)	β estimate	SE	*t* value	*P* value	ΔR^2[a]	f^2[b]
Gamified PE[c] → cognitive performance	Urban	366	.35[d]	0.06	5.83	<.001	0.05	0.16
Gamified PE → cognitive performance	Rural	303	.31[d]	0.07	4.43	<.001	0.05	0.15
Gamified PE → cognitive performance	High-tech access	400	.37[d]	0.05	7	<.001	0.07	0.18
Gamified PE → Cognitive Performance	Moderate tech access	451	.34[d]	.05	6.8	<.001	0.05	0.16
Gamified PE → cognitive performance	Low-tech access	178	.28[d]	0.06	4.67	<.001	0.04	0.14

[a]ΔR^2: *P*<.05.

[b]f^2: *P*<.05.

[c]PE: *P*<.05.

[d]Indicates a 1% significance level.

Table 12 shows a substantial influence of gamified PE on cognitive performance across all groups (β=.28-.37; *P*<.001). Impacts were higher for urban students and those with high technological access (β=.35 and .37, respectively) and lower for rural students and those with low access (β=.31 and .28, respectively). Moderation had medium to high impacts, with ΔR^2 values ranging from 0.04 to 0.07 and f^2 effect sizes from 0.14 to 0.18. These findings suggest that gamified PE interventions based on AI are generally effective, with urban students and those with greater technological access benefiting more cognitively.

Discussion

Principal Findings

This study examined how intrinsic motivation and AI-based feedback affect high school students' cognitive performance after gamified PE. The first objective was to explore the effects of gamified PE and teacher support on students' cognitive performance; statistically significant benefits were shown, confirming Hypothesis 1. The second goal was to assess how physical exercise enjoyment and peer collaboration affect cognitive performance, which was confirmed by the strong positive connections between these factors and cognitive performance, supporting Hypothesis 2. The findings supported the third aim, that is, determining whether gamified PE

XSL•FO
RenderX

influences cognitive performance and whether intrinsic motivation mediated this impact. The positive effect of gamified PE on cognitive performance was partially mediated by intrinsic motivation, but AI-based feedback enhanced it, supporting Hypothesis 3. Gamified PE improves cognitive performance through motivational and technical processes, in line with the research's goals and theoretical framework.

Interpretation and Implications

Gamified PE improves cognitive function, suggesting that schools can create engaging, dynamic, and technologically advanced learning environments. Gamification boosts cognitive functioning by focusing students, simplifying problem-solving, and stimulating active involvement. Well-designed, gamified PE interventions may achieve these aims, supporting the view of Barz et al [102] that game-based learning may boost motivation and cognition. The SDT concept was reinforced by intrinsic motivation, which asserts that students who feel autonomous, competent, and socially engaged are more likely to participate in meaningful activities and achieve higher-order cognitive achievements. This suggests that gamified PE improves cognition and intrinsic motivation, which sustains engagement and learning [103]. Student involvement and academic success are highest in PE programs that incorporate enjoyable and independent activities. Social and instructional factors, including a friendly teacher, exercise, and teamwork, promote learning. Game-based and AI-supported learning benefit from human facilitation, although instructors' guidance, encouragement, and scaffolding are still needed. Teamwork promotes collaboration, communication, and executive functioning, which may explain its cognitive advantages. These findings support more comprehensive theoretical frameworks that promote student-centered, socially engaged, and holistic learning environments [104]. AI-based feedback moderates the effect of adaptive, real-time recommendations on learning. AI-assisted strategy correction, refinement, and progressive advancement, delivered through rapid, tailored feedback, boosts cognitive performance beyond the reach of gamification. Recent AI-assisted learning experiments have shown potential for cognitive optimization and personalized skill improvement [105].

Comparison With Existing Literature

This study builds on previous classroom gamification research. Gamification and AI feedback in PE can enhance cognitive performance, contrary to previous research on academic participants [106,107]. While gamification has been shown to improve motivation, little research has linked it to cognitive outcomes in PE [108,109]. These findings suggest that technology-driven feedback and compelling design may boost students' cognitive performance. The study contributes to AI in education research by confirming previous classroom-based studies [110,111] that real-time adaptive feedback increases learning. This study combines SDT and CLT to advance theory. Gamified experiences increase learning via intrinsic motivation and cognitive load. These results provide a foundation for future research on integrated, technologically advanced, motivation-based educational interventions.

Practical Implications

The findings suggest that AI-based feedback mechanisms could be beneficial to educational institutions, particularly in technologically advanced cities. To achieve this, AI-powered educational systems must be funded. These systems should have adaptive capabilities and age-appropriate user interfaces to provide children with timely, individualized feedback on their PE, behavioral engagement, and cognitive attention. Policy cooperation among Chinese education ministries, IT businesses, and AI research institutes may accelerate the development of educational systems tailored to the nation. To ensure that technology enhances human teaching, a national AI-in-education framework must guide deployment, data ethics, privacy protection, and teacher capacity-building. Pilot studies in schools with suitable digital infrastructure may examine the effects of AI-enhanced, gamified learning on academic achievement. Since public and semigovernment institutions had larger performance disparities, the findings imply a shift toward socially and motivationally enhanced learning. Policies should prioritize training PE instructors to create welcoming, inclusive, and inspirational learning environments. To stimulate cognitive development through intrinsic motivation and peer collaboration, schools must prioritize students' mental health, incorporate team-building activities, and use inclusive instructional techniques that cater to their unique social identities and needs. Teacher performance measurements should incorporate student-centered learning, emotional support, and inclusive engagement as part of education reforms. Physical exercise, reflection, feedback, and cognitive challenge must be balanced in gamified learning settings that promote collaboration and active learning.

Limitations

This study has made many essential contributions. However, there are some limitations. Although the research used a large and diverse sample from 4 metropolitan cities, its cross-sectional design limits causal inferences. SEM and bootstrapping provide more compelling findings; however, experimental or longitudinal designs are necessary to determine the long-term impact of gamified PE and AI feedback on cognitive function. Second, self-report assessments may be biased by social desirability or cognitive misunderstanding, even when administered under supervision to children aged 10-12 years. Future studies could triangulate findings and improve measurement validity by using multi-informant data, such as behavioral observations or teacher ratings. The generalizability of the results is another issue. The sample included students from urban and suburban public, private, and semigovernment schools, but not rural or low-tech institutions. This raises the question of how AI-based gamified systems can effectively serve diverse socioeconomic and geographical conditions. Future research should examine how infrastructural variations affect such efforts and the digital divide. Although this study focused on cognitive function, it did not examine emotional regulation, academic resilience, or physical health. Future multidimensional research should examine how gamified and AI-supported instructional techniques affect broader student capacities. This study focused on AI feedback as a moderator and intrinsic motivation as a mediator. Other factors, such as self-efficacy,

XSL•FO
RenderX

goal orientation, and support from family and friends, influence students' attitudes toward gamified learning. Future studies should incorporate additional mediators and moderators to gain a deeper understanding of the complex interplay among human, systemic, and technological factors. In conclusion, qualitative research methods, such as student interviews or classroom ethnographies, can complement quantitative approaches by providing contextual insights into learners' experiences and preferences. By addressing these limitations, future research may enhance the theoretical and practical understanding of how gamified, technology-enhanced education can improve student learning and growth.

Conclusions

The study concludes that Gamified PE with intrinsic motivation and AI-based feedback improves high school students' cognitive performance. These findings demonstrate that technology-based student-centered PE programs improve engagement, motivation, and cognition. Gamification and AI in education may improve students' overall development and academic and social results outside of the classroom. Future research should examine the long-term impacts, demographic factors, and technological developments to enhance the cognitive and motivational benefits of school-based treatments. To capitalize on the full potential of gamified PE for cognitive development, policymakers in education must institutionalize gamified pedagogy into the national PE curriculum. Schools should update their PE curriculum to highlight the connection between physical health and emotional and intellectual development. The curriculum should incorporate more structured, game-based learning methods that enhance cognitive abilities. In PE, goal-setting, point-scoring, and challenge-based learning help students concentrate, recall, and solve issues. The Ministry of Education, along with state and regional education bureaus, should educate PE teachers in gamified teaching methods to meet pedagogical criteria, engage students, and measure academic achievement.

This study advances the literature by introducing a technology-driven model of PE that combines gamification with AI-based feedback to enhance students' cognitive abilities. This study demonstrates the synergistic effects of gamification, intrinsic motivation, and AI-supported feedback on cognitive development, in contrast to previous research that has primarily focused on conventional PE or singular teaching methodologies. This study contributes to the existing literature on digital and AI-enhanced education by using a substantial, multicity sample and SEM to demonstrate the validity of these connections. The findings have substantial implications for educational institutions, educators, and policymakers, suggesting that interactive, AI-driven PE programs can effectively enhance student engagement, learning processes, and cognitive performance in genuine educational environments.

Acknowledgments

No generative artificial intelligence tools were used in the writing, editing, data analysis, or preparation of this paper.

Data Availability

The dataset generated and analyzed during this study are not publicly available due to privacy protections for minors and institutional restrictions. Deidentified data may be made available upon reasonable request to the corresponding author, subject to ethical approval.

Funding

No external financial support or grants were received for this work.

Authors' Contributions

JZ contributed to the study's conceptualization, methodology development, data collection, data curation, formal analysis, and drafting of the original paper. SSO supported the conceptualization of the research, assisted with data collection, and contributed to critical review and paper editing. YX supervised the overall study, provided guidance throughout the research process, contributed to study design and interpretation of findings, participated in paper revision, and managed project administration as the corresponding author.

Abstract

Background: Exergaming, which combines physical activity with interactive gaming, has been shown to improve motor skills and fitness. However, exergaming's potential in complex, open-skill sports such as tennis, which require real-time coordination, decision-making, and technical precision, remains underexplored. Furthermore, only a few studies have evaluated the impact of exergaming on both technical skill development and psychological outcomes such as motivation and confidence, especially among novice players. This study addresses these gaps by comparing the combination of exergame-based tennis training and on-court tennis training (EBTT+OCTT) with on-court tennis training alone (OCTT×2) in improving technical skills, grip strength, confidence, and motivation.

Objective: This study aims to assess the effect of exergaming tennis in developing tennis technical skills, grip strength, confidence level, and motivation level.

Methods: In a 12-week quasi-experimental trial, 66 novices were randomized to either the EBTT+OCTT or the OCTT×2 group. Participants consisted of 22 males and 44 females, with the mean BMI and age of approximately 22 (SD 2.9) kg/m^2 and 26 (SD 7) years, respectively. The EBTT+OCTT group had 1 weekly session of OCTT and 1 session of exergaming training using Virtual Tennis (PlayStation 3 Move), while the OCTT×2 group completed 2 weekly on-court sessions. Outcomes included tennis technical skills such as groundstroke technique, service speed, and service accuracy (assessed using the Hewitt tennis test), grip strength (using a handheld dynamometer), confidence (using the Sports Confidence Inventory), and motivation (using the Sport Motivation Scale). Mean differences (MDs) between pre- and postintervention were collected and analyzed using repeated-measures ANOVA (α=.05) and Pearson correlation analysis. Effect sizes were calculated using partial eta squared (ηp^2), where values ≥0.14 indicated large effects.

Results: After 12 weeks of training, both EBTT+OCTT and OCTT×2 groups showed significant improvements (P<.001) in tennis technical skills (MD=17.06-22.62), grip strength (MD=9.59-11.04 kg), and confidence levels (MD=23.29-26.28). These outcome measures have large effect sizes (ηp^2=0.84-0.92); however, they did not significantly differ (P>.05) across the groups when compared, with $P_{grip\ strength}$=.24, P_{hit}=.97, $P_{accuracy}$=.86, $P_{speed=}$.72, and $P_{confidence}$=.31. In terms of motivation, EBTT+OCTT retained intrinsic motivation (IM) better than OCTT×2, with significant reductions in IM, mainly IM-to-know (MD=7, SD 2.95) and IM-to-accomplish (MD=5, SD 3.77) observed in the OCTT×2 group (P<.001). Grip strength, confidence, and motivation levels (except amotivation) showed positive correlations with tennis technical skills (r=0.39-0.80).

Conclusions: EBTT+OCTT and OCTT×2 significantly improve tennis skills and confidence levels in novice players, although no significant differences were found between the two. However, EBTT+OCTT appeared to better sustain IM. Thus, EBTT+OCTT may serve as a supplementary tool for novice players to better learn tennis.

KEYWORDS

exergaming; tennis; sports skills; psychology; sport training

Introduction

Technological innovations have facilitated the integration of physical activity through electronic platforms, particularly via exergaming—interactive video games that require physical movement for gameplay [1]. Substantial evidence demonstrates the efficacy of exergaming in enhancing motor coordination, reaction time, and physical fitness across various populations, including pediatric, geriatric, rehabilitation, and special needs cohorts [2,3]. These systems present novel opportunities for incorporating exercise into daily life, prompting investigation of their applications in sports training. According to the existing literature, most research has focused primarily on endurance and closed-skill sports (eg, cycling, running, and rowing), as their predictable, self-paced nature translates effectively to virtual environments [4-6]. In contrast, open-skill sports such as tennis have received limited attention due to the technical challenges of accurately replicating their complex biomechanics and decision-making demands in digital platforms [4]. Tennis demands precise mind-body coordination, decision-making skills, and real-time reactions [7]. While exergaming shows potential for early skills acquisition, the current literature lacks studies examining its effects in skill-based sports.

Tennis is a complex, open-skill sport that demands not only physical skill and execution of techniques such as serving and groundstrokes but also strong psychological attributes, including confidence and motivation [7,8]. Technical proficiency, such as accurate and powerful strokes, is fundamental to performance, yet these motor skills do not operate in isolation, and physical capability, such as grip strength, may also play a role in ensuring these skills are executed appropriately [4,9,10]. In addition, psychological readiness can influence how consistently and effectively players perform under pressure, make decisions, and maintain effort during training or competition [7,11].

While physical outcomes have been moderately investigated, there is a lack of research examining psychological outcomes, particularly confidence and motivation, which are known to influence motor learning and sports performance [4,7,11]. Confidence, for example, plays a key role in motor learning and performance; players with greater sport confidence are more likely to take risks, recover from mistakes, and execute techniques successfully under stress [7,12]. Similarly, motivation, especially intrinsic motivation (IM), affects the degree of engagement, persistence, and enjoyment during practice, which can directly enhance motor learning and skill retention [7,13]. These psychological factors are not only relevant to sport performance but may also be interrelated with technical skill development, making it important to study both domains simultaneously [7,11-13]. For instance, a motivated and confident player may be more willing to engage in deliberate practice, which leads to better technical improvement. Only a limited number of studies have concurrently examined the interrelationship between technical and psychological skills in an exergaming context, leaving a gap in understanding how these domains interact to support performance and engagement.

Exergaming, by blending physical movement with gaming elements, has the potential to impact both domains [1]. It can foster motor skill repetition in a stimulating environment while simultaneously supporting motivation and self-confidence through goal-setting and feedback [3]. However, most previous exergaming research has focused either on general fitness or cognitive outcomes, with limited exploration of its impact on sport-specific technical skills and psychological outcomes in a combined manner.

While both exergaming and traditional on-field exercises aim to promote physical fitness, they differ considerably in context, delivery, and user engagement. Research has consistently demonstrated that on-field exercises such as tennis, football, and badminton contribute to improved cardiovascular fitness, enhanced muscular strength, better body composition, and overall physical and mental well-being [8,14]. However, despite their benefits, on-field exercises can present certain challenges, such as time constraints, limited access to appropriate facilities, weather conditions, and personal motivation [14-16]. Exergaming, in contrast, combines physical movement with interactive digital gameplay, making exercise more accessible, enjoyable, and gamified [3]. Research has shown that adding exergaming to exercise regimes such as badminton, tennis, and golf can help encourage social interaction, allowing users to participate in cooperative or competitive activities with family, friends, or online communities, which may improve the appeal and sustainability of physical activity [17,18].

Tennis was chosen in this study because there is limited research examining this sport. There was also a need to evaluate whether skills learned through exergaming can transfer to real tennis performance. Although understanding the rules and strategies of tennis is important, mastery of the sport requires repeated physical practice to develop technical proficiency, coordination, and real-time decision-making skills. Exergaming may help players develop motor skills to respond to service and shots through repetitive practice, combining mental, visual, and motor learning.

Thus, the main objectives of this research were to determine whether integrating exergame-based tennis training and on-court tennis training (EBTT+OCTT) can help improve tennis technical skills, grip strength, confidence, and motivation levels compared with only the traditional on-court tennis training (OCTT×2). In addition, this research aimed to determine whether there is any correlation between grip strength, confidence, and motivation, to better understand their interrelationship and impact on tennis performance.

Methods

Study and Trial Designs

This quasi-experimental study was conducted in Malaysia, where participants were initially randomly allocated to either the EBTT+OCTT group or the OCTT×2 group as a parallel-group experimental study (aged 18 to 40 years, with

XSL•FO
RenderX

balanced randomization in a ratio of 1:1). However, about 9%-10% (OCTT×2 [n=3] and EBTT+OCTT [n=4]) of participants in each group requested to change their assigned allocation, and these requests were accommodated to minimize participant dropout. These requests were made before commencement of the experimental procedure, and no participants were switched during the experimental period.

Participants

Social media postings and word-of-mouth marketing were used to recruit research participants. Participants were predominantly urban residents, consisting of university students and young professionals from diverse socioeconomic strata. The sample size calculator program G*Power (version 3.1.9.4; Heinrich Heine University) was used to determine the sample size. A repeated measures ANOVA (within- and between-groups' interactions) was selected as the statistical test. The calculation was based on a large effect size (f=0.4), a significance level of 0.05, and a power (1−β1) of 0.95 [19]. The large effect size was chosen based on previous literature in sports and exergaming interventions reporting medium to large effect sizes for motor and psychological outcomes [20,21]. In addition, as this study was exploratory and involved multiple dependent variables with expected training-related gains, a conservative large effect size was used to ensure adequate statistical power. Two groups (EBTT+OCTT and OCTT×2) and 2 measurement time points (pre- and posttraining) were included, with an estimated correlation of 0.5 between repeated measures. The analysis determined that a minimum of 24 participants (12 per group) were required. To account for a potential dropout rate of 20%, 29 participants were required in total. This study recruited 66 participants in total, with 33 participants assigned to each group (Textbox 1).

Textbox 1. The inclusion and exclusion criteria of the study.

Inclusion criteria

- Individuals with less than 1 year of tennis experience.
- Aged between 18 and 40 years.
- No medical history or surgical history.
- Physical activity level below moderate as assessed by the International Physical Activity Questionnaire (IPAQ).

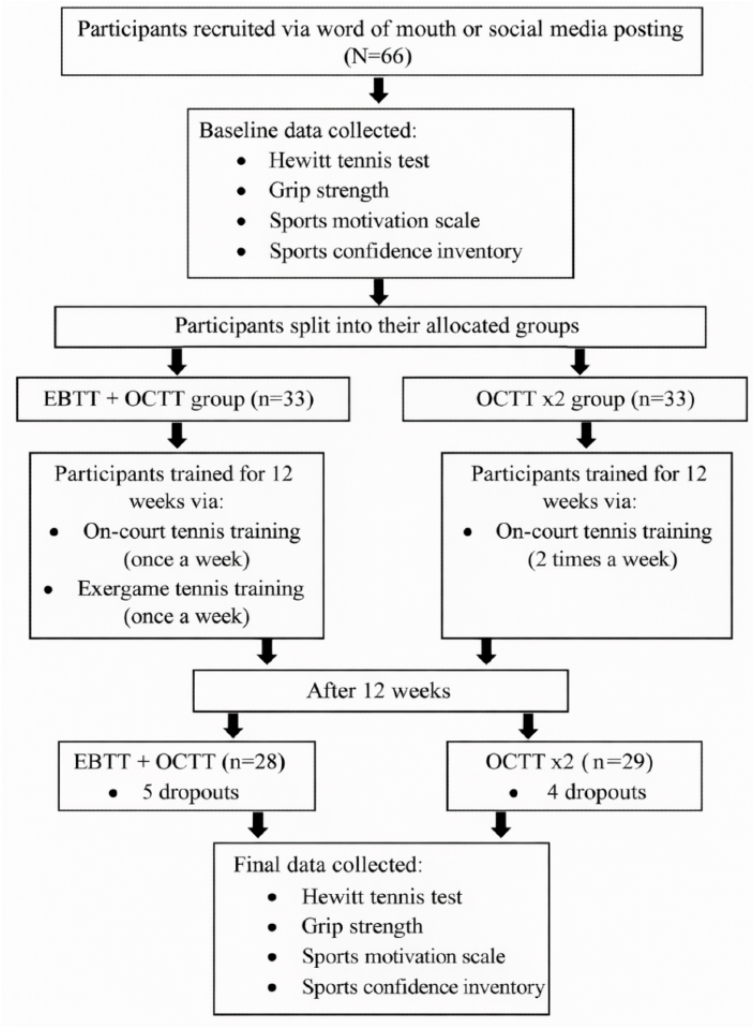
Exclusion criteria

- Individuals who are obese (BMI>30 kg/m^2).
- Individuals who do not understand English or Malay.

In the recruitment process, 74 individuals were screened, and 66 met the inclusion criteria. The others were excluded for reasons such as having over a year of tennis experience (3 individuals), a high International Physical Activity Questionnaire (IPAQ) score (2 individuals), a BMI exceeding 30 kg/m² (2 individuals), or cardiorespiratory conditions such as asthma (1 individual). The final sample (22 males and 44 females with a mean age of 26.3 years) represented the university-affiliated and local recreational tennis community, which is roughly 60% female and predominantly aged 18 to 35 years. The participants' weekly physical activity levels, averaging about 760 metabolic equivalents of task minutes on the IPAQ scale, aligned with those of a low-to-moderately active urban adult population. The low to moderate IPAQ score was selected because it can enhance the responsiveness to training interventions, as individuals with lower activity levels are more likely to demonstrate measurable improvements in physical and psychological outcomes [4,7]. Furthermore, exergaming interventions have been primarily designed for and shown to be particularly beneficial in low-active or novice populations, supporting the appropriateness of this inclusion criterion [7,22]. A standardized IPAQ score was also required to reduce variability in fitness and motor performance that might influence the responsiveness to training, particularly since the study targeted novice players [22].

Experimental Procedure

Sixty-six individuals were divided into two groups, with a total of 33 individuals in each of the OCTT x 2 and EBTT+OCTT groups. The participants in the EBTT+OCTT group practiced tennis on both the exergaming platform and the traditional tennis court, whereas the OCTT×2 group practiced only on the traditional tennis court. Before the training started, the participants' consent, demographic data, physical activity level via IPAQ, and baseline data such as sports motivation test, sports confidence inventory, grip strength via handheld dynamometer, and technical skills via the Hewitt tennis test were collected. All questionnaires and outcome measures were valid and reliable [22-26].



Both groups followed identical protocols for their on-court training sessions, which were conducted on tennis courts and with equipment meeting International Tennis Federation regulatory standards [27]. The sessions were done for 1.5 hours, comprising a warm-up period of 15 minutes, a 1-hour main practice, and a 15-minute cool-down. The exercise session duration and frequency were set following the American College of Sports Medicine guidelines [28,29]. The OCTT×2 group practiced on-court tennis twice a week, whereas the EBTT+OCTT group had one on-court and one exergaming session per week. In addition to the on-court tennis practice, participants in the EBTT+OCTT group also practiced tennis using a video game version of Virtual Tennis (Sports Champion

XSL•FO
RenderX

2, Zindagi Games, San Diego Studio) on a gaming device, the PlayStation 3 Move, for 1.5 hours.

Training included swing practices such as service, forehand, and backhand, and matches (either with a virtual avatar or among themselves). Matches were conducted between the 10th and 12th weeks. Both groups performed the task for 12 weeks (24 practice sessions). There was no group switching among participants during the experimental period. Four individuals in the OCTT×2 group and 5 in the EBTT+OCTT group dropped out during the second and third weeks, respectively, during the 12-week training period. Figure 1 provides the flowchart of the experimental design.

Figure 1. Flowchart of the quasi-experimental study. EBTT: exergame-based tennis training; OCTT: on-court tennis training.

Outcome Measures

Measurement of Tennis Technical Skills

In this study, the Hewitt tennis test was used to assess the player's technical skills, such as service speed, service accuracy, and tennis strokes (forehand and backhand). This test was done pre- and post-12 weeks of practice. It has been demonstrated that this test is reliable and valid to conduct [25]. Participants in the tennis hit test aimed to score points by hitting balls into specific zones over the net, using forehand or backhand strokes during 10 trials. In the service accuracy and speed test, they served 10 balls into a target area, with accuracy scores based on placement and speed determined by the ball's bounce distance after hitting the service court. Each subtest score is:

- Groundstroke (hit) score: participants earned 1-5 points per stroke based on where the ball landed on a court target zone. The maximum score for this test was 50.
- Service accuracy score: participants were instructed to serve into marked target zones on the court. Points were awarded based on the accuracy of placement, with a maximum of 50 points.
- Service speed score: speed was estimated based on the bounce distance of the ball in the service court, categorized into point zones, with a maximum possible score of 50.

All outcomes were treated as continuous variables (range: 0-50) and used in the statistical analysis. The normal value given by Hewitt's Tennis test scores (score of 1-50) for beginners was graded from A (>18 points) to F (<3 points), where "A" represents an excellent score and "F" represents a very poor score [25]. While scoring the participant, the assessor was aware of the participant's group allocation.

Measurement of Grip Strength

Measuring grip strength with handheld dynamometers was used due to their high validity and reliability [30,31]. Standardized

XSL•FO
RenderX

protocols were followed to ensure accurate and comparable data. This typically involves a seated position with elbows flexed at 90 degrees, neutral wrists, and the handgrip aligned with the forearm [30,31]. Following the standardized protocol, 3 attempts were made for the dominant hand with rest intervals in between attempts. The highest value in kilograms (kg) was recorded and used for analysis. Grip strength was treated as a continuous variable in the statistical analysis. Measurements were taken pre- and post-12 weeks of training. The normal value for grip strength in Malaysia for males aged 18 to 54 ranged from 37 kg to 42 kg, whereas for females of a similar age, it ranged from 22 kg to 25 kg [32,33].

Measurement of Motivation and Confidence Level

The Sports Motivation Test (SMT) and the Sports Confidence Inventory (SCI) were used to measure motivation and confidence levels of participants when playing sports pre- and post-12 weeks of training. The SMT, developed by Pelletier et al [34], is a self-report questionnaire that assessed 7 types or subscales of motivation: IM-to-know, IM-to-accomplish, IM-to-experience stimulation, extrinsic motivation (EM)–identified, EM-introjected, EM–external regulation, and amotivation. Participants indicated the extent to which each statement reflected their motivation for engaging in sports, ranging from "not at all true" to "very true." Each subscale score was calculated as the sum of all 4 items belonging to that subscale, resulting in 7 separate subscale scores ranging from 4 to 28. These subscale scores were used as separate continuous outcome variables in the analysis of motivation change over time and in correlation with tennis performance. The SMT is widely used in research settings to examine athletes' motivation and understand the factors that drive their engagement in sports. High internal consistency is indicated by Cronbach alpha coefficients ranging from 0.70 to 0.90 [24,34].

The SCI, developed by Vealey [35], is a widely used questionnaire designed to assess athletes' self-confidence in sports situations. Participants rate their level of confidence in each statement on a scale ranging from "strongly disagree" to "strongly agree." The SCI measures both general and sport-specific self-confidence across various domains, such as skill execution, physical conditioning, and resiliency [23]. The total confidence score ranges from 8 to 72, with higher scores indicating greater sport-specific confidence. All 8 items were summed to calculate a total confidence score, which was used in pre-post comparisons and correlation analyses as a continuous variable. According to reliability assessments, the SCI has a high degree of internal consistency, with Cronbach alpha values between 0.70 and 0.90 [35]. Test-retest reliability has also been established, demonstrating stability over time.

Data Analysis

SPSS software, created by International Business Machines, was used to gather and analyze the data. Normality was evaluated using the Shapiro-Wilk test, which is highly effective at detecting nonnormality [36]. For normally distributed data, repeated measures ANOVA was performed. Final analysis was conducted per protocol outlined in the "Data Analysis" section, where participants were analyzed according to the group they actually participated in, instead of their original randomized groups. In addition, a modified intention-to-treat (ITT) analysis was also performed, in which all participants who were randomized initially and completed the study were included in the analysis according to their originally assigned groups. This analytical approach excludes missing data from participants who dropped out of their respective interventions. To evaluate whether the treatment effects differed significantly between modified ITT analyses and per-protocol analyses, treatment effects from both approaches were compared. The primary comparison was based on the magnitude and 95% CIs of the treatment effects. Consistency between modified ITT and per-protocol analyses effects was interpreted as evidence of robustness. Effect sizes were evaluated using partial eta squared (ηp^2), with results classified as small (0.01-0.06), medium (0.06-0.14), or large (≥0.14) [37]. Partial eta squared (ηp^2) was used as the measure of effect size for the repeated-measures ANOVA results, as it is appropriate for estimating effect sizes in factorial and within-subject designs. Unlike Cohen *d*, which is suited for simple 2-group comparisons, ηp^2 provides a proportion of variance explained by each effect (main and interaction), making it more suitable for analyzing group × time interactions in repeated-measures designs [37]. If the time (pre-post training) and group interaction are significant, posthoc pairwise comparisons were used; however, if only the time effect is significant, but there is no interaction between time and group, paired *t* tests were used to confirm improvement or mean difference (MD) in each group. A 95% CI of the MD was also calculated to determine the range within which the true difference between population means is likely to fall. The correlation between the changes (differences between pre- and postintervention) in players' grip strength, confidence, and motivation levels with their tennis technical skills was analyzed using Pearson's product-moment correlation coefficient (*r*). According to Cohen [38], the strength of the relationship is weak (*r*=0.10), moderate (*r*=0.30), or strong (r=0.50). Pearson *r* value was squared and multiplied by 100 (r^2) to determine the percentage of variation explained by 1 variable for another. In this study, r^2 was used to determine the percentage of variability in tennis technical skills accounted for by grip strength, confidence, and motivation levels. Findings with a $P<.05$ were considered statistically significant.

Ethical Considerations

This study involving human participants was reviewed and approved by the Universiti Malaya Research Ethics Committee, Malaysia. The ethics approval was granted on January 26, 2023 (UM.TNC2/UMREC_2286). Written informed consent was obtained from all participants before enrollment in the study. Participants were informed about the study objectives, procedures, potential risks and benefits, and their right to withdraw at any time without penalty. The study did not involve any secondary use of existing data; all data were collected prospectively as part of this trial. To ensure participant privacy and data confidentiality, all data collected remained anonymous by assigning unique participant codes. Personal identifiers were not linked to the study data. Electronic records were stored securely on password-protected devices. Participants did not receive any monetary compensation for their participation. However, they were provided with gift vouchers from local

XSL•FO
RenderX

grocery stores and restaurants and were allowed to retain access to the tennis training facilities during the study period at no cost, as a token of appreciation for their involvement. Written informed consents were also obtained from participants when their images were used in the papers. This trial was not preregistered, as it did not measure any clinical outcomes.

Results

Overview

The results are provided in 2 parts: the first part is the comparative analysis of the physical variables (tennis technical skills and grip strength) and psychological variables (confidence and motivation levels) between EBTT+OCTT and OCTT×2, and the second part is the correlation analysis of the relationships between grip strength, confidence, and motivation with the tennis technical skills. All variables are presented as mean and SD for parametric data. Demographic data, including BMI, age, sex, and physical activity level, were collected. Independent *t* tests revealed no significant differences between groups in age, training experience, sex (male and female), BMI, and physical activity levels (Table 1).

Table 1. Summary of demographic data for the quasi-experimental study.

Parameter	EBTT+OCTT[a] (n=33)	OCTT×2[b] (n=33)	*P* value
Age (y), mean (SD)	26.82 (7.08)	25.85 (6.15)	.64
Sex, n (%)			
Male	10 (30)	12 (36)	.68
Female	23 (70)	21 (64)	.79
Training experience (mo), mean (SD)	3.3 (2.44)	2.9 (3.12)	.86
Height (m), mean (SD)	1.64 (0.66)	1.65 (0.58)	.34
Weight (kg), mean (SD)	60.1 (7.8)	59.6 (7.7)	.54
BMI (kg/m^2), mean (SD)	22.35 (2.94)	21.89 (2.90)	.57
International Physical Activity Questionnaire (METs[c]), mean (SD)	808.94 (300.97)	712.35 (311.81)	.43
Dropouts, n (%)	5 (15)	4 (12)	—[d]

[a]EBTT+OCTT: exergame-based tennis training with on-court tennis training.

[b]OCTT: on-court tennis training.

[c]MET: metabolic equivalent of task.

[d]Not applicable.

Data collections were conducted from January to April 2024. During the 2nd and 3rd weeks of the study, 4 participants from the OCTT×2 group and 5 from the EBTT+OCTT group dropped out due to work schedules, health issues, transportation difficulties, or family emergencies (Table 1). The data of participants who dropped out were not used in the analysis. Shapiro-Wilk normality tests indicated that the differences between paired variables in the EBTT+OCTT and OCTT×2 groups were not statistically significant (P>.05), confirming that all paired variables were normally distributed.

In general, the treatment effect estimates from the modified ITT and per-protocol analyses were generally consistent for all outcome measures. The outcome measures showed overlapping 95% CIs and similar significance levels (P) between the 2 analyses, indicating no meaningful difference between the 2 analytical approaches. The table on the modified ITT analysis is provided in Multimedia Appendix 1.

Effects of EBTT+OCTT and OCTT×2 on Physical and Psychological Variables

Effect of EBTT+OCTT and OCTT×2 on Grip Strength

Both groups showed a significant improvement (P<.001) with a large effect size (ηp^2=0.84) from pre- to posttraining (Table 2). A total of 28 of 33 participants in the EBTT+OCTT group have an increase in grip strength by 1.5 times or 11.04 kg on average, while 29 of 33 participants in the OCTT×2 group improved their grip strength by 1.6 times or an average of 9.59 kg. However, grip strength showed no significant difference between groups (P=.24) with a small effect size (ηp^2=0.03).

XSL•FO

[c]OCTT: on-court tennis training.

Effect of EBTT+OCTT and OCTT×2 on Technical Skills

Technical skills were categorized into 3 measures: forehand and backhand (hit) score, service accuracy, and service speed. Significant differences (P<.001) were found in all 3 measures, pre- and posttraining, for both groups, with large effect sizes: ηp^2_{hit}=0.88, $\eta p^2_{accuracy}$=0.92, and ηp^2_{speed}=0.91. In the EBTT+OCTT group, 28 of 33 participants' hit score increased by 5 times (MD 17.14), service accuracy by 6.3 times (MD 22.32), and service speed by 6.1 times (MD 17.75). In the OCTT×2 group, 29 of 33 participants' hit score increased by 4.2 times (MD 17.06), service accuracy by 5.9 times (MD 22.62), and service speed by 6.8 times (MD 17.21). However, for all technical skill outcome measures, there were no significant differences between groups (P_{hit}=.97, $P_{accuracy}$=.86, and P_{speed}=.72), with small effect sizes (ηp^2_{hit}=0.01, $\eta p^2_{accuracy}$=0.03, and ηp^2_{speed}=0.01) (Table 2).

Effect of EBTT+OCTT and OCTT×2 on Confidence Level

The main effect of time was significant (P<.001) with a large effect size (ηp^2=0.84), indicating that participants in both groups showed significant improvement from pre- to posttraining. In the EBTT+OCTT group, 28 of 33 participants improved their confidence level by 23.29 points (~1.6 times on average), whereas in the OCTT×2 group, 29 of 33 participants increased by 26.28 points (~1.8 times) compared with baseline. However, the interaction between pre-post training and the group was not significant (P=.31) with a small effect size of 0.02, suggesting no overall difference between the EBTT+OCTT and OCTT×2 groups (Table 2).

Effect of EBTT+OCTT and OCTT×2 on Motivation Level

Overall, 28 of 33 participants in the EBTT+OCTT group showed a significant decrease in IM-to-accomplish, EM-identified, and EM-introjected. Whereas 29 of 33 participants in the OCTT×2 group, other than a significant increase in amotivation level, there were significant decreases in IM-to-know, IM-to-accomplish, EM-identified, EM-introjected, and EM–external regulation. In terms of the comparison between groups, the reduction of IM-to-know score and IM-to-accomplish score was greater in the OCTT×2 group than the EBTT+OCTT group, leading to a statistical significance, P<.001, when compared. A large effect size was also found, ηp^2 (IM-to-know)=0.25, and ηp^2 (IM-to-accomplish)=0.12. The only finding in EM that was statistically significant (P<.001) with a large effect size of ηp^2=0.30 was the decrease in the EM–external regulation score of OCTT×2 in comparison to EBTT+OCTT (Table 3).

Relationship Between Grip Strength, Confidence, and Motivation With Tennis Technical Skills

Relationship Between Grip Strength and Tennis Technical Skill

The bivariate correlation between grip strength and tennis hit score was significantly positive (r=0.70; P<.001). Grip strength was also significantly positively correlated with service accuracy (r=0.45; P<.001) and service speed (r=0.42; P=.001). The

XSL•FO
RenderX

proportion of variance (r^2) explained by grip strength for tennis hit score, service accuracy, and service speed was 0.50, 0.20, and 0.17, respectively.

Table 3. Comparison of different motivation levels within and between groups.

Outcome measures	Pretest, mean (SD)	Posttest, mean (SD)	Value, MD[a] (95% CI; % changed)	Within-group *P* value	Between groups *P* value
IM[b]-to-know					<.001

[d]OCTT: on-court tennis training.

[e]EM: extrinsic motivation.

Relationship Between Confidence Level and Tennis Technical Skill

For confidence, the bivariate correlation with tennis hit score (r=0.70; P<.001) and service speed (r=0.33; P=.01) was positive and significant. However, the correlation between confidence and service accuracy was not significant (r=0.21; P=.12). The coefficient of determination (r^2) for confidence with tennis hit score and service speed were 0.50 and 0.11, respectively.

Relationship Between Motivation Level and Tennis Technical Skill

IM had significant positive correlations with tennis hit score and service accuracy. The correlations with IM-to-know, IM-to-accomplish, and IM-to-experience stimulation were r=0.60, 0.45, and 0.80 for tennis hit score, and r=0.35, 0.40, and 0.40 for service accuracy. However, there was no significant correlation between tennis service speed score and IM-to-know, IM-to-accomplish, and IM-to-experience, where r=0.21 (P=.11), 0.18 (P=.18), and 0.18 (P=.18), respectively. The r^2 values for tennis hit score and IM-to-know, IM-to-accomplish, and IM-to-experience stimulation were 0.36, 0.21, and 0.62, respectively. For service accuracy, the r^2 values were 0.12, 0.16, and 0.16.

EM showed significant correlations (P<.001) only with tennis hit score, with r = 0.60 (EM-identified), r=0.67 (EM-introjected), and r=0.64 (EM–external regulation). There were no significant correlations with service speed ($P_{\text{EM-identified}}$=.21, $P_{\text{EM-introjected}}$=.72, and $P_{\text{EM–external regulation}}$=.65) or accuracy ($P_{\text{EM-identified}}$=.86, $P_{\text{EM-introjected}}$=.26, and $P_{\text{EM–external regulation}}$=.45). The r^2 values for tennis hit score and EM-identified, EM-introjected, and EM–external regulation were 0.36, 0.45, and 0.41, respectively.

XSL•FO
RenderX

Finally, amotivation was negatively correlated with tennis hit score (r=–0.39; P<.001), but there were no significant correlations with service speed (P=.46) or accuracy (P=.60). The r^2 between tennis hit score and amotivation was 0.15, meaning that 15% of the variability in tennis hit scores could be predicted by amotivation. Table 4 provides the correlation between grip strength, confidence, and motivation levels with tennis technical skills.

Table 4. Correlation analysis (Pearson r and 2-tailed *P* value) between grip strength, confidence, and motivation levels with tennis technical skills.

Outcome measures	Hit scores	Accuracy scores	Speed scores
Grip strength			
r	0.70[a]	0.45[a]	0.42[a]

Discussion

Principal Findings

In general, both EBTT+OCTT and OCTT×2 groups demonstrated significant improvements (P<.001) in tennis technical skills, all with large effect sizes, though no significant between-group differences were found across hit scores (P=.97), service accuracy (P=.86), and service speed (P=.72). The absence of significant between-group differences should not be interpreted as evidence of equivalence between the interventions, as this study was not designed or powered to assess equivalence or noninferiority. Grip strength increased significantly (P<.001) in both groups, with no significant interaction effects (P=.24). Confidence levels also improved significantly (P<.001) in both groups, but without significant between-group differences (P=.31). In terms of motivation, the EBTT+OCTT group showed significant decreases (P<.001) in EM-identified and

XSL•FO
RenderX

EM-introjected, while the OCTT×2 group showed significant reductions (P<.001) in IM-to-know, IM-to-accomplish, EM-identified, and EM–external regulation. Notably, the OCTT×2 group experienced significantly greater decreases in IM-to-know, IM-to-accomplish, and EM–external regulation compared to EBTT+OCTT, all with large effect sizes. Correlational analysis revealed strong positive relationships (r>0.50) between hit skill and grip strength, confidence level, IM-to-know, IM-to-experience stimulation, and all EM subscales. However, a negative correlation was observed between hit skill and amotivation (r=–0.39).

Comparison With Previous Work

Effect of Exergaming on Grip Strength

This study found significant improvements in grip strength in both EBTT+OCTT and OCTT×2 groups. Grip strength increased by 1.5 times in the EBTT+OCTT group and by 1.6 times in the OCTT×2 group. These results align with previous research on sports training and muscular strength. The likely mechanism is the repeated high-intensity activation of the forearm and hand muscles required for racket control and stroke execution. A previous study and a review have corroborated that regular engagement in sports requiring sustained gripping actions and upper limb coordination, such as tennis, induces significant neuromuscular adaptations that manifest as measurable strength gains in distal upper extremity musculature [9,39]. The observed grip strength improvements in the EBTT+OCTT group (1.5 times) demonstrated comparability with findings from an electromyography biofeedback exergaming study, which reported a 0.17 times enhancement in grip strength following training [40]. The substantially greater improvements observed in this quasi-experimental study may be attributable to the longer intervention duration (12 weeks vs 2 weeks), allowing for more pronounced neuromuscular adaptation. These results support the theoretical framework suggesting that exergaming systems designed to replicate sport-specific movements can elicit muscular engagement patterns and strength development comparable to conventional training modalities [40]. While the between-group comparison revealed no statistically significant difference in grip strength improvement, the marginally lower gain in the EBTT+OCTT condition may reflect biomechanical differences in equipment characteristics. Specifically, the substantially lighter mass of the exergaming controller (90 g) compared to a standard tennis racket (280 g-300 g) potentially reduced the mechanical loading and strength demands during gameplay. Nevertheless, the significant improvements observed in the EBTT+OCTT group suggest that exergaming tennis, while not specifically designed for grip strengthening, can effectively enhance grip strength through repeated sport-specific movement patterns. These findings expand current understanding of EBTT+OCTT's therapeutic potential and its capacity to produce physiological adaptations similar to traditional training approaches.

Effect of Exergaming on Technical Skills

This study showed significant improvements in technical skill scores, with large effect sizes in both EBTT+OCTT and OCTT×2 groups. These results suggest that exergaming and traditional training are both effective for enhancing tennis skills. Improvements were likely driven by repetitive practice, whether in virtual or real settings, which aligns with previous research on motor learning in neurological rehabilitation [41]. This reflects the motor learning principle of practice, where skills must be rehearsed correctly to be mastered [42].

In the EBTT+OCTT group, hit scores increased by 5.5 times, service accuracy by 6.3 times, and service speed by 6.1 times. In the OCTT×2 group, hit scores rose by 4.2 times, service accuracy by 5.9 times, and service speed by 6.8 times. These findings are consistent with earlier studies, showing that exergaming can enhance motor skills and physical performance comparably to on-court training [42-45]. For example, one study reported that both exergaming and on-court training improved tennis players' reaction time by 1.03 times, indicating that exergaming may help players prepare for incoming shots [43]. Similar results have been observed in children, where exergaming improved forehand and backhand skills by 1.5 times compared to 1.33 times in traditional training [44]. The greater improvement observed in this study (average skill increase of 5.5 times) compared with previous work (around 1.3 times) may be explained by the novice status of participants. Before the training, their baseline skills were poor, scoring below 6 of 50 on the Hewitt tennis test. However, with structured guidance and consistent practice, their skills improved dramatically over 12 weeks. This reflects the principle of specificity, where training effects are specific to the practiced activity [46]. As EBTT+OCTT replicates tennis movements, skill gains in the virtual setting were transferred to real-world performance.

Supporting evidence comes from studies in other domains. Exergaming-based balance training improved balance by 1.67 times, similar to conventional balance training [47]. Another study on adolescent tennis players reported a 0.38-times increase in Universal Tennis Rating when training combined with virtual reality and tablet-based cognitive drills was compared to regular training [45]. Collectively, these findings highlight that exergaming can be as effective as traditional training for enhancing technical performance. The shared success likely stems from common motor learning principles and practice specificity [46,47]. Finally, this study extends the literature by focusing on novice players. Exergaming provided an engaging, space-efficient alternative for skill development, requiring only about 4×3 meters of training space.

Effect of Exergaming on Confidence Level

The study found that both EBTT+OCTT and OCTT×2 significantly improved participants' confidence in tennis performance. Confidence increased by 1.6 times in the EBTT+OCTT group and by 1.8 times in the OCTT×2 group. These results align with the self-efficacy theory, which highlights mastery experiences as a core source of confidence [48]. In this trial, structured and repetitive practice enabled participants to progressively master tennis skills, enhancing their belief in their abilities. The large effect sizes further indicate that both training types were highly effective in fostering a sense of control over performance, consistent with self-efficacy principles [49].

Previous research supports this view, showing that repeated practice in real sports settings increased athletes' confidence

XSL•FO
RenderX

by 1.21 times, thus preparing them for competition [50]. Similarly, exergaming interventions have been shown to enhance confidence in other contexts, such as fall-prevention training for older adults, which raised confidence in avoiding falls by 1.05 times [51]. However, only a few studies have directly assessed exergaming's impact on sports confidence. This trial helps address that gap, showing that tennis-specific exergaming can enhance confidence comparably to on-court training. Notably, there was a study that found exergaming to be less effective than traditional training for psychological outcomes. The trial reported that while exergaming boosted enjoyment and engagement, it did not significantly improve confidence in novice athletes [52]. The difference may reflect variations in exergame type, intervention length, or participant skill level. This study used tennis-specific exergaming directly relevant to participants' skill goals, while the comparison study [52] used non–sport-specific games.

Overall, the comparable benefits of EBTT+OCTT and OCTT×2 suggest that exergaming can be a valuable addition to sports training, particularly where access to courts or equipment is limited. It may also provide a psychologically supportive environment for beginners or individuals with low self-confidence by reducing the pressures of real-world competition.

Effect of Exergaming on Motivation Level

In the EBTT+OCTT group, apart from an increase in amotivation levels, there was a decline in all other motivation categories. Significant decreases were observed only in IM-to-accomplish (by 0.09 times), EM-identified (by 0.22 times), and EM-introjected (by 0.15 times), with medium and small effect sizes, respectively. In the OCTT×2 group, aside from increases in amotivation and IM-to-experience, other motivation levels also declined. Significant decreases were noted in IM-to-know (by 0.28 times), IM-to-accomplish (by 0.24 times), EM-identified (by 0.20 times), and EM–external regulation (by 0.25 times), all with large effect sizes (ηp^2=0.12-0.30). These results suggest that both EBTT+OCTT and OCTT×2 may influence IM in complex ways. According to self-determination theory, IM is driven by the inherent satisfaction of performing an activity [53]. The observed decreases in IM components, such as IM-to-accomplish, could suggest that the initial novelty and enjoyment of mastering new skills may diminish over time as tasks become repetitive or as participants reach a plateau in skill development [53]. This aligns with past research showing that continuous, repetitive training can sometimes reduce IM, especially when the perceived challenge or novelty decreases [54]. This pattern is also supported by another study, where motivation level was reduced by 1.08 times in general, and amotivation increased by 3.69 times when the participants were provided with a wearable healthy lifestyle technology (Fitbit by Fitbit Inc) for 8 weeks [55]. These results may indicate that, over time, both intrinsic and EM decline. However, it should be noted that maintaining motivation is essential for sustaining motivation without the need to alter or add new training equipment. Thus, the results from this quasi-experimental study suggest that EBTT+OCTT was able to sustain IM more than OCTT×2.

The Interrelationship Between Grip Strength, Confidence Level, and Motivation Level Toward an Individual's Tennis Skills

The interaction between motivation, confidence, and grip strength appears central to enhancing tennis performance. In this study, grip strength showed strong positive correlations with tennis hit score (r=0.70), service accuracy (r=0.45), and service speed (r=0.42). This suggested that stronger grip strength contributed to more powerful and accurate strokes. Similar findings have been reported in previous studies, where grip-strengthening exercises improved forearm speed and service performance [10,20,56]. Stronger grip strength enhances the transfer of force from the lower body and core to the racket, leading to greater ball velocity and control. In this study, participants initially had low grip strength (mean=18.74 kg) and poor Hewitt's tennis test scores, often falling in the "D" or "F" range. Their early struggles in returning balls accurately highlighted the importance of grip strength for technical execution.

Exergaming, such as traditional training, improved grip strength in this study. The EBTT+OCTT group increased grip strength by 1.5 times, while the OCTT×2 group improved by 1.6 times. Although no significant difference was found between the groups, the repetitive upper-limb motions in exergaming likely contributed to strength gains. Past research supports this, showing that interactive games involving hand and arm actions can build muscular endurance and functional fitness [21,57,58]. The moderate correlation between grip strength and service speed (r=0.42) further supports its role in stroke performance. While this study did not establish equivalence between EBTT+OCTT and OCTT×2, the findings suggested that exergaming offered a meaningful, engaging way to strengthen tennis-related muscles.

Confidence also emerged as a critical factor. Posttraining, confidence levels rose significantly in both groups and were positively correlated with tennis hit scores (r=0.70) and service speed (r=0.33). Confidence helped participants take risks, handle pressure, and execute skills more effectively. Early in training, participants' low confidence coincided with poor accuracy and hesitancy. By the end of the training, confidence scores improved from 35 of 72 to 61 of 72, accompanied by fourfold increases in hit scores. Previous studies confirm that self-efficacy and confidence are linked to better performance, reduced anxiety, and resilience under stress [48,59-62]. Exergaming may support confidence development by providing progressive challenges and instant feedback, enabling athletes to see measurable progress. This study found confidence increased by 1.6 times in EBTT+OCTT and by 1.8 times in OCTT×2, showing that both methods are effective.

Motivation, particularly IM, also played a key role. Players with high IM were more committed to practice, strengthening both skills and confidence. In this study, IM correlated strongly with hit scores (r=0.60, 0.45, and 0.80 for IM-to-know, IM-to-accomplish, and IM-to-experience, respectively), while EM showed weaker links to performance. Although overall motivation decreased slightly over the 12 weeks, the decline was smaller in EBTT+OCTT, suggesting exergaming helped

XSL•FO
RenderX

sustain interest. This aligns with previous research showing that task-oriented environments emphasizing skill mastery foster stronger IM than competition-focused settings [63-66]. Exergaming creates such an environment by offering clear goals, instant feedback, and playful competition, all of which help maintain engagement.

Taken together, the results suggest that grip strength, confidence, and motivation interact in a reinforcing cycle. Stronger grip strength enhances stroke performance, which boosts confidence. Increased confidence encourages effort and persistence, feeding back into skill gains. Intrinsic motivation sustains this process by making practice enjoyable and rewarding. Exergaming supports this loop by providing variety, feedback, and achievable challenges, which help maintain both confidence and motivation. While not a full replacement for on-court training, EBTT+OCTT appears to be a valuable complement, especially for novices or those with limited access to facilities. Exergaming requires minimal space, engages players psychologically, and offers cost-effective benefits in both sporting and rehabilitation contexts [49]. Coaches and practitioners could integrate exergaming to enhance early skill acquisition, sustain motivation, and reduce barriers to participation.

Exergaming Studies in Other Sports and Psychological Domains

The results of this study are consistent with previous exergaming interventions across a range of sports and populations. For example, in a study involving junior athletes practicing basketball, handball, and volleyball, exergaming significantly improved reaction time over 3 months, indicating its utility in sport-specific skill enhancement [67]. Similarly, in a soccer-based exergaming study, players demonstrated improved reaction time and passing accuracy, with larger effects observed in novices compared to experienced athletes [68]. These findings support the results of this quasi-experimental study, whereby novice players may be particularly responsive to exergaming interventions, potentially due to a greater scope for technical and psychological adaptation.

From a psychological perspective, the results align with previous studies showing that exergaming enhances motivation, confidence, and enjoyment. A study found that adolescents who engaged in exergaming reported significantly greater IM and self-efficacy compared to traditional physical education groups [69,70]. Likewise, another study demonstrated that virtual cycling games increased motivation and adherence among older adults [71]. While the effect sizes in this quasi-experimental study were large in terms of motivational outcomes, this may reflect the unique engagement and gamified feedback inherent in exergaming platforms, which are particularly effective in novice or recreational populations. In contrast, elite athletes may show more modest gains due to ceiling effects and previous high-level training.

Limitations

This study has several limitations that should be acknowledged. First, the findings may only be generalizable to novice players, as the participants recruited had less than 1 year of tennis experience. This may limit the applicability of the results to more experienced or elite players, who may respond differently to exergaming-based interventions. To address this, this quasi-experimental study standardized the training program and ensured participants had similar baseline experience levels. Future studies should explore the effects of exergaming among intermediate or advanced players to assess broader applicability.

Second, the dropout rate was approximately 12% in the OCTT×2 group and 15% in the EBTT+OCTT group. Although this attrition was within acceptable limits for a quasi-experimental design, it could have influenced group comparisons and reduced statistical power. Another key limitation was the group allocation switching that occurred before the start of the experiment, where 7 participants requested to join the group of their preference (OCTT×2 [n=3] and EBTT+OCTT [n=4]). This introduced self-selection bias and could potentially affect the internal validity of the study's results, especially for outcomes related to motivation. Furthermore, the per-protocol analysis of data reflected the partial allocation of participants' chosen group, as opposed to randomized groups. This limits the statistical strength and validity of the results reporting motivational outcomes typically associated with randomized designs. As such, findings about motivation in this study should be interpreted with caution, and future studies should consider more rigorous strategies to ensure the robustness of randomization. To mitigate this, the study recruited more participants than the minimum sample size required by power analysis to maintain sufficient statistical validity. Although participants who had requested the group change may have had pre-existing differences in motivation, their baseline levels remained similar compared to those who remained in their allocated groups. In addition, the consistency in results between the modified ITT and per-protocol analyses strengthens the validity of the findings, suggesting that the results are robust to missing data and protocol deviations. However, future studies should incorporate strategies such as participant incentives, participant blinding, or shorter program durations to enhance retention.

Third, the exergaming environment may not fully replicate the physical, cognitive, and environmental demands of real-life tennis. Factors such as court size, surface type, weather conditions, and opponent variability are absent in virtual simulations, potentially limiting the ecological validity of the findings. To address this limitation, EBTT+OCTT participants also received one on-court tennis session per week to complement the virtual training. However, further research should explore advanced platforms (for example, augmented or mixed reality) to better simulate real-world playing conditions.

Fourth, the sex distribution in the study sample was skewed, with approximately 63% female participants. This imbalance may introduce sex-related bias and limit the generalizability of the results across sexes. While the study analyzed group-level performance rather than sex-specific differences, future studies should aim for a more balanced male-to-female ratio or consider conducting sex-stratified analyses.

Fifth, although the study used validated tools to assess motivation, confidence, grip strength, and tennis skills, it relied

XSL•FO
RenderX

primarily on quantitative methods. This limit understanding of participant experiences and perspectives regarding the training. Incorporating qualitative methods, such as interviews or focus groups, in future studies could provide richer insight into how and why exergaming may influence motivation and performance. At the same time, the assessor was not blinded to group allocation due to practical constraints inherent in sport-specific field testing, which could introduce potential bias. The tennis skill assessments required direct interaction and real-time scoring, making blinding operationally difficult and largely unfeasible. To minimize bias, a single trained assessor was used to ensure consistent scoring procedures across all participants.

Finally, while no statistically significant differences were found between EBTT+OCTT and OCTT×2 for most outcome measures, this should not be interpreted as evidence of equivalence between the 2 training modalities. The study used standard hypothesis testing and was not designed or powered to formally assess equivalence or noninferiority. Therefore, the finding of nonsignificant *P* values reflects a failure to reject the null hypothesis, not confirmation that the interventions are equally effective. Future studies using equivalence or noninferiority trial designs may be warranted to further evaluate whether EBTT+OCTT can produce outcomes comparable to traditional training.

Future Directions

Future research should consider several aspects to build upon the findings of this study. First, as mentioned previously, studies should explore the effectiveness of EBTT+OCTT in populations with varying levels of tennis proficiency, including intermediate and elite players, to determine whether skill transfer and psychological benefits persist across experience levels. Second, longitudinal studies with extended follow-up periods are required to assess the sustainability of improvements in technical skills, grip strength, motivation, and confidence beyond the 12-week intervention period. Third, more immersive technologies such as virtual reality or augmented reality could be integrated into exergaming systems to better replicate real-world conditions and improve ecological validity. Fourth, future trials should investigate how exergaming can be personalized based on individual learning styles, physical abilities, or motivational profiles, which may enhance engagement and outcomes. Fifth, incorporating qualitative methods could provide deeper insights into users' experiences and perceived barriers or facilitators to exergaming adoption. Finally, exergaming could be examined as a rehabilitation tool for individuals with musculoskeletal or neurological impairments, to determine its utility in clinical sports medicine or physiotherapy settings.

Conclusion

In conclusion, this quasi-experimental study demonstrated that both EBTT+OCTT and OCTT×2 significantly improved tennis technical skills, grip strength, and confidence level among novice players over 12 weeks. EBTT+OCTT also helped sustain participants' IM level. Although between-group differences were not significant for most outcomes, EBTT+OCTT was more effective in sustaining IM. The observed positive associations between tennis skills, grip strength, confidence, and motivation suggest a correlated process where improvements in one domain support gains in others. Overall, evidence points toward EBTT+OCTT as a feasible and engaging supplementary approach for developing both physical and psychological aspects of tennis performance in novice players. However, given the study's design and population, conclusions should be interpreted with caution and not generalized beyond novice recreational players. Further controlled studies are needed to confirm the broader applicability and long-term effects of exergaming in sport-specific training.

Abstract

Background: Children with autism spectrum disorder (ASD) exhibit cognitive, motor, and social difficulties that affect engagement, causing developmental delays, behavioral challenges, and obesity—interrelated concerns in daily functioning and well-being. Although interactive interventions have incorporated physical activity, they often rely on limited physical involvement and lack iterative, expert-informed design, as built on pre-existing game frameworks. Physical activity is often operationalized as constrained input (eg, gestures or in-place actions) rather than exertion-intensive, whole-body exercise, and design guidance for adapting exercise content under ASD-oriented safety and cognitive-sensory constraints remains limited. These limitations highlight the need for exergames that promote sustained, full-body participation aligned with developmental goals, motivating formative, co-design with expertise and initial field testing in this population.

Objective: We aim to iteratively design exercise-based serious games (SGs) for children with ASD through a structured, expert-informed co-design process involving 21 professionals across special education, adapted physical education, and human-computer interaction, and to examine feasibility and use contexts through an exploratory multiple-case pilot study.

Methods: We derived serious exergames using 4 design methods—stakeholder interview, concept mapping, creative matrix, and visualize the vote. Two exergames—"Fruit Sorting Run" and "Hazard Avoiding Ride"—were developed, integrating full-body running and cycling movements into goal-directed tasks under ASD-oriented constraints. We conducted a multiple-case pilot with 3 children with ASD. During gameplay, caregivers labeled engagement using a binary input interface, and we conducted postsession caregiver interviews to capture complementary observations.

Results: Engagement in both exergames tended to increase over normalized time. Generalized estimating equations with a logit link and an autoregressive working correlation of order 1 (AR1), including participant indicators, showed a statistically significant association between normalized time and engagement in Fruit Sorting Run (per 0.1 increase: β=0.48; odds ratio 1.62, 95% CI 1.09-2.38; P=.02) and Hazard Avoiding Ride (per 0.1 increase: β=0.66; odds ratio 1.93, 95% CI 1.04-3.60, P=.04). Caregiver interviews reinforced these findings, reporting increased attention, motivation, and enjoyment across both activities.

Conclusions: The findings support the applicability of an expert-informed design approach and the viability of the resulting exergames, integrating goal-directed physical activity, virtual agent–based prompting, and stakeholder-informed considerations such as motor-cognitive alignment, interactive scaffolding, and support for daily living skills. Distinct from prior SG approaches that operationalize physical activity through discrete gestures or in-place interactions, the proposed exergames embed sustained, exertion-intensive, whole-body movement within structured gameplay. Within this exploratory multiple-case pilot, engagement trajectories tended to increase over time. These preliminary observations provide an initial basis for a testable hypothesis that exertion-intensive, full-body SGs with virtual agent–based prompting may be associated with increasing engagement over time, meriting further examination in larger samples and applied educational and therapeutic contexts.

Introduction

Background

Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by cognitive, motor, and social difficulties [1], which affect daily functioning [2] and overall well-being [3]. Reduced participation highlights the importance of active engagement in supporting adaptive functioning and skill acquisition. A lack of active engagement may lead children with ASD to experience further developmental delays [4], increased risk of stereotyped and challenging behaviors [5], and a higher incidence of obesity [6]—all of which are interrelated and pose significant concerns. Given the scope of these difficulties, the continued rise in ASD diagnoses over the past decades underscores the importance of creating accessible interventions to support active participation in everyday contexts [7]. For example, serious games (SGs) have been explored as digital interventions that target functional outcomes beyond entertainment [8,9], including social communication, executive functioning, and motor coordination [10,11]. Recent SGs have broadened interaction design through modalities such as motion-tracking [12-15], interactive stimuli [16-18], extended reality [14,19], and socially assistive robots [20-23] or virtual agents (VAs) [24,25], enabling diverse forms of feedback and goal-directed activities [26-28]. Within this design space, SG interventions for children with ASD have positioned movement-based physical activities as a central design emphasis to support active participation.

Related Works

Constrained Physical Interaction in Exergames

While prior interactive systems for children with ASD have incorporated physical activity, often using motion-tracking technologies to facilitate interaction, these have primarily involved constrained forms of bodily input or static posture—particularly basic motion gestures [13,14,17,26,28-30] as well as touch [24] and button presses [18]. For example, Bhattacharya et al [26] used Kinect to design motion-based activities to engage students with ASD in a classroom setting by encouraging them to make specific movements or gestures to animate elements of a story on a screen. To improve eye-body coordination, Caro et al [28] proposed the FroggyBobby game, which used Kinect motion-tracking to control the upper limbs as the tongue of Frog and catch as many flies as possible through limb movements. Bossavit et al [27] presented a natural user interface SG that supported movement-based interaction for high-functioning children with ASD [27]. Similarly, Pena et al [29] introduced "Circus in Motion," a multimodal exergame designed to support vestibular therapy through in-place actions involving the head, upper limbs, lower limbs, and jumping movements for people with ASD. These systems relied on in-place movements of the upper or lower limbs, using predefined gesture-based inputs that were stylized or scripted, and structured in ways that may limit the continuity and spontaneity of physical involvement, revealing a gap in current approaches. This study adopts full-body exercises to extend beyond discrete interaction gestures—short, predefined inputs involving single-limb or in-place movements—by embedding physical activities into gameplay through whole-body movements designed to be accessible to children with ASD.

Toward Exertion-Intensive Serious Game Design

As supporting evidence, studies in behavioral intervention have demonstrated that higher-intensity physical activity, even when delivered as simple exercises like jogging or walking, can enhance engagement and reduce stereotyped behaviors among children with ASD. For example, Nicholson et al [31] reported improved on-task behavior following antecedent jogging sessions, and Neely et al [32] found that exercise until satiety produced the greatest behavioral benefits compared with no or brief exercise. These findings suggest that more rigorous and sustained physical activity may have specific benefits for attention and behavior regulation, highlighting the need to design interactive systems that embed such activity within playful and intrinsically motivating formats, such as exertion-intensive SGs, to enhance both engagement and functional outcomes for children with ASD. While some studies have incorporated task-oriented physical activities, these interventions were primarily designed for vocational purposes targeting adolescents or young adults, such as the "Mopping Game," which used mixed reality to support vocational training [14]. Other examples, such as "PuzzleWalk," or commercial games like "Pokémon GO [33]," combined walking with pre-existing games and primarily targeted adults [15,34], therefore often lacking iterative expert involvement and offering limited flexibility beyond pre-existing game frameworks. In addition, designing exertion-intensive SGs for children with ASD requires careful selection, adaptation, and progression of exercises to balance capability and cognitive–sensory tolerance while maintaining safety constraints. Design guidance on exercise content for SG-based interventions in this population remains limited [35], motivating a formative co-design process with special education and adapted physical education (APE) professionals.

Objective

The primary objective of this study is to iteratively design serious exergames through a structured co-design process involving professionals from multiple disciplines, including special educators, APE therapists, and human-computer interaction (HCI) researchers. Building on a series of expert interviews and collaboration, the study focuses on exergame development from the initial selection of exercises to the progressive shaping of gameplay. This process spans conceptualization, design, and development, and aims to support active participation and functional development in children with ASD. To explore feasibility and use contexts, we conducted an exploratory multiple-case pilot with 3 children with ASD,

XSL•FO
RenderX

focusing on case-based description of engagement and interaction patterns.

Methods

Ethical Considerations

This study involving autistic participants was conducted following the ethical guidelines and regulations of the Institutional Review Board at Gwangju Institute of Science and Technology (approval number HR-61-04-04). The approved protocol includes the involvement of professionals from multiple disciplines and the participation of children with ASD and their legal guardians (eg, parents).

Participant recruitment was conducted in accordance with Institutional Review Board guidelines. The study was introduced at the "Dream Tree Children Education Center" by therapists; 4 parents voluntarily enrolled their children for the experiment. Prior to participation, the experimental procedure and the role of the proxy user were explained to the parents, and informed consent was obtained. Additionally, each parent provided written assent, acknowledging their voluntary participation and the use of their data for research. They were informed that the experiment could be discontinued at any time upon request by the child, guardian, or therapist. The experiment commenced upon confirmation of the child's willingness to participate, and participants received monetary compensation equivalent to approximately US $70.

To maintain confidentiality, all data were deidentified immediately upon collection. Unique identification codes were assigned to each participant, and personally identifiable information was stored separately in a secure, password-protected database, with access restricted to the primary researcher.

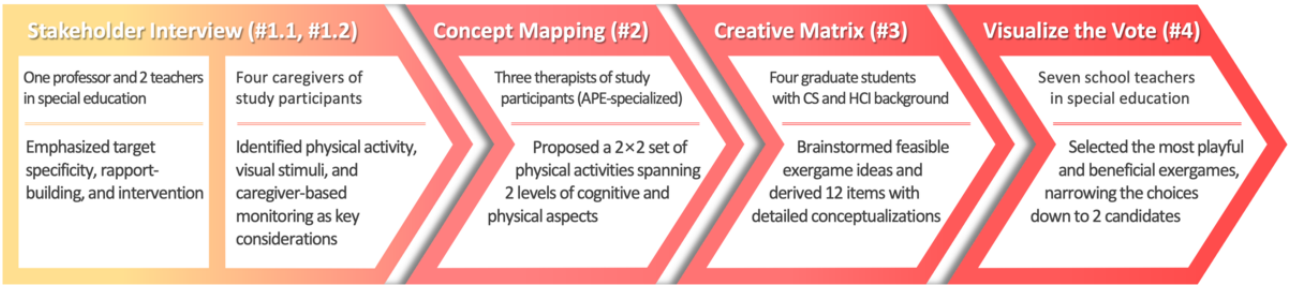
Interdisciplinary Co-Design

Design Considerations

This study involved collaborations with multidisciplinary experts, with participation formats—ranging from semistructured interviews to group sessions—structured around the needs of each phase. Experts were recruited from a pool of professionals who expressed interest in related local research programs (Table 1) and were selected based on their specific domain expertise to facilitate concept refinement, activity framing, and final selection (Figure 1).

To formulate exergames tailored for children with ASD, we applied the LUMA framework, which offers structured methods for synthesizing expert-derived insights into actionable design decisions [36]. Stakeholder interview—a design method for eliciting field-informed input through direct dialogue—was used to refine initial design directions. Concept mapping was then applied to organize therapist-proposed exercises by aligning cognitive and motor capabilities. Creative matrix, a method for generating ideas at the intersections of exercise and game features, was used to conceptualize exergames. Then, visualize the vote, a method for polling collaborators to reveal preferences and opinions, was used to select exergame concepts.

Table 1. Expert configuration across the study process, with numbers representing the composition of experts (n=21) recruited at each stage of the multistage exergame design for children with autism spectrum disorder (ASD).



Stage	Expert group	Expertise (average years of affiliation)	Collaboration type	Expert role
1.1	Professor (n=1); teachers (n=2)	Special education (>20)	Onsite semistructured interview (individual)	ASD heterogeneity, design refinement
1.2	Caregivers (n=4)	Caregiving expertise (>5)	Onsite semistructured interview (individual)	Refining intervention elements
2	Therapists (n=3)	APE[a] (>5)	Online semistructured interview (as a group)	Framing APE content
3	Researchers (n=4)	Computer science/HCI[b] (>7)	Practitioner ideation (as a group)	Exergame conceptualization
4	Teachers (n=7)	Special education (> 15)	Online semistructured interview (Individual)	Final exergame selection

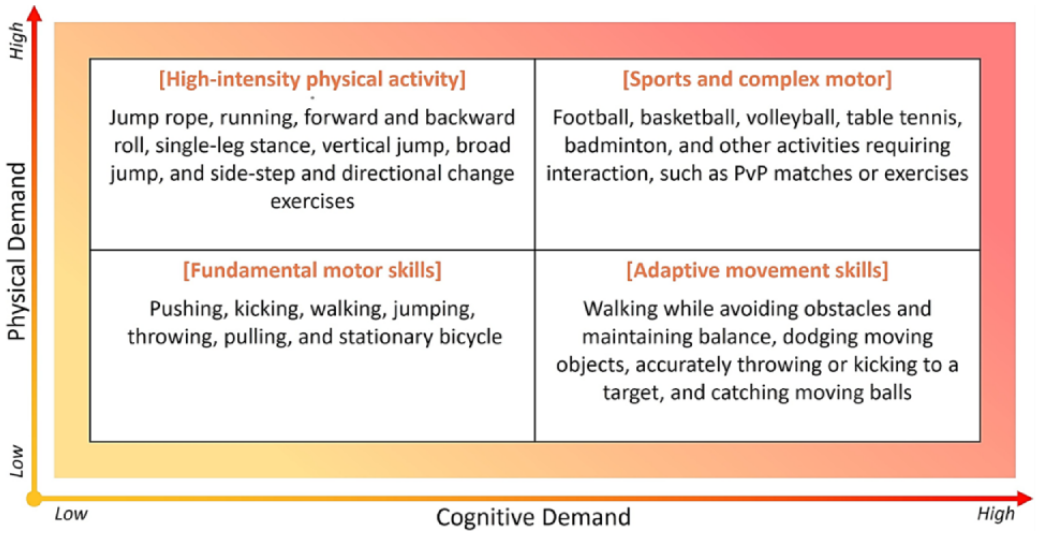
APE: adapted physical education; CS: computer science; HCI: human-computer interaction.

Design Method 1: Stakeholder Interview



To address the heterogeneity of ASD diagnoses across regions and to refine the initial game design approach, we conducted individual interviews (n=3) with a professor in special education and 2 special education teachers (>20 years of experience). The first expert interview indicated that the broad spectrum of disabilities necessitates specifying target groups or focusing on specific participants (eg, symptom, degree, and age), suggesting a case study approach. The interview also highlighted the importance of designing experiences that foster a sense of achievement through engagement, particularly by building rapport when introducing unfamiliar characters, game elements, or devices. Additionally, experts discussed the role of rapport and the potential use of virtual or realistic agents. To enhance interaction and motivation, they emphasized the incorporation of promptings and reinforcement feedback to support participation for children with low motivation.

The second interview with the caregivers of our study participants (n=4) highlighted attentional challenges in children with ASD, emphasizing the need for interventions that incorporate physical exertion and visual stimuli (eg, interactive elements) to sustain engagement across varying levels of symptom severity. In particular, these elements were identified as critical for maintaining attention and eliciting curiosity. The caregivers also noted that children with ASD often exhibit emotional fluctuations and that facial expressions and behaviors may not reliably reflect their internal emotional states (eg, a child may smile despite experiencing anxiety). Given these considerations, the interviews underscored the importance of monitoring engagement through observers with an in-depth understanding of the child's behavioral cues, such as caregivers, to more accurately interpret emotional and attentional states.

Design Method 2: Concept Mapping

We collaborated with therapists (n=3) who have expertise and experience (>5 years) in APE to derive readily applicable physical activities tailored to children with ASD participating in this study. These experts were APE specialists practicing at local centers, selected to reflect the practical constraints and requirements of the target environment. The therapists proposed a set of exercises that the participants were likely to recognize and engage with. To incorporate both cognitive and physical aspects, they organized these activities within a 2×2 framework, which served as a foundation for identifying and refining exergame ideas (Figure 2). This framework guided exercise selection for children with ASD, which subsequently structured a brainstorming session to develop exergame concepts for implementation.

Figure 2. Therapist-proposed exercises serving as the basis for exergame design, organized in a 2×2 matrix according to cognitive and physical demands (n=3). Cognitive demand increases along the horizontal axis, and physical demand increases along the vertical axis. PvP: player vs player.

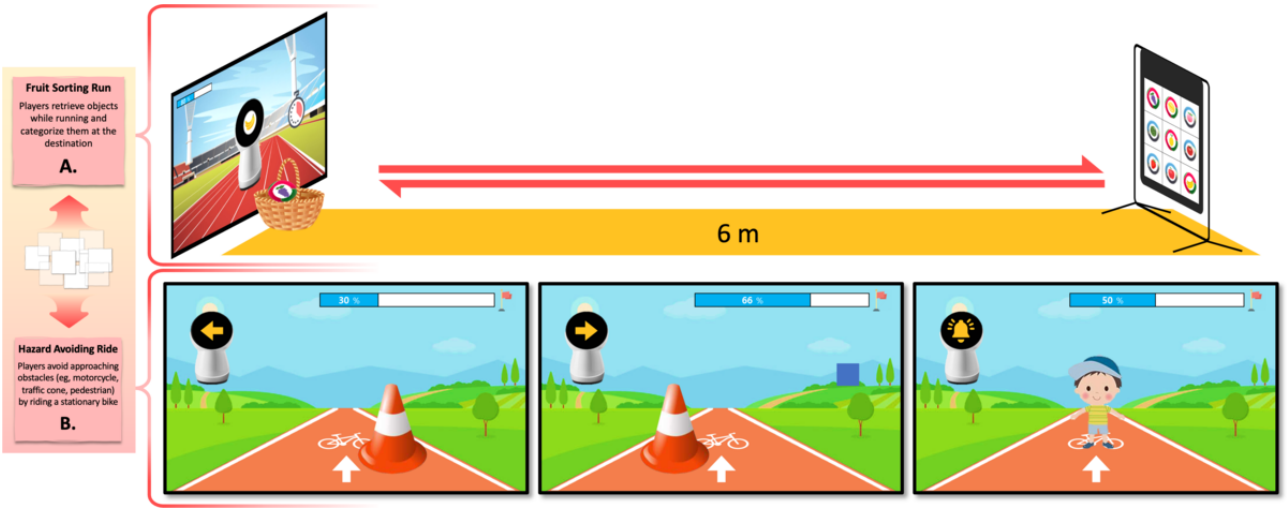
XSL•FO
RenderX

Design Method 3: Creative Matrix

Based on suggestions of physical activities spanning low to high physical and cognitive loads, graduate students (n=4) with an HCI background brainstormed feasible exergames that integrate cognitive and physical demands. The criteria included embedding physical activity scenarios, ensuring accessibility for children aged approximately 10 years, maintaining feasibility for children with ASD, and supporting daily living skill improvement. We derived 12 exergames along with their detailed conceptualizations and prioritized them through a voting process involving special education teachers (Figure 3).

Figure 3. Brainstormed exergame concepts generated through practitioner ideation based on adapted physical education (APE) and human-computer interaction (HCI) expertise, with concepts 1 and 4 selected as final candidates through a voting process involving special education teachers (n=7).

Design Method 4: Visualize the Vote



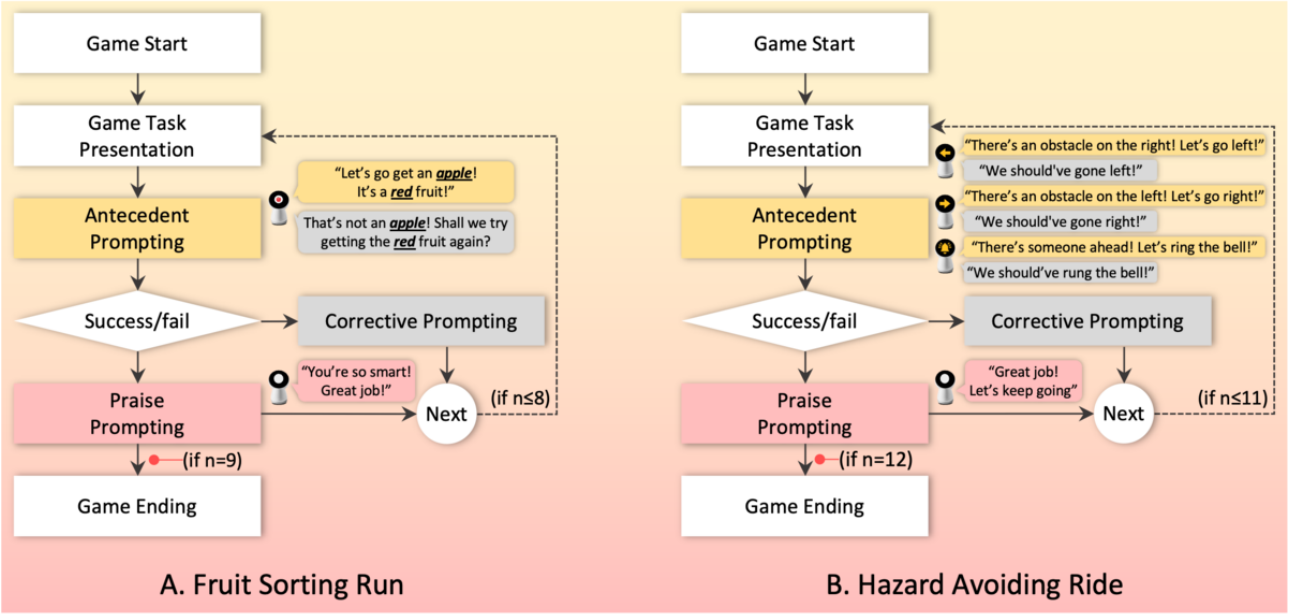
The final selection process involved special education teachers (n=7) and focused on the following two aspects (1) playfulness, ensuring that children with ASD can actively participate, and (2) the potential developmental benefits of the game, such as supporting daily living skills. Each teacher was asked to select up to 3 exergames they considered the most playful SGs. Two exergames—"Fruit Sorting Run" (1) and "Hazard Avoiding Ride" (4)—received the highest number of votes (5 and 4, respectively) and were the only ones selected by all participants.

Design Principles and Exergame Development

Overview of the 2 Serious Exergames

Through an iterative design process involving multidisciplinary expertise, we derived and finalized 2 exergames: Fruit Sorting Run and Hazard Avoiding Ride (Figure 4). Rooted in running and bicycling activities, these games integrate full-body dynamics with daily living skills training in accordance with SG design principles. The resulting system supports exertion-intensive gameplay under ASD-oriented constraints through VA-mediated scaffolding and audiovisual feedback for immediate reinforcement [37] within an animated game environment [24,35]. To prioritize predictability and minimize cognitive load, difficulty levels are kept constant; this approach enables children to focus on functional task performance—fruit categorization and hazard avoidance—while mitigating potential anxiety associated with increasing difficulty [38]. The system was implemented using the Unity 2D engine and refined through iterative adjustments following an initial evaluation session involving a therapist and a child with ASD.

Figure 4. Illustrations of the developed exergames based on running and bicycling, depicting (A) the Fruit Sorting Run game and (B) the Hazard Avoiding Ride game, along with their spatial setup and representative in-game interfaces.



XSL•FO
RenderX

Exergame 1: Fruit Sorting Run

This game aims to enhance visual-perceptual abilities by having children classify velcro balls, each labeled with a fruit image, while walking back and forth across a 6 m straight area (Figure 4A). The game starts in a static game scene where the VA appears at the center of the screen in the running track background. The child observes a fruit image presented on the VA's screen, runs to the back wall to retrieve a ball with the corresponding image, and places it in a basket positioned below the screen. A total of 9 velcro balls are used, each depicting a different fruit (eg, peach, grape, apple, strawberry, tomato, banana, watermelon, oriental melon, and lemon), and all are randomly placed on the sticky wall. The child is tasked with collecting 9 randomly presented fruit images within a given time limit. The game ends when all balls have been transferred and the progress bar is completely filled. The exergames developed in this study were structured according to the following game logic (Figure 5A).

Figure 5. Game logic and structured prompting flow for the 2 developed exergames, illustrating how tasks progress across stages and branch according to success or failure, while different prompting strategies are applied conditionally throughout gameplay; antecedent prompts appear earlier in the flow, corrective prompts are introduced following unsuccessful attempts, and praise prompts accompany successful task completion, each distinguished by a consistent color scheme.

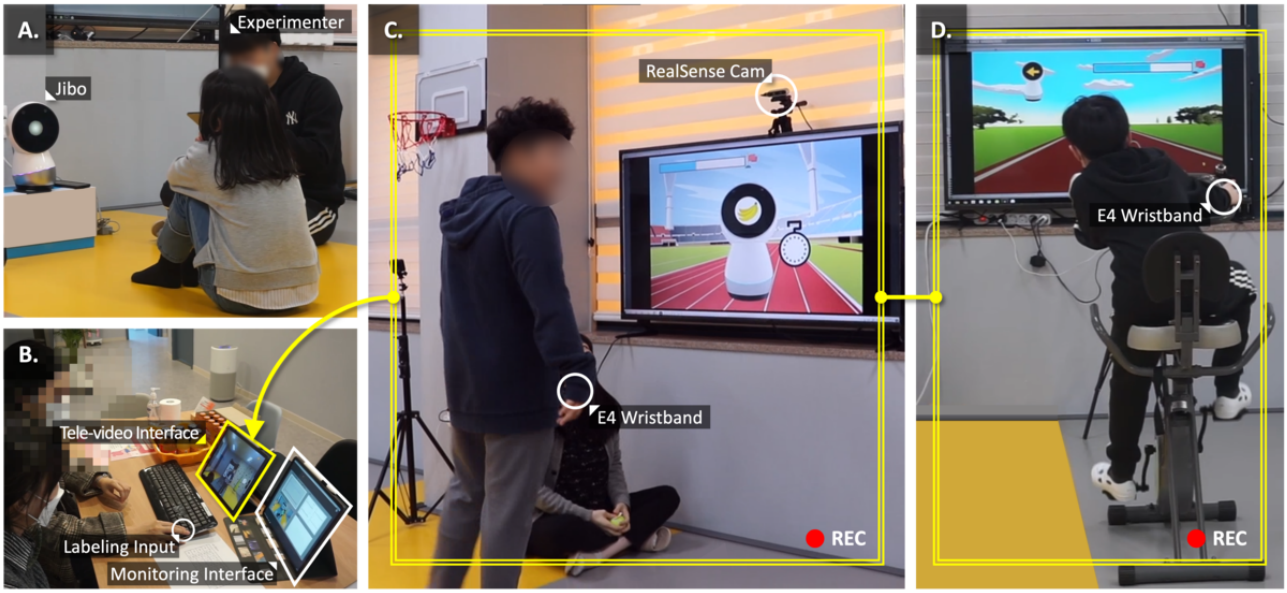
Exergame 2: Hazard Avoiding Ride

This game aims to enhance visual-perceptual abilities by having children ride a stationary bicycle while avoiding obstacles that appear on the left or right side of the VA's screen through body tilting. Three types of events are randomly presented: (1) a traffic cone on the left, (2) a traffic cone on the right, and (3) a pedestrian ahead (Figure 4B). Participants are required to tilt their bodies in the opposite direction of the obstacle (eg, to the right when a traffic cone appears on the left, and to the left when it appears on the right). When a pedestrian appears in front of the player, the participant must press a bell attached to the bicycle to signal a warning. The game consists of 12 sessions and ends when the progress bar is fully filled according to game logic (Figure 5B).

Virtual Agent Integration

To facilitate sustained engagement and provide prompting support within exergames, a VA was integrated into the system. The VA was modeled after Jibo [23], a human-like robot with a head and torso [37,39] that was used to build rapport with children with ASD before gameplay [24,25]. During gameplay, the VA appeared in the game scene and delivered prompts aligned with 3 established categories [40]. These prompts included not only verbal instructions but also visual cues displayed on the VA's screen to guide task execution. Specifically, antecedent prompting involved directive cues presented before task initiation to guide the child's actions (eg, "Let's go get an apple"). Corrective prompting was provided after an attempted response to help the child adjust or refine their behavior (eg, "That's not an apple! Shall we try getting the red fruit again?"). Praise prompting consisted of positive reinforcement to encourage continued engagement throughout the tasks (eg, "Great job!" and "Yes, that's correct"). In each gaming context, prompting strategies were tailored based on the task flow and game-specific mechanics of each exergame (Figure 5).

Adjustments Following Initial Evaluation



A preliminary study with a child with ASD (a boy, aged 11 years) and one therapist highlighted the need for explicit background audio, auditory prompting, and causal feedback; the volume of prompting and game-related sound effects was increased. Feedback for the final stage was added to support a sense of completion (eg, flag or applause). The study also identified the importance of a progress bar, which enabled the child to track both task progression and their own pace [38]. The progress bar was filled as each session ended. For the Hazard Avoiding Ride, the original 24-session version was reduced to 12 sessions to keep the total duration within 3 minutes, which applies to both exergames.

XSL•FO
RenderX

Exergame Setup

Exergames were implemented at a local special education center that supports mental and physical health, as well as basic motor function development, for children with ASD. A 55-inch screen was placed in front of the players to display the exergames (Figures 6C and 6D). A wearable E4 wristband and 2 cameras were used to minimize external stimuli and accommodate hypersensitivity in children with ASD [41]. The E4 wristband was attached to the participant's wrist and connected to the SG to monitor behavioral and physiological data streams. Two cameras were positioned at the front and back to capture the player's behavior and record video. Building on this setup, a real-time visualization platform was developed and deployed to facilitate engagement labeling by parents during gameplay. The platform synchronized sensor data with live video and was displayed on two 12.9-inch iPad Pro tablets—one displaying a live video feed of the child, and the other presenting time-series plots visualizing variations in physiological and behavioral signals, including engagement status, accelerometer data, galvanic skin response, heart rate, skin temperature, and motion tracking.

Figure 6. The implemented exergame system at Dream Tree Children Education Center, depicting each study phase: (A) rapport building, (B) engagement labeling and monitoring, (C) Fruit Sorting Run, and (D) Hazard Avoiding Ride. Gameplay video streams from (C) and (D) were transmitted in real time to the engagement labeling interface shown in (B).

Procedure

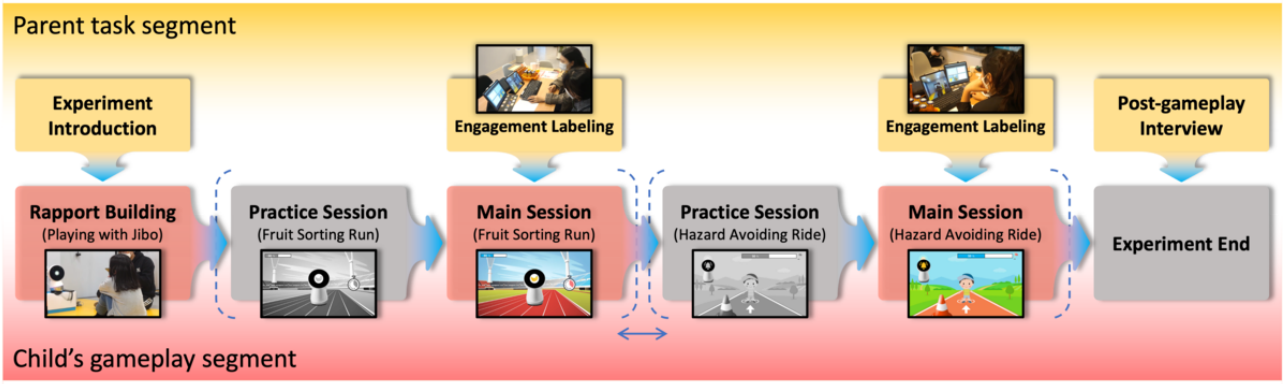
To examine the practical applicability of the iteratively developed exergames, we conducted a human-participant study involving children with ASD. In line with case-oriented approaches used in ASD-related studies—where high interindividual variability necessitates detailed observation at the individual level—3 children with ASD (P1-P3), aged between 10 years and 13 years (mean 11, SD 1.3 years), were finally recruited and evaluated [42]. P4, who was originally scheduled to participate, withdrew consent. The refusal stemmed from P4's sense of loss and emotional displacement after observing P3 (a peer identified as a rival) establishing a close and successful play interaction with the Jibo robot in a preceding session, effectively feeling that the friend (robot) had been taken. The demographic details of the participants are summarized in Table 2. All planned engagement labeling data and playtimes were collected without missing entries for the included participants.

XSL•FO
RenderX

Table 2. Pilot study demographics and clinical characteristics of children with autism spectrum disorder (ASD); 4 participants (P1-P4) were initially enrolled, with P4 withdrawing prior to study completion and excluded from subsequent analyses.

Participant (age in years)	Gender	Disability	K-Disability Grade[a] (DSM-5[b])	Rapport level[c]	Elementary school grade[d]	Communication capacity
P1 (10)	Female	ASD	G-2 (≈ L-2)	L-2	G-2	Inexpressible
P2 (13)	Male	ASD	G-2 (≈ L-2)	L-1	G-5	Inexpressible
P3 (11)	Male	ASD	G-2 (≈ L-2)	L-5	G-3	Expressible
P4 (11)	Male	ASD	G-2 (≈ L-2)	L-5	G-3	Withdrew

[a]The K-Disability Grades constituted the national clinical classification system for ASD (Republic of Korea). While structurally distinct from the DSM-5, shared criteria like the intelligence quotient (IQ) threshold (IQ<70) allow for cross-reference; specifically, Grade 2 aligns with Level 2 based on this threshold. Corresponding DSM-5 levels are included for cross-reference purposes.



[b]DSM-5: Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition.

[c]Rapport level was evaluated by a therapist using a single item on a 5-point Likert scale ("strongly disagree" to "strongly agree"): "Overall, the interaction felt highly coordinated and established a positive, enjoyable connection." This measure captures the 2 critical rapport dimensions emphasized in the Gratch et al [43] framework: coordination and connection.

[d]Korean elementary school education spans grades 1 to 6.

Before gameplay, participants were introduced to the exergames and informed of their respective roles (Figure 7). A preliminary session was conducted to facilitate rapport building (Figure 6A). During this session, participants interacted with Jibo, a physically embodied robot operated by the experimenter using a Wizard-of-Oz protocol. Children engaged in interactive play with the robot, which included head tilting to navigate a spaceship and responding to movement prompts (eg, dancing or playing guitar), involving audiovisual and physical interaction. The main session began after the therapist confirmed that sufficient engagement and rapport had been established. A practice session followed to assess the child's readiness to engage with the exergames. Children who were able to follow the game flow—either independently or as determined by the therapist—proceeded to the main game session. The 2 exergames were presented in a counterbalanced order to ensure equitable exposure. The child participated in both games while each child's parent, located in a separate room, labeled engagement status using a binary scheme (not engaged=0, engaged=1) based on real-time observation (Figure 6B) [44]. Parents were instructed to press the "Enter" key when the child appeared engaged and to refrain from pressing otherwise, following predefined operational definitions and behavioral indicators (Table 3). Before the main session, the experimenter explained the criteria and conducted a calibration using practice examples. We adopted binary labels to reduce boundary ambiguity that can increase subjectivity in finer-grained schemes (eg, ternary or multilevel labels). If the labeler judged that the annotation was incorrect over a given time-series interval, the label assignments for that interval were revised. After the gameplay session, a parent interview was conducted to gather feedback based on proxy observations of the child's experience [45,46].

Figure 7. Experimental procedure across child and parent segments, depicting the full study timeline from start to end. The parent (top) and child segments (bottom) were conducted concurrently within the same session; rapport building began at experiment onset, engagement labeling was applied only during main sessions, and postgameplay interviews followed experiment completion. Back-view photos were retained as they do not permit identification; blur was applied where needed to prevent participant identification. Frames are arranged left to right to show the temporal progression; each game session (practice + main) followed a counterbalanced order across participants.

XSL•FO
RenderX

Table 3. Behavioral criteria for caregiver-based engagement labeling during exergame play, including binary engagement labels, their definitions, and corresponding observable behavioral indicators used to guide labeling.

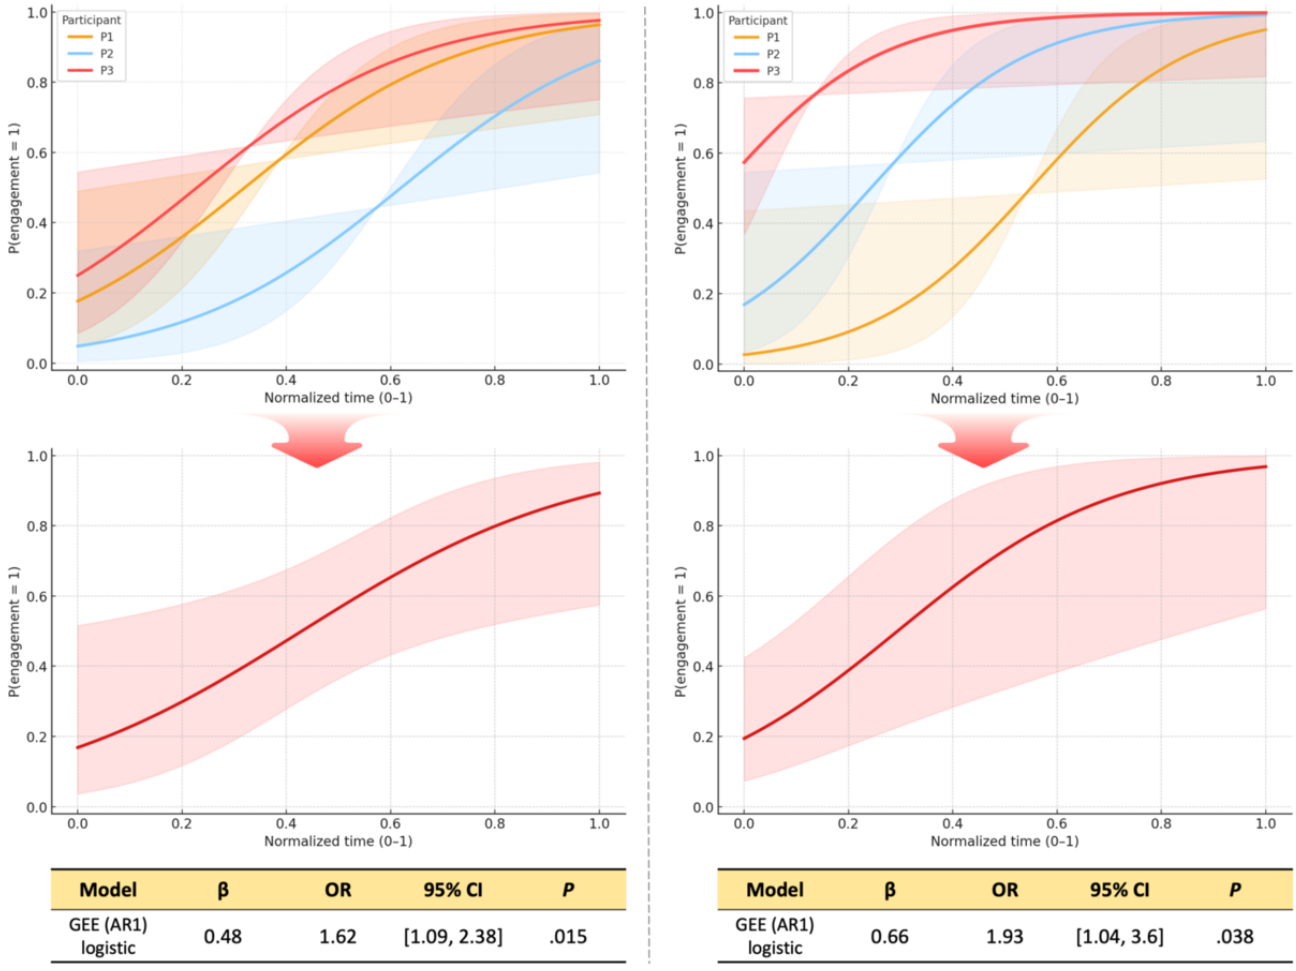
Engagement label	Definition	Behavioral Indicators
Not engaged=0	The child shows no cognitive or motor participation relevant to the exergame.	(1) Looking away from the screen or robot, (2) leaving the play area, (3) stopping movement, or (4) engaging in unrelated behaviors.
Engaged=1	The child demonstrates active participation in the gameplay task.	(1) Orienting toward the screen, (2) following prompts, (3) moving body parts according to task goals, and (4) responding to game feedback

Results

Overview

We analyzed the temporal trends in engagement status of children with ASD, based on labels provided by their caregivers during gameplay. As each child engaged in the game for a different time duration, we first summarized the total playtime for each child (Table 4). While P1 recorded a session of 3 minutes 13 seconds in the Hazard Avoiding Ride, the average playtime across games generally aligned with expert guidance for children with ASD. To support time-aligned comparisons of engagement across participants, the time axis for each child was normalized by dividing the elapsed time by the total game duration, resulting in a scale from 0 to 1. We then modeled changes in engagement over normalized time using generalized estimating equations (GEE) with a logistic link function to account for repeated measures within participants. Specifically, we fit a GEE logistic model with an autoregressive working correlation of order 1 (AR1), treating each participant as a clustering unit and including participant indicators to control participant-level baseline differences. Engagement status (not engaged=0, engaged=1) served as the outcome variable. Given the small number of participants, we interpret inferential statistics as exploratory and emphasize effect sizes with CIs.

Table 4. Play durations per participant (P1-P3) for each exergame in minutes and seconds, showing participant-level variation in playtime.



Exergame type	P1	P2	P3	Mean (SD)
Fruit Sorting Run	2 min 25 s	2 min 59 s	2 min 1 s	2 min 28 s (29 s)
Hazard Avoiding Ride	3 min 13 s	2 min 25 s	1 min 55 s	2 min 31 s (39 s)

Engagement Trends Over Time

Engagement in both the Fruit Sorting Run and Hazard Avoiding Ride tended to increase over normalized time (Figure 8). Using GEE with a logistic link to account for repeated measures within participants (AR1 working correlation; participant indicators included), normalized time was significantly associated with a higher probability of engagement status =1 in the Fruit Sorting Run (per 0.1 increase: β=0.48; odds ratio 1.62, 95% CI 1.09-2.38; *P*=.02). The Hazard Avoiding Ride showed the same direction of association (per 0.1 increase: β=0.66; odds ratio 1.93, 95% CI 1.04-3.60; *P*=.04). The results present participant-specific predicted probabilities and a population-averaged trend estimated from GEE logistic models with an AR1 working correlation (95% CI). Consistent with these estimates, model-estimated P(engagement=1) tended to be higher at later normalized timepoints in both activities.

Figure 8. Engagement trends over normalized time (generalized estimating equations [GEE] logistic, autoregressive working correlation of order 1 [AR1]). Shaded bands indicate 95% CIs. Top: individual-level predicted probabilities shown to illustrate engagement trends. Bottom: population-averaged predicted probabilities across children with autism spectrum disorder (ASD), forming the basis for the model estimates reported in the accompanying table, with (A) Fruit Sorting Run and (B) Hazard Avoiding Ride. OR: odds ratio.

Model	β	OR	95% CI	*P*
GEE (AR1) logistic	0.48	1.62	[1.09, 2.38]	.015

A. Fruit Sorting Run

Model	β	OR	95% CI	*P*
GEE (AR1) logistic	0.66	1.93	[1.04, 3.6]	.038

B. Hazard Avoiding Ride

Postinterview With Caregiver

Along with the temporal trends observed during gameplay, caregiver interviews with all 3 participating children with ASD (P1-P3) supported the observed engagement patterns. The interviews revealed distinct yet converging increases in engagement, along with perceptions of each game's strengths and suggestions for improvement. Feedback was analyzed by game type to understand how each activity influenced engagement. In the Fruit Sorting Run, caregivers reported that participants remained attentive and engaged throughout the session. P1 appeared focused and responded positively to praise, suggesting a sense of achievement. The caregiver noted that adaptive verbal cues could further support engagement when the child was not running. P1 also showed difficulty differentiating fruits with similar colors and shapes (eg, apple vs tomato; oriental melon vs lemon), which sometimes interrupted task progression. P2 expressed a stronger preference for the Fruit Sorting Run over the Hazard Avoiding Ride. Although he showed initial hesitation, he maintained effort throughout the activity, even though he typically disengages when bored. The caregiver noted that the task aligned with his everyday preference for sorting beads by color and type, which may have supported sustained participation. Because communication was challenging, P2 relied primarily on visual prompts. P3, who usually avoids running, remained physically active without breaks and showed enjoyment. His caregiver observed that he took pride in the fruit-sorting task, which may have contributed to sustained engagement. In the Hazard Avoiding Ride, similar patterns of engagement were reported. All 3 children showed attention and engagement patterns that were consistent with an increasing trend over time, despite differences in prior experience. According to P1's caregiver, the child focused on the task and followed the VA's instructions, with interest increasing as the session progressed. P2, unfamiliar with bicycling, found the activity novel and remained highly concentrated; the caregiver noted that repeated exposure could promote learning. P3 was initially anxious but became increasingly engaged. Unlike in typical physical or leisure activities—where he often loses interest—he demonstrated more active and enjoyable participation once familiar with the game.

Discussion

Principal Results

The primary goal of this study was to design full-body serious exergames for children with ASD through an iterative, expert-informed process that emphasized both playfulness and potential functional benefits. As a result, 2 exergames were developed—Fruit Sorting Run and Hazard Avoiding Ride—each designed to promote engagement through physical activity aligned with functional skill development. To achieve this, rather than relying on a single design iteration or a pre-existing game framework, we adopted a multiphase participatory approach that integrated input from special education experts, caregivers, therapists, and HCI researchers across 4 structured phases (Figure 1). This process yielded not only 2 target exergames but also a systematic methodology that highlights the role of stakeholder involvement in tailoring game content to the cognitive, motor, and daily needs of children with ASD.

Three design considerations emerged from this process: (1) grounding gameplay in goal-oriented exercises aligned with the cognitive and motor capabilities of the target population. The exergame conceptualization was grounded in a 2×2 activity matrix informed by therapist categorization of physical and cognitive demands—a structured method that reflects prior evidence showing that tasks calibrated to users' cognitive and motor levels support skill development and adaptive functioning in children with ASD [47]. This approach reflects SG design principles that promote aligning game tasks with users' motor and cognitive abilities through intended in-game goals [38]. Recent studies have further shown that exercises aligned with the cognitive and motor abilities of children with ASD not only improve gross motor skills but also help motivate participation among children with ASD [48,49]. (2) Engagement scaffolding mechanisms—such as prompts and feedback from VAs—were incorporated to support sustained interaction. Existing VA-based systems for children with ASD have demonstrated the utility of contingent feedback in guiding user responses. These systems primarily focused on low-level interactions, responding to gaze [24], nonverbal conversational cues [50], or emotional expressions [51]. While such approaches support reciprocal interaction, they typically emphasize momentary cue–response dynamics rather than task-oriented guidance. Our VA expands on these foundations by delivering gameplay tasks directly, combining verbal instructions and visual cues to deliver gameplay tasks. (3) Prioritizing gameplay elements perceived by stakeholders—especially educators and caregivers—as playful, goal-oriented, and compatible with daily routines, the design approach reflects established principles in SG design for children with ASD [38]. Routine exercises that align with daily activities [52], such as jogging and cycling, can promote active engagement of children with ASD [53] and lead to improvements in skills in planning, inhibition, and cognitive flexibility, along with reductions in repetitive behaviors [54].

The pilot field study suggested that engagement trajectories tended to align with an increasing trend over time during gameplay, despite differences among participants in age, school grade, and rapport levels with the VA and occasional distraction or disengagement reflecting common attentional variability in children with ASD; behavioral labeling and caregiver interviews supported this overall pattern. Caregiver interviews indicated that even children with limited prior experience or low baseline motivation (eg, unfamiliar with bicycling [P2], typically avoidant of running, or prone to early disengagement [P3]) became more involved as they grew accustomed to the game structure. Caregivers noted that children responded positively to praise prompting (P1) and showed behavioral responses to antecedent prompting, following the VA's instructions as interest and task focus increased during gameplay—a pattern similarly emphasized by Bernardini et al [24], who reported that children with ASD showed increased responsiveness to directive prompts delivered by a VA. Caregivers also noted that children with limited expressive communication (P1 and P2) relied more on intuitive, visual prompting; therefore, follow-up work should present options through explicit and intuitive visual media and avoid ambiguous choice boundaries. This design choice aligns with established intervention practices that commonly use visual supports, structured prompting, and reinforcement to sustain task participation [24]. Observations during gameplay further suggested that adaptive prompting, triggered in moments of hesitation or disengagement, could support sustained interaction and re-engagement [55]. Taken together, these findings highlight the VA's role in supporting engagement through prompting during gameplay.

Limitations and Future Directions

This study aimed to develop full-body serious exergames for children with ASD through an iterative, expert-informed design process. As an initial exploration, we tested the games with 3 children to examine engagement patterns during gameplay. Although all participants showed an upward trend in engagement, the small sample size can limit the interpretation of these patterns across the wider population of individuals with ASD. Given the heterogeneity in cognitive, motor, and behavioral characteristics, further studies with larger and more varied samples are required to examine whether similar engagement trends appear across individuals. Examining which child characteristics (eg, communication level, sensory sensitivity, motor proficiency, and baseline interest) are associated with engagement trajectories and responsiveness to prompts may be valuable for informing individualized interaction profiles. This direction may support tailoring prompt timing, modality (visual/verbal), and reinforcement style to the needs of each child rather than applying a single prompting approach. Expanding the dataset would also support future work on adaptive prompting strategies [55].

Physiological signals (eg, heart rate and skin conductance) were streamed during gameplay to assist annotators' contextual interpretation; however, these data were not incorporated into the present analysis. As the study focused on behavioral engagement labeled by caregivers, physiological measures were treated as supplementary rather than analytic components. Future work may integrate these multimodal data to model engagement dynamics more comprehensively. In particular, combining physiological signals with gameplay context (eg, pauses, slowed pace, and errors) may help detect hesitation or overload and trigger context-sensitive prompts.

XSL•FO
RenderX

The engagement labels used a binary scheme, which reduces engagement to an on/off state and may not capture brief fluctuations or multidimensional aspects of engagement. Future work may consider multilevel or continuous labeling, along with complementary measures, to represent engagement dynamics with higher temporal resolution. Such representations can also enable evaluating how different adaptive prompting strategies affect distinct engagement components (eg, attention vs task persistence) across children.

While prompting was delivered through a VA, it was not dynamically tailored to individual behaviors. To enable context-sensitive and engagement-responsive interaction, future studies will aim to recognize engagement status in real time and apply machine learning to model and deliver adaptive prompting, aligned with O'Guinn et al [56]. Building on this direction, future work will extend the current VA-based prompting scheme from a fixed, prespecified schedule to an engagement-responsive strategy. A feasible next step is to evaluate fixed prompting versus adaptive prompting using a single-case experimental design, such as a multiple-baseline design across participants. Baseline sessions would follow the current fixed prompting logic, whereas intervention phases would introduce adaptive prompting that adjusts timing and modality based on predefined behavioral triggers observable in the existing system (eg, sustained disengagement, repeated errors, or prolonged response latency). Engagement trajectories, recovery from disengagement, and prompt responsiveness would be compared within individuals across phases, enabling rigorous individual-level evaluation under substantial interindividual variability in children with ASD.

Finally, although increased engagement was observed, the study did not assess therapeutic or educational outcomes. Future research should investigate whether these exergames can support specific intervention goals, such as improving emotional regulation, reducing stereotyped behaviors, or enhancing functional skills [57]. If such outcomes are demonstrated, the system may also offer practical value to special educators seeking to promote active participation in school-based or clinical settings. To situate the system within the broader intervention landscape, future studies will test deployment across common contexts (school-based sessions, clinical programs, and home practice) and assess feasibility factors relevant to practitioners (eg, setup time, supervision demands, and alignment with individualized goals).

Conclusions

This study presented the iterative design and initial field evaluation of 2 full-body serious exergames for children with ASD, developed through a multiphase, expert-informed process involving 21 professionals from special education, APE, and HCI. Grounded in goal-directed physical activity and supported by engagement scaffolding mechanisms such as VA-based prompting, the exergames were tailored to promote interaction aligned with developmental needs. The design process was shaped by 3 core considerations: aligning gameplay with children's cognitive and motor capabilities, incorporating scaffolding mechanisms to support engagement, and ensuring playfulness and perceived developmental value, such as supporting daily living skills.

Beyond prior SG approaches that primarily relied on discrete gestures or in-place interactions, this study advances exertion-intensive, whole-body exergame design by embedding sustained physical activity within structured gameplay, shaped through a series of expert collaborations. As an exploratory multiple-case pilot, we tested the 2 developed exergames with 3 children with ASD to examine feasibility and engagement patterns during gameplay, observing increasing engagement trends over time despite inter-individual differences.

By integrating expert-driven design with case-based field evaluation conducted in a special education setting, this work contributes a grounded design and evaluation framework for developing exertion-intensive exergames for children with ASD. This contribution extends prior work on serious exergames for children with ASD by demonstrating how therapist-informed exercises and structured prompting strategies can be systematically translated into playable, full-body game mechanics. While these observations remain preliminary, they provide initial indications that should be examined and strengthened with larger samples. Taken together, this exploratory multiple-case pilot provides an initial basis for a testable hypothesis that full-body serious exergames, paired with VA-based prompting, may be associated with increasing engagement over time, which should be examined in larger samples.

Acknowledgments

We express our sincere appreciation to Director Choongman Lee of the Dream Tree Children Education Center for his role in supporting this work. We also extend our thanks to the children with ASD, their parents, and other caregivers for their participation, as well as to the 21 special education teachers for contributing their time and perspectives. The authors declare the use of generative artificial intelligence (AI) in the research and writing process. According to the GAIDeT taxonomy (2025), generative AI use was limited to proofreading and language editing under full human supervision. The tool used was ChatGPT-5.2 (OpenAI). Responsibility for the final manuscript lies entirely with the authors, and generative AI tools are not listed as authors or responsible for the final outcomes. This declaration is submitted under collective responsibility.

Funding

This work was supported in equal parts by the National Research Foundation of Korea (NRF) grants funded by the Korea government (MSIT) (RS-2024-00343397; RS-2025-16902996).

Abstract

Background: People with intellectual and developmental disabilities (IDDs) face difficulties in being included in activities with their peers due to differences in cognitive abilities and social skills. Video games offer a promising medium to support inclusion, physical activity, and social engagement, but current solutions struggle to provide equitable experiences to heterogeneous groups of users, especially in multiplayer real-time contexts.

Objective: This study aims to co-design and develop an inclusive collaborative real-time multiplayer exergame, assessing its usability, the impact of accessibility features, and players' satisfaction and enjoyment.

Methods: The exergame *Elemental* was co-designed following the CeHRes (Centre for eHealth and Wellbeing Research) Roadmap, involving clinicians, educators, engineers, and individuals with IDDs. A total of 2 cooperative minigames were developed: Igloo (focused on stimulus collection) and Volcano (focused on enhancing collaboration), playable with 4 different input devices (buttons, tablet, hand-tracking, and full-body tracking). Customizable facilitation options were implemented to adapt gameplay to sensory, cognitive, and motor needs. Young adults with IDDs participated in a 2-phase study testing whether personalized accommodations could eliminate performance disparities: (1) Igloo in homogeneous groups, based on functioning and expected behavior and interaction with stimuli, without facilitations, using all devices to identify optimal input methods, and (2) Volcano in heterogeneous groups using their best-performing devices with individualized facilitations tailored by educators. Data collected included in-game performance (accuracy, reaction time, and collaboration contributions), behavioral observations, and questionnaires on satisfaction and usability from players. Nonparametric analyses were used to assess relationships between disability severity, performance, and the impact of facilitations.

Results: A total of 11 individuals (2 male and 9 female; mean age 25.1, SD 4.4 years) with different IDD diagnoses were recruited from an association supporting individuals with cognitive impairments. In the Igloo sessions, performance was negatively correlated with intellectual disability severity (ρ=–0.87, 95% CI –1.00 to –0.56; P<.001) and reaction time was positively correlated (ρ=0.69, 95% CI 0.08-0.94; P=.02). Instead, no significant correlation between performance and intellectual disability severity was observed in the Volcano sessions (ρ=0.24, 95% CI –0.48 to 0.79; P=.48). These results highlight that tailored support (personalized facilitations and best-suited devices) can foster equitable participation even in heterogeneous groups. Behavioral analysis revealed frequent peer collaboration. Participants reported high usability and satisfaction (median 4/5, IQR 0.5).

Conclusions: This study introduces an inherently accessible, co-designed multiplayer exergame. Unlike approaches that adapt games or create separate disability-specific solutions, Elemental was conceived as inclusive from the outset. By demonstrating that personalized features can eliminate performance disparities, this work highlights how inclusive co-design can transform an

XSL•FO
RenderX

activity into an inclusive, collaborative, and enjoyable experience for individuals with different abilities and intellectual impairments, supporting the shift from fitting individuals into existing digital spaces to designing environments able to embrace diversity.

Introduction

Problem

In recent years, there has been significant growth in awareness surrounding the needs of people with intellectual and developmental disabilities (IDDs) [1], but the attention of the scientific community is often directed toward diagnostics, etiology, and therapy [1,2]. While these are important, a broader perspective is needed that considers how people with IDDs experience daily life and participate in their communities. Building on the European Disability Strategy 2010-2020 [3], emphasis was placed on empowering people with disabilities to fully participate in society. Key objectives included independent living and community inclusion through "deinstitutionalization"—shifting from institutional care to community-based support that enables individuals to exercise choice and control over their lives.

This policy shift recognizes that people with IDDs often spend their time in group settings with peers and educators in day programs, schools, and residential facilities, where quality of life depends heavily on meaningful participation in shared activities, including play and recreation [4,5]. Within this framework, promoting autonomy and inclusion requires addressing not only environmental and social barriers but also developing essential life skills—emotional skills, social skills, and thinking skills—which are crucial for improving well-being, happiness, and interpersonal relations to facilitate full participation in community life [6].

Despite these policy commitments, people with IDD continue to face exclusion from leisure activities with their peers, with factors such as disability severity, environmental barriers, and societal attitudes exacerbating this phenomenon [7]. These barriers are especially difficult to eliminate when people with IDDs must engage in activities and tasks designed solely for neurotypical people, given that IDDs encompass a wide range of conditions with varying support needs, making each person's requirements for meaningful participation quite different [8,9]. This diversity is especially important to consider in group settings where people with different abilities come together for shared activities, yet activities are typically designed without accounting for this individualized support emphasized in current inclusion frameworks [10].

Nevertheless, the social model of disability reminds us that all disabilities, including IDDs, stem not only from their underlying medical causes but also from the interaction between individuals and personal and environmental factors [11]. In group settings where people with IDDs spend much of their time, the design of activities, tools, and spaces should prioritize their needs, remove existing barriers, and prevent the creation of new ones [12]. When designing games, activities, and experiences for these environments, accessibility should be a crucial aspect to take into consideration. Accessibility means creating experiences that work for everyone in the group, regardless of different abilities and support needs. Therefore, accessibility is not only about adapting existing activities but about designing inclusive experiences from the start that allow everyone to participate meaningfully together [13].

Yet accessibility is not an easy feature to obtain, particularly when considering social contexts in which multiple individuals must interact. People with disabilities are drastically different from one another. Their needs may be complex, difficult to accommodate, or conflicting with the needs of another person when interacting in social contexts [14]. Although accessibility tools enable people with disabilities to use instruments and services, they often achieve this through extensive customization that creates separate experiences, potentially perpetuating feelings of exclusion. Thus, it is crucial to design and create an experience that is usable by all, while being perceived as fair and engaging.

Review of Relevant Scholarship

Video games present a promising medium to address these challenges in group settings. They have shown positive effects on the quality of life of people with disabilities, providing entertainment opportunities, and have potential for inclusion through their ludic aspect that boosts motivation [15,16]. Moreover, they offer extreme customizability, making them particularly adequate to craft individualized experiences. The provided benefits are not limited to entertainment but encompass the possibility of providing therapeutic activities and social inclusion. Exergames, for example, are video games that combine gaming elements with physical activity, encouraging movement and exercise. These games can be useful for people with IDDs [17], as they offer a fun and engaging way to stay active, which is particularly important in a population that usually has lower physical activity levels [18]. Exergames can improve gross motor functioning and balance, contributing to an overall improvement in physical and mental health, while exploiting their fun side to motivate players [19].

Despite this potential, accessibility barriers in mainstream video games have made them almost unusable for people with disabilities, leading to their exclusion from this social phenomenon [20]. Lack of accessibility in a video game usually stems from the difficulty or impossibility of (1) capturing stimuli (sensory disability), (2) determining responses (cognitive disability), and (3) using input interfaces (motor disability) [21]. These issues are particularly problematic in multiplayer games,

XSL•FO
RenderX

where several people participate simultaneously. Playing together requires that the games be accessible and that the players be prepared for different levels of ability, allowing all individuals to engage in the game at the same level of experience [22].

Encouragingly, the field of video games is recently becoming more and more accessible, with major companies such as Microsoft paying closer attention to all customers' needs [23]. Efforts were made to develop or adapt video games to be accessible to various disabilities, including sensory, motor, and cognitive impairments, through software and hardware features.

Software ones are easier to implement and customize, alleviating barriers from various disabilities. For hearing impairments, subtitles are now widely adopted. Games such as Fortnite [24] and Minecraft [25] have added the possibility to display symbols or text accompanied by visual effects indicating the direction of an acoustic stimulus. Visual impairments are addressed in games such as The Last of Us [26], specifically in its second instalment, equipped with a text-to-speech system and audio pings that allow the player to locate enemies and loot. Software interventions allow for improved accessibility for people with cognitive disabilities as well. For example, Celeste [27] has an "Assist Mode" which allows for granular control of the game speed, delaying the reaction times necessary to make progress in the game.

From a hardware standpoint, to overcome motor and visual disabilities, controllers have instead been adapted to meet players' needs. Guitar Hero was adapted for people with blindness (Blind Hero) [28], providing inputs through haptic stimuli via gloves rather than screen visuals. For limited mobility, Xbox has developed the "Xbox Adaptive Controller," [29] a larger controller that can be customized with additional elements such as joysticks, buttons, and switches to meet players' motor needs.

However, multiplayer games for people with IDDs remain understudied in literature and scarcely found in market solutions, as the challenge is not limited to making the games accessible, but to making the experience fair and enjoyable for everyone. Moreover, most current solutions lack a portfolio of settings that allows to create a truly customized experience.

Hypothesis, Aims, and Objectives

Given these premises, the aims of this study are (1) to describe the co-design and development of an inclusive, collaborative, real-time multiplayer exergame; (2) to assess its usability with a group of individuals with IDDs through the analysis of players' behavior; (3) to assess the impact of accessibility features on performance; and (4) to evaluate players' satisfaction and enjoyment.

Methods

This study combined a participatory co-design and development phase with a prospective 2-phase evaluation of the resulting exergame. The design was nonrandomized and observational with repeated measures across sessions.

Co-Design and Development of the Elemental Game

Overview

During the creation of the game, particular care was devoted to the design process, as the users' needs are very diverse and should be carefully considered to deliver an enjoyable experience. Consequently, the design process followed a pipeline inspired by the CeHRes (Centre for eHealth and Wellbeing Research) Roadmap 2.0 [30], a framework for the participatory development of eHealth technologies. The sequential steps of the CeHRes Roadmap are "Contextual Inquiry," "Value Specification," "Design," "Operationalization," and "Summative Evaluation," although "Operationalization" was not included in this work, since it is a step that is better suited for commercial solutions.

Contextual Inquiry

This phase is crucial to lay down the foundations for the entirety of the design and development process. Its main goals are to identify the main actors involved in this study and the types of users of the game, to characterize the context in which the game would be used, and to analyze the main criticalities to be improved in the current context.

First, an internal brainstorming session with clinicians (neuropsychiatrists, psychologists, and psychomotor therapists), engineers (biomedical engineers and computer science engineers), and educational professionals (educators and teachers) was conducted to characterize the IDD population that would benefit from an inclusive exergame, following stakeholder identification best practices [31]. All professionals had expertise in the fields of inclusion, education, and eHealth, and were thus chosen because of their miscellaneous experiences with disability in various contexts.

The contexts in which the game would be used were analyzed through extensive literature research, with special attention to users' daily lives and behaviors and to legislative and ethical issues.

Information gathered from stakeholders was then combined with scientific evidence to identify the main criticalities and pain points in the current solutions.

From this analysis, the target population was identified as adults with IDDs because of their experience in structured group settings. Adults with IDDs represent a particularly important population to address, as they face increasing challenges in accessing engaging and accessible activities as they age, while spending significant portions of their time in organized social environments where inclusive activities could have a substantial impact.

Through contextual analysis of the daily life of Italian adults with IDDs, it was found that they regularly participate in educational and recreational activities within contexts created by associations, day programs, and residential facilities, where they engage in group activities with the support of clinicians and educators. These structured social environments present an ideal setting for implementing inclusive gaming experiences, as they already facilitate group participation and have support staff present who can assist with activity facilitation.

XSL•FO
RenderX

Furthermore, these contexts align with the deinstitutionalization principles emphasized in current disability policy, as they represent community-based settings where people with IDDs can develop social skills, engage in meaningful activities, and participate in shared experiences with their peers.

Value Specification

The discussion that originated during the "Contextual Inquiry" was crucial to refine the original, coarser idea of an inclusive exergame into a set of technical and functional specifications. Several needs emerged, which were then mapped to functional requirements, as seen in Textbox 1. Some functional requirements appear more than once, since they respond to more than one need.

Textbox 1. Needs and their correspondence to functional and technical requirements.

Customization

- User profiles
- Possibility to tweak settings at runtime
- Multiple input devices

Collaboration

- Multiplayer game
- Real-time gameplay

Accessibility

- Multiple input devices
- Facilitations tailored for each need

Inclusion

- Facilitations tailored for each need
- Encouragement and rewards

Clinically-informed design

- Facilitations tailored for each need

Engagement

- Encouragement and rewards
- Possibility to tweak settings at runtime
- Attractive user interface
- Real-time gameplay

Variety

- Multiple games

Cost-effectiveness

- Reliance on inexpensive third-party services

Cross-context deployment

- Possibility to deploy on local servers

Game Design

Overview

Once the functional requirements of the game were defined, the design phase began. For each functionality, mock-ups were produced, analyzed, and discussed in multidisciplinary teams to assess the feasibility and adequacy of proposed solutions. After refinements, the technical team provided low-fidelity prototypes to be tested in a protected environment to identify any technical or usability issues. Finally, high-fidelity prototypes were tested by the main stakeholders to further refine the game.

The exergame developed was called Elemental and follows the daily activities of a little dragon named Blaze. Two minigames, the Igloo and the Volcano, were developed. In the Igloo, players should collect as many frozen objects as possible, whereas in the Volcano, all players must work together to guide Blaze,

XSL•FO
RenderX

who is carrying stones, through a volcanic path toward the exit. The 2 minigames take place in the narrative framework of building a magical house for a farmer friend of Blaze, incorporating windows crafted from the ice collected and walls from the stones. This storyline was designed to promote altruism and reciprocal support among players.

The game uses a unique cooperative control system where each minigame requires players to manage distinct gameplay elements, making every participant essential to overall success while eliminating competitive dynamics. Although each player operates from their individual screen, all participants collectively control the same character, creating a truly collaborative gaming experience that emphasizes teamwork over individual achievement.

Facilitation Options

Facilitation options address multiple needs identified during the value proposition phase, particularly customization and accessibility. Since people with disabilities have vastly different needs, customization alone is insufficient: facilitation design must be guided by clinical evidence to effectively enable people with IDDs. These options were co-designed with clinicians to translate clinical requirements into implementable technical specifications (Table 1). Moreover, the approach to their definition should not rely too heavily on diagnoses, but on specific needs, as generalization is harmful not only across diagnoses, but across individuals with the same diagnosis as well. Because of this reason, some facilitation options were grouped together as presets, allowing for a quick selection, but there is always the option to toggle individual settings as well, to cater to every case.

Table 1. Definition of clinical requirements and their translation into functional requirements and practical game implementations.

Impairment	Clinical requirement	Functional requirement	Game implementation of the facilitator
Cognitive and sensory	Emphasizing one's own task	Enhanced input feedback and action clarity	• Reducing the visibility of other players' stimuli • No distractors • Absence of stimuli requiring an inhibition response
Cognitive	Frequency modulation of stimuli	Adjustable game parameters	• Current player's stimuli appear less often
Cognitive and physical	Assisted action	Additional reference on the screen and compensatory reaction	• 3D model that mimics the actions that the player is supposed to do • Automatic progression after long pauses
Sensory	Reduced audio stimuli	Reduced volume of music and sound effects	• Reduced sound
Physical	Reduced movements	Reduction of frequency and range of motion	• Current player needs to move less often and with smaller movements • Player can play while seated
Sensory	Visual contrast modulation	Visual emphasis of important game elements	• Increased contrast

Further images of the facilitation options visible on screen are available in Multimedia Appendix 1.

Instrumentation

A total of 4 distinct input systems were integrated to allow for a broader range of interaction modalities with the game:

- Cosmo Switch Buttons by Filisia [32], which are multicolored Bluetooth accessibility buttons that the user could push with their hands to control game actions.
- An iPad tablet by Apple [33], whose gyroscope was leveraged for a motion-based interaction. Users could hold the device with both hands on opposite sides and tilt it to control the interaction.
- The Leap Motion Controller by Ultraleap [34], which allows hand tracking. This device allowed users to interact with the game by moving their hands, without holding physical controllers; instead, a virtual representation of the hands interacted with virtual targets.
- The Homing system by Tecnobody [35], a small PC that uses an RGB-D camera to provide full-body tracking. This system allowed user to move freely and interact with virtual targets through a virtual representation of their body.

These devices require varying ability levels, meaning the motor and cognitive effort needed to interact with the game differs across input methods. Each device demands different combinations of cognitive and motor skills, which enhance the exergame's accessibility and adaptability. This approach ensures that players with diverse needs and capabilities can find suitable ways to participate, creating a more inclusive gaming experience.

Architecture

Overview

The technical architecture of the platform was designed to support real-time multiplayer gameplay with extensive customization capabilities and future extensibility. The system consists of a Unity-based game client and a dedicated game server, both architected to accommodate variable numbers of

XSL•FO
RenderX

players, multiple input devices, and individualized user profiles with tailored facilitations.

Client

The game client was developed using Unity 2022.3.10f1. As a real-time multiplayer platform consisting of several minigames, special attention was devoted to its code structure and architectural design. The design prioritizes modularity, particularly given that the game supports different input devices that can assume any role and accommodates a variable number of players per match. Furthermore, since the platform is designed with the future addition of new minigames and features in mind, extensibility was a key consideration throughout development.

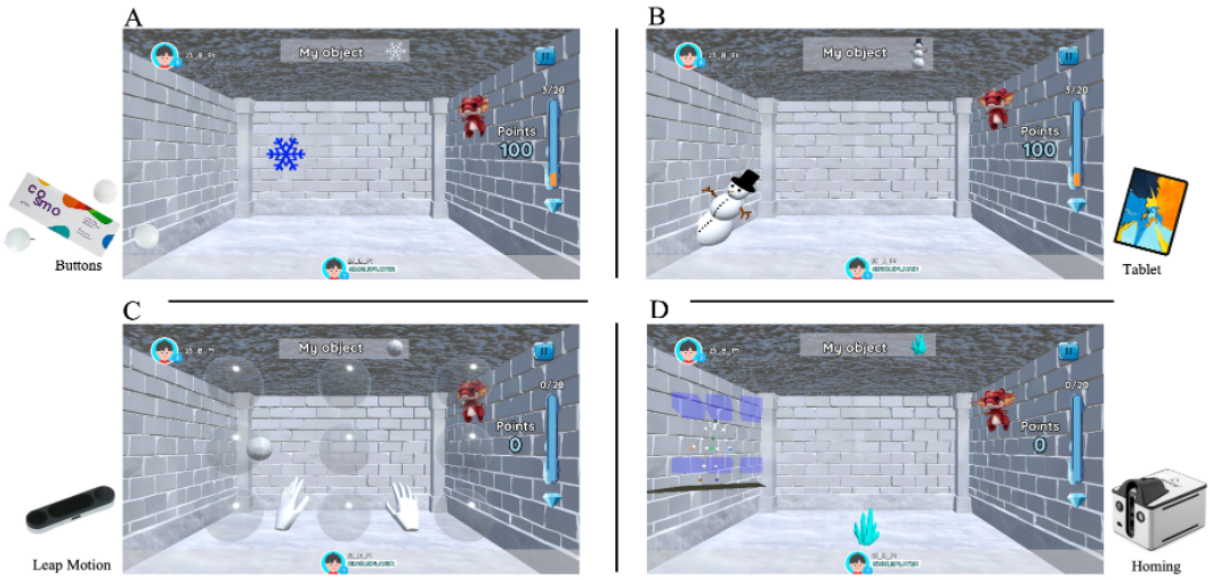
Server

For the multiplayer game server, the main requirements considered were real-time functionality as well as turn-based multiplayer support. The service needed to support user profiles and authentication, enabling caregivers to log in and select individual profiles. Each profile maintains separate settings and facilitations, game points, and progression data, all of which must be centrally manageable by the caregiver.

A central control dashboard was required for the platform, accessible via the internet to allow teachers to edit student profiles. Additional requirements included minimal dependency on third-party online services, deployability on local servers, customization capabilities via scripts, and cost-effectiveness.

Given these comprehensive requirements, Nakama Game Server was selected as the optimal solution. The game server uses a CockroachDB instance as its primary database, where both game and analytical data are stored.

The Elemental Game



The Igloo Game

The first minigame is the Igloo minigame. The stimuli presented are objects thematically connected to ice and snow. The stimuli appear on the screen for a fixed amount of time, and each player must interact with their input device to collect the object before it disappears. Table 2 contains the presented stimuli, the device associated with each of them, and the movement that needs to be carried out to collect the object. Examples of the different interfaces can be seen in Figure 1.

Table 2. Correspondence between input devices, stimuli, and requested movement.

Device	Object	Movement
Cosmo Buttons	Colored snowflakes	Push the button with the same color as the snowflake on the screen
Tablet	Snowmen	Tilt the tablet rightwards or leftwards
Leap Motion	Snowballs	Position the hands to intercept the snowballs
Homing	Crystals	Depending on where the crystals appear, position oneself to the left, center, or right, then jump or squat

Figure 1. The user interface for each input device in the Igloo minigame. (A) The buttons and the snowflakes they have to collect, (B) the tablet and the snowman that must be collected by tilting the tablet, (C) the Leap Motion Controller with the virtual hands guided by the player's hands that can collect the snowballs when interacting with the virtual bubbles, and (D) the Homing which presents a virtual representation of the player's skeleton and the crystal they can collect.

The focus of this game is the collection of predefined appearing stimuli, which must be followed by a reaction of the player to collect their target stimulus. Its structured and stimulus design makes it well suited for comparing performance across different

XSL•FO
RenderX

input devices and for collecting reaction time data. The setting is as simple as possible, and the only mechanic is the one that allows the player to collect the object. Moreover, to assess and, eventually, train inhibition, random red stimuli appear. These stimuli are distractors, and players should ignore them.

Several game parameters can be adjusted:

- The presence of red distractors.
- The number of stimuli on the screen at the same time.
- The total number of objects that appear in a match.
- The duration of each stimulus.

The Volcano Game

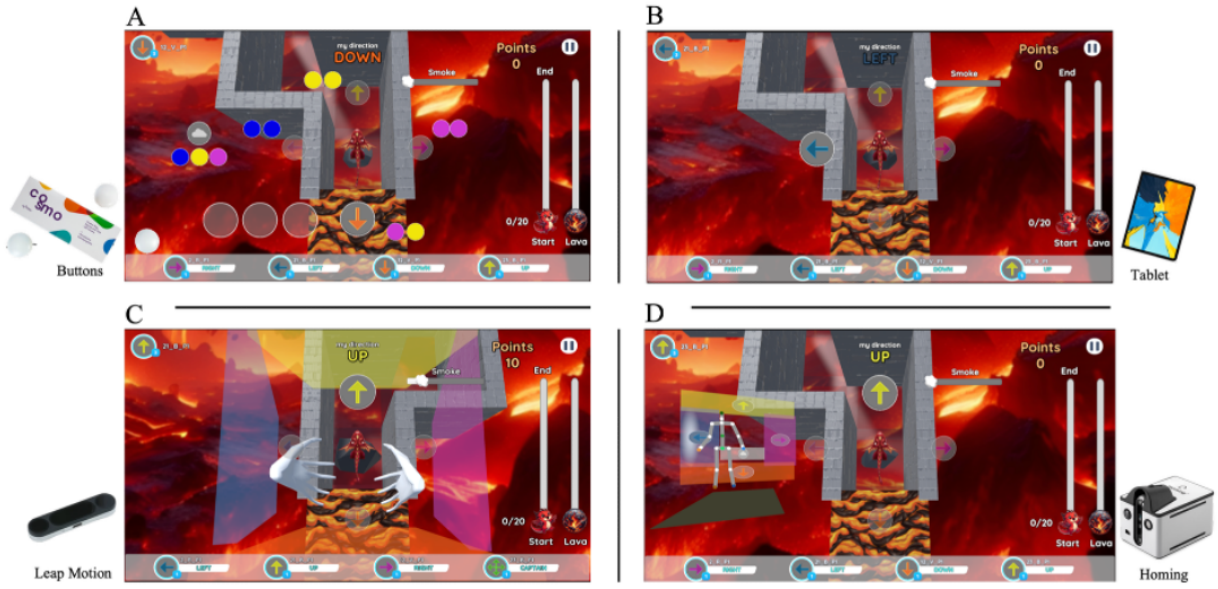
The Volcano minigame challenges players to guide Blaze safely out of a volcano following a path before rising lava reaches him, while also clearing the fog that gradually obscures the screen, hindering the visibility of all the players.

Each player controls Blaze's movement in 1 of 4 directions (top, bottom, left, and right) and is called to perform the correct movement depending on their input device when Blaze arrives at a point in the path in which he needs to go in that direction. The direction is randomly assigned at the beginning of the match, and the path is procedurally generated to make sure that the path is navigable given the number of players and to ensure that everyone plays a crucial role in successfully leading Blaze to the exit.

The main aim of the Volcano minigame is collaboration, so a crucial mechanic is suggestions. When it is not their turn, players can still perform their own movements, signaling the direction they think the active player should go. The active player will see the suggestions on their own screen.

Another collaboration mechanic is the fog. During the entirety of the match, the screen will become less and less visible due to the fog produced by the volcano. To clear it, players must perform other movements, generally more physically demanding. The removal of the fog is much faster if all players contribute to it.

Table 3 contains the input devices and, for each of them, the movements requested to move Blaze along the path and to remove the fog. Examples of the different interfaces can be seen in Figure 2.



Several game parameters can be adjusted:

- The length of the path.
- The speed of the lava.
- The intensity of the fog.

Table 3. Correspondence between input devices and requested movements for path progression and for fog removal.

Device	Movement for path progression	Movement for fog removal
Cosmo Buttons	Push the buttons in a predetermined sequence, one for each direction (shown on screen)	Push the buttons in a predetermined sequence (shown on screen)
Tablet	Tilt the tablet toward the desired direction	Shake the tablet horizontally
Leap Motion	Move both hands toward the desired direction	Shake hands vertically
Homing	Move both hands toward the desired direction	High knee running

Figure 2. The user interface for each input device in the Volcano minigame. (A) The buttons with a sequence corresponding to each action, (B) the tablet that must be tilted, (C) the Leap Motion with the virtual hands that must collide with virtual walls, and (D) the Homing with a virtual skeleton and targets to be touched in order to perform the corresponding action.

XSL•FO
RenderX

Testing

In this phase, the game was tested on its final users to assess its usability, accessibility, and players' satisfaction and enjoyment.

Inclusion and Exclusion

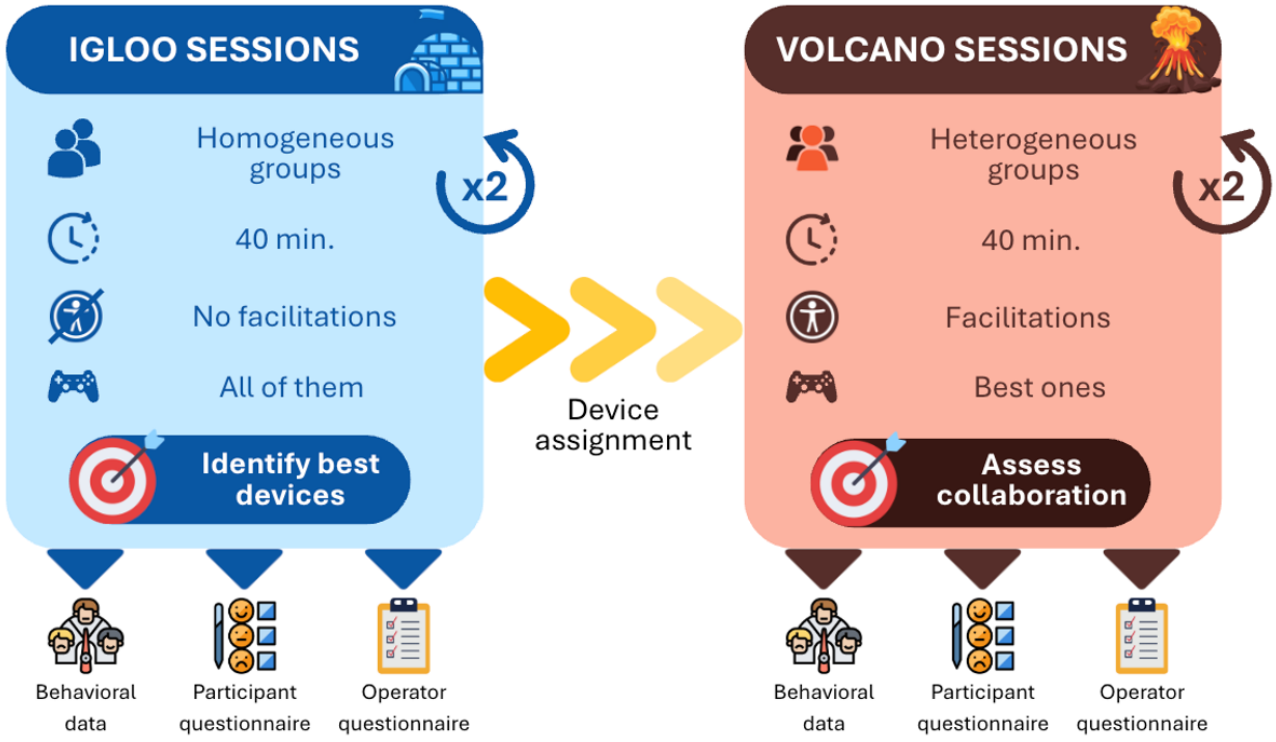
Inclusion criteria were being a young adult with IDD attending the collaborating association and being able to participate in the testing sessions. The exclusion criteria were complete blindness, contraindication for immersive technologies (eg, photosensitive epilepsy), and conditions causing loss of voluntary hand movement (eg, tetraplegia).

Participant Characteristics

The severity of the IDD among recruited participants was classified by one of the educators that follows them during the association's activities into 4 categories: "mild," "moderate," "severe," or "profound," based on their intellectual functioning and adaptive behavior. The educators who provided the severity classification regularly worked with the participants during the association's activities and familiarized them with the game context through narration, photos, and videos. This process allowed participants to be gently introduced to the experience and enabled a semiquantitative evaluation of their functional abilities relevant to the exergame.

Sampling Procedures

Young adults with IDD were recruited from the Associazione per lo Sviluppo del Potenziale Cognitivo (ASPOC) in Lecco (Italy) [36], a parent-led association supporting individuals with cognitive impairments. Recruitment followed a convenience sampling approach, based on the availability of eligible members and agreement from educators and legal guardians. Data collection took place at the Polo territoriale di Lecco of Politecnico di Milano, with 1 session per week over consecutive weeks between October and November 2024. No monetary compensation was provided.



Sample Size, Power, and Precision

No formal a priori power analysis was conducted because the study aimed primarily to evaluate usability, accessibility, players' satisfaction and enjoyment, and preliminary performance patterns in a real-world group setting.

Conditions and Design

The protocol, represented in Figure 3, consisted of 4 total 40-minute testing sessions. During each testing session, an operator was available for each participant to explain gameplay and interaction details and to support them in case of difficulties.

Figure 3. Protocol scheme overview. The protocol included 2 Igloo sessions (homogeneous groups, no facilitations, 40 minutes each) to identify optimal devices, followed by 2 Volcano sessions (heterogeneous groups, personalized facilitations, 40 minutes each) to assess collaboration. Behavioral data and questionnaires (participant and operator) were collected after each session.

The protocol started with 2 sessions devoted to the Igloo minigame. Considering that the Igloo minigame is designed to collect appearing stimuli, participants were divided into homogeneous groups, that is, groups included individuals with comparable functioning, expected behavioral and interaction with game stimuli, according to the qualitative assessment of the educator in order to ensure a smooth gameplay experience for all group players. To evaluate their initial interaction with the technology, each participant was supposed to play this minigame using all devices, with no facilitation options and with fixed settings. A first match served as a familiarization phase, followed by a standard trial in which each player had to collect 5 stimuli, each appearing one at a time and requiring a reaction within 10 seconds.

XSL•FO
RenderX

Device performance accuracy was analyzed to define 2 pairs of input modalities (higher- and lower-performing). For each participant, mean accuracy was calculated for each device pair. Within each Volcano minigame group, participants were ordered by intellectual disability severity, with ties resolved by prioritizing those with lower cumulative mean accuracy. Participants were then assigned to the device pair yielding higher mean accuracy, subject to logistical constraints in device availability and balanced group allocation. The Volcano minigame was then played in heterogeneous groups, combining individuals with varying technological proficiency to encourage reciprocal help.

All participants used facilitation options tailored to their individual needs as determined by their educator. Assignment criteria included:

- Clearer input instructions: for those who require an appropriate stimulus but can be easily distracted.
- No distracting stimuli: for those who experience performance anxiety, helping them focus on essential gameplay elements without further distractions.
- 3D model advisor: for players who can imitate movements or those who usually try to click on the screen instead of moving.
- Auto-go: for players with severe difficulties in initiating movements, particular difficulties with a device, extreme performance anxiety, or extremely slow movements.
- Seated mode: for those who present mobility impairments.
- Less movement: for those who may encounter difficulties in understanding movement-based tasks and in executing physical actions.
- High contrast: for players with visual impairments.

Due to the modular nature of the facilitation system, each participant had the possibility to have more than one facilitation option active at a time.

Measures and Covariates

Since the aims of this work were both to assess the impact of accessibility features on performance and to evaluate usability and players' satisfaction and enjoyment, the collected data can be categorized into 2 groups: game performance data and behavioral, satisfaction, and usability data. The first group includes in-game indicators recorded by the game platform, while the second comprises data obtained from behavioral observations of operators and ad hoc questionnaires completed by operators and participants, as described in the following paragraphs.

Intellectual disability severity was the main participant-level variable examined in relation to performance outcomes. In addition, device assignment, facilitation options, group composition, and minigame condition were considered relevant contextual factors when interpreting performance outcomes.

Data Collection

Game Performance Data

Several performance indicators were collected within each minigame. In the Igloo minigame, the main indicators collected were accuracy and reaction time. Accuracy was defined as the ratio between the number of objects successfully collected and the total number of objects available, considering only the second match since the first match served as familiarization. Reaction time was defined as the time elapsed between the appearance of the stimulus on the screen and the moment when the player collected the stimulus.

In the Volcano minigame, two main metrics were collected: accuracy and contributions to fog removal. Accuracy was defined as the ratio between the number of movements each player made for path progression (excluding clearing fog movements) during their designated turn and the total number of path-progression movements they made, considering both designated and nondesignated turns. Contribution to fog removal was measured as the number of times each player spontaneously performed the expected movement for the assigned device to clear the fog.

Behavioral, Satisfaction, and Usability Data

To assess the overall game experience, one operator collected the participant behaviors that emerged during gameplay. Each observed behavior was categorized along 3 dimensions: emotional valence (positive/negative), mode of expression (verbal/nonverbal), and social context (individual/social).

At the end of each session, operators present at each station completed an ad hoc questionnaire designed to assess usability and the ease of use of the technology for each player. This operator questionnaire was adapted from relevant items of the *International Classification of Functioning, Disability, and Health*, and consisted of 6 questions:

- Q1: Did the player interact with technology/experience in an accepting rather than oppositional way?
- Q2: Was the player able to use the technology by understanding its requirements and actively participating in the activity?
- Q3: Was the player able to control the movements required to perform the technology-based activity?
- Q4: Did the player demonstrate appropriate behavioral and emotional regulation during the activity?
- Q5: Did the player interact with others in a contextually and socially appropriate way?
- Q6: Did the player engage with others to achieve the goal of the activity? (Volcano only)

Questions were answered on a 5-point Likert scale, with response options ranging from 1 ("not at all") to 5 ("a lot"): not at all, no, fairly, yes, and a lot. The first 3 questions were repeated for each device, while the latter 3 were compiled once for each testing session.

Finally, to collect players' satisfaction and their opinion regarding the usability of the system, an ad hoc questionnaire was used:

- Q1: Did you enjoy playing this game?
- Q2: Would you like to play this game again?
- Q3: Did you understand how to play?
- Q4: Is it easy to play this game?
- Q5: Did you feel good at it?
- Q6: Did you play with your teammates? (Volcano only)

XSL•FO
RenderX

Questions were answered on a 5-point Likert scale, with response options ranging from 1 (“not at all”) to 5 (“a lot”): not at all, no, so and so, yes, and a lot. The augmentative and alternative communication was used to increase the accessibility of the questionnaire. This questionnaire was administered to each participant at the end of each session.

Quality of Measurements

To enhance the quality of measurements, a familiarization match was performed before the standard trial of the Igloo minigame, and an operator was present at each station during testing to explain gameplay and support participants in case of difficulties. Behavioral observations were recorded during gameplay using predefined categories derived from the co-design phase. Additionally, augmentative and alternative communication was used to increase the accessibility of the questionnaires.

Analytic Strategy

Game Performance Data

The analysis aimed to investigate the presence of a relationship between intellectual disability severity and gaming performance and, if present, to test whether personalized facilitations adopted during gameplay could mitigate it.

Indeed, it was hypothesized that the Igloo minigame, played without facilitations and using all available devices, would show a significant inverse correlation between disability severity and performance, while the Volcano minigame, played with personalized facilitations and optimal device assignments, should not show such a relationship. Given the limited sample size, nonparametric statistical methods were used throughout the analysis. Data were analyzed in Python 3.9 using medians and IQRs both at the individual level and grouped by device. To examine the association between disability severity and game performance, Spearman rank correlation (α=.05) analyses were conducted. Specifically, correlations were computed between intellectual disability severity scores and individual median accuracy values for both minigames. For the Igloo minigame, additional analyses were performed to assess the correlation between intellectual disability severity scores and individual reaction times.

Behavioral, Satisfaction, and Usability Data

Behavioral observations were analyzed using frequency counts for each behavior category.

Data from the operator questionnaire were analyzed using the median and IQR between participants for each minigame, question, and device. For the answers regarding sessions in which the participants used the same devices, the median response was considered.

Concerning the satisfaction and usability questionnaire, for each minigame and each question, the median and IQRs were computed across sessions and participants.

Ethical Considerations

This study was conducted in accordance with a protocol approved by the Politecnico di Milano Ethics Committee (approval number 19/2023). Given that all participants had IDD, informed consent was obtained from their legal guardians prior to participation. Researchers explained the project to participants to ensure their understanding of the study procedures and their right to withdraw at any time.

All participant data were pseudonymized to protect privacy and confidentiality. Participant identifiers were stored in a separate database from gameplay and behavioral data, with access restricted to authorized research personnel only. The linkage between personal information and pseudonymized codes was maintained securely and separately from the analytical dataset.

Participants received no monetary compensation for their involvement in the study. However, all activities were designed to be engaging and enjoyable, with breaks provided as needed.

No identifiable participants appear in any figures or videos in the main manuscript. The supplementary materials include video demonstrations of gameplay; however, these feature researchers rather than study participants, ensuring that no participant identification is possible.

Results

The Elemental Game

Videos showing player interactions with the game devices and photos of the facilitation options used during the testing sessions are available in Multimedia Appendix 2.

Recruitment

Table 4 contains information about participants, including sex, age (mean 25.1, SD 4.4 years), diagnosis, and the disability level they were classified into.

Statistics and Data Analysis

Game Performance Analysis

Igloo Minigame

Table 5 displays for every participant the group to which they were assigned, their intellectual disability severity, median accuracy obtained for every device, and their general median accuracy across all devices. Although groups included participants with varying disability severity levels, their functioning and expected behavior and interaction with game stimuli were considered sufficiently comparable for the purposes of the Igloo game. This decision was made to ensure a smooth and coherent gameplay experience for all participants, even when groups were heterogeneous in other aspects. Missing data occurred for participant 010 (moderate intellectual disability severity), who did not use the tablet and Leap Motion devices, and participant 011 (mild intellectual disability severity), who did not use the tablet and Homing devices in the Igloo minigame, due to unexpected unavailability during scheduled sessions.

[a]Not available.

At the device level, based only on the second match played by each participant, the buttons yielded the highest accuracy (median 1.00, IQR 0.00), followed by the tablet (median 1.00, IQR 0.20), the Leap Motion (median 0.90, IQR 0.35), and thus the Homing system (median 0.40, IQR 0.40). Reaction times increased from the buttons (median 1.89, IQR 2.09 seconds) to

XSL•FO
RenderX

the Leap Motion (median 2.63, IQR 3.32 seconds), the tablet (median 3.63, IQR 2.25 seconds), and the Homing system (median 5.13, IQR 3.28 seconds). Figure 4 displays, for each device and intellectual disability severity, the boxplots of accuracy and reaction times considering only the second match played by each participant. For each device, a clear pattern emerges: as the level of intellectual disability severity increases, accuracy progressively decreases, while reaction times correspondingly increase.

Figure 4. Boxplots representing the accuracy (left) and the reaction time (right) for each device and intellectual disability severity, considering only the second match played by each player per device in the Igloo minigame. Each point represents a single measurement.

The Spearman correlation between the intellectual disability severity and the overall median accuracy per participant resulted in a coefficient of –0.87 (95% CI –1.00 to –0.56) with a *P* value of <.001, indicating that as intellectual disability increases, the accuracy decreases. A significant positive association was also found between intellectual disability severity and overall reaction time per participant (ρ=0.69, 95% CI 0.08-0.94; *P*=.02), indicating that as intellectual disability increases, reaction times increase too.

Volcano Minigame

Table 7 displays for every participant the group to which they were assigned, their intellectual disability severity, the facilitation options used, their median accuracy for each device used, and their overall median accuracy.

Figure 5 shows boxplots of accuracy per device and intellectual disability severity. The only apparent exception concerns the mild category for the Buttons and tablet devices. However, as reported in Table 7, this result reflects data from a single participant who was assigned these devices based on availability within their group.

XSL•FO
RenderX

Table 7. Participants' intellectual disability level and their Volcano minigame performance data.

Group	Participant	Intellectual disability severity	Facilitation options	Accuracy, median (IQR)

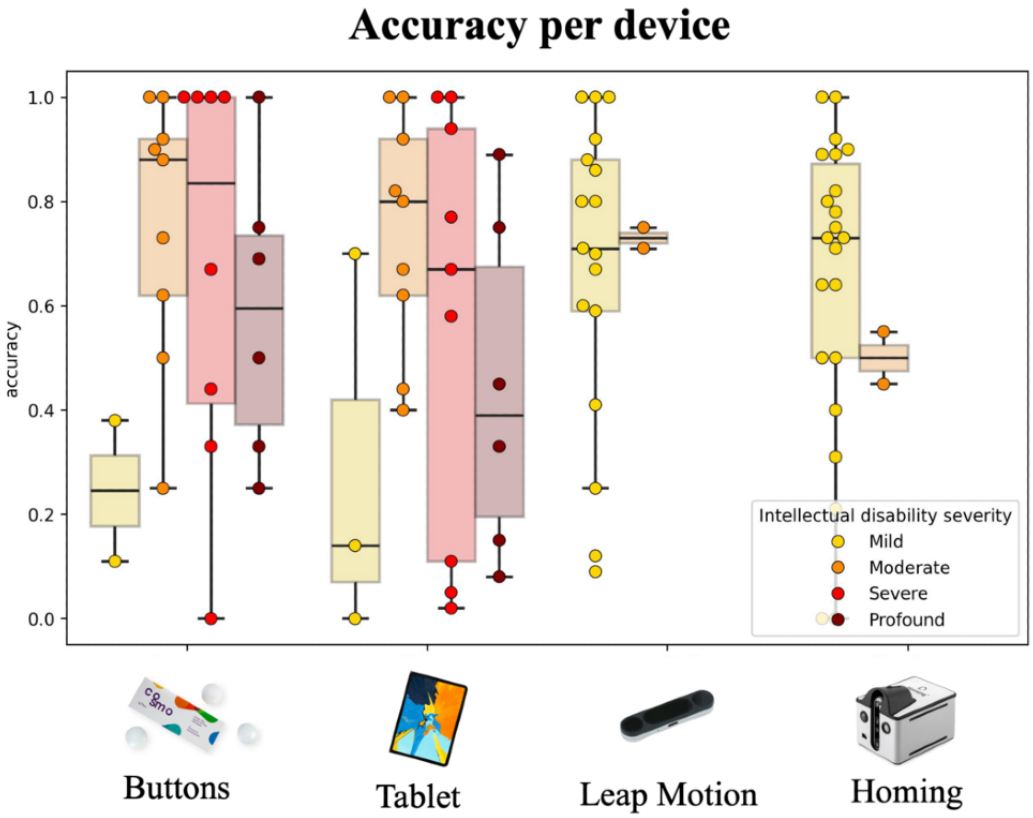
[b]None.

Figure 5. Boxplots representing the accuracy per device and intellectual disability severity in the Volcano minigame. Each point represents a single measurement.



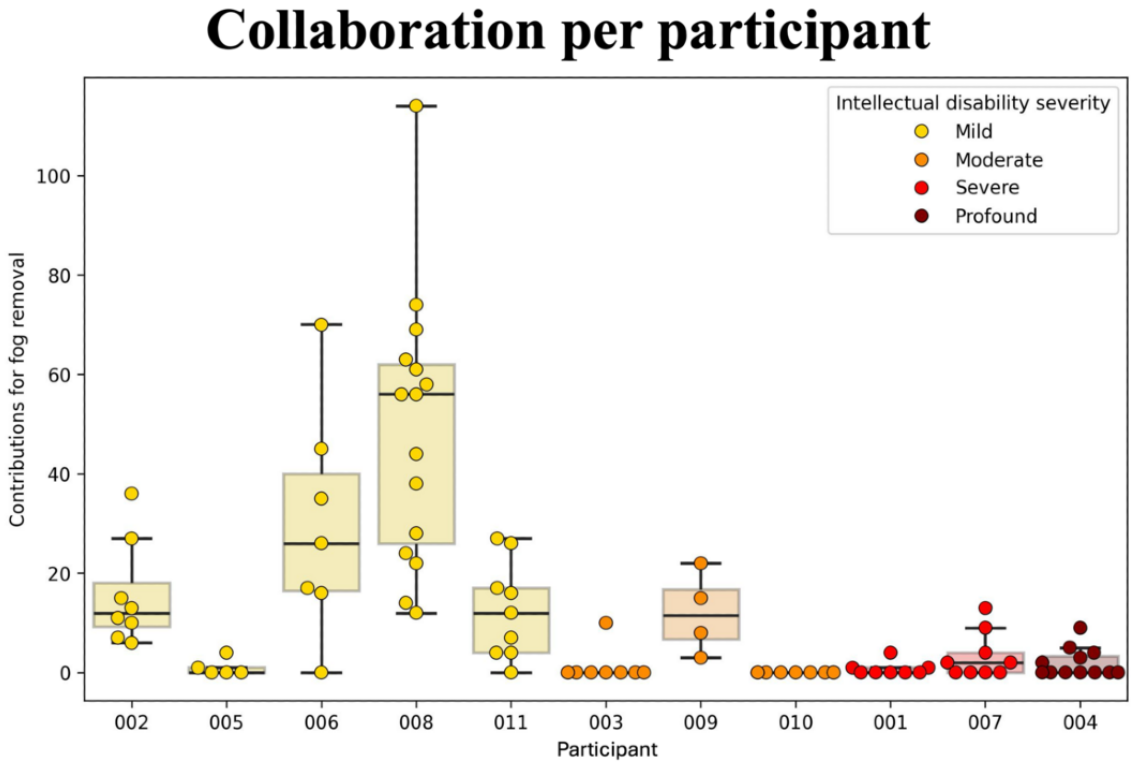


Figure 6 shows boxplots of the number of fog removal movements by individual user. Users are color-coded according to their intellectual disability severity level, with data pooled across all devices.

XSL•FO
RenderX

Figure 6. Boxplots representing the number of movements made by each participant to help remove the fog in the Volcano minigame. Each point represents a single measurement.

The Spearman correlation between intellectual disability severity and overall median accuracy yielded a *P* value of .48 (ρ=0.24, 95% CI –0.48 to 0.79), indicating no significant correlation was found. To verify that this observation was not driven by a single participant (ID 005), whose data represent the apparent exception among participants with mild intellectual disability severity, the analysis was repeated excluding their data, and the correlation remained nonsignificant (*P*=.82).

Behavioral, Satisfaction, and Usability Analysis

To analyze the types of behaviors observed during playtime, the total occurrences for each behavior category were obtained and presented in Table 8, divided per minigame.

Table 9 presents the median and IQRs for each question in the questionnaire completed by each operator at each game station, separately for both minigames.

Table 10 shows the medians and IQRs of the satisfaction and usability questionnaire for each question and minigame.

Table 8. Behaviors emerged during playtime for each minigame, divided into the 8 categories that emerged from the co-design phase.

	Positive verbal individual	Positive nonverbal individual	Positive verbal social	Positive nonverbal social	Negative verbal individual	Negative nonverbal individual	Negative verbal social	Negative nonverbal social
Igloo	100	22	0	1	1	0	0	0
Volcano	34	119	31	1	1	2	0	0

Table 9. Results of the questionnaire compiled by operators regarding the usability of the system by participants for each device and minigame[a].

	Q1, median (IQR)		Q2, median (IQR)		Q3, median (IQR)	
	Igloo	Volcano	Igloo	Volcano	Igloo	Volcano
Buttons	5 (0)	4 (0)	5 (0.5)	3.25 (0.5)	5 (0.5)	3.25 (0.88)
Tablet	4 (1)	3.5 (0.38)	4 (2)	3 (0.38)	4 (2)	2.75 (0.88)
Leap Motion	5 (1.75)	5 (0.5)	5 (1.75)	4.5 (0.5)	5 (2)	4.5 (1.5)

[a]N/A: not applicable.

Discussion

Principal Findings

This study aimed to co-design, develop, and evaluate Elemental, an innovative exergame that fully personalizes the gaming experience to accommodate each player's needs, while still aiming to deliver an enjoyable and collaborative multiplayer experience. The evaluation of Elemental involved a group of individuals with IDDs and assessed usability, the impact of accessibility features on performance, and players' satisfaction and enjoyment. The findings suggest that the co-design process led to the development of a feasible multiplayer exergame; that personalized devices and facilitation options reduced performance disparities associated with intellectual disability severity; and that participants reported positive usability, satisfaction, and enjoyment. Behavioral observations further suggested that the game supported collaboration during play. In line with the European Disability Strategy [3], this study supported that meaningful participation in digital gaming is possible, even for heterogeneous and demanding groups, when the design process is carried out with the participation of stakeholders and with the user in mind.

The co-design approach, based on the CeHRes Roadmap 2.0 [30], successfully identified the key challenge in group settings: accommodating diverse needs without creating separate experiences. This challenge is consistent with broader accessibility and inclusive design literature, which emphasizes that inclusion should be addressed at the level of design rather than through compensatory adaptations alone [12,13]. Unlike existing games that are either developed for neurotypical users and subsequently adapted or designed exclusively for people with disabilities [20], Elemental was conceived as inherently accessible. This addresses a persistent gap where specialized games often feel patronizing to neurotypical users, while mainstream games exclude people with disabilities [37]. Elemental was thus designed as a collaborative multiplayer exergame, offering all participants the same core experience, enriched by a customization layer that supports diverse needs without compromising the shared gameplay dynamics and overcoming traditional accessibility features. This solution enhances engagement and interaction among users with varied functional profiles, fostering meaningful cooperation. Unlike typical commercial or academic solutions that prescribe specific input devices for users with disabilities [16,17], the Elemental platform integrates multiple input modalities [2], ranging in complexity and interaction style, encouraging players to explore and engage in ways that suit their individual capabilities and preferences. This approach prioritizes user agency and enjoyment, rather than creating separate interaction pathways.

However, the main objective of this work was not only to develop an engaging game, but also to assess the impact of the aforementioned facilitation options. Elemental was thus developed as a modular platform, consisting, as of now, of 2 minigames: the Igloo and the Volcano. The first minigame's purpose was to assess participants' accuracy and reactiveness when playing with no facilitations and with the entire range of devices; the second minigame, on the contrary, was played with facilitations and with the best-performing devices, to assess accessibility features' impact, enjoyment, and collaboration. The game was tested by a group of 11 adults with IDDs of varying severity, aged from 19 to 36 years. The initial interaction of participants with input devices was assessed through performance indicators of the Igloo minigame. Participants played with all input devices and no facilitation options, and the collected data revealed notable differences across devices. In the Igloo minigame, performance worsened as intellectual disability severity increased, indicating that even accessibility-focused games remain unequally usable when the experience and the interactions are not personalized, supporting the idea that traditional "one-size-fits-all" approaches systematically exclude people based on their functional limitations [38]. Despite participants with the most severe conditions being able to effectively use a limited number of devices, the others achieved good performance scores across all input methods.

Thus, to evaluate the accessibility potential of the exergame, in the Volcano minigame, players were assigned appropriate devices and played with tailored facilitation options, derived from the co-design phase to cover sensory, cognitive, and motor impairments, coherently with the main difficulties found in literature [21]. In the Volcano minigame, the absence of a significant association between disability severity and performance suggests that personalization can reduce performance disparities in heterogeneous groups. This result is likely linked to the combination of tailored facilitation options, assignment of more suitable devices, the group settings, familiarization effects, and specific game mechanics, such as the collaborative mechanics that allowed peers to support one another during play.

The heterogeneous grouping implemented in the Volcano minigame further facilitated peer support through verbal interactions, with behavioral data showing substantial verbal collaboration. This aligns with evidence suggesting that structured group activities can foster social participation and strengthen interpersonal skills in individuals with IDDs [6] and that meaningful engagement in shared leisure activities is associated with improved quality of life outcomes in this population [5]. Moreover, the high satisfaction scores and positive behavioral observations suggest that inclusive design does not compromise engagement. This is consistent with the

XSL•FO
RenderX

broader literature on game-based approaches, which highlights how ludic elements can sustain motivation and active participation, particularly in populations that may otherwise struggle to engage with conventional activities [15]. Operators rated most aspects of usability highly, while participants reported enjoyment and willingness to play again. These findings challenge the paradigm commonly adopted when making the digital space accessible [21]. Rather than separate experiences or simplified gameplay, true accessibility emerged in a richer, more flexible environment where everyone's contribution mattered.

Limitations

This study had a few limitations. First, even though the questionnaires used to assess the opinions of operators and the usability and satisfaction of participants were adapted from existing questionnaires and classifications, they would require further validation and broader application to ensure their reliability and effectiveness. Additionally, due to unforeseen circumstances, not all participants were able to attend every scheduled session, and all sessions took place in the afternoon, potentially affecting participant performance due to fatigue. Another potential bias arose from logistical constraints in device availability, which occasionally required participants to use suboptimal configurations. However, this only affected individuals with lower-severity disabilities, and each case was closely monitored to ensure full participation and comfort.

Future studies should be conducted with a larger sample size, including both individuals with IDDs and neurotypical development, to better assess the game's inclusivity, accessibility, and the effects of cooperation on players' performance. Additionally, incorporating children in future research could help assess the game's potential for this population.

Furthermore, it would be extremely interesting to assess whether playing the game could have some positive long-term impact on players' lives. People with disabilities often have lower physical activity levels compared to the general population [18], and an engaging exergame such as Elemental could serve as a catalyst to increase habitual movement in this group, leveraging the motivational potential of play to overcome common barriers to physical activity. Similarly, further studies could organize longer and more frequent testing sessions, investigating whether some sort of training with this exergame can boost collaboration levels and reactiveness even outside of the game space.

Conclusions

This study set out to co-design, develop, and evaluate the feasibility of Elemental, an inclusive multiplayer serious game for young adults with developmental disabilities. The findings indicate that, when an exergame is built through a structured co-design process, equipped with tailored features, and played under appropriate conditions, it can be both accessible and engaging for players with markedly diverse abilities and varying severity of intellectual impairment. The results further suggest that personalized devices and facilitation options can reduce performance disparities associated with intellectual disability severity. Beyond the specific game presented here, these results provide preliminary evidence for a design approach in which accessibility is embedded from the earliest stages of technology development rather than retrofitted through compensatory adaptations or separate, disability-specific solutions. Aligned with the social model of disability and the community-inclusion goals of the European Disability Strategy [3], such an approach has the potential to create meaningful opportunities for participation, social interaction, physical activity, and enjoyment for individuals who might otherwise encounter barriers to sharing activities with their peers. The same principles could support inclusive activities in educational and community-based environments, where adults with IDDs spend much of their time. Future studies with larger samples, ideally including both individuals with IDDs and neurotypical participants, are needed to confirm these findings, and longitudinal studies are required to evaluate their long-term benefits and impact. Ultimately, this work offers proof of concept for a fundamental shift: from asking how people with disabilities can be fitted into existing digital spaces, to asking how digital spaces can be designed to embrace diversity and to accommodate everyone's needs.

Acknowledgments

The authors wish to thank the Associazione per lo Sviluppo del Potenziale Cognitivo (ASPOC) for their precious collaboration.

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), proofreading and editing were delegated to GenAI tools under full human supervision. The GenAI tools used were ChatGPT by OpenAI, Claude by Anthropic, and Copilot by Microsoft. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. Declaration submitted by: collective responsibility.

Abstract

Background: Adults with mobility impairments have limited opportunities for physical activity due to environmental barriers and lack of accessible exercise options. Active video games (AVGs) have shown promise for increasing physical activity by integrating movement into engaging gameplay. However, most commercial AVG controllers are not usable by those with severe mobility limitations. The GAIMplank is a novel adaptive game controller that translates trunk movements into gameplay, addressing this accessibility gap and enabling seated participation for individuals with limited lower-extremity function.

Objective: This study aimed to assess feasibility and acceptability of a 6-week GAIMplank-based intervention in adults with mobility impairments and to evaluate participants' perceived exertion, enjoyment, and engagement during gameplay. In addition, qualitative feedback was used to characterize participants' experiences with the intervention and to provide insight into implementation considerations for adapted exergaming in this population.

Methods: In total, 6 adults (2 female; mean age 65.2, SD 12.4 years) with mobility impairments due to stroke or Parkinson participated in a concurrent mixed methods single-arm pilot study. The intervention consisted of twice-weekly AVG sessions over 6 weeks using the GAIMplank controller to play video games. Self-report baseline measures included physical function, exercise expectations, and level of physical activity. During gameplay sessions, ratings of perceived exertion (RPEs), engagement, and enjoyment (0-10 rating scale) were collected. Additionally, physical activity and exergame enjoyment surveys were completed after sessions 1, 5, and 12. After the intervention, acceptability, appropriateness, and feasibility of the intervention (0-5 rating scale) were assessed. Qualitative data were collected through session comments and postintervention semistructured interviews. Descriptive statistics were used to summarize quantitative data, thematic analysis for qualitative data, and integration to examine convergence.

Results: Participants reported moderate RPEs during gameplay (median RPE 5, IQR 3-6) and high levels of enjoyment and engagement (median scores of 9, IQR 6-10 and median 10, IQR 8-10, respectively). The intervention was well-received, with high scores on the acceptability, appropriateness, and feasibility measures. Qualitative findings highlighted engagement and enjoyment of the games, as well as participants' perceptions of mental stimulation, sustained attention, and positive emotional experiences during gameplay. Several participants also described a "masking effect," in which physical effort was not perceived as traditional exercise due to immersion in gameplay. Technical challenges related to controller responsiveness were reported, but they did not appear to substantially reduce overall engagement.

Conclusions: Findings from this mixed methods pilot study suggest that AVGs, delivered using an adapted controller such as the GAIMplank, appear feasible and enjoyable in this small pilot sample, supporting the need for further evaluation in larger, controlled studies. While standardized cognitive or mental health outcomes were not assessed, participant feedback indicates

XSL•FO
RenderX

potential psychological benefits that warrant further investigation. Future studies should explore the long-term effects of AVG interventions and identify strategies for maximizing their benefits.

Introduction

Adults with disabilities experience persistent inequities in physical activity participation and are substantially less likely to meet aerobic and muscle-strengthening physical activity guidelines than adults without disabilities. National surveillance analyses in the United States indicate large gaps in the number of adults with disabilities meeting the guidelines, underscoring the need for scalable, accessible approaches that can be performed in safe and convenient settings [1]. In parallel, public health guidance, including the World Health Organization's 2020 recommendations, explicitly recognizes that people living with disability should engage in regular physical activity, while also emphasizing the importance of adapting activities to ability and context [2]. For adults with mobility impairments, barriers such as transportation, limited program availability, inaccessible facilities, fatigue, and difficulty identifying enjoyable activities can constrain participation in conventional exercise options. Technology-enabled approaches have been highlighted as one pathway to reduce access barriers by enabling activity in controlled environments (eg, home or clinic) and supporting adaptation, personalization, and engagement [3].

Active video games (AVGs), also known as exergames, have emerged as a promising approach to promote physical activity across diverse populations, including older adults and individuals with disabilities [4-8]. Recent evidence indicates that AVGs can support improvements in physical health, functional ability, and participation when appropriately tailored to user needs [9-13]. For example, case-based and small-scale intervention studies have demonstrated the feasibility of integrating exergaming into rehabilitation and community settings, with reported benefits in mobility, engagement, and user satisfaction [10]. In addition to physical outcomes, AVGs have been shown to foster social interaction and enhance engagement through interactive and immersive gameplay [4-8,14]. By integrating physical movements within gameplay, AVGs offer an engaging alternative to traditional exercise modalities and may help reduce sedentary behavior, particularly for individuals who face barriers to conventional physical activity opportunities [15-17].

Exergaming embeds physical activity within a motivating task. Recent work highlights its feasibility and potential benefits when specifically tailored to user capabilities and settings [18,19]. Research indicates that AVGs can facilitate light-to-moderate intensity physical activity, contributing to improved physical fitness and reduced sedentary behavior [15,16,20]. Recent evidence further suggests that exergaming can meaningfully contribute to weekly physical activity and improve functional outcomes like balance and mobility, although results vary by game type, dose, and population [21,22]. In older adults, AVGs have been shown to enhance muscular strength, cardiorespiratory fitness, mobility, and balance [23-26]. Systematic review evidence also suggests that exergaming may promote positive emotional experiences across populations, with reported effects on outcomes such as happiness, anxiety, depressive symptoms, vitality, and intrinsic motivation [27]. More recent review evidence in older adults further suggests potential benefits for mood and social engagement, while a 2026 meta-analysis found a small but statistically significant overall cognitive benefit in community-dwelling older adults, although findings remain heterogeneous across outcomes and populations [28,29].

Recent trials and reviews in certain disability populations (eg, stroke, Parkinson disease, and multiple sclerosis) indicate that exergaming interventions can be feasible and may improve physical activity participation and related outcomes when appropriately adapted to users' functional abilities and delivered with adequate support and progression [18,19]. For example, a 2026 pilot randomized controlled trial in people with moderate to advanced Parkinson disease reported positive acceptability in 84% of participants, attendance adherence of 99.7%, and no intervention-related adverse events, with exploratory findings suggesting possible benefits for health-related quality of life and loneliness [30]. However, variability in intervention dose, outcome selection, and accessibility of commercial hardware remains a major implementation barrier. These challenges underscore the need to evaluate adapted interfaces and delivery models that accommodate users who require seated play or have limited limb function.

Key factors influencing the effectiveness of AVGs include player enjoyment, engagement, and perceived exertion. Enjoyment and engagement have been identified as mediators between gameplay and energy expenditure, suggesting that more enjoyable and engaging games may lead to higher levels of physical activity [31]. Additionally, perceived exertion during AVG play is often lower than actual exertion, indicating that players may not fully recognize the physical benefits they are attaining [32].

Research on physical activity for individuals with mobility impairments is increasing and has shown that AVGs present viable and enjoyable means for them to engage in physical activity [7,33-35]. A growing body of literature indicates that people with physical disabilities can increase their energy expenditure during AVG play, including those with mobility impairments such as cerebral palsy, spinal cord injury, stroke, and other neurological conditions [33,34,36,37]. Furthermore, AVGs can mitigate common environmental barriers to

XSL•FO
RenderX

conventional exercise such as facility and program access and transportation. At the same time, recent adaptive gaming research suggests that participation barriers extend beyond device availability and include access to centralized information resources, financial assistance, professional support for setup and configuration, and opportunities to try equipment before adoption. These broader implementation factors are important when considering whether adapted gaming approaches can be translated into routine home, community, or clinical use for people with physical disabilities [38]. Since AVG devices are relatively affordable, they also hold promise as a scalable solution for promoting higher levels of physical activity and fitness among people with disabilities.

Despite these findings, an ongoing limitation in the translation of exergaming to adults with mobility impairments is that many commercial systems rely on standing balance, rapid lower-extremity stepping, or controllers that are not feasible for seated users or those with limited limb function. Consequently, even as exergaming evidence grows, fewer studies evaluate interventions using adapted interfaces designed specifically for seated play and for people with more severe mobility limitations, creating a gap between what is theoretically promising and what is practically accessible.

To address this need, our research and engineering team has developed AVG controllers that are accessible to people who are unable to stand for long periods, cannot stand on a small platform due to poor balance or extreme obesity, cannot safely stand on a small platform due to balance limitations or body size, or who primarily use a wheelchair for mobility [33,37,39-42]. Most recently, we developed the GAIMplank controller and evaluated its usability among people with mobility impairments [42]. During usability testing, a sample of 21 adults was able to successfully access and play a series of standard PC video games using trunk or body movements to produce gameplay action. Participant usability scores and qualitative feedback indicated above-average usability for the GAIMplank system. In addition, participants enjoyed the activity and reported gameplay as light-to-moderate intensity activity.

Although these findings support the GAIMplank's usability and perceived exertion during single-session gameplay, usability alone does not establish whether an adapted interface can be delivered as an intervention over time or whether it will be acceptable and engaging across repeated sessions. Building from these promising usability results of the GAIMplank controller, the next step is to evaluate whether a multisession intervention using this adapted interface is feasible and acceptable in adults with mobility impairments, and whether participants report adequate perceived exertion alongside enjoyment and engagement, key determinants of sustained participation. Therefore, the aim of this concurrent mixed methods single-arm pilot study was to evaluate a 6-week AVG intervention delivered twice weekly to adults with mobility impairments by assessing quantitative outcomes (perceived exertion, engagement, and enjoyment) and qualitative perspectives regarding the intervention's acceptability, appropriateness, and feasibility.

Methods

Research Design Overview

This study used a concurrent mixed methods single-arm pilot design [43]. In this design, quantitative (feasibility, enjoyment, and engagement) and qualitative (participant feedback and staff observations) data were collected simultaneously and integrated to provide a comprehensive evaluation of the GAIMplank intervention. The rationale for using a mixed methods approach was to triangulate objective descriptive statistics with subjective participant experiences to assess the protocol's feasibility and acceptability among adults with mobility limitations.

Researcher Description

Our team comprises experts in exercise physiology, health services research, and engineering. Two of the researchers (CJM and SM) are trained in qualitative and mixed methods research. One researcher was involved in data collection (CJM), and three (CJM, LAM, and SM) were involved in data analysis and integration of the results. The team has published a few other mixed methods studies.

Inclusion and Exclusion

Inclusion criteria were (1) being aged 18 years or older, (2) self-reported physical disability that limits mobility, and (3) ability to communicate in English. Exclusion criteria were (1) significant impairment in visual acuity that prevents following video games on a 52″ television screen, (2) body weight >400 lbs, (3) cognitive or linguistic problems with understanding instructions or filling in self-administered outcome measures in English as determined by a score of <17 on the telephone version of the Mini-Mental State Examination, (4) any other conditions that would limit ability to play video games, (5) cardiovascular disease event within the past 6 months, (6) severe pulmonary disease or renal failure, and (7) ongoing exacerbation of a health condition.

Participant Recruitment

Recruitment Process

Both quantitative and qualitative data were collected from the same participants. Flyers were distributed to local organizations serving adults with disabilities. Individuals who were interested in participating called the number listed on the flyer to speak with the recruitment coordinator, who provided a brief overview of the project and a series of screening questions to determine eligibility. In addition, phone calls were made to previous research participants who had agreed to be contacted for other studies. If deemed eligible, the first laboratory visit was scheduled.

Sampling

This was a pilot feasibility and acceptability study of the adapted GAIMplank. A convenient sampling of 6 participants was recruited. Of the 6 participants who consented and started the study, a total of 4 completed the intervention.

XSL•FO
RenderX

Data Collection Location

Data collection took place in the RecTech Exercise Science and Technology Laboratory at the University of Alabama at Birmingham.

Ethical Considerations

This study was conducted in accordance with ethical principles for research involving human participants. The study protocol was reviewed and approved by the University of Alabama at Birmingham Institutional Review Board (approval IRB-300009049). The study was classified as nonexempt human subjects research involving no more than minimal risk, in accordance with applicable federal regulations. All participants provided informed consent prior to participation in the study. Participants were informed about the purpose of the study, study procedures, potential risks and benefits, voluntary participation, and their right to withdraw at any time without penalty. Participant privacy and confidentiality were protected throughout the study. All data were deidentified prior to analysis and stored on a secure, password-protected server accessible only to authorized study personnel. No direct identifiers were included in the dataset, and results are reported in aggregate to prevent identification of individual participants. No images or supplementary materials included in this manuscript contain identifiable information about individual participants. Participants received compensation of up to US $125 for participating in the study. The money was distributed in the form of gift cards as follows: upon completion of visit 2 (US $25) and at the end of the 6 weeks after completion of the assessments (US $100).

Adapted Gaming Board (GAIMplank) and Game Selection

Our engineering design and development team, with the Rehabilitation Engineering Research Center on Interactive Exercise Technologies and Exercise Physiology for People with Disabilities, previously built a proof-of-concept wheelchair-accessible adapted gaming controller for the Nintendo Wii home video game console [39]. Our research team tested its usability rating compared to the commercial off-the-shelf balance board controller provided with the Wii console [40]. From that, we developed a new iteration of the adapted board, now called the GAIMplank, and tested its usability [42]. The GAIMplank was designed as a wheelchair-accessible AVG controller for PC-based gameplay and includes a balance board platform with roll-on access, height-adjustable handrails, embedded load cells, and custom electronics that translate shifts in the player's center of balance into game inputs. As with the previous version, the GAIMplank was mapped to operate as a typical joystick controller. Leaning movements of the trunk created corresponding action in the game (ie, lean forward, move character forward or up, lean right, and move right; Figure 1). External buttons to activate actions such as jump or shoot could be configured in various formations on a flexible arm within the player's reach, held by the player, or placed in the player's lap. A trigger button used for acceleration or shooting could be held in the hand. Full technical details have been reported previously [42].

XSL•FO
RenderX

Figure 1. Participant playing an active video game using the GAIMplank. Participant is seated in a chair on top of the GAIMplank using his body (leaning right and left) to control movement of the car on the screen, holding a variable trigger in his hand for acceleration.

Activity guidelines developed a priori by the research team were used to inform video game task selection and progression. The final list of games for use during the intervention is presented in Table 1.

Table 1. List of the off-the-shelf video games played during the intervention, including a short description of each game, trunk movements required for gameplay, and any external buttons and their action used.

Game	Genre	Game description	Trunk-leaning movements required	External buttons used
Feather	Flight, exploration	Relaxing flight to explore a scenic natural landscape	All directions	None
Flower	Adventure	Serene journey as a flower petal navigating landscapes in the wind	All directions	Button to accelerate
Bezier	Arcade, shooter	Fast-paced shooter with neon visuals	All directions	Button to shoot
Space Invaders Extreme	Arcade, shooter	Classic arcade-style shooting game	Left, right	Button to shoot
Explorers	Adventure	Exploration and resource management as an adventurer	All directions	None
The Lost Night	Adventure, shooter	Atmospheric adventure evading threats and making key decisions	Right, left, up, down	Button to shoot
Let's Go Nuts	2D platformer, action	Jump, avoid danger, and collect nuts while leveling up	Left, right	Button to jump
Omeganaut	Shooter	Control a spacecraft battling enemies across levels	All directions	Button to shoot
Stardust Galaxy Warriors	Shooter, action	Soar in space using weapons to combat enemy ships and asteroids	All directions	Up to 4 buttons for weapon use
Shipwreck	Adventure, action	Retro adventure with island exploration and enemy fighting	All directions	Button to use objects, attack, interact
Galaga	Arcade, shooter	Space shooter, defend against alien enemies, rescue captured ships, and boost firepower	Left, right	Button to shoot
Sheepy	2D platformer	Guide a sheep jumping over obstacles and shooting lollipops	Left, right	Up to 3 buttons to run, jump, shoot
Horizon Chase Turbo	Racing, sports, arcade	Arcade racing games with various cars and tracks to select from	Left, right	Variable trigger for car acceleration
Sonic Mania	2D platformer, action	Fast-paced adventure, run, jump, collect golden rings, and beat enemies	Left, right	Button to jump and roll

Participant Visits

During the first visit to the laboratory, informed consent was obtained, baseline assessments were collected, and the gameplay sessions were scheduled. Participants then attended individual gameplay sessions supervised by a member of the research team 2 times weekly for 6 weeks, for a total of 12 sessions. This schedule was selected to balance safety, standardization, repeated exposure to the adapted gaming system, and participant burden. It also provided adequate exposure for a pilot study while remaining manageable for adults with mobility impairments who may experience fatigue, transportation, or other participation barriers. The intervention protocol included various PC video games that were compatible with the GAIMplank. For each gameplay session, participants played seated in a standard 4-legged chair or their wheelchair. During the first 4 visits, participants played 5 minutes of 3 or 4 preselected games to expose them to the various game options available for subsequent sessions.

As the weeks progressed, participants advanced to longer continuous bouts of activity until they achieved approximately 50 minutes of activity. This target duration was selected pragmatically to provide a meaningful amount of active gameplay each week, considering broader physical activity recommendations, while remaining feasible and tolerable for participants with mobility impairments in a supervised laboratory setting. Although this dose was not intended to meet weekly physical activity guidelines, it supported progressive engagement while accounting for participant tolerance and the need to monitor fatigue and safety. The research team started each game at the basic or beginner level and advanced it to the next level as dictated by game progression and participant preferences. The gameplay sessions were adjusted by the research team based on participant needs with continued progression and balance of activities. Progression of activities and gameplay duration was guided by participant safety, independence, use of appropriate movement strategies, level of engagement, and fatigue.

After the last gameplay session, participants completed an acceptability, appropriateness, and feasibility survey as well as a semistructured interview conducted by a member of the research team. The interviews focused on topics related to participants' experience of and engagement with the adapted gaming board.

Data Collection

The mixed methods concurrent design procedures are presented in Textbox 1.

Timing of quantitative and qualitative data collection, analysis, and integration throughout the 6-week active video gaming intervention

Quantitative data

- Baseline
  - Participant demographics
  - Patient-Reported Outcomes Measurement Information System Physical Function—Short Form 20a
  - Multidimensional Outcome Exercise Expectations Scale
  - Physical Activity Scale for Individuals With Disabilities
- Gameplay sessions 1, 5, and 12
  - Physical Activity Enjoyment Scale
  - Exergame Enjoyment Questionnaire
- Each gameplay session
  - Game enjoyment rating scale
  - Game engagement rating scale
  - Game rating of perceived exertion
- Postintervention
  - Acceptability, appropriateness, and feasibility of the active video gaming intervention survey

Qualitative data

- Each gameplay session
  - Gameplay experience
- Postintervention
  - Participant feedback interviews

Quantitative Measures

Participant Characteristics

Demographics (baseline) data included age, sex, race, primary mobility impairment, and assistive device use for mobility.

Patient-Reported Outcomes Measurement Information System Physical Function—Short Form 20a (Baseline)

The Patient-Reported Outcomes Measurement Information System Physical Function—Short Form 20a assesses an individual's self-reported capability to perform physical activities [44]. It measures various aspects of physical function, including mobility (eg, walking and running), upper extremity function (eg, reaching and grasping), and activities of daily living (eg, bathing and dressing). It is standardized and validated for a variety of populations, including those with chronic conditions and disabilities. The form includes 20 questions, each scored from 1=without any difficulty to 5=unable to do so. Raw scores were converted to a *T* score using the Patient-Reported Outcomes Measurement Information System scoring manual. The *T* score is standardized (mean 50, SD 10), with higher scores indicating better physical functioning and lower scores reflecting limitations or difficulties in physical activities. Severity of impairment is indicated as mild (40-45), moderate (30-40), or severe (below 30).

Physical Activity Scale for Individuals With Disabilities (Baseline)

The Physical Activity Scale for Individuals With Disabilities (PASIPD) is a self-report questionnaire designed to assess physical activity levels among individuals with disabilities [45]. It evaluates the frequency, duration, and intensity of various activities over the past 7 days, including leisure, household, and work-related activities. The PASIPD includes 13 items that cover a variety of physical activities, such as walking or wheeling, light and heavy household chores, and recreational activities. The PASIPD score is calculated by multiplying the time spent in each activity (hours per week) by its metabolic equivalent value and then summing these products across all activities. Scores range from 0=no activity to over 100 metabolic equivalent/hours per day, which indicates very high levels of physical activity.

Multidimensional Outcome Exercise Expectations Scale (Baseline)

The Multidimensional Outcome Exercise Expectations Scale (MOEES) is a validated 15-item tool [46] used to measure an individual's expectations about the benefits of engaging in

XSL•FO
RenderX

regular exercise. The scale evaluates 3 key dimensions of exercise outcome expectations including physical (n=6 items), social (n=4 items), and self-evaluative (n=5 items) benefits. Items are rated on a 5-point Likert scale, in which 1 represents strongly disagree and 5 represents strongly agree. Each subscale was scored by summing the numerical ratings for each response, with a higher score on any subscale indicating a stronger belief in the positive outcomes associated with exercise related to that specific dimension. An overall total score was also computed by summing all items, with higher scores (range 15-75) indicating stronger positive expectations for exercise outcomes.

16-Item Physical Activity Enjoyment Scale (Gameplay Sessions 1, 5, and 12)

The Physical Activity Enjoyment Scale (PACES) was designed to measure an individual's enjoyment of physical activity. The 16-item version was used for this study [47]. Each of the items on PACES was rated on a 5-point Likert scale from 1=strongly disagree to 5=strongly agree. In total, 7 of the items were negatively worded and reverse-scored, and then, all items were summed for a total score ranging from 16 to 80. A higher score indicated greater enjoyment of the AVG physical activity.

Exergame Enjoyment Questionnaire (Gameplay Sessions 1, 5, and 12)

The 20-item Exergame Enjoyment Questionnaire (EEQ) was designed to measure enjoyment of exergames [48]. In total, 8 items were negatively worded and reverse-scored, and then, all items were summed for a total score ranging from 20 to 100. A higher score indicated greater enjoyment of the exergames.

Rating of Perceived Exertion During Gameplay (Each Gameplay Session)

Participants provided a rating of perceived exertion (RPE) score after each game using the OMNI Scale of Perceived Exertion [49], with a score ranging from 0=extremely easy to 10=extremely hard.

Game Enjoyment and Engagement Rating Scales (Each Gameplay Session)

Participants rated their level of enjoyment of each game using a 10-cm visual analog scale from 0=least enjoyment to 10=most enjoyment. Participants also rated their level of engagement during each game using a 10-cm visual analog scale from 0=least engaged to 10=most engaged.

Implementation Outcomes (Postintervention): Acceptability, Appropriateness, and Feasibility of the AVG Intervention

At the completion of the intervention, participants completed the Acceptability of Intervention Measure (AIM), Intervention Appropriateness Measure (IAM), and Feasibility of Intervention Measure (FIM) [50]. Each of the 3 measures was comprised of 4 questions rated on a 5-point scale from 1=completely disagree to 5=completely agree. A score for each measure was computed by averaging the responses, with scores ranging from 1 to 5 (higher scores indicate better perceived acceptability, appropriateness, and feasibility).

Qualitative Data Sources

Gameplay Observations (Each Gameplay Session)

During each gameplay session, the research staff maintained field notes on observations, such as GAIMplank responsiveness, specific participant assistance needs, and participants' spontaneous verbal feedback about their experience.

Participant Feedback Interviews (Postintervention)

The research staff conducted semistructured interviews after participants completed the intervention. A series of questions was used to guide the conversation, and directed prompts were used as needed. The interviews were audio-recorded, transcribed verbatim, and checked for accuracy against the audio recordings.

Several differences between the original trial registration, institutional review board–approved protocol, and final assessment battery should be noted. The original trial registration listed the International Physical Activity Questionnaire for People with Disabilities as the physical activity outcome measure; however, prior to intervention data collection, the research team replaced it with the PASIPD to maintain consistency with related studies and better align with the study population. This change was approved by the institutional review board, but the ClinicalTrials.gov record was not updated at that time due to an administrative oversight. In addition, the Short Form 36 Health Survey (version 2) was included in earlier study documentation but was not collected to reduce participant burden. RPE, engagement or enjoyment ratings, AIM/IAM/FIM, EEQ, and MOEES were included in the institutional review board–approved protocol and collected as part of planned study procedures but were not prospectively added to the ClinicalTrials.gov registration. The ClinicalTrials.gov record has since been updated to reflect the final outcome measures.

Data Analysis and Integration

Quantitative Data Analysis

Quantitative data were analyzed using descriptive statistics. Demographic and baseline characteristics of participants were summarized using means and medians for continuous variables and frequencies for categorical variables. Surveys were scored using the standard scoring protocols for each instrument.

Qualitative Data Analysis

Qualitative data were analyzed using thematic analysis. Two coders (SM and LAM) coded the data and met to resolve coding discrepancies. Codes were generated from recurring themes and patterns related to participants' experiences during the intervention. Codes were grouped into broader themes that captured key aspects of participants' experiences, such as perceived exertion, enjoyment, engagement, and overall acceptability of the intervention.

Mixed Methods Integration of Quantitative and Qualitative Data

Quantitative and qualitative findings were integrated to provide a comprehensive understanding of participants' experiences. A joint display was used to compare and contrast quantitative and qualitative results, highlighting areas of convergence and

XSL•FO
RenderX

divergence. The integration of quantitative and qualitative data provided a holistic view of the intervention's impact. Quantitative data offered objective measures of perceived exertion, enjoyment, and engagement, while qualitative data provided deeper insights into participants' subjective experiences. This mixed methods approach allowed for a more nuanced understanding of the feasibility, acceptability, and potential benefits of the AVG intervention for adults with mobility impairments.

Validity, Reliability, and Methodological Integrity

Quantitative Validity and Reliability

Standardized tools (Patient-Reported Outcomes Measurement Information System Physical Function—Short Form 20a, MOEES, and PASIPD) provided construct validity for baseline and activity assessments. The real-time data collection using the OMNI scale and visual analog scales ensured consistent, immediate measurement of the gameplay experience.

Qualitative Methodological Integrity

Trustworthiness was maintained through verbatim transcription of all interviews and verification against the audio recordings. Methodological rigor was maintained through a systematic thematic analysis of staff notes and participant interviews to identify recurring patterns. While the thematic saturation was not reached due to the small sample size, the findings were grounded in direct participant evidence.

Mixed Methods Integrity and Integration

The integration of the concurrent mixed methods datasets was formalized through a joint display, which enabled direct comparison of quantitative scores with thematic feedback. This process ensured convergent validity, as qualitative quotes were used to contextualize and explain the quantitative findings.

Results

Overview

In total, 24 individuals were contacted during recruitment and screening. A total of 18 did not proceed to enrollment because they did not respond, declined participation, or were unavailable, resulting in a final enrolled sample of 6 participants. The average age of the participants was 65.2 (SD 12.4) years, and most had experienced a stroke. All but one person used an assistive device for mobility. Additional participant details are presented in Tables 2 and 3. Patient-Reported Outcomes Measurement Information System Physical Function scores indicated a moderate level of impairment in physical function for 4 participants, 1 participant with mild impairment, and 1 participant with severe impairment (AVG-06) who subsequently dropped out. MOEES scores indicated that all participants had strong positive beliefs regarding the value of exercise. The daily physical activity level of individuals ranged from low to moderate, as reported on the PASIPD scale. Participant AVG-02 dropped out after the second gameplay session, and AVG-06 after the sixth gameplay session, both due to health reasons.

Table 2. Participant (N=6) demographics including age, sex, race, mobility impairment, and assistive devices used for mobility.

ID	Age	Sex	Race	Mobility impairment	Assistive device
AVG-01	44	Female	African American	Stroke	Wheelchair
AVG-02	57	Female	White	Stroke	None
AVG-03	72	Male	White	Stroke	Cane
AVG-05	68	Male	White	Stroke	Cane
AVG-06	75	Male	White	Parkinson disease	Wheelchair
AVG-07	75	Male	African American	Stroke-like symptoms	Cane

Table 3. Self-report survey scores collected at baseline for physical function (PROMIS PF20a[a]), outcome expectations for exercise (MOEES[b]) subscale and total scores, and daily physical activity (PASIPD[c]) are listed for each participant[d,e].

ID	PROMIS PF20a (*T* score)	MOEES, physical (5 to 30)	MOEES, social (5 to 20)	MOEES, self-evaluative (5 to 25)	MOEES, total (15 to 75)	PASIPD (0 to 100+)
AVG-01	33.1	17	13	21	51	3
AVG-02	39.3	29	16	23	68	40
AVG-03	33.9	25	12	20	57	52
AVG-05	37.2	30	20	25	75	18
AVG-06	21.7	24	13	18	55	6
AVG-07	43.7	28	16	25	69	51.5

[a]PROMIS PF20a: Patient-Reported Outcomes Measurement Information System Physical Function—Short Form 20a.

[b]MOESS: Multidimensional Outcome Exercise Expectations Scale.

[c]PASIPD: Physical Activity Scale for Individuals With Disabilities.

[d]The Patient-Reported Outcomes Measurement Information System scores are reported as standardized *T* scores (mean 50, SD 10), with higher scores indicating better physical functioning with mild impairment score of 40-45, moderate 30-40, and severe <30. For each MOEES score, a higher score indicates a stronger belief in the positive outcomes associated with exercise in a specific dimension. The PASIPD score is calculated by multiplying the time spent in a variety of physical activities (hours per week) by its metabolic equivalent value and then summing across all activities. Scores range from 0 (no activity) to over 100 metabolic equivalent/hours per day (very high).

[e]PROMIS PF20a: median 70 (IQR 61-76); MOEES, physical: median 27 (IQR 24-29); MOEES, social: median 15 (IQR 13-16); MOEES, self-evaluative: median 22 (IQR 20-25); MOEES, total: median 63 (IQR 55-69); PASIPD: median 29 (IQR 6-52).

Participant data for each week are shown in Table 4. As noted, minutes of gameplay increased each week. The number of different games played per week ranged from 2 to 8 and declined in the later weeks, as participants found the games they liked and stuck with them. Recorded RPE scores were in the moderate intensity exercise range for the majority of players, who reported above-average enjoyment most weeks. All participants reported high (≥8) engagement each week.

XSL•FO
RenderX

Table 4. Minutes and number of games played per week for each participant, along with weekly median self-report ratings of perceived exertion (RPE), engagement, and enjoyment (0-10 rating scale)[a].

Participant ID and week	Total time played (minutes)	Games played, n	RPE (0-10), median (IQR)	Enjoyment (0-10), median (IQR)	Engagement (0-10), median (IQR)

6	103	2	6 (5-6)	10 (10-10)	10 (10-10)

[a]Higher RPE scores indicate greater perceived exercise intensity, whereas higher enjoyment and engagement reflect more positive gameplay experiences.
[b]Not available.

Rankings of the most-played games and the average RPE, enjoyment, and engagement for each game are presented in Table 5. The top 3 games based on total minutes played across participants across sessions were *Space Invaders*, *Let's Go Nuts*, and *Horizon Chase Turbo*, representing 3 different game genres, shooter, platformer, and racing, respectively. Participants rated all 3 games high for both enjoyment and engagement and reported perceived exertion as somewhat hard, suggesting moderate-intensity exercise. The least played games were those that required movement in all directions. Although participants

XSL•FO
RenderX

rated several games as not highly enjoyable, they still reported that the games were engaging.

PACES scores indicated a moderate level of enjoyment at each time point across participants, with a range of 40 to 50 (Table 6). For all participants, EEQ scores were above average at each time point, ranging from 54 to 86.

Table 5. Total gameplay minutes for each active video game across all participants and all intervention sessions, with median self-reported ratings of perceived exertion (RPEs), enjoyment, and engagement (0-10 rating scales) aggregated across participants and sessions for each game.

Game name	Time played (minutes), total	RPE (0-10), median (IQR)	Enjoyment (0-10), median (IQR)	Engagement (0-10), median (IQR)
Space Invaders	416	6 (6-7)	10 (7-10)	10 (9-10)
Let's Go Nuts	338	5 (2-6)	10 (9-10)	10 (9-10)
Horizon Chase Turbo	323	6 (2-7)	9 (7-10)	10 (9-10)
Sonic Mania	207	4 (1-6)	10 (9-10)	10 (9-10)
Sheepy	125	3 (2-6)	9 (8-10)	10 (9-10)
Galaga	83	6 (4-7)	9 (4-9)	9 (7-10)
Omeganaut	66	5 (5-6)	9 (5-10)	10 (8-10)
Explorers	65	5 (4-6)	7 (4-9)	9 (8-10)
Bezier	60	6 (3-6)	6 (6-8)	8 (8-10)
Feather	60	3 (1-7)	5 (4-7)	8 (7-9)
Flower	40	3 (1-4)	6 (3-9)	9 (8-9)
Shipwreck	27	5 (5-8)	4 (2-8)	9 (6-10)

Gameplay Sessions: Staff and Participant Comments

Overview

A summary of staff and participant comments highlights themes that occurred during the gameplay sessions (Figure 2).

Figure 2. Thematic map.

Technical Issues With the GAIMplank Board

The board often needed to be reset or recalibrated due to unresponsiveness or incorrect movement detection. This was a recurring issue across multiple sessions. There were also consistent reports of the board having a delayed response to participants' movements, sometimes taking several seconds to register actions. The board often struggled with detecting left and right movements accurately, and there were instances in which it would push participants to one side or fail to recognize movements in specific directions.

Participant Frustration and Adaptation

Participants frequently expressed frustration when the board did not respond as expected, mainly when it affected their ability to control their avatars and play the games effectively. Despite initial difficulties, some participants adapted to the board's quirks over time, improving their gameplay and finding ways to work around the technical limitations.

Engagement and Enjoyment

Participants' enjoyment varied depending on the game and the responsiveness of the board. Some games were more engaging and enjoyable, while others led to frustration due to technical issues. Participants preferred games that were less affected by the board's technical issues and that matched their interests and abilities. Certain games encouraged more physical movement, which staff and participants reported as a positive aspect. However, the board's effectiveness in promoting physical activity was inconsistent due to technical problems. Games requiring complex or rapid movements were particularly challenging for participants, often due to the board's delayed response or inability to register movements accurately.

Proactive Problem-Solving

Staff frequently intervened to reset or recalibrate the board, troubleshoot issues, and encourage participants. Staff noted that some games were not well-suited to the board's capabilities, suggesting a need for better alignment between game design and the adapted controller's functionality.

XSL•FO
RenderX

These themes emphasize the need to address technical issues with the GAIMplank board to improve the overall experience and effectiveness of AVG interventions for individuals with mobility impairments. Ensuring that equipment performs reliably and providing adequate support during gameplay can enhance participant engagement, enjoyment, and physical activity outcomes.

Postintervention: Participant Interviews, Experience, and Feedback

Overview

Overall, participants had a positive experience using the gaming board, describing it as fun and enjoyable; however, some noted a learning curve when using the board to play some games. Initial frustration gave way to enjoyment as they became more accustomed to the adapted gaming board. Favorite aspects of the 6-week program included the ability to choose games, interaction with others (ie, research staff), and enjoyment of the games themselves. The least favorite aspects were minimal and included the effort of coming to the laboratory. In addition, some participants found gameplay challenging because the board was not responsive to their movements, but they learned how to adapt for gameplay control. Participants generally felt comfortable and challenged using the adapted board. They noted improvement in their ability to use the board and increased comfort as they became more familiar with the system. Participants were unsure about the board's potential to increase their physical activity but acknowledged its usefulness for individuals with impaired physical abilities. They saw the leaning movements as a form of exercise**.** One participant said he considered getting old games out at home since the study brought back memories. Participant feedback and quotes are organized in the context of the primary outcomes, perceived exertion, enjoyment, and engagement, followed by participant thoughts on feasibility, appropriateness, and acceptability.

Perceived Exertion: Effortless Physical Activity

Participants highlighted that adapted video games not only stimulated them mentally, but that the body motion the games required challenged them physically. The competitive nature of games like *Let's Go Nuts* and *Space Invaders* motivated players to engage in different movements, leading to physical exertion without conscious effort because they were engrossed in gameplay. One participant reported postsession soreness, due to the physical demands of gameplay. Overall, participants saw the AVGs as effective tools for physical activity (Textbox 2).

Textbox 2. Participant experiences of physical activity and exertion during gameplay.

"Let's go nuts and space invaders that challenge me mentally as well as ... physical exercise with body motion" [AVG-07].

"... after the session I was physically sore. ... I'm 90% sure that the soreness was from doing the exercising during the games, but I wasn't 100% sure if it was that or it was my disability because the stroke is left side ... but I'm pretty sure I was sore from moving around quite a bit" [AVG-05].

"You know, especially for people that are worse off than me, some people I'm sure that movement is good exercise, you know, I mean, it's exercise for me too. But, obviously I can do bigger and better things, but that's pretty cool that that's you are getting exercise out of playing the games" [AVG-05].

Enjoyment: Achievement and Interaction Over Frustration

Participants reported significant enjoyment when playing adapted video games, highlighting their engaging quality. Initial frustrations with response times diminished over time, leading to increased enjoyment. The games fostered a sense of achievement, nostalgia, and joy in participants, who anticipated that gameplay would be enjoyable for others with disabilities (Textbox 3).

Textbox 3. Fun, challenge, and enjoyment during gameplay.

"Wonderful, lots of fun, always enjoyable" [AVG-01].

"Enjoyment with interaction ... Enjoyable. Lots of fun. ... Have thought about getting old games out at home since the study brought back memories" [AVG-03].

"Was frustrated not being able to move quickly enough, other times not responding as quickly as I wanted it to. But I enjoyed it as we went on, I got better. So it really is something I think people would enjoy, people like me with disabilities" [AVG-05].

Engagement: Competitive and Supportive Environment

Participants demonstrated gameplay engagement through factors such as competitive motivation, learning, a sense of accomplishment, and staff support. This engagement shaped their connection to the AVG intervention. Interaction with and support from research staff fostered a motivating environment for participation. The competitive elements of gameplay significantly enhanced commitment among individuals with a competitive nature. Progress in learning, from overcoming challenges to strategic development and improved performance, sustained engagement (Textbox 4).

XSL•FO
RenderX

Textbox 4. Competition, learning, and mastery sustained engagement.

"Didn't seem like playing for long due to having fun" [AVG-03].

"My favorite no doubt about this is 'Let's Go Nuts' and the reason is the competitive nature of the game. You know, being a coach as many years as I coach, you know that competitive nature haven't left me yet, even though I left the coach in the room, the nature still within me. So anytime I get into a competitive environment it just motivates me" [AVG-07].

"Learning experience, it was frustrating, but fun and more fun than frustrating. Once I got better. Once I got the concept and started getting, you know, it's like the more you play a game, the better you get. That's the way it was. The more I did it, the better I enjoyed it and the better I became. At first it was frustrating because I wasn't able to, like, keep the car on the track or shoot. Things are I wanted to go because I'm pushing the button but not leaning. And then I realized I'm not leaning. You know, so I got better and I enjoyed that. Once I got that part down and got my movements a little better" [AVG-05].

"First you have to analyze the game you plan. And realize that we have to develop a strategy for tech. You just can't go out" [AVG-07].

Acceptability, Appropriateness, and Feasibility: Inclusive Device

Participants expressed a general sense of acceptability toward the adapted gaming device, highlighting feelings of accomplishment and the potential for continuous improvement with practice. Additionally, participants emphasized the device's usefulness for individuals with varying abilities. This inclusivity enhances its acceptability, as it provides an accessible way for individuals to engage in meaningful physical activity. Finally, the device offered enjoyment, with participants expressing hope that others, regardless of ability, would derive as much satisfaction from it as they did.

> *You feel sense of accomplishment. Made me feel like I was getting better and it's something that if I practice I could do even better so. You know, it was OK.* [AVG-05]

Participants recognized the gaming device's suitability for those with mobility limitations, highlighting the enjoyment it produced and its accessibility for individuals with disabilities. One participant noted that while the physical activity aspect was valuable, the mental benefits—such as improved focus, distraction from personal challenges, and emotional enjoyment—may have had an even greater impact. Participants also noted that the game helped shift attention from their condition to the present activity.

> *I think this game is extremely beneficial to people who are stationary with their legs. Because not only will it entertain them mentally, but will entertain them physically too. I think the mental exercise will provide more for them than the physical. It'll get their mind focused off their condition, and focused on enjoyment. Right. It's distracting with you from what you're going through to what you're doing.* [AVG-07]

Participants' feedback suggests that the adapted gaming board is a feasible tool for increasing physical activity among individuals with disabilities. Its enjoyable and engaging nature makes it easier for users to stay active without feeling burdened by the idea of exercise. One participant noted that the fun aspect made time pass quickly, indicating that the games can sustain an individual's attention and promote consistent activity. Overall, the gaming board's adaptability and engaging design make it a feasible and effective option for promoting physical activity among people with disabilities.

> *Enjoyable. Lots of fun. Didn't seem like playing for long due to having fun ... Useful for those who have more limited abilities.* [AVG-03]
>
> *So it really is something I think people would enjoy, people like me with disabilities ... You know, especially for people that are worse off than me, some people I'm sure that movement is good exercise, you know, I mean, it's exercise for me too. But, obviously I can do bigger and better things, but that's pretty cool that that's you are getting exercise out of playing the games.* [AVG-05]

Table 8 presents the integrated findings, which show strong convergence between the quantitative and qualitative data analyses across all key intervention outcomes. In the case of perceived exertion, the quantitative median RPE of 6, indicating moderate-intensity exercise, was contextualized by the qualitative theme of "effortless physical activity." Participant described a "masking effect," in which competitive gameplay and mental focus shifted attention away from physical effort, making exercise a byproduct of play. Similarly, high quantitative ratings for enjoyment (9) and engagement (10) aligned with qualitative reports that mastery of adapted controls and positive staff interactions effectively outweighed initial technical frustrations. The implementation outcomes for acceptability, appropriateness, and feasibility were corroborated by participant feedback, which identified the GAIMplank as a highly suitable and inclusive device for individuals with varying mobility levels. The synthesis underscores that the AVG intervention was both physically engaging and enjoyable and was well-received by participants to stay active.

XSL•FO
RenderX

Table 8. Results: joint display integrating quantitative and qualitative findings across key intervention outcomes.

Outcome	Quantitative	Qualitative theme	Qualitative quotes	Integration
Perceived exertion	Median gameplay RPE[a] across participants was 6 (on 0-10 rating scale)	Effortless physical activity: Exercise occurred as a byproduct of gameplay competition.	• "... you're getting more exercise than you feel like as you're not focusing on the exercise as much as you were on the competition. And when I left there, someday I feel like down, I mean a mile I ran, but I'm not conscious of what I'm doing ... I don't know how they measure how much you got of it, but if you can measure it, you'll realize you got more out of it than you" [AVG-07].	Results converge: Competitive gameplay masked physical effort, allowing moderate exertion without the conscious burden of exercise.
Enjoyment	Median gameplay enjoyment was 9 (on 0- to 10-point scale)	Achievement and interaction over frustration: Mastery of the adapted controls led to joy and nostalgia.	• "Enjoyment with interaction ... Enjoyable. Lots of fun. Didn't seem like playing for long due to having fun ... Have thought about getting old games out at home since the study brought back memories" [AVG-03].	Results converge: High enjoyment score reflects the positive experiences of gameplay, which surpasses the initial technical hurdles and "learning curve."
Engagement	Median gameplay enjoyment was 10 (on 0-10 rating scale)	Competitive and supportive environment: Mental strategy and staff interaction led to deep engagement.	• "Didn't seem like playing for long due to having fun" [AVG-07]. • "My favorite no doubt about this is Let's Go Nuts ... the competitive nature of the game ... motivates me" [AVG-07]. • "Meeting y'all (staff), interacting with new people" [AVG-05].	Results converge: The perfect engagement score aligns with participants feedback on positive engagement facilitated by encouraging research staff and strategic demands by the gameplay.
Implementation outcomes (acceptability, appropriateness, and feasibility)	Agreed or completely agreed (AIM[b], IAM[c], and FIM[d])	Inclusive device: Perceived as highly suitable for varying mobility levels and mental distraction.	• "Useful for those who have more limited abilities" [AVG-03]. • "I think its game is extremely beneficial to people who are stationary ... It will get their mind, focus on condition, and focus on enjoyment" [AVG-07].	Results converge: The adapted board provided an acceptable, appropriate, and feasible means of engaging in physical activity. The intervention provided an accessible and enjoyable way for persons with mobility impairments to stay active.

[a]RPE: rating of perceived exertion.

[b]AIM: Acceptability of Intervention Measure.

[c]IAM: Intervention Appropriateness Measure.

[d]FIM: Feasibility of Intervention Measure.

Discussion

Principal Findings

This concurrent mixed methods pilot study evaluated a 6-week AVG intervention delivered using the GAIMplank controller among adults with mobility impairments. The primary aims were to examine perceived exertion, enjoyment, and engagement during gameplay and to assess implementation outcomes—acceptability, appropriateness, and feasibility—using both quantitative ratings and qualitative feedback. These findings extend prior exergaming research by demonstrating the feasibility of a multisession intervention using an adapted controller specifically designed for seated users with mobility impairments, addressing an important accessibility gap identified in prior work. Overall, participants who completed the intervention described AVG gameplay as physically effortful without "feeling like exercise," reported high enjoyment and engagement, and viewed the intervention as acceptable and suitable for their needs. In this small sample (n=6 enrolled; n=4 completers), median RPE scores of approximately 6 and high enjoyment and engagement scores (≥9) were observed across sessions (Table 4), supporting these overall perceptions. Qualitative findings generally aligned with quantitative results and highlighted practical implementation considerations, particularly intermittent controller responsiveness, that are important for future work.

Comparison to Prior Work

Participants' reported experiences suggest that AVG gameplay using the GAIMplank can elicit meaningful physical effort for seated users with mobility impairments, with perceived exertion often described as not feeling like exercise because participants were focused on the game. This perception aligns with evidence that perceived exertion during AVG can be lower than actual exertion when attention is focused on gameplay [20], while

XSL•FO
RenderX

potentially minimizing the subjective burden often associated with traditional exercise. Several participants described exertion emerging as a byproduct of gameplay competition and strategy rather than conscious exercise effort. This is consistent with the observed median RPE values in the moderate range across most participants and sessions (Table 4). This phenomenon aligns with prior research, showing that perceived exertion during active gaming can differ from physiological demand, leading users to underestimate activity intensity when attention is directed toward gameplay rather than bodily sensations [32]. Such an effect may be particularly relevant for individuals who report that exercise is tiring or feels like hard work, as exergaming may support motivation and sustained engagement over time [16,32]. Consistent with prior studies demonstrating light-to-moderate intensity activity during AVG play [51-53], these findings support the feasibility of adapted exergaming as one option to increase movement opportunities for adults with mobility impairments.

Enjoyment and engagement are commonly identified as important factors for continued participation in exergaming and have been linked to energy expenditure during AVG play [8,31]. In this study, participants frequently described an initial learning curve and frustration, often associated with controller responsiveness or unfamiliarity with the control scheme, followed by increased enjoyment as they gained mastery and confidence. Median enjoyment and engagement scores were consistently high (typically ≥9; Tables 4 and 5), which was reflected in participants' qualitative feedback. Competitive elements, clear objectives, and opportunities for progression appeared to support sustained engagement, suggesting that game selection and alignment with user preferences are critical components of intervention success. Importantly, participants remained engaged despite occasional technical challenges, which may reflect the value of gradual progression and consistent staff support. These findings are consistent with prior work in adults with physical disabilities, indicating that adapted exergaming systems can be both enjoyable and engaging when aligned with individual capabilities and preferences [8,37].

Implementation outcomes (AIM/IAM/FIM) and participant feedback suggested that the intervention was acceptable, appropriate, and feasible within a supervised laboratory environment [50]. Participants highlighted several factors that supported feasibility, including having multiple games to choose from, gradual increases in gameplay duration, and real-time assistance from research staff. High ratings on the AIM, IAM, and FIM measures (Table 7) further support these perceptions of acceptability and feasibility. These findings align with recent adaptive gaming literature, emphasizing that successful implementation depends not only on device design but also on access to appropriate setup support, configuration, and user guidance [38]. At the same time, recurring controller unresponsiveness and delayed input occasionally disrupted gameplay and reduced enjoyment. For future research and translation, priorities include improving controller reliability and calibration, selecting games that are well-matched to the adapted interface, and implementing structured onboarding procedures to promote early success and minimize frustration, as reflected in participant feedback and documented technical issues. Addressing these factors will be critical for translating adapted exergaming interventions beyond supervised settings into home and community settings.

Although standardized cognitive or mental health outcomes were not included in this study, participants frequently described mental stimulation, enhanced focus, and positive emotional experiences during gameplay. These observations are consistent with prior systematic review evidence, suggesting that exergaming may promote positive emotional experiences [27]. More recent evidence also suggests potential benefits for mood, social engagement, and certain cognitive outcomes in older adults, although findings remain heterogeneous across populations and outcome measures [28,29]. Given the exploratory nature of these observations and the absence of validated outcome measures in this study, conclusions regarding cognitive or psychological effects remain limited. Future studies should incorporate standardized assessments of mood, affect, and quality of life to more rigorously evaluate these potential benefits.

Strengths and Limitations

This study had several limitations. The sample size was very small, with only 4 participants completing the full intervention; therefore, findings are preliminary, not generalizable, and limited to descriptive interpretation consistent with feasibility study aims. Two participants withdrew due to health reasons, which highlights the need for careful monitoring and support for individuals with complex health conditions. As a feasibility pilot, the study was designed primarily to evaluate usability, acceptability, and procedural viability rather than to estimate intervention effects. Therefore, quantitative outcomes should be interpreted descriptively and with caution. Technical issues with the GAIMplank interfered with some gameplay sessions (<20%) and may have confounded the measures of engagement and enjoyment. Exercise intensity was measured as perceived exertion, not objective physiological intensity. Finally, the absence of standardized cognitive or mental health measures limits conclusions regarding psychological outcomes, despite participant comments suggesting mental engagement and emotional benefits.

Despite these limitations, this pilot study contributes preliminary evidence supporting the feasibility and acceptability of adapted AVG for adults with mobility impairments who are unable to use commercial standing-based systems [37,40,42]. The findings identify key design and implementation considerations—such as hardware reliability, game selection, progression, and support—that are likely to influence user experience and participation. More broadly, accessible seated exergaming has the potential to expand opportunities for enjoyable physical activity among individuals with mobility impairments [37,40,42]. As noted in a recent scoping review that evaluated the effects of assistive technology for adapted gaming, evidence of positive outcomes has been reported, but continued development of accessible gaming technologies is needed to support broader implementation [54]. Taken together, these findings illustrate how quantitative outcomes (Tables 4-7) and qualitative data converge to support the feasibility and acceptability of the intervention in this sample, as reflected in

XSL•FO
RenderX

the integrated findings presented in Table 8. This study contributes to this growing area by evaluating not just usability, but the feasibility of repeated-session engagement using a seated, trunk-controlled interface.

Future Directions

Future research should prioritize larger, controlled studies with improved hardware reliability, objective measures of physical activity and function, and validated psychosocial outcomes to evaluate effectiveness, longer-term engagement, and scalability across settings.

Conclusions

Findings from this mixed methods pilot study suggest that AVGs, delivered using an adapted controller like the GAIMplank, are a feasible and enjoyable way to promote physical activity among adults with mobility impairments. The study also points out practical issues that will matter for future use, including controller reliability, selecting games that work well with the controller, and having clear staff support and set-up procedures. More broadly, accessible seated exergaming may expand the options for enjoyable physical activity for people with mobility impairments. Future research should prioritize larger, controlled studies with improved hardware reliability and include objective measures of activity intensity and function, along with validated psychosocial measures. Longer-term studies are also needed to examine sustained use and potential benefits over time and to better understand what approaches best support continued participation.

Acknowledgments

The authors thank Rebecca Rogers, Katherine Grindle, Eric Evans, and the University of Alabama at Birmingham School of Health Professions honors students for their assistance with this project. The authors also thank Emily Delzell for her editorial review and assistance in the preparation of this manuscript. The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: literature search and systematization, text generation, proofreading and editing, and summarizing text. The GenAI tool used was ChatGPT (OpenAI), GPT-5.5 Thinking model, and M365 Copilot based on the GPT-5 chat model. Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Funding

Funding support was under a grant from the National Institute on Disability, Independent Living, and Rehabilitation Research (NIDILRR grants 90REGE0002 and 90REGE0019). NIDILRR is a center within the Administration for Community Living, Department of Health and Human Services. The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Loneliness has been linked to reduced mental and physical health. The “loneliness epidemic” is recognized as a public health crisis. However, questions remain about the potential of video games, which people play by themselves, to help reduce perceived loneliness.

Objective: This study explored the extent to which open-world games (eg, *The Legend of Zelda: Breath of the Wild*) and fun, accessible games (eg, *Yoshi’s Crafted World*) can help reduce loneliness in adults. We examined how such gameplay can foster a stoic approach to life and how stoicism mediates the reduction of perceived loneliness.

Methods: A cross-sectional survey was conducted using convenience sampling near a video game store. The sample comprised 2252 adults aged 21 years and older (women: n=966, 42.90%; men: n=1281, 56.90%; prefer not to disclose: n=5, 0.20%). Participants completed a questionnaire to measure perceived loneliness and stoicism, as well as their gameplay habits. Data were analyzed using ANOVA and moderated mediation with the PROCESS macro (bootstrapped samples=5000; 95% CI) to examine the effects of video gameplay on stoicism and loneliness, with the α level set at .05.

Results: Zelda players indicated higher stoicism (mean 4.87, SD 0.11; 95% CI 4.66-5.08) than nonplayers (mean 3.23, SD 0.07; 95% CI 3.09-3.37; $F_{1,2252}$=164.95; P<.001). Yoshi players also noted significantly higher stoicism (mean 4.49, SD 0.12; 95% CI 4.27-4.72) than nonplayers (mean 3.61, SD 0.05; 95% CI 3.50-3.71; $F_{1, 2252}$=48.33; P<.001), with a significant interaction effect ($F_{1,2252}$=7.89; P=.005) on stoicism. Furthermore, Zelda players indicated lower loneliness (mean 3.02, SD 0.11; 95% CI 2.81-3.22) than nonplayers (mean 4.28, SD 0.07; 95% CI 4.14-4.42; $F_{1, 2252}$=98.32; P<.001). Yoshi players also noted significantly lower loneliness (mean 3.09, SD 0.12; 95% CI 2.86-3.32) than nonplayers (mean 4.21, SD 0.05; 95% CI 4.10-4.32; $F_{1, 2252}$=76.32; P<.001). Moderated mediation analysis demonstrated that Zelda gameplay was positively associated with stoicism (β=1.28, 95% CI 1.07-1.50; P<.001), and stoicism was negatively associated with perceived loneliness (β=−0.49, 95% CI −0.52 to −0.45; P<.001).

Conclusions: This study is innovative in identifying stoicism as a potential emotional pathway through which video games may reduce loneliness. Moving beyond views of gaming as passive escapism, our findings suggest that specific gameplay experiences may serve as active spaces for cultivating resilience. We introduce a “digital diet” framework, indicating that balancing open-world challenges (eg, Zelda) with low-stakes restoration (Yoshi) produces synergistic psychological support. Practically, thoughtfully curated gaming experiences may serve as scalable and cost-effective digital adjuncts for public mental health interventions addressing the loneliness epidemic.

Introduction

Overview

Addressing perceived loneliness is perhaps one of the most pressing psychosocial challenges of our time [1-7]. Its importance today is magnified by a unique confluence of technological [8,9], societal [10,11], and economic factors [12] that differentiate the modern experience of loneliness from that of any previous generation [13]. Critically, the "loneliness epidemic" is a recognized public health crisis [14-20]. Loneliness is no longer seen as just a fleeting feeling [21]; it is now understood to have severe consequences for both mental health [22,23] and physical health [24], on par with smoking and obesity [25,26].

Chronic loneliness is linked to a 26% increased risk of premature mortality [24,27]. It is associated with higher levels of cortisol (the stress hormone) [28], increased inflammation [29], weakened immune systems [30,31], high blood pressure [32], and heart disease [33]. Furthermore, loneliness is deeply detrimental to mental health [34,35], and is associated with depression, anxiety, and substance abuse [36-40]. It can create a negative feedback loop where loneliness leads to increased social anxiety [21] and negative perceptions of social interactions [24], which, in turn, lead to further isolation [38]. Addressing loneliness is, therefore, a critical public health priority [21,37]; mitigating it can reduce the burden on health care systems and improve overall population well-being.

Despite society existing in the most technologically connected age [21], modern social platforms often promote performative interactions rather than authentic vulnerability, fostering feelings of inadequacy or "FOMO" (Fear of Missing Out) [41] or "FOBO" (Fear of a Better Option Elsewhere). Concurrently, participation in traditional localized communities has declined [42]. Modern, individualized lifestyles [43] and high-stress "hustle" cultures can crowd out the energy required to nurture relationships [42], increasingly leading to a sense of existential isolation [44].

In prior research, the role of video games in relation to loneliness has yielded mixed findings. On one hand, loneliness has been associated with problematic gaming outcomes, such as internet gaming disorder, in some populations [18]. On the other hand, socially oriented gaming interventions have been explored as a possible way to reduce loneliness, particularly among older adults [6]. However, what remains uncertain is the potential for mainstream single-player game genres, specifically open-world and fun, accessible games, to mitigate loneliness internally. While existing work has begun to examine the social potential of multiplayer or socially oriented gaming, the current literature lacks a clear understanding of the internal cognitive and emotional pathways through which specific single-player game environments might alleviate perceived loneliness without relying on digital socializing.

Background on Stoicism and Loneliness

In the context of performative connection and external pressure, stoicism can offer a counterintuitive but powerful solution. Stoicism does not simply advocate to "meet more people." It addresses the root perception of lack [45]. That is, stoicism shifts the source of validation from external to internal [45-47]. If an individual's sense of worth comes from their own character and virtues, they are less vulnerable to the approval and curated feeds of others [45-48]. Critically, stoicism helps reframe solitude, transforming loneliness into purposeful solitude—a time for reflection, self-improvement, and cultivating inner peace [45]. When one is comfortable with oneself, one can attract healthier connections and engage with the world from a place of strength, not lack.

While theoretical frameworks relevant to endurance, self-regulation, and responses to adversity can be found in stoic writings [45-48], direct quantitative evidence examining the association between stoicism and lower levels of loneliness remains limited. However, empirical support exists for some of the psychological mechanisms often linked to stoic practice. For example, cognitive behavioral therapy has frequently been connected to stoic principles, particularly the role of cognition in shaping emotional experience [49,50], and a cognitive behavioral therapy–based intervention has been shown to reduce loneliness in a randomized controlled trial [16]. Furthermore, recent psychometric research conceptualizes philosophical stoicism as a specific, measurable set of attitudes and behaviors rather than a strictly fixed personality trait [51]. While intervention studies explicitly targeting stoicism remain rare, evidence from clinical settings suggests that cognitive processes closely aligned with stoic practice, such as appraisal and reinterpretation, may be malleable [16,49]. Thus, a secondary aim of this study is to address this empirical gap by providing quantitative evidence on whether self-reported stoic attitudes are negatively associated with perceived loneliness.

Stoicism teaches individuals to direct their energy only toward things within their control (their judgments, values, and actions) and to accept what they cannot control (external events, other people's actions). The practice of accepting and embracing everything that happens (*amor fati* or love of fate) is viewed not as a setback but as a necessary part of life's journey [45,47,48]. According to stoicism, true happiness (*eudaimonia*) comes from living a life of virtue (wisdom, courage, justice, and temperance), not from seeking external pleasure or avoiding pain [45]; it is also seen as a path toward mental freedom [52,53]. In addition to this, contemplating potential setbacks (*premeditatio malorum* or the premeditation of evils) can help reduce their emotional impact and prepare individuals for adversity [45,46]. Stoicism aims for a state of *ataraxia* (freedom from distress) [45,46], offering a recalibration of one's emotional baseline to recognize that peace and joy are possible internal states, independent of external circumstances. Finally, a core stoic exercise is *memento mori* ("remember you must die"), not to be morbid, but to appreciate the preciousness of life and to prioritize what truly matters [45-47]. That is, to appreciate the beauty of something precisely because it is fleeting.

Background on Video Gameplay, a Stoic Mindset, and Loneliness

Video Gameplay and Loneliness

Prior empirical research demonstrates that video games can positively impact mental well-being and provide experiences of relaxation and cognitive escapism [54,55]. Furthermore, broader reviews indicate that game-based digital interventions can reduce mental health symptoms in clinical contexts [56,57]. Building on such evidence of gaming's capacity to enhance mastery and overall well-being, we posit that the structured environments of open-world and fun, accessible games could potentially serve as a novel context for cultivating attitudes aligned with stoic philosophy.

By design, open-world games often place players in vast, indifferent environments where survival requires adaptability and resilience. *The Legend of Zelda: Breath of the Wild* serves as a prime, concrete example of this dynamic, as it forces players to embrace a harsh, often unforgiving environment. This is a direct practice of *amor fati*.

In addition, gameplay emphasizes self-reliance and internal resources (virtue as the sole good). Link begins the game with nothing. He is amnesiac, weak, and stripped of all past glory. Progress in the game is not handed to anyone. Players must cook their own meals, forage for ingredients, scavenge for weaker weapons, and slowly learn to conquer challenges through their own wits, courage, and perseverance. The game constantly reinforces the idea that one has the resources within oneself to overcome obstacles. This builds self-sufficiency, a core stoic value. Players learn to rely on their judgment and abilities rather than waiting for rescue or a lucky break.

Moreover, the game's core loop is exploration and observation, not just action. Stoicism begins with the "discipline of perception," which involves judging events clearly and without unnecessary emotional baggage.

Furthermore, accessible, low-stakes games, such as Yoshi, can help strengthen the stoic focus on the present moment through mindfulness and simplicity. The mindfulness is baked into the esthetic and gameplay. *Yoshi's Crafted World* is hand-crafted from cardboard and yarn, encouraging you to appreciate the beauty in simple, everyday objects. The pace is slower, and the goal is often to stop, look around, and find a hidden flower or a shy Poochy pup. This is a practice in appreciating the present moment for its own sake, not just for survival. For someone feeling lonely, this directly counteracts rumination about the past or anxiety about the future, anchoring them in a gentle, pleasant now.

Moreover, games such as *The Legend of Zelda: Breath of the Wild* and *Yoshi's Crafted World* reinforce the idea that purpose is often found in caring for others and contributing to a collective good. They practice the stoic concept of *sympatheia*, the interconnectedness of all people [45]. By engaging in a game that is literally about helping and supporting others (even in a simple, cartoonish way), players can strengthen the neural pathways for empathy and the understanding that we are part of a whole. This directly combats the isolated, ego-centric perception that fuels loneliness.

Loneliness is often less about being physically alone and more about a state of mind characterized by a feeling of lack or neediness, a sense of disconnection from the world and others, as well as anxiety about one's place and ability to cope. The stoic mindset cultivated by *The Legend of Zelda: Breath of the Wild* can help directly address these feelings. That is, the game helps reframe solitude from a state of *loneliness* to one of peaceful aloneness, self-reliance, and agency. The quiet, expansive landscapes are not empty; they are full of possibility that one gets to engage with on one's own terms. This teaches players to enjoy their own company and to see alone time not as a deficiency, but as an opportunity for exploration and self-discovery. One becomes a complete unit unto oneself, less dependent on others for validation or entertainment.

Stoicism teaches that people are part of a larger, rational cosmos. *The Legend of Zelda: Breath of the Wild* mimics this by fostering a connection to something larger and by making players a small part of a vast, open world. One's journey is one's own, but it is woven into the fate of Hyrule. This sense of being part of a larger whole, even when alone, can be profoundly comforting and diminish the feeling of being a lonely, isolated individual.

The Perfect Stoic Diet

Playing *The Legend of Zelda: Breath of the Wild* builds the core, resilient stoic muscles: courage, endurance, acceptance, and self-reliance. Playing a Yoshi game rehabilitates those muscles with stretches of joy, nurtures them with empathy, and keeps them flexible with mindfulness and play. Together, they form a holistic practice. Open-world games such as *The Legend of Zelda: Breath of the Wild* teach players to be strong enough to be alone without being lonely. Fun and accessible games such as Yoshi, on the other hand, can remind one that the world is also a place of softness, connection, and simple joys worth engaging with. Together, these games remind us that light-heartedness and profundity are not opposites but essential partners on the path to a good life. By becoming more stoic, one becomes more resilient, self-contained, and at peace with one's own presence. This inner fortitude is the ultimate cure for loneliness, as it means one is never truly without a stable and capable companion: oneself.

Thus, the aim of this study is to investigate the potential of open-world and fun, accessible video games for reducing loneliness and enhancing stoicism in adults. To achieve this, we address four distinct but interconnected research questions: First, to what extent, if at all, can video gameplay help reduce the risk of loneliness? Second, how does a stoic approach to life, afforded by these games, serve as an emotional pathway to alleviate that isolation? Third, what role do popular open-world video games play in facilitating this resilient stoic mindset? Finally, how does the addition of fun, accessible games (eg, *Yoshi's Crafted World*) interact with open-world gameplay (eg, *The Legend of Zelda: Breath of the Wild*) to further enhance stoicism and ultimately mitigate people's loneliness?

XSL•FO
RenderX

Methods

Research Design

As part of this study, we conducted a cross-sectional survey using a convenience sampling approach. We followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1) to report observational, cross-sectional studies [58] and collected the data in November 2025 and December 2025.

Inclusion and Exclusion

Participants were invited to take part in the study if they were aged 21 years or older. To allow for robust statistical comparisons, prior or current video game experience was not required. Specifically, we compared nonplayer participants with participants who currently or recently played open-world games (eg, *The Legend of Zelda: Breath of the Wild* or *The Legend of Zelda: Tears of the Kingdom*; see Figures 1-3 for visual context of the vast, open-world environments that require a stoic approach) and/or fun, accessible games (eg, *Yoshi's Crafted World* or *Yoshi's Wooly World*; see Figures 4 and 5 for the gentle, nurturing environments).

Sampling Procedures

A total of 3 trained research assistants, who were blind to the study's research questions, approached potential study participants near a video game store in a busy shopping mall. This was done to capture some variance in terms of whether people were playing or had recently played an open-world game such as *The Legend of Zelda: Breath of the Wild* or *The Legend of Zelda: Tears of the Kingdom* and/or fun, accessible games such as *Yoshi's Crafted World* or *Yoshi's Wooly World*. The research assistants informed potential participants that the study, which focused on daily activities, would contribute to current academic research at a university and that participation would not take longer than 7 minutes in total. The research assistants also checked participants' IDs for age in cases where potential participants appeared younger.

Sample Size, Power, and Precision

Over the course of 5 weeks, the research assistants managed to recruit a total of 2300 participants and invited them to complete a brief survey on a tablet. Because 48 participants stopped midway through answering the measurement items and, hence, did not complete the entire questionnaire, their responses were discarded from the study, and the total effective response rate is 2252 (97.90% completion rate).

Participant Characteristics

The final sample consisted of 2252 participants (women: n=966, 42.90%; men: n=1281, 56.90%; prefer not to disclose sex: n=5, 0.20%). Because participants with incomplete responses were excluded during the initial screening phase, there were no missing data in the final analyzed dataset.

Measures and Covariates

Participants answered 3 questions about perceived loneliness that were adapted from previously published and validated scales [59-61]: "How often do you feel a sense of emptiness around you?", "How often do you feel that there is no one you can turn to?", and "How often do you feel that you lack companionship?" (1="never" to 7="always"). Furthermore, participants answered 3 questions about their stoic attitudes and behaviors using items that were adapted from previously published and validated scales designed to measure the core practices of modern stoicism [49-51], "I reflect on the temporary nature of things to help me appreciate them more," "I consciously consider whether things are within my control before deciding how to act," and "When facing a difficulty, I focus on my own virtuous response rather than complaining about the situation itself" (1="very inaccurate" to 7="very accurate"). Participants then indicated whether they are currently playing or have recently played a Yoshi game such as *Yoshi's Crafted World* or *Yoshi's Wooly World* (0="no" and 1="yes"), and an open-world game from the Legend of Zelda series, such as *The Legend of Zelda: Breath of the Wild* or *The Legend of Zelda: Tears of the Kingdom* (0="no" and 1="yes"). As a control, participants indicated their gender (0="female" and 1="male"). To ensure the quality of measurement, all scale items were reviewed by the research team for clarity and consistency.

Statistical Analysis

We followed the recommended procedures for conducting confirmatory factor analyses and examined the factor structure and reliability scores for all the measurement items in our survey study [62,63]. This was done to assess whether the items in the study significantly loaded on their intended factors and had weak cross-loadings. Furthermore, we examined the average variance extracted and composite reliability scores for the measurement scales in our study. Moreover, we tested whether the average variance extracted for each construct was indeed greater than the squared correlations between the construct and other variables in our survey [64]. The hypothesized model was tested using confirmatory factor analysis in IBM SPSS AMOS 29.0 with maximum likelihood estimation.

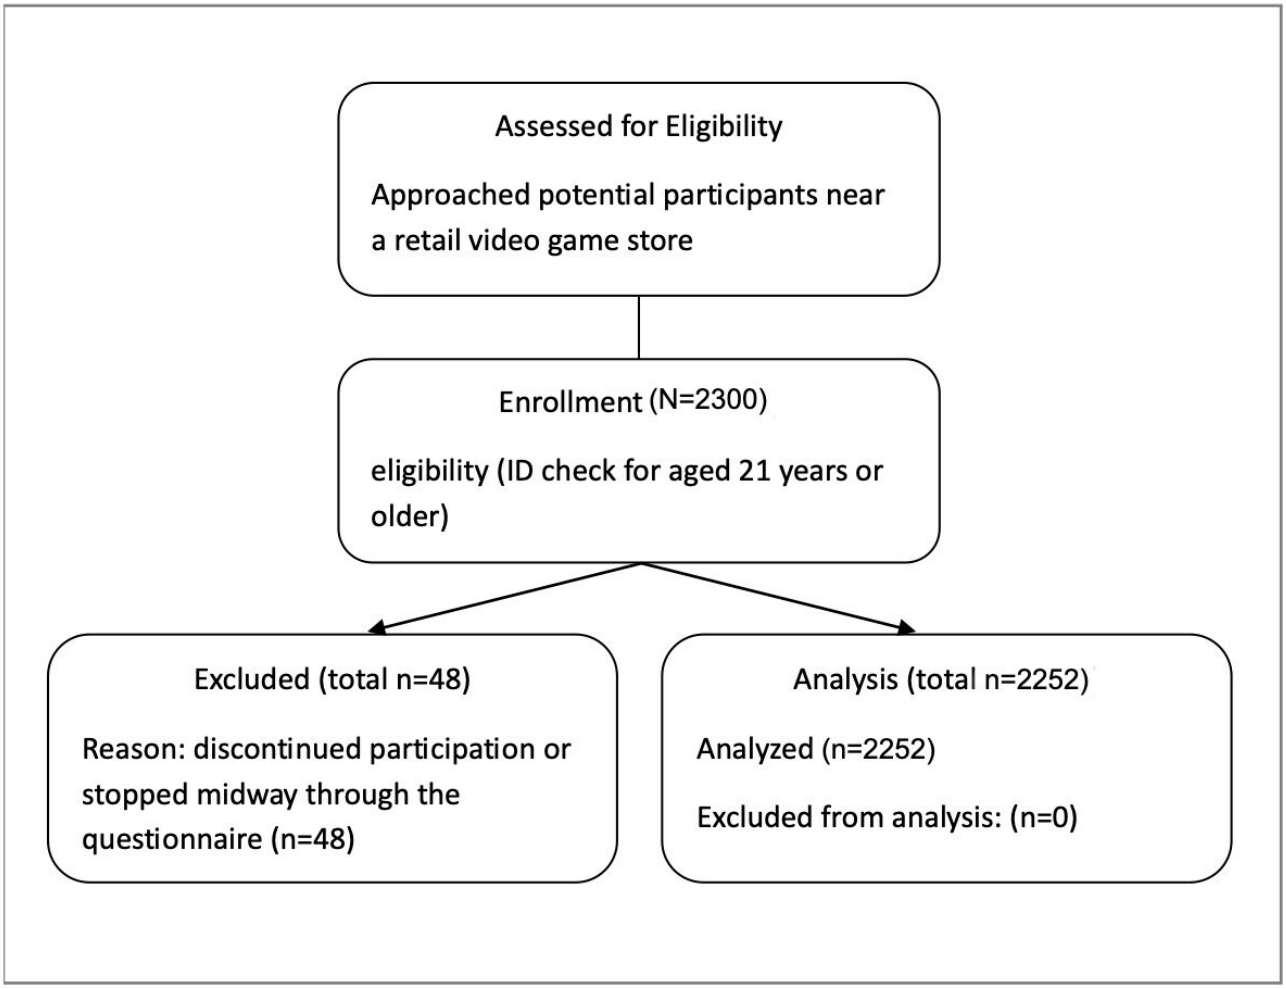
Next, we conducted an ANOVA to examine the variances across the different groups in our study (ie, open-world game: no vs yes; fun, accessible game: no vs yes). In addition, we conducted a moderated mediation analysis using the PROCESS macro [65] (model 8; bootstrapped samples=5000; 95% CI) to examine the effects of popular open-world gameplay such as *The Legend of Zelda: Breath of the Wild* (independent variable) as well as gameplay of fun, accessible games, such as *Yoshi's Crafted World* (moderator) on stoicism (mediator) and loneliness (dependent variable). To ensure that PROCESS did not treat sex as a continuous variable, sex was coded as a dummy variable (0="female" and 1="male"). Due to the insufficient sample size (n=5), the "prefer not to disclose" category was excluded from the moderated mediation analysis.

Ethical Considerations

Ethical approval for this study was obtained from Kyushu Sangyo University's ethics committee (#2025 - 0019). The procedure ensured compliance with the university's research ethics guidelines and the principles of the Declaration of Helsinki. All data collected were anonymized and kept confidential within the research team. Study participants provided informed consent and were told that they had the right to withdraw from the study at any time without providing a specific reason for withdrawal. Furthermore, we ensured that no identification of individual participants or users in any images included in the paper (eg, in-game screenshots and participant flowchart) or supplementary material was possible. After completing the brief survey, each study participant was thanked for their time and debriefed about the study. Study participants did not receive a financial reward.

Results

Participant Characteristics



The demographic and baseline gameplay characteristics of the sample are detailed in Table 1 and Figure 6.

How often do you feel that you lack companionship?	0.90
Stoicism (α=.94; CR=.93; AVE=.83)	
I reflect on the temporary nature of things to help me appreciate them more	0.92
I consciously consider whether things are within my control before deciding how to act	0.88
When facing a difficulty, I focus on my own virtuous response rather than complaining about the situation itself	0.93

[a]CR: composite reliability.

[b]AVE: average variance extracted.

Primary Analyses: ANOVA

A set of 2 ($Zelda_{open\text{-}world\ gameplay}$: no vs yes)×2 ($Yoshi_{fun,\ accessible\ gameplay}$: no vs yes) ANOVA on stoicism showed a significant main effect of open-world gameplay such that participants who played an open-world game like *The Legend of Zelda: Breath of the Wild* indicated higher levels of stoicism (mean 4.87, 95% CI 4.66-5.08) than participants who did not (mean 3.23, 95% CI 3.09-3.37; $F_{1,\ 2252}$=164.95; *P*<.001). Moreover, the results demonstrated a significant main effect of fun, accessible gameplay, such that participants who played a Yoshi game noted significantly higher levels of stoicism (mean 4.49, 95% CI 4.27-4.72) than study participants who did not (mean 3.61, 95% CI 3.50-3.71; $F_{1,\ 2252}$=48.33; *P*<.001). In addition to this, we observed a significant interaction effect of open-world× fun, accessible gameplay ($F_{1,\ 2252}$=7.89; *P*=.005). Gender had no effect on stoicism ($F_{1,\ 2252}$=0.01; *P*=.91; Multimedia Appendix 1).

Furthermore, we conducted a set of 2 ($Zelda_{open\text{-}world\ gameplay}$: no vs yes)×2 ($Yoshi_{fun,\ accessible\ gameplay}$: no vs yes) ANOVA on loneliness. The results showed a significant main effect of open-world gameplay, such that participants who played an open-world game like *The Legend of Zelda: Breath of the Wild* indicated lower levels of loneliness (mean 3.02, 95% CI 2.81-3.22) than participants who did not (mean 4.28, 95% CI 4.14-4.42; $F_{1,\ 2252}$=98.32; *P*<.001). In addition, the results showed a significant main effect of fun, accessible gameplay such that participants who played a Yoshi game noted significantly lower levels of loneliness (mean 3.09, 95% CI 2.86-3.32) than study participants who did not (mean 4.21, 95% CI 4.10-4.32; $F_{1,\ 2252}$=76.32; *P*<.001). The results also showed a significant interaction effect of open-world× fun, accessible gameplay ($F_{1,\ 2252}$=4.78; *P*=.03), while gender had no effect on loneliness ($F_{1,\ 2252}$=0.34; *P*=.56; Multimedia Appendix 2).

Primary Analyses: Moderated Mediation

We conducted moderated mediation analyses using PROCESS macro [65] (model 8; bootstrapped samples=5000; 95% CI; sample size=2252) with $Zelda_{open\text{-}world\ gameplay}$ as the independent variable, stoicism as the mediator, $Yoshi_{fun,\ accessible\ gameplay}$ as the moderator, and loneliness as the dependent variable with gender as a potential confound. The results showed that $Zelda_{open\text{-}world\ gameplay}$ (independent variable) had a significant and positive effect on stoicism (β=1.28, SE=0.11, *t*=11.83; *P*<.001; 95% CI 1.07-1.50; Table 3). Furthermore, $Yoshi_{fun,accessible\ gameplay}$ had a positive influence on stoicism (β=0.53, SE=0.14, t=3.70; *P*<.001; 95% CI 0.25-0.81) and the results showed a significant interaction effect of Zelda and Yoshi gameplay on stoicism (β=0.72, SE=0.26, *t*=2.81; *P*=.005; 95% CI 0.22-1.22). Gender had no influence on stoicism (β=0.01, SE=0.08, *t*=0.11; *P*=.91; 95% CI –0.14 to 0.16; Table 3).

Table . Cross-sectional survey moderated mediation regression results: effects of open-world and fun, accessible gameplay on stoicism[a].

Predictor	B	SE	*t* test	*P* value	95% CI
DV: Stoicism					
Constant	2.95	0.13	23.39	<.001	2.70 to 3.20
$Zelda_{open\text{-}world\ gameplay}$	1.28	0.11	11.83	<.001	1.07 to 1.50
$Yoshi_{fun,\ accessible\ gameplay}$	0.53	0.14	3.70	<.001	0.25 to 0.81
Interaction Zelda × Yoshi gameplay	0.72	0.26	2.81	.005	0.22 to 1.22
Gender	0.01	0.08	0.11	.91	–0.14 to 0.16

[a]R=.33; R^2=.11; mean square error=3.19; $F_{4,\ 2247}$=72.37; P<.001.

The conditional effects of the focal predictor (open-world gameplay such as *The Legend of Zelda: Breath of the Wild*) on stoicism at values of the moderator (fun, accessible gameplay such as Yoshi: no vs yes) are shown in Table 4.

Table . Cross-sectional survey conditional effects: effects of the focal predictor ($Zelda_{open\text{-}world\ gameplay}$) on stoicism at values of the moderator ($Yoshi_{fun,\ accessible\ gameplay}$).

	Effect	SE	*t* test	*P* value	95% CI
Zelda -> stoicism					
Yoshi gameplay: no	1.28	0.11	11.83	<.001	1.07-1.50
Yoshi gameplay: yes	2.00	0.23	8.64	<.001	1.55-2.46

The moderated mediation analyses further showed that stoicism was significantly negatively associated with participants' perceived loneliness (β=−0.49; SE=0.02; *t*=−26.46; *P*<.001; 95% CI −0.52 to −0.45; Table 5). In addition, the direct effects of Zelda and Yoshi gameplay on loneliness remained significant such that Zelda (β=-0.36; SE=0.10; *t*=−3.72; *P*<.001; 95% CI −0.56 to −0.17) and Yoshi (β=−0.58; SE=0.13; *t*=−4.62; *P*<.001; 95% CI −0.83 to −0.33) gameplay were significantly negatively associated with loneliness (Table 5). The interaction of Zelda×Yoshi gameplay (β=−0.21; SE=0.22; *t*=−0.93; *P*=.35; 95% CI −0.65 to 0.23) on loneliness was not significant and the results showed no effect of gender on loneliness (β=−0.04; SE=0.07; *t*=−0.60; *P*=.55; 95% CI −0.17 to 0.09; Table 5).

Table . Cross-sectional survey moderated mediation regression results: effects of open-world and fun, accessible gameplay on loneliness[a].

Predictor	B	SE	T	*P* value	95% CI

Discussion

Principal Findings

In alignment with our stated objectives, this study investigated the potential of open-world and accessible video games to reduce perceived loneliness and enhance stoicism in adults. Addressing our four core research questions, the findings demonstrated that, first, engagement with these focal games is significantly and negatively associated with perceived loneliness. Second, our theoretical model revealed that stoicism serves as a significant emotional pathway, inversely linking gameplay to feelings of isolation. Third, open-world gameplay (eg, The Legend of Zelda) was strongly associated with a more resilient, stoic mindset. Finally, we observed a significant interaction effect, indicating that the addition of accessible games (eg, Yoshi) positively synergizes with open-world gameplay to further enhance stoicism.

The observed synergy between open-world and accessible gameplay, termed the “Perfect Stoic Diet,” suggests potential as a scalable public health intervention. Traditional mental health services often contend with well-documented barriers, including broad gaps in care availability [66], cost and access challenges [67], and stigma related to mental illness [68]; in contrast, these gaming experiences are widely accessible [54,56]. While the upfront costs of commercial video games and required hardware present a tangible barrier for some vulnerable populations, broader research supports the idea that game-based digital interventions may offer scalable and relatively cost-effective adjuncts to conventional therapy, particularly for individuals from at-risk populations who might otherwise remain underserved [56,57]. Leveraging the immersive nature of these games to foster a stoic mindset provides a novel, decentralized pathway for addressing the loneliness epidemic [21,37].

Comparison With Prior Work

Prior research examined video games and digital environments through the lens of cognitive escapism, relaxation, and mental well-being [54,55], including discussions on bridging gaming and mental health science [69]. Broader digital well-being research further shows that online environments can shape anxiety, stress, and psychological experiences in complex ways, depending on platform features, user goals, privacy concerns, and social dynamics [70-75]. Prior studies also investigated how various digital offerings can help users by offering them hope and making their lives easier [76-78]. However, the specific role of single-player video games as active spaces for cultivating emotional resilience remains underdeveloped. Our findings extend this literature by suggesting that open-world environments, such as *The Legend of Zelda: Breath of the Wild*, may afford more than passive escapism: in our data, they were associated with a stoic mindset that helped players reframe solitude.

Furthermore, while some loneliness-focused gaming interventions have explored social or multiplayer experiences, particularly among older adults [6], this study contributes a novel perspective by suggesting that single-player, mainstream games may mitigate loneliness through internal cognitive processes rather than digital socializing. By linking gameplay to stoic principles [45-48], this study offers quantitative evidence that specific single-player gameplay experiences may serve as an internal emotional pathway for alleviating perceived loneliness.

Finally, while public health research emphasizes the serious physical and mental health consequences of loneliness [14,21,25], game-based digital intervention research has only recently begun to examine how different genres may produce distinct psychological affordances [56,57,79]. Our research introduces the concept of a “digital diet,” suggesting that the psychological benefits of gaming are not monolithic. Specifically, our findings indicate that balancing open-world challenge and autonomy with the low-stakes, calming qualities of accessible games, such as *Yoshi’s Crafted World*, produces a synergistic pattern of psychological support. This extends previous frameworks of digital well-being by suggesting that a thoughtfully curated combination of gameplay experiences may offer a more robust buffer against loneliness than singular game genres alone.

Limitations

As part of this study, we explored the role of open-world and fun, accessible games in facilitating stoicism and reducing loneliness. Future work studying the potential influence of other types of games on adults' loneliness is richly deserving. Moreover, we invite additional work to conduct randomized controlled studies across different participant pools—explicitly accounting for unmeasured confounding variables such as socioeconomic status (eg, income level, educational attainment, and working conditions), marital status, living arrangements, and baseline social contact—to establish causality and help strengthen confidence in the generalizability of the current results. In addition, we did not account for participants' varied lifestyles or capture their social media usage as part of this study. We invite future work to explore how social media usage and individuals' lifestyles (eg, taking regular walks in parks, etc) may influence loneliness in tandem with video gameplay. Additionally, we captured self-reported levels of stoicism. A promising avenue for future research is to investigate objective measures of stoicism and assess its role in the relationship between gaming and loneliness.

Furthermore, it is important to acknowledge potential confounding variables related to our sample composition. Because we did not collect data on the general gaming habits of participants who answered "no" to playing the focal games (ie, The Legend of Zelda or Yoshi), it remains unclear whether this control group consisted of strictly nongamers or players of other video game genres. Similarly, while our sample consisted of adults aged 21 years and older, the differing target demographics and inherent appeal of open-world versus fun and accessible games may introduce subtle confounding factors. Capturing participants' complete digital diets is a necessary step for future research to isolate these variables more effectively.

Finally, it is important to note the limitations regarding our analytical approach. Because we conducted a cross-sectional survey and all variables were measured at the same time, the temporality of the variables cannot be firmly established. Consequently, the mediation analyses may be considered exploratory. Furthermore, the assumptions regarding the absence of confounding among these variables must be interpreted with caution. Since we were not able to collect data on various demographic information of participants and other potential confounding variables, we invite future research to investigate some of these additional variables that may lead to important insights. We strongly encourage future studies to conduct longitudinal observations to better establish the temporality and relational dynamics of these variables.

Future Research

This study has a number of limitations, which also offer promising paths for additional work. Previous research has shown that users may at times feel uneasy about different digital offerings [80-82], while at the same time being able to incorporate digital solutions as part of their concept of self if and when these offerings are seen as enabling their lives and making their lives easier [83]. Future studies that further explore the role of video games in making users' lives easier and helping them through the day by affording emotional reactivity are very promising. In addition to this, we invite work to explore the potential for video games in enhancing individuals' mental health and broader well-being by offering benefits that resemble relaxation, restoration, or meditative forms of psychological recovery [54,55]. Moreover, an increasing number of people may feel overwhelmed by the burden of modern life (24/7 news cycles, an "always on" social media culture, etc) and may lose the ability for childlike wonder and joy [56,57,66-68,79,84], while becoming increasingly detached from nature [85,86]. Yet, people also strive for meaning in their lives [87]. The current findings show how a game can be more than entertainment, how ancient wisdom can be applied to modern problems [45,50], and how interactive experiences may help cultivate a life with less loneliness and more meaning [44,87]. How fun and accessible video gameplay may interact with gameplay of open-world games to help players anchor more strongly in day-to-day life and help them manage daily worries and discomfort is worthy of further investigation [54,79]. Thus, we invite future research to help bridge gaming and mental as well as physical health science to help individuals create a personal, life-affirming way to live such that if a demon told them that they would have to live this exact same life, with all its pain and joy, over and over again for eternity, they would react not with despair but rather with triumphant joy [88].

Conclusions

The findings of this study highlight the potential for video games to help combat loneliness. First, this study is innovative in identifying stoicism as an active emotional pathway through which video games may reduce loneliness. Second, unlike existing studies that view gaming primarily as passive escapism, our findings suggest that video games can serve as active spaces for cultivating mental resilience. Third, it introduces a novel 'digital diet' framework to the field, showing that balancing open-world challenges (eg, The Legend of Zelda) with low-stakes restoration (eg, Yoshi) produces a synergistic pattern of psychological support. Finally, regarding broader real-world implications, these findings position thoughtfully curated video games as scalable and cost-effective digital adjuncts for public mental health interventions addressing the loneliness epidemic [21,37].

Acknowledgments

The authors thank Wendelin Buchinger for his ideation and the insights he shared based on his in-depth gameplay analysis (> 12,700 hours of gameplay of *The Legend of Zelda: Breath of the Wild* – this is not a typo!). Furthermore, the authors thank all the study participants for their time. In addition, the authors would like to thank Nintendo for granting permission to take photos

Abstract

Background: Longer life expectancy makes physical exercise crucial for active aging. However, adherence to traditional exercise among community-dwelling older adults is generally low. Virtual reality (VR) and mixed reality (MR) Tai Chi exergames, as novel health promotion tools, show significant potential, particularly for older adults exercising in a home setting.

Objective: This study aimed to evaluate the usability and feasibility of a VR and MR Tai Chi exergame for community-dwelling older adults, focusing on subjective experience, physiological comfort, and objective interaction performance. The study also explored the relationships between key usability factors and sought to quantify links between objective accuracy and subjective experience (the Game Experience Questionnaire or Virtual Reality Sickness Questionnaire [VRSQ]) to inform choices of display mode, feedback strength, and session length.

Methods: Of the 86 community-dwelling older adults recruited for this study, data from 70 participants were considered valid after an initial screening, during which 16 (18.6%) were excluded due to issues with VR adaptation. Participants were sequentially assigned in a rotating order to 1 of 4 variants (VR/MR×soothing/intense) to balance exposure; however, primary analyses were preplanned to be collapsed across variants, focusing on whole-sample usability and feasibility rather than confirmatory between-group hypotheses. The primary outcome measures included the Game Experience Questionnaire, VRSQ, and objective gameplay logs.

Results: The VR/MR Tai Chi game demonstrated good overall usability and acceptability among the screened participants. Subjective experience was highly positive, with median scores for “positive affect” (median 4.0) and “competence” (median 3.8) being significantly high, whereas the median for “Challenge” (median 1.4) was significantly low (P<.001 for all). Physiological comfort in the postscreening sample was acceptable, with the most common mild symptoms being dizziness with eyes closed (20.0%) and vertigo (18.6%), both of low severity; however, the initial exclusion of 18.6% of participants due to VR discomfort is noteworthy. Therefore, generalizability is limited because the analyzed sample overrepresents older adults who tolerate immersive displays. Accuracy showed significant positive correlations with flow (ρ=0.342) and competence (ρ=0.322), whereas the VRSQ total score was significantly negatively correlated with positive affect (ρ=−0.334, P=.005).

Conclusions: Tai Chi exergames based on immersive technologies offer a feasible and attractive pathway for promoting physical exercise among community-dwelling older adults, particularly within the home environment, supporting the goal of aging in place. As a single, laboratory-based session, the reported satisfaction may partly reflect a novelty effect; therefore, longer-term, home-based follow-ups are needed to assess durability. Analysis of the key usability factors provides guidance for specific design choices, while also indicating directions for future research, such as longitudinal evaluations, extension to more diverse populations, and application in real-world home settings.

Introduction

The trend of people getting older around the world is accelerating. By 2050, there will be more than 2 billion people over the age of 60 years, and older adults will make up a larger share of the world’s population, especially in developing areas [1]. This change in the population puts more pressure on the economy and shows how important programs such as “Healthy

XSL•FO
RenderX

Aging" and letting older people "age in place" are. Regular exercise is very important for healthy aging [2]. It helps keep people healthy, helps them stay independent, makes them feel better mentally, and improves their quality of life [3]. These benefits make exercise a good and useful way to help older people all over the world. However, older adults often face numerous barriers that make it hard for them to participate in traditional exercise programs. These problems include not being motivated, being afraid of falling, and not being able to get to the right facilities [4]. These challenges show that conventional exercise models often fail to meet the emotional and experiential needs of older adults. Recent studies suggest that digitally delivered, personalized interventions, such as programs incorporating wearable technology, remote coaching, and motivational messaging, can significantly improve adherence and reduce fear of falling [5,6]. This points to the need for approaches that improve enjoyment and intrinsic motivation in older adults.

To tackle this issue, immersive exergames that combine virtual reality (VR) and mixed reality (MR) technologies are a viable solution. This research concentrates on the integration of Tai Chi with VR/MR technologies. Tai Chi is particularly suitable for older adults due to its proven efficacy in enhancing dynamic balance and substantially decreasing both the frequency of falls and the fear of falling, which is a significant psychological impediment to physical activity engagement in this demographic [7]. These advantages render Tai Chi a pragmatic and psychologically beneficial approach for enhancing mobility and self-assurance in older adults. VR/MR Tai Chi exergames are meant to be a safe, easy, and fun way to work out at home. These exergames can address many limitations of traditional exercise by providing virtual practice environments that are controllable. They may also boost intrinsic motivation by enhancing feelings of autonomy and competence. Although extended reality technologies hold substantial promise for helping older adults, several challenges remain, such as the high cost of equipment, steep learning curves, and cybersickness. Notably, previous research has emphasized that cybersickness is a frequent and underestimated barrier that may lead to user dropout and restrict broader adoption in unsupervised home settings [8,9]. These usability and safety issues should be addressed before extended reality solutions can be widely implemented among older populations.

Although VR and MR exergames show promise for helping older adults avoid falling, there is insufficient systematic research comparing how different display modes and feedback systems affect this group. Some early evidence suggests that augmented reality, a type of MR, may be better for older adults because it gives them a better sense of their body and space, which makes them feel less likely to fall [10]. This points to a research gap in comprehending the preferences and reactions of older users to various immersive environments. Recognizing the distinct interactive experiences of older adults is essential for effective design, particularly in unsupervised home contexts. Hence, distinguishing between VR and MR modes goes beyond being a mere technical matter; it has direct implications for the safety, comfort, and acceptance of these technologies among older adults using them independently at home.

This work provides evidence to guide the development of immersive health care applications to enable older individuals to practice independently at home, a key component within the "aging in place" plan. With professional guidance lacking within home contexts, intrinsic motivational abilities and efficacy and safety of the game within itself become paramount [11]. Thus, this work's investigation into aspects such as cybersickness and "accuracy-competence paradox" remains a key focal point within this work to aid in determining if such technology can be disseminated and leveraged effectively.

Specifically, this study will seek to answer the following core questions:

1. Overall usability and acceptance: How does age affect subjective experience (eg, "empowerment" feelings), physiological comfort (ie, cybersickness symptom occurrence), and objective interaction efficacy (eg, the "accuracy-competence paradox") while playing the VR/MR Tai Chi game?
2. Internal links between fundamental factors: How does objective gameplay performance (eg, pointing precision) influence subjective psychological experiences (eg, flow, competence)? Do users' physiological symptoms of discomfort affect positive emotions? Are positive emotions correlated to users' inherent traits, such as age?

Through systematic investigation of these questions, this study aimed to contribute empirical evidence to be used in designing immersive health applications among older people [12].

Methods

Ethical Considerations

The study received ethics approval and adhered to guidelines for research involving human participants.

Research Ethics Approval

This study received ethics approval from the Institute of Visual Informatics, Universiti Kebangsaan Malaysia. The approval was granted on July 2, 2024, with the reference number UKM.IVI.600-4/6/P130610.

Informed Consent

All participants provided written informed consent before the start of any experimental procedures. The researchers clarified the study's objectives, methods, possible risks (including cybersickness symptoms), and potential benefits. They also made it clear to participants that they could withdraw from the study at any point without facing any consequences.

Privacy and Confidentiality

All personally identifiable information and harvested data were fully anonymized to ensure respondent privacy. Data were stored securely on a password-protected server, and only central research team staff had access.

Compensation

Participants did not receive any monetary or nonmonetary compensation for their participation. Their involvement in this study was entirely voluntary.

Study Design

Overview

This study was designed as a pilot study using a 2×2 factorial design (display mode: VR/MR×feedback: soothing/intense) to effectively explore the feasibility of varying exergame configurations before a large trial. Participants were sequentially assigned to 1 of the 4 conditions using a rotating 1:1:1:1 schedule upon enrollment. The primary goal of this multicondition design was not to conduct formal hypothesis testing between groups, which would require a much larger sample. Instead, its purpose was to ensure that our usability and feasibility assessment covered a range of potential interaction styles. This approach allows us to identify any major negative outcomes (eg, excessive cybersickness or frustration) that might be unique to a specific condition, providing critical insights for optimizing a single, refined protocol for future, larger-scale home-based studies.

Recruitment, Screening, and Final Sample

A research team initially recruited 86 community-dwelling older people who were capable of living independently, via media such as community promotions at community centers and newspaper advertising locally. Such a process was used to maintain the sample's characteristics closely aligned with those of the target end user group for future home-based VR/MR Tai Chi exergames [13].

In this pilot phase of research, screening led to a dropout of 16 participants (16/86, 18.6% of the original sample) who could not accommodate to the virtual environment or who experienced severe dizziness. Notably, this screening process suggests that the final sample was skewed to some degree to VR tolerance, that is, comprised individuals better predisposed to accommodate virtual environment exposures. This characteristic is relevant in estimating the extent to which the findings generalize to a broader community of older individuals.

We performed an analysis of the 16 participants who were excluded due to a failure to adapt to VR. This group comprised 11 (68.8%) women and 5 (31.2%) men, a gender distribution similar to that of the retained sample. However, a systematic difference was evident in age: 43.8% (7/16) of participants excluded were aged older than 75 years, a proportion more than double that of the sample maintained (15/70, 21.4%). This finding suggests that older age could be a determining factor in intolerance to VR in this population.

Inclusion and Exclusion Criteria

The aforementioned recruitment and screening processes adhered to clearly defined criteria. The inclusion criterion was enrollment of participants aged 60 years and older [14,15]. Exclusion criteria encompassed any known adverse reactions to VR experiences and severe cardiorespiratory or musculoskeletal diseases that would significantly impede participation in the experimental procedures, severe vision loss, and other health conditions unsuitable for the use of immersive devices (eg, vertigo and epilepsy).

Self-report alone was considered insufficient; therefore, a brief experiential screening was recommended before unsupervised use.

Demographic Characteristics, Health Status, and Exercise Habits

Data regarding demographic information, health background, and daily exercise habits were collected from the 70 valid participants using a self-developed "basic information questionnaire." The detailed characteristics are presented in Table 1.

The 70 valid participants included in the final analysis exhibited certain demographic tendencies: they were predominantly female (52/70, 74.29%) and largely comprised "younger" older adults aged 60 to 75 years (55/70, collectively 78.56%). In terms of health status, although a considerable proportion (40/70, 57.14%) self-reported chronic conditions such as cardiopulmonary diseases, they were also individuals who actively managed their health, with a high percentage (66/70, 94.29%) undergoing regular physical examinations. This characteristic of "living actively with illness" suggests that the sample group might hold a more open attitude toward health-promoting interventions, but it also necessitates that such interventions ensure safety and appropriateness.

150 - 160	36 (51)
160 - 170	20 (29)
>170	1 (1)
Weight distribution (kg)	
30 - 40	2 (3)
40 - 50	8 (11)
50 - 60	36 (51)
60 - 70	18 (26)
70 - 80	4 (6)
>80	2 (3)
Self-reported illness status	
No reported cardiopulmonary illness	30 (43)
With cardiopulmonary disease	40 (57)
Regular physical examination	
Yes	66 (94)
No	4 (6)
Weekly exercise frequency	
Exercise daily	66 (94)
Exercise 3 - 5 times per week	1 (1)
Rarely exercise	3 (4)

This pilot group reported very high levels of physical activity, such that the vast majority (66/70, 94.29%) used a daily exercise regimen and participated in a broad range of activities, such as walking, square dancing, and Tai Chi. Overall, this sample is a subgroup of predominantly female, aged between 60 and 75 years, who exercise on a regular basis, approach health care management in an active manner, and have good tolerance to VR environment (as a consequence of preliminary screening that eliminated 18.6% (16/86) who reported dizziness while experiencing VR). These characteristics are relevant to explain why this sample reports such a high level of interest and positive response to the VR Tai Chi game. While these same characteristics will limit how widely the investigation can be generalized to broader older groups, such as those who exercise less or who possess poorer VR tolerance.

VR Tai Chi Exergame and Experimental Equipment

Intervention and Equipment

The VR Tai Chi exergame used in this study was designed for older individuals. Its fundamentals can be equally analyzed using the MDA (mechanics, dynamics, and aesthetics) approach [16,17].

Mechanics

It guides users through 16 selected Tai Chi exercises. It is interactive via a head-mounted display (HMD) and hand

XSL•FO
RenderX

controllers reacting to head and hand movements. Users must synchronize their pose to 3 hotspots (head and both hands) provided in the on-screen instruction. A movement only proceeds after a successful success window, and a movement can save up to 3 hotspot holds (left hand, right hand, and HMD) before advancing. If users complete the entire sequence of 16 movements ahead of schedule, they will repeat the sequence immediately, beginning with the first movement. This generous success condition was a conscious design choice intended to provide a sense of accomplishment. It has 2 display modes, VR and MR, and can come equipped with either soothing or upbeat music and vibration feedback. Additionally, players can skip the current move or pause at will during gameplay.

Dynamics

Playing involves players' efforts at mirroring exemplified postures, receiving immediate multisensory feedback, and regulating progression during a trial lasting a maximum of 5 minutes. One key dynamic reveals itself in the gamification mechanics: participants can choose to meet only the bare minimum threshold needed for progress ("single hotspot for 3 s") to progress effortlessly or shoot for immaculate matching across all hotspots to progress to a higher "accuracy" level. This allows participants to balance challenge against victory on a preference and ability level. It is this dynamic that later results regarding user experience build upon.

Aesthetics

The game aims to evoke multidimensional aesthetic experiences, such as a "sense of competence" from successfully completing movements, a "sense of challenge" from improving performance, feelings of "relaxation or motivation" engendered by different musical feedback, and a "sense of immersion" provided by the VR/MR environments. These subjective experiences are intended to encourage physical exercise in older users in an engaging manner, and their achievement was assessed using the Game Experience Questionnaire (GEQ) [18,19]. Design philosophy appears to be interested in desirable affective effects and perceived competence corresponding to self-determination theory principles, such that satisfying the need for competence can improve intrinsic motivation.

Experimental Equipment

This study used the Meta Quest 3 (Meta Platforms, Inc) HMD for presenting both VR and MR conditions [20,21]. The choice of specific, commercially available hardware, such as the Meta Quest 3, enhances the transparency and potential replicability of the study.

Activity Area

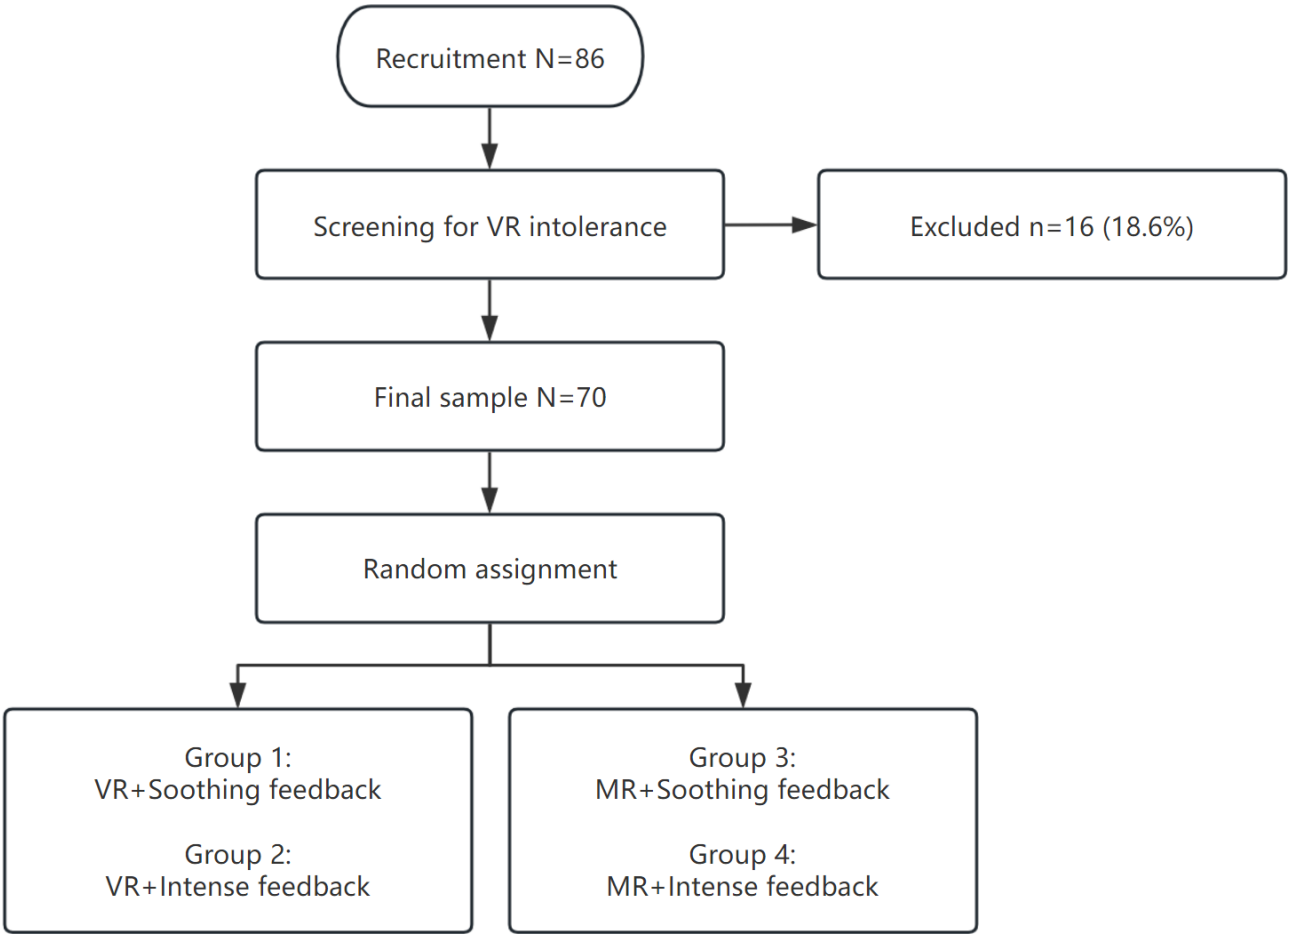
Exercise took place in an area of approximately 5 m^2, comparable to a typical living room, to ensure home feasibility and safety [22,23].

Experimental Procedure

Group allocation followed a prespecified rotating schedule (1:1:1:1) prepared before data collection; participants had no influence on assignment.

Experimental Preparation and Adaptation Training

When participants arrived at the laboratory, they first completed an informed consent process and a general information questionnaire. Next, a short adaptation training session was completed to enable participants (and especially those without any training in VR/MR) to become familiar with both the immersive environment and how to use the equipment. This adaptation step is a valuable step in acclimating older adults to new technology, such as VR, because it can be used to help reduce technology anxiety and achieve a minimum baseline level of comfort and competence in how to use the equipment before beginning the intervention [24,25].



Exergame Intervention

A visual summary of the participant flow and 2×2 design (VR/MR×soothing/intense) appears in Figure 1. This approach ensured that group sizes remained balanced and that potential confounding factors, such as personal preference or prior experience, were minimized. Participants followed a fixed 16-movement sequence; each 5-minute session could end before all movements were finished due to the time limit or restart at the first movement if the sequence was completed early. After this orientation, each participant performed 2 formal 5-minute gameplay sessions under their assigned experimental condition (VR/MR×soothing/intense feedback). The better performance out of the 2 sessions was recorded for analysis. All single-session metrics (eg, posture, accuracy) were computed per session; the higher of the 2 sessions was retained for analysis. This procedure ensured that every participant experienced the complete set of movements while also minimizing the impact of first-trial unfamiliarity on the final outcome [26].

VR provided a fully virtual scene; MR overlaid guidance onto the real room (Figure 2). "Soothing" used gentle cues; "intense" used more salient multimodal cues; task rules were identical [27].

Safety and Supervision

The experimental protocol was observed and supervised in a one-on-one capacity by trained researchers to be able to control and respond to any new sensory stimulus or sensation of disorientation. Subjects were informed they could withdraw from participation at any time if they experienced any type of discomfort or abnormal level of fatigability. Such precautions are particularly relevant in research among older individuals and potentially disorienting technologies such as VR. To regulate fatigue and potential dizziness between sessions, exposure was scheduled in 2 approximately 5-minute sessions, and participants could rest and pause whenever needed.

XSL•FO
RenderX

This was a single-visit, supervised laboratory study, consisting of the 2 gameplay blocks described earlier, with no home-based or longitudinal follow-up. Postsession questionnaires captured immediate responses; repeated exposures to control for novelty were not implemented.

Outcome Measures

Overview

This research took a multidimensional perspective to assess usability and feasibility, where primary data were drawn from:

1. GEQ [18]: An adapted 32-item version of the basic module of the GEQ (skipping item 3 in the original 33-item) was used to measure seven aspects of game experience: flow, competence, positive affect, negative affect, tension/annoyance, challenge, and sensory/imaginative immersion. Item 3 ("I was interested in the game's story") was excluded from the component immersion because our own game did not have a story. Component flow and competence scores were of particular importance to intrinsic motivation. Component scores were calculated as the means of their items on a scale ranging from 0 to 4.
2. The Virtual Reality Sickness Questionnaire (VRSQ) [28]: It was used to detect and quantify physiological symptom indicators of distress that users may experience while controlling VR/MR hardware, such as eye strain, nausea, headache, disorientation, and dizziness. It is a 9-item measure scored on a 0- to 3-point scale, and the VRSQ total score was calculated as the mean of these items, which provided a final score between 0 and 3. It has been shown to be a valid measure in the original investigation of the VRSQ for cybersickness because it was very highly correlated with existing motion sickness indices.
3. Objective game performance logs: Primary objective metrics were derived from automatically collected gameplay data provided by the game's backend system. They were "game score," "movement accuracy," "mean time per round," "task completion rate," "movement level (extracted from hand movement and head movement trajectory)," and "cumulative game time." These data were direct evidence to substantiate the assessment of whether users could use the game in an efficient manner.

We took an integrated approach, triangulating subjective experience (GEQ), physical comfort (VRSQ), and actual performance (game logs) to provide a sound foundation for a unified and rigorous assessment of the game's usability and feasibility.

We adopted a target engineering level of 80% movement precision to be used as an internal and exploration benchmarking.

Psychometric Properties of Outcome Scales

Internal consistency was evaluated on the present sample using Cronbach α and Spearman-Brown split-half coefficients. As several components (tension/annoyance, challenge, and negative affect) exhibited pronounced floor effects with near-zero variance, internal consistency coefficients for these scales were not estimable; for these, we report distributional summaries only. Reliability results for all measures are presented in Table 2. Per the GEQ guidelines, we dropped the story-related immersion item (item 3), leaving 5 items for this component; reliability values in Table 2 reflect this adapted set.

Table . Internal consistency of Game Experience Questionnaire and Virtual Reality Sickness Questionnaire (VRSQ) subscales.

Measure	k (items)	Cronbach α	Split-half (Spearman-Brown)
Sensory and imaginative immersion	5[a]	0.657	0.583
Flow	5	0.546	0.539
Tension/annoyance	3	N/A[b] (floor effect)	N/A[b] (floor effect)
Challenge	5	N/A[b] (floor effect)	N/A[b] (floor effect)
Negative affect	4	N/A[b] (floor effect)	N/A[b] (floor effect)
Positive affect	5	0.86	0.85
VRSQ total	9	0.782	0.689

[a]Game Experience Questionnaire core scored 0 - 4; immersion used items 12, 18, 19, 27, 30 (item 3 removed). Split-half denotes Spearman-Brown.

[b]N/A indicates nonestimable due to floor effect (near-zero variance).

Operational Definitions

The key game performance indicators were defined as follows: score was the system-generated composite points; accuracy (%) was the proportion of frames where hotspots were within tolerance; and posture (count) represented the total number of successful hotspot holds. Per movement, the player aligns the left and right controllers and the HMD with 3 predefined hotspots; holding any hotspot for ≥3 seconds is counted as one successful hotspot hold. The 16-movement sequence loops whenever it is completed before the 5-minute limit; therefore, posture is an open-ended count (no fixed cap) within the time window. For interpretability, 48 holds correspond to one full loop (16 movements×3 hotspots).

Data Preparation and Statistical Analysis

Overview

Consistent with the a priori plan, no confirmatory between-condition hypothesis testing (main effects or interaction) was conducted. To enhance transparency,

XSL•FO
RenderX

per-condition descriptive summaries (medians and IQRs for the 4 cells) are provided in Table 3.

Table . Per-condition descriptive statistics.

Outcome[a]	Group A: VR[b] soothing (n=17), median (IQR)	Group C: VR intense (n=19), median (IQR)	Group B: MR[c] soothing (n=17), median (IQR)	Group D: MR intense (n=17), median (IQR)
Positive affect	4 (3.8 - 4)	4 (3.8 - 4)	4 (3.4 - 4)	4 (3.8 - 4)

Data Cleaning

Handled sporadic missingness via median imputation only; no multiple imputation was performed [29].

Analysis Plan

Data normality was examined using the Shapiro-Wilk test [30,31]. Most key variables were found not to be normally distributed (Table 4). Nonparametric methods were consequently unanimously selected across hypothesis testing to yield robust and valid inferences. That is, median dimension scores on the GEQ were compared against a theoretical midpoint score of 2.0 using 1-sample Wilcoxon signed-rank tests. Wilcoxon tests correspondingly compared the median against a theoretical score of 0 on the VRSQ symptom scores (rated 0 - 3) to determine whether symptoms were distinctly present. With the exploratory nature of this item-level analysis, no adjustment for multiple comparisons was made on these 9 tests. Spearman ρ was used to examine associations between key factors. A level of significance was predetermined at an α of .05.

Overall Usability Analysis

Descriptive statistics summarized the GEQ, the VRSQ, and game log indicators as median (IQR) [19,32].

Results

Participant Flow and Analysis Overview

In total, 86 older adults were recruited; 16 (18.6%) discontinued during acclimation due to intolerance, and data from 70 (81.4%) participants were analyzed. Participant flow and group allocation are shown in Figure 1. Per-condition medians (IQRs) for the 4 cells are available in Table 3.

Scale Reliability

Internal consistency was good for positive affect (α=.860; split-half=0.850) and acceptable for the VRSQ total (α=.782; split-half=0.689). Competence (α=.667; split-half=0.750) and sensory/imaginative immersion (α=.657; split-half=0.583) were in the moderate range, whereas flow was borderline (α=.546; split-half=0.539). Coefficients for tension/annoyance, challenge, and negative affect were not estimable due to floor effects (near-zero variance; Table 2).

Before the main analysis, the assumption of normality for the key-dependent variables was assessed using the Shapiro-Wilk test. The results are detailed in Table 4. While a few indicators did not significantly deviate from normality (eg, *challenge*, *P*=.16; game log *score*, *P*=.06; *posture*, *P*=.06; *movement distance (m)* *P*=.29), the majority of variables substantially deviated (eg, *accuracy*, *P*=.032; most GEQ/VRSQ dimensions, *P*<.001). Therefore, to maintain consistency and ensure robust inference across all analyses, nonparametric procedures were uniformly adopted.

Descriptive Statistics

We reported per-condition descriptive statistics for key outcomes across the 2×2 design (VR/MR×feedback intensity). As planned, no between-condition inferential tests were conducted; values are summarized as median (IQR) for interpretability with nonnormal distributions (see Table 3 for the 4 cells).

XSL•FO
RenderX

Overall Usability and Acceptability of the VR Tai Chi Game

To evaluate the overall usability and acceptability of the VR Tai Chi game for older users, this study collected and analyzed survey data from GEQ, VRSQ, and objective game performance log data.

Subjective Game Experience (GEQ)

As reflected in Table 5, subjective gaming experience as measured using the GEQ was highly positive. The median levels on positive aspects like "positive affect" (median 4.0), "flow" (median 4.0), "competence" (median 3.8), and "sensory/imaginative immersion" (median 3.8) all far surpassed the theoretical midpoint of the scale (P<.001 in all). Medians on negative aspects such as "tension/annoyance" (median 0) and "negative affect" (median 0) were below midpoint to a statistically significant degree (P<.001 in both). The median level on "challenge" was low to a statistically significant degree as well (median 1.4, P<.001).

Table . Descriptive statistics and one-sample Wilcoxon signed-rank test for Game Experience Questionnaire dimensions.

Dimension	Values, median (IQR[a])	*P* value[b]
Competence	3.8 (3.2 - 4)	<.001
Sensory/imaginative immersion	3.8 (3.2 - 4)	<.001
Flow	4 (3.2 - 4)	<.001
Tension/annoyance	0 (0 - 0)	<.001
Challenge	1.4 (1 - 1.6)	<.001
Negative affect	0 (0 - 0.25)	<.001
Positive affect	4 (3.8 - 4)	<.001

[a]Game Experience Questionnaire scores were rated on a 0 - 4 scale.

[b]*P* values reflect a one-sample Wilcoxon signed-rank test comparing the median score against the theoretical midpoint of 2.0.

Physiological Comfort (VRSQ)

The physiological comfort of the screened participants was assessed using the VRSQ. Overall, the incidence and severity of reported symptoms were low. Detailed item-level medians, statistical test results, incidence rates, and severity scores for reporters are presented in Table 6. The *P* values in the table should be interpreted as exploratory signals of which symptoms were most frequently endorsed, rather than as confirmatory hypothesis tests.

Table . Overall Virtual Reality Sickness Questionnaire main symptom statistical analysis.

Symptom item	Median	*P* value	Incidence rate (%)	Mean severity for reporters
General discomfort	0 (0-0)	.08	4.3	1
Fatigue	0 (0-0)	.04	7.1	1.4
Headache	0 (0-0)	.16	2.9	1
Eye fatigue	0 (0-0)	.002	15.7	1.273
Difficulty concentrating	0 (0-0)	.18	2.9	1.5
Head fullness	0 (0-0)	.01	10.0	1.286
Blurred vision	0 (0-0)	.01	10.0	1.143
Dizziness when closing eyes	0 (0-0)	<.001	20.0	1.214
Dizziness/vertigo	0 (0-0)	<.001	18.6	1

Game Performance

A look at the in-game objective performance data listed in Table 7 reveals wide individual variations among older adult participants. Participants demonstrated a fluid interaction rhythm with a median time spent per action of 6.4 seconds. However, large variations across major indicators were apparent due to wide IQRs seen across score and accuracy measurements (Table 7). Median movement accuracy was 68.5% (IQR 54.2% - 82.3%). Scores higher than 48 indicate that participants completed more than a single loop (or accrued numerous hotspot holds within a movement) within a 5-minute period.

XSL•FO
RenderX

Table . Key game performance indicators.

Indicator	Values, median (IQR)
Score	96 (70.25-133.5)
Posture[a] (count; no fixed cap, 48=one loop)	47 (39.75-55)
Accuracy (%)	68.5 (54.2 - 82.3)
Average time spent (s)	6.4 (5.5-7.5)
Movement distance (m)	273.5 (231.5-317.25)

[a]Posture counts the total hotspot holds within the retained 5-min session (best-of-two). The 16-movement sequence loops if completed early.

Correlation Analysis of Key Usability Factors

Correlation between major usability factors was examined using Spearman rank correlation analysis, and the results were presented in Table 8. Flow was significantly positively correlated with accuracy (ρ=.342; *P*=.004), and competence was significantly positively correlated with accuracy (ρ=.322; *P*=.007). VRSQ total score was significantly inversely correlated to positive affect (ρ=−0.334; *P*=.005). Competence was not significantly correlated with age (ρ=−0.179; *P*=.14).

Table . Spearman ρ correlation analysis (n=70).

Hypothesis	Variable 1	Variable 2	Correlation coefficient	*P* value
H1	Flow	Accuracy	0.342[a]	.004
H2	VRSQ[b] total score	Positive affect	−0.334[a]	.005
H3	Accuracy	Competence	0.322[a]	.007
H4	Age	Competence	−0.179	.14

[a]Correlation is significant at the 0.01 level (2 tailed).

[b]VRSQ: Virtual Reality Sickness Questionnaire.

Discussion

Subjective Experience Profile: High Perceived Competence With Low Perceived Challenge

As presented in Table 5, medians for positive affect, flow, and competence were above the scale midpoint, whereas challenge was markedly below (all *P*<.001). We observe a distinct user experience profile: high perceived competence and low challenge. For older adults who begin using exergames at home, this combination may be most relevant in reducing frustration and promoting first-time engagement [33,34]. At the same time, future research should gradually increase difficulty in an adaptive manner such that motivational support is balanced against accurate skill acquisition in free-living situations [35,36].

The internal consistency profile reveals adequate internal consistency on positive affect and satisfactory consistency on total VRSQ and moderate-to-borderline level in several components of the GEQ. Borderline α on flow is likely owing to constrained variance and the brevity and heterogeneity of item material in this first-stage application involving a single session; such findings on these components should consequently be interpreted correspondingly cautiously.

Physiological Comfort (VRSQ): Acceptability in Screened Sample and Potential Challenges

Regarding physiological comfort, the VR Tai Chi game demonstrated good tolerability within the screened participant sample, but this conclusion must be interpreted with caution [37]. The initial exclusion of a high 18.6% of recruits due to inability to adapt or strong VR-related sickness signifies a considerable bias in the VR tolerance of the final analyzed sample. Consequently, the currently observed low levels of cybersickness might overestimate the game's physiological comfort among the general older adult population. Although within the screened "more tolerant" sample, the average reported levels and perceived severity of various physiological discomfort symptoms (mainly mild "dizziness when closing eyes," "vertigo," and "eye fatigue") were low, 15% to 20% of participants still reported these mild symptoms [38]. This implies that cybersickness continues to be a primary barrier that has to be cleared ahead of VR technology deployment to older age categories. This 18.6% exclusion rate translates directly to current technological or design limitations in making VR universally comfortable among older adults and places a realistic limit on such interventions' immediate impact absent substantive improvements. For plans to promote such VR/MR Tai Chi games to the home environments of community-dwelling older adults, this high initial exclusion rate reveals key practical challenges. In home settings lacking immediate professional guidance, effective user screening, clear adaptation training guidelines, and easy-to-operate personalized comfort settings (eg, mode switching, visual effect adjustments) will be prerequisites for ensuring user safety and continued use [15,39]. To mitigate cybersickness at home, key strategies include starting with MR or low-vection scenes, using brief (≈5 min) sessions, ensuring proper headset fit with stable frame rates, and avoiding artificial locomotion. Furthermore, even mild symptoms, when experienced during unsupervised long-term home use, could affect user experience and adherence, thus

XSL•FO
RenderX

necessitating continuous design optimization to minimize discomfort as much as possible [40].

Accuracy-Competence Paradox

Despite a median movement accuracy of 68.5% (IQR 54.2% - 82.3%), which was below our predefined exploratory benchmark of 80%, participants reported high perceived competence (median 3.8), reflecting a rule set that credits partial hotspot matches (≥1/3 for ≥3 s). This system focuses on older users' positive affective experiences to improve long-term exercise adherence while reducing frustration and elevating confidence but without concomitant increases in stricter movement norms. However, this dilemma positions an additional discussion regarding such a game's effectiveness as a very precise device for training within corresponding trade-offs between motivation and skill fidelity.

The permissive rule (≥1 hotspot for ≥3 s) retains motivation but tends to overcredit partial matches. Future iterations will include adaptive multipoint matching and more informative corrective cues to put verifiable and perceived competence into alignment while retaining engagement [41]. It presents a foundational tension: the probable discrepancy between perceived benefit/competence and verifiable physiological/skill-based benefit [42]. While perceived competence is central to adherence, if it is not adequately correlated to correct movement execution, long-term benefit to health can be undermined and signal a need for "verifiable competence" feedback loops that remain motivating. For a mass market product like this, selling independent home-based exercise to older people, such a motivational design can serve to buffer against users experiencing "anxiety alone" if having trouble and will invite continued participation [35]. It does raise a valuable question, though: without professional instruction in a home environment setup, how can it be ensured that movements/movement effectiveness is appropriate? Therefore, future iterations of the gameplay might involve implementing tiered success criteria or optional stepwise movement guidance and feedback modules such that users can reach a personally optimal balance between enjoying playing the game and checking movement correctness in accordance with their own needs [43].

Insights From Correlation Analysis of Key Usability Factors

The interplay between gameplay performance, user comfort levels, and subjective experience yields direct design recommendations for successful home-based exergames. It was found that "accuracy" was strongly positively correlated with "flow" and "competence." This indicates that more precise movement performance can guide users into a state of deep, immersive focus, forming a positive feedback loop of "successful execution → flow experience → enhanced participation." This also offers a more nuanced interpretation of the "accuracy-competence paradox": the game provides a high baseline of perceived competence for all participants through its lenient judgment, and on top of this, higher accuracy leads to an even stronger sense of competence, cleverly balancing universal motivation with individual rewards. This suggests that users do derive satisfaction from objective mastery; while a safety net of easy success is important, completely removing skill development or clear performance feedback might make the game less engaging long term for some [44,45]. Furthermore, the analysis also highlighted the impact of users' individual states: the degree of physiological discomfort (VRSQ total score) was significantly negatively correlated with "positive affect." This warns that even mild discomfort can negatively affect older users' enjoyment, which is particularly critical in home settings lacking immediate help, thereby re-emphasizing the necessity of minimizing cybersickness risks [46]. Finally, a positive signal was that the study found no significant relationship between "age" and "competence," suggesting that the game possesses good age inclusivity within the 60 to 75 years age group, and users' perceived competence did not systematically diminish with increasing age. This has positive implications for its promotion among diverse community-dwelling older adult groups, although caution is advised when generalizing this conclusion to very old adults [39,47].

Limitations

A number of limitations can be applied to this work. A selection bias in this sample exists since a large number of preliminary participants were lost due to side effects associated with VR, and the resulting group was predominantly female, younger, and physically active. This extremely high level of preexisting physical activity may not be characteristic among this typically sedentary population that such home-based exergames aim to reach but may not serve adequately and hence might limit how much our findings generalize to less active older individuals in this regard. This may inflate physiological comfort but restrict findings' generalizability to a wider range of heterogeneous older people, especially older individuals who may be less technology-savvy or physically constrained. Finally, a single, brief VR intervention cannot eliminate any novelty effects or long-term adherence or long-term effects on health and retention of skill in a naturalistic home environment.

Future Direction

Future research will need to proceed beyond virtual-simulated laboratory settings to home-based settings and use strategies such as Ecological Momentary Assessment to assess long-term use, adherence, skill learning, and actual resultant health effects. It will be important to diversify the samples of participants to include a broader age range, a wider range of health statuses, and a wider range of technology backgrounds to assess the generalizability of such findings. Studies will need to work toward developing adaptive VR systems capable of shifting difficulty and feedback in a dynamic fashion, dependent upon user progress. We will assess fixed versus adaptive thresholds and include per-user calibration routines within a home-based study.

This will aid in connecting, keeping participants motivated, and ensuring appropriate skill acquisition to promote successful unsupervised home-based practice. Although this current system used the Meta Quest 3 headset and hand tracking, future work could include alternative systems (eg, Xbox/Kinect) or outward-facing full-body tracking systems to better assess posture in unsupervised home-based settings. Ecological Momentary Assessment is described as a future longitudinal

XSL•FO
RenderX

assessment methodology to assess adherence and in-the-wild engagement but not a single-session assessment of emotion.

Conclusions

This study demonstrates that well-designed VR/MR Tai Chi exercises can be a realistic and inspiring alternative exercise among community-dwelling older adults, supporting aging in place initiatives. A self-reported profile of high competence but low challenge perception implies early initiation but will need variable difficulty to maintain motivation in alignment with acuity of therapy for long-term use at home. Although physiologically tolerable in this prescreened population, a high entry exclusion rate due to cybersickness is a major barrier to wider use. A future direction to wider use success is a balance between motivational design of content and therapy acuity and modifications to system usability and comfort to provide net health gains in homeowner unsupervised use.

Acknowledgments

The authors are very grateful to the older residents of Chang'an Community in Changde City, Hunan Province, for participating in the experiment.

Funding

Funding was partly supported by a research grant from Universiti Kebangsaan Malaysia (GUP-2019-066).

Data Availability

The datasets generated and/or analyzed during this study are not publicly available due to participant privacy and confidentiality considerations and institutional ethics restrictions. Deidentified data are available from the corresponding author upon reasonable request for noncommercial research purposes, subject to approval by the relevant ethics committee where applicable and the signing of a data use agreement. The analysis code used in this study is available from the corresponding author upon reasonable request.

Abstract

Background: Cognitive impulsivity is a multifaceted construct associated with symptom severity, functional impairment, and poor quality of life in eating disorders (EDs) and mental ill-health. However, objective assessment of cognitive impulsivity is piecemeal and complex, with many assessment tools lacking psychometric evaluation and ecological validity. Furthermore, validated assessment tools are rarely perceived to be engaging or meaningful by individuals who complete them, limiting their utility in research and forming a barrier to clinical translation. Thus, although cognitive impulsivity predicts treatment engagement and outcomes, it is rarely assessed or addressed in a clinical context.

Objective: We aimed to redesign and evaluate the Cognitive Impulsivity Suite (CIS), a validated gamified assessment battery of cognitive impulsivity, through user-centered co-design, agile game development, and user-centered evaluation. This collaborative study partnered researchers with individuals with lived experiences (LEs) of EDs and commonly co-occurring mental ill-health, and game development experts.

Methods: In a sequential mixed methods design, we first defined user requirements through inductive thematic analysis of data from 2 focus groups incorporating 7 individuals with LE of EDs and commonly co-occurring mental health conditions (mean age 27.6, SD 7.03 y; 4 women, 2 men, 1 nonbinary), researchers, clinicians, and technology professionals. Agile game development was achieved through 6-week-long sprints, involving game developers and a play-testing team of researchers. During LE evaluation, we collected and analyzed data from an expanded sample (n=18; mean age 30.5, SD 6.56 y; 12 women, 3 men, 2 nonbinary), using a pragmatic blending of qualitative and quantitative research methods. This included inductive and deductive thematic analysis of “thinking aloud” data, descriptive statistics, and ANOVA tests of the Game User Experience Satisfaction Scale, short version (GUESS-18) surveys.

Results: We co-designed guiding principles and ideas for aesthetics, story concepts, and gameplay features, which closely aligned with leading theories of psychological well-being, clinical evidence concerning ED recovery, and gamification frameworks. Qualitative evaluations of the new tool, CIS *Papillon Park*, showed user engagement and motivation were driven by opportunities for autonomy, personal accomplishment, and simulated interpersonal relationships, aligning with approaches to gamification based on self-determination theory. In quantitative evaluation, a mean GUESS-18 composite score of 45.9 (SD 9.85) showed CIS *Papillon Park* achieved sound overall user satisfaction, with subscale scores revealing strengths in usability, narrative, visual and audio aesthetics, and personal gratification.

Conclusions: The contributions of this study are grounded in its integration of user-centered co-design and evaluation, agile game development, and theory-driven approaches to cognitive assessment and gamification, to redesign and evaluate a validated online task battery. The resulting CIS *Papillon Park* combines appealing aesthetics, gamification elements that address cognitive, emotional, and social needs, and accessible playing experiences, which maximized user satisfaction and engagement while prioritizing psychological safety. Next steps involve psychometric evaluation and dissemination.

Introduction

Cognitive impulsivity is a multifaceted construct that describes rapid, unplanned reactions without sufficient regard for their potential consequences, which arise from alterations in multiple processes, including attentional control, reflection, and feedback monitoring or shifting [1-3]. Distinctive patterns of cognitive impulsivity are well-documented characteristics of eating disorders (EDs) [4-8]. Furthermore, similar patterns are observed in conditions that commonly co-occur with EDs, such as mood and anxiety disorders, obsessive-compulsive disorder, substance and behavioral addictions, and attention-deficit/hyperactivity disorder [9-14]. Although causal pathways remain uncertain, elevated cognitive impulsivity has been shown to predict future onset of these disorders [15], to become more pronounced with illness duration [16], and to predict treatment outcomes [17]. Furthermore, research indicates greater severity of cognitive dysfunction in EDs is associated with symptom severity, functional impairment, and poorer quality of life [18,19]. Importantly, objective assessment of cognitive impulsivity has improved our understanding of shared and unique risk, maintenance, and treatment response mechanisms across EDs and commonly co-occurring conditions [20-24]. Nomothetic assessment of cognitive impulsivity has also facilitated the identification of novel treatment targets and neurocognitive interventions, while idiographic assessment may help identify which individuals will most benefit from those treatments [25-30]. As such, incorporating objective assessment of cognitive functioning in clinical assessment, diagnosis, and treatment planning may offer an opportunity to bridge critical treatment gaps, and help us to better understand and respond to complex clinical phenomena, such as diagnostic crossover, heterogeneity, and comorbidity [31-33]. However, despite persistent calls for this translation, objective assessment of cognitive impulsivity remains absent from routine clinical practice [34,35].

Specific barriers have been identified that limit the research impact and translation of cognitive impulsivity assessments. The first concern is the quality and quantity of existing tools, whereby many measure discrete facets of cognitive impulsivity and fail to predict real-world impulsive behaviors [36], and lack robust psychometric or normative evaluation [24,37-41]. Furthermore, the sheer array of tools, paradigms, and analysis methods creates onerous administration for clinicians and researchers, and limits replicability, comprehensiveness, and comparison [42,43]. Finally, a few of the evidence-based tools are well-accepted or engaging to users, leading to performance invalidity [44-46], limiting research participation and uptake in clinical or self-assessment contexts [47-53]. One approach to address these barriers is gamification—the process of creating opportunities for subjective value [54] through the introduction of game-like elements and mechanics [55]. Central to this approach is that gamification activates intrinsic motivational processes, thus drawing on self-determination theory, which posits human behavior is motivated by needs for competence, autonomy, and relatedness [56]. Gamification also reflects principles from other influential theories and frameworks, including social learning theory, social cognitive theory, behaviorism, and flow [57]. Gamification elements may therefore target a range of mechanisms to strengthen intrinsic motivation—cognitive (eg, achievement, progression, and mastery), emotional (eg, enjoyment, satisfaction, and immersion), or social (eg, collaboration and teamwork) [58,59]. Evidence suggests these can be achieved through various "gameful affordances" [54], for example, decomposing demanding activities into clear, achievable subtasks; creating meaning through narrative, characters, and storytelling; providing feedback, rewards, and visible indicators of progress; enabling exploration and customization; including teammates and social supports; and calibrating difficulty to optimal levels for each player [58-61]. Together with game design elements, such as aesthetic appeal, these in turn foster the desired player behavior or outcome, such as long-term user engagement, satisfaction, and consistent effort [57,62-66]. The Cognitive Impulsivity Suite (CIS) is an online task battery that was designed using these principles [3]. The CIS comprehensively assesses key cognitive processes associated with impulsive behaviors in an integrated environment, featuring a cohesive "Wild West" story and visual design. Multiple mechanisms are assessed in a single session, allowing outcomes to be analyzed and interpreted in a holistic manner, while using gamification to maximize consumer engagement [67-69]. Research has demonstrated this integrated task structure to be valid and reliable in assessing cognitive impulsivity in clinical and community samples, whether administered online or in-person [3,70,71]. However, it has also highlighted opportunities to broaden the reach and enhance the impact of the tool, particularly by advancing its clinical translation, and to improve user satisfaction, including for those with lived experience (LE) of EDs and commonly co-occurring conditions [72,73].

Lack of input from users is a second well-documented barrier limiting the research impact and clinical translation of cognitive assessments and similar technology-enabled tools [74-78]. In response, there is growing acceptance of the need to meaningfully engage users throughout the design, implementation, and evaluation of mental health interventions [79,80], service improvements [81,82], and priorities and processes for research [83-86]. Human- and user-centered design approaches to these health innovations, which prioritize user needs and iterative development processes, have been shown to maximize their usability and satisfaction, and support the translation of evidence-based innovations from research to practice [87-89]. Similarly, co-design approaches, which incorporate multiple stakeholders, including users with LE, can help to maximize the relevance and benefits of health innovations for those users [90,91], promote behavior change [92], support empowerment, uptake, and engagement [93,94], and reduce waste [95,96]. However, although emerging research suggests user-centered and lived-experience informed co-design is well suited to developing and improving cognitive assessment tools, this remains rare [78,97-99]. Additionally, though usability and user satisfaction are recognized as critical to long-term uptake and translation of health innovations, few gamified assessments or interventions are evaluated on this basis [42,88,100].

XSL•FO
RenderX

Our aims for this study were to redesign the CIS and to evaluate user satisfaction, using a collaborative sequential mixed methods co-design framework, informed by both evidence and experience [89,101]. Specifically, our researchers synthesized research evidence and stakeholder feedback to identify the need to reimagine the CIS and to ensure it retained its validated scientific structure (ie, the same cognitive constructs would be assessed in the same manner). Individuals with LEs would co-design guiding principles and ideas for game concepts and features through focus groups, alongside technology experts and researchers (refer to Ideation and Design Phase section), and would leverage their LEs to test and evaluate the new product (refer to Evaluation Phase section). Clinicians would cofacilitate focus groups and provide guidance to researchers to support the psychological well-being of participants. Technology experts would produce the new games through an iterative agile development process in close collaboration with researchers (refer to Production Phase section).

Methods

Overview

We used a sequential mixed methods co-design approach to reimagine the CIS assessment tool [102,103]. We adopted a pragmatic paradigm to achieve our objectives [104], centering users with LE as key informants at critical stages of the design process to maximize usability and satisfaction with the assessment tool [87], integrating researcher perspectives to retain the mechanistic structure of the original CIS games [101], and acknowledging the resource-limited context [89,92]. As such, our methodology adopts a framework that combines user-centered approaches to specifying requirements and evaluating the design, with rapid, low-cost production [105-107]. Here, we define co-design as a participatory process in which stakeholders with various forms of relevant expertise collaborate to address a problem concerning a system or tool [108-110]. This methodology was driven by an ethical commitment to elevate the voices of individuals with LE who will be most impacted by our research [111,112]. Furthermore, the research team values the deep experiential insights and "practical knowing" that can be accessed through participatory inquiry and researcher reflexivity, while also endorsing a critical realist perspective that values quantitative measurement of psychological phenomena [113]. Given this standpoint and our research goals, we adopted a thematic analysis (TA) approach to qualitative data analysis, a family of analytical methods that centers participant perspectives, and that acknowledges the active role of the researcher [114-116].

Details of research designs, participants, data collection, and data analysis for each phase (ideation and design, production, and evaluation) are reported below according to American Psychological Association mixed methods journal article reporting standards [117].

Ideation and Design Phase

Research Design Overview

The qualitative ideation and design phase aimed to specify user requirements and produce a detailed design brief to guide the reproduction of the CIS. This was conducted through 2 focus group co-design sessions, which incorporated individuals with LEs of EDs and general mental health concerns, researchers, clinicians, and technology professionals. Our LE co-design approach in this phase was informed by the Australian Eating Disorder Research and Translation Center, which funded the production and evaluation phases of this project [86,118], and by user-centered design principles for eHealth and serious games [87,107,119].

Ideation and Design Study Participants

Researcher Description

The research team includes a PhD candidate with experience in qualitative and quantitative research, psychological assessment, and software development life-cycle (EC), a clinician-researcher with experience in EDs, addiction, and trauma (AA), a psychologist (LH), and a researcher with experience in qualitative and quantitative research and measurement development (CM). Noting researcher reflexivity and self-reflection as a critical aspect of reflexive TA [120-122], the research team reflected on their positionality and perspectives relevant to the research objectives and aimed to faithfully represent the user requirements and design preferences identified from this phase. Researcher identity and positionality statements are provided in Table S2 in Multimedia Appendix 1.

Participants

A total of 7 individuals participated in the focus groups. Participant characteristics are reported in Table 1. While there is no universally agreed-upon sample size for TA research [123,124], this sample size was deemed practical to manage [125] and sufficient to achieve the research goals based on previous research [78]. Importantly, we aimed to produce one acceptable solution to our identified research problem, rejecting the concepts of a single correct solution or "data saturation," which do not form part of TA approaches to qualitative inquiry [121,126].

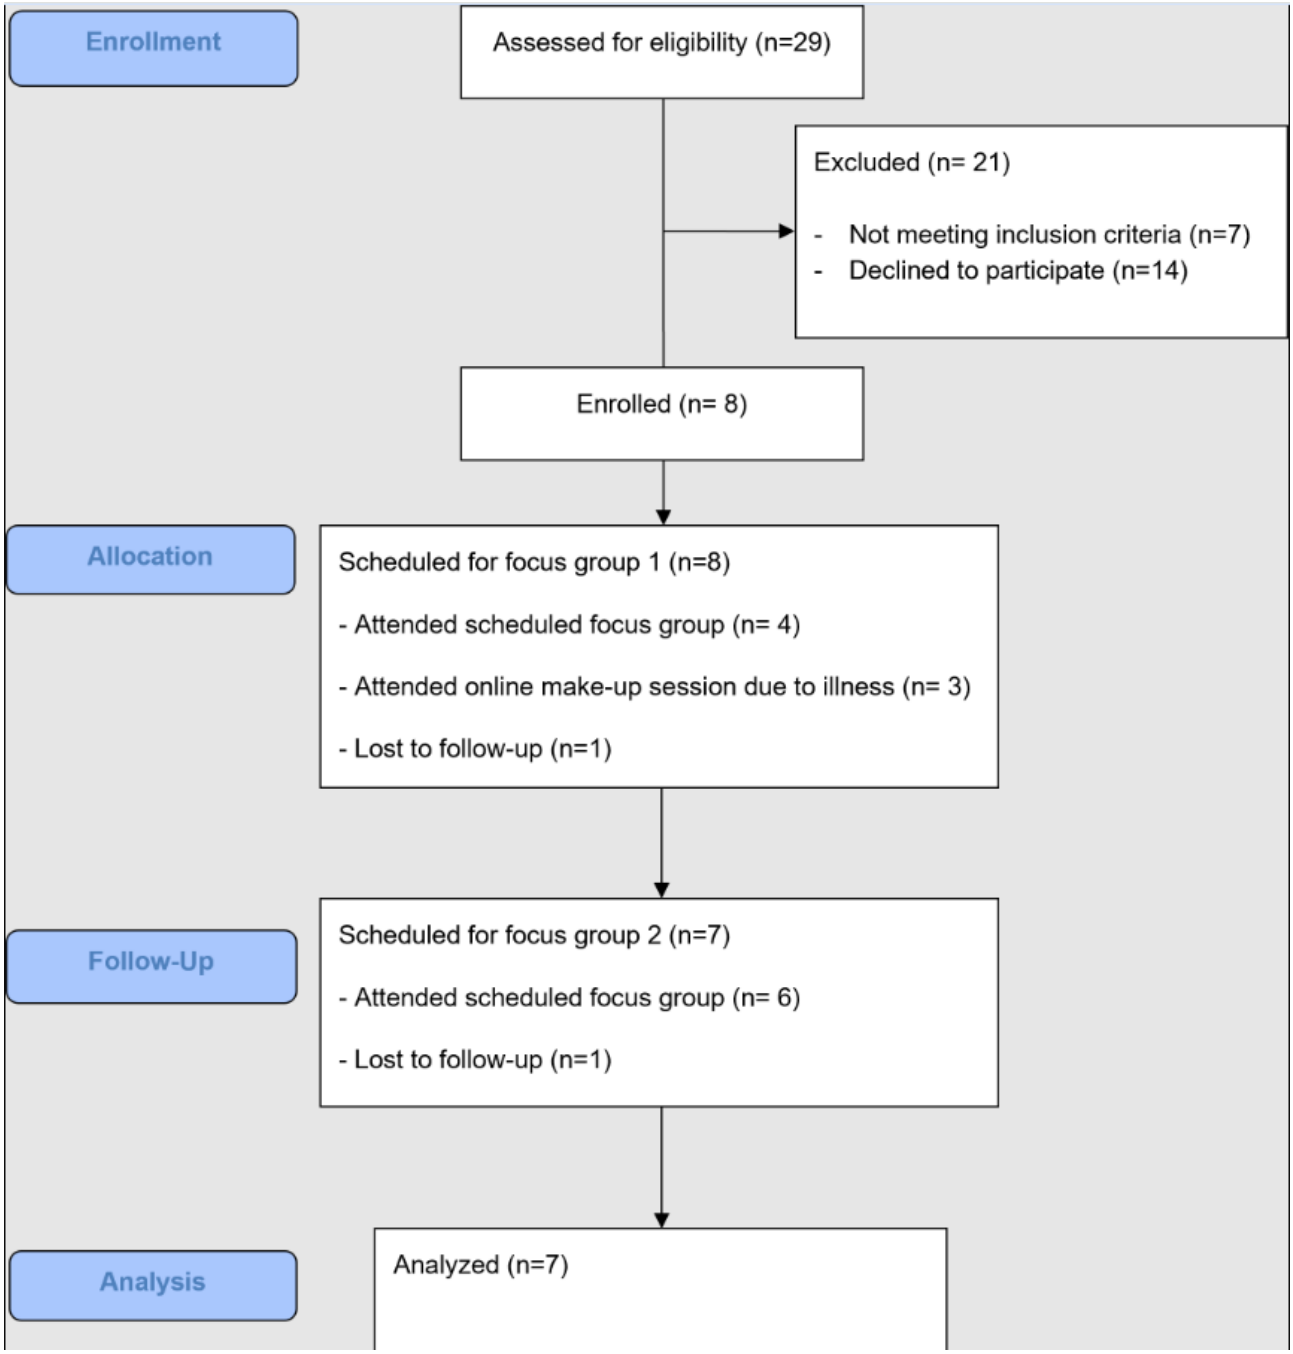
Researcher-Participant Relationship



There was an established relationship between the research team attending the focus groups (AA, EC, and LH) who had collaborated on the development of the original CIS [3]. There were no preexisting relationships between the research team and any of the participants. Ethical concerns relevant to this research context included the unequal power relationship between researchers and participants. In addition to informed consent and ethical review procedures, psychologist, LH, attended the focus groups with the expressed role of supporting participant well-being.

Participant Recruitment and Selection

We recruited participants aged 18 - 40 years who had current or past diagnoses of any ED. For safety and compliance, exclusion criteria were currently experiencing psychotic symptoms, bipolar disorder, and suicidality. Additionally, we excluded individuals who had previously completed the CIS. Participants were recruited using Meta advertisements, existing participant databases, and through local and national ED organizations (eg, InsideOut Institute, Australia & New Zealand Academy of Eating Disorders, and Scientific Work in Anorexia Nervosa & Other Eating Disorders).

Of the 29 who expressed interest in the study, 22 met eligibility criteria. A total of 7 participants were selected and attended the first focus group, with 6 participants returning for the second focus group (Figure 1). Focus groups were held in person at Monash University between June and July 2023. Participant characteristics are reported in Table 1.

Figure 1. Design-phase participant flowchart.

XSL•FO
RenderX

The figure depicts a flowchart of participants who were enrolled, screened, allocated, and completed the ideation and design phase of the CIS redevelopment project from April to July 2023.

Ideation and Design Data Collection

Participants provided informed consent and completed screening and enrollment questionnaires using REDCap (Research Electronic Data Capture) [127,128]. Eligible individuals were contacted to confirm eligibility and be briefed on focus group procedures. Participants attended 2 focus group sessions, scheduled 1 month apart, which were cofacilitated by EC and AA, and attended by a game development professional and a psychologist (LH). Each focus group lasted 3 hours.

Participants were asked open questions to generate ideas for a gamified cognitive assessment tool that should appeal to diverse audiences with EDs and commonly co-occurring conditions (refer to section S4 in Multimedia Appendix 1 for focus group guides). To avoid influencing ideas, participants were not shown visuals depicting the original game. Instead, brief details of the CIS's general purpose, structure, and basic schematics were shared. A brief feedback survey collected their group and research experiences, such that improvements could be made for the second session (section S4.2 in Multimedia Appendix 1) [129-131]. In the second focus group, we honed design concepts and features and clarified key topics of conversation from the first session. Following the second session, participants were again invited to complete a brief survey to evaluate their experiences. Throughout these sessions, the facilitators, psychologist, and technology professional engaged in active discussions and whiteboarding with participants, prompting iterative review, expansion, and refinement of ideas. Sessions were audio recorded using Echo360 or Zoom software, and transcripts were redacted to protect anonymity.

Ideation and Design Data Analysis

Data were analyzed according to the 6 stages of reflexive TA by Braun and Clarke [114]. An inductive approach was used to explore participants' ideas and perspectives, while acknowledging the positivist, cognitive-behavioral perspective inherent in psychological assessments and the constraints imposed by the existing validated task structure. Reflexive TA further acknowledges that themes are actively generated in a subjective process, whereby the researcher interprets meaning from participant statements [126,132]. Final transcripts were coded by EC using NVivo 14 (Lumivero) [133].

In the first stage of reflexive TA, *deep familiarization*, transcripts and recordings were reviewed. The second stage involved *initial coding*, whereby an open coding approach to label segments of text within the data was used. In stage 3, *generating themes*, codes were grouped into categories to generate the main themes. Stage 4 involved *reviewing themes* to ensure a rich understanding of the data, whereby AA, LH, and CM were consulted to provide feedback on the drafted themes and possible interpretations. Themes were further refined in stage 5, *theme finalization*. Finally, stage 6, *interpreting and reporting*, involved the research teams' continued revision of the codes and themes during the write-up phase.

Production Phase

Research Design Overview

The production phase involved implementing the design ideas and guiding principles defined in the Ideation and Design Phase section. Here, we engaged *Noble Steed Games* (NSG) as an expert partner to design and produce the revised CIS. The new CIS was produced in an agile development process, involving 6 week-long iterative and collaborative sprints between NSG and the research team between March and April 2025. This approach was informed by guidelines and case studies concerning the pragmatic integration of user-centered design and LE co-design principles with the challenges of producing highly technical solutions that require expert knowledge, within a context of limited time and resources [88,92,105,106].

Production Participants

The production team involved 4 members of the NSG team, alongside the first author (EC). A play testing team was formed to assess usability and the extent to which the new CIS achieved user requirements and research objectives [119]. This team involved EC, CM, 3 student researchers, and 4 members of the AVG research group. All play testing members were familiar with LE co-design guiding principles and design ideas, and with the original CIS.

Production Procedures

NSG used CIS *Choices in the Wild West*, co-designed guiding principles, and cogenerated design ideas to inform their production of the new version of the CIS, referred to as *Papillon Park* (section S4, Multimedia Appendix 1). For the *Reflection* mini-game, NSG sourced copyright-free images from Unsplashed and Pexels, which were processed by EC to standardize size, color, contrast, and luminance properties using the *magick* package in R (R Core Team) [134]. During each sprint, NSG produced a specific deliverable (eg, wireframes for each mini-game; scene, stimulus, and character art; and scripts and instruction text), which were reviewed and refined in consultation with EC. Once available, playable prototypes were deployed to secure Monash servers, such that game functionality and data capture could be tested. These prototypes were further refined in response to play testing feedback, for example, by modifying stimulus timing and on-screen positioning to ensure target constructs were being effectively assessed. Following completion of the agile production period, ad hoc updates and refinements were defined by EC and implemented by NSG in response to LE play testing and evaluations. No research data were collected or analyzed during this phase.

Evaluation Phase

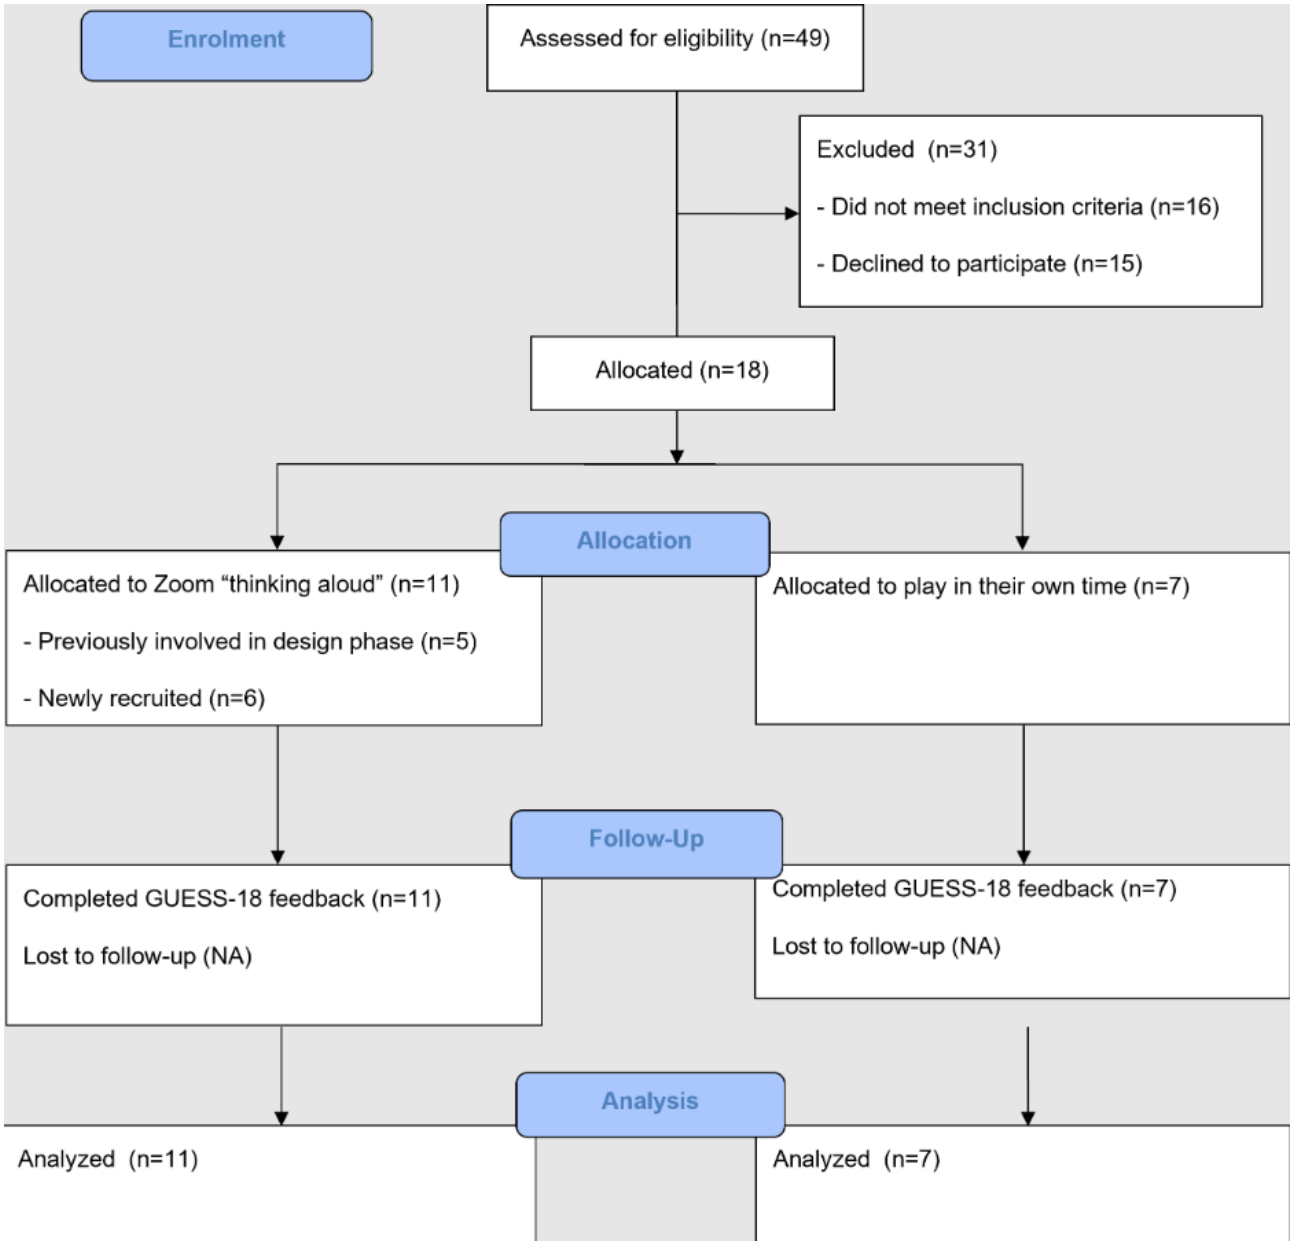
Research Design Overview

The evaluation phase aimed to explore user experience satisfaction and the extent to which the design of CIS *Papillon Park* met user requirements [87,119]. To achieve these goals, we adopted a convergent mixed methods design. The GUESS-18 questionnaire was selected as an effective tool for quantitative data collection [135,136] and analyzed using descriptive and inferential statistics [116,137,138]. "Thinking aloud" was selected as an appropriate method for qualitative data collection,

XSL•FO
RenderX

whereby participants provide a verbal commentary while playing the games [139,140], which was analyzed using deductive and inductive cycles of TA. While this method departs from the "Big Q" paradigm described by Braun and Clarke [115], this approach allowed us to answer our research questions by structuring our analysis according to the user requirements defined during the ideation and design phase, and is well-suited to convergent mixed methods approaches [116].

Evaluation Study Participants



Participants

We sought to retain participants from the ideation and design phase while recruiting additional participants to expand our sample size and composition. We planned to divide this sample into 3 approximately equal groups to examine whether participation in the ideation and design phase, or the process of "thinking aloud" while playing, influenced subsequent quantitative evaluations of user experiences and satisfaction.

Participant Recruitment and Selection

Participants who contributed to the ideation and design phase were invited to the present phase via email. Additional participants were recruited through Meta advertisements and existing participant databases. Identical inclusion and exclusion criteria used in the ideation and design phase were used. Of the total, 5 of the ideation and design phase participants returned for the evaluation phase. Of the 43 additional recruited participants, 27 met eligibility criteria, and 13 completed the study. All 5 participants from the ideation and design phase were invited to attend 1-hour Zoom sessions to play CIS *Papillon Park* while providing "thinking aloud" feedback. Newly recruited participants were split into 2 groups, such that 6 also completed Zoom "thinking aloud" sessions, and 7 played the game in their own time, according to their availability and preferences (Figure 2). Sessions took place in April 2025.

RenderX

Sample Size, Power, and Precision

We did not perform an a priori power analysis. The target sample size of 21 participants was instead determined by the depth-oriented approach of the qualitative component of the evaluation phase, in accordance with established guidelines for this methodology and previous research [78,123].

Setting

Participants were provided with a link to access the CIS *Papillon Park* online and were instructed to use a computer with a keyboard (ie, not a phone or tablet). Participants were informed that the CIS would take approximately 40 minutes to complete and to complete the games in a single sitting. Participants completing "thinking aloud" sessions were provided with the link during their Zoom session, while those playing in their own time received it via email through REDCap. The 3 mini-games were presented in a randomized order, and server logs were used to confirm completion.

Quantitative Measures

The Game User Experience Satisfaction Scale, short version (GUESS-18) was used to gather quantitative feedback [135,136]. GUESS-18 is a psychometrically validated tool with 9 subscales that assess how various game attributes contribute to user satisfaction (Table S3.1 in Multimedia Appendix 1). Participants rated 18 items (eg, "I think the game is visually appealing") on a 7-point scale from 1 (*strongly disagree*) to 7 (*strongly agree*) with a neutral midpoint of 4 (*neither agree nor disagree*). One item ("I feel bored while playing the game") is reverse-coded. Subscale scores (1-7) are calculated by averaging numeric ratings for component questions, and a composite score (9-63) is obtained by summing subscale scores, with higher scores indicating greater user satisfaction. In this study, internal reliability for the composite scale was excellent (Cronbach α=0.93, Zumbo ordinal α=0.95). For subscales, refer to Table S3.2 in Multimedia Appendix 1.

After critically analyzing the alignment of the GUESS-18 subscale constructs to the co-designed guiding principles in the ideation and design phase (Table S3.3 in Multimedia Appendix 1), 2 items were developed to explore theme, *No Trigger Warnings Needed* ("I feel the games are appropriate for someone with lived experiences like mine," "I feel the games are appropriate for someone with lived experiences like mine," "I feel the games are triggering for someone with lived experiences like mine" [reverse coded]). Space for additional open-text feedback was provided at the end of the instrument.

Evaluation Data Collection

Participants provided informed consent and completed screening and enrollment questionnaires online via REDCap [127,128].

Qualitative Data Collection

Of the 18 participants, 11 confirmed their availability for "thinking aloud" sessions to take place via Zoom [139]. During the session, participants were asked to access CIS *Papillon Park* online and provide a running commentary of their thought process as they proceeded through the game. Participants were advised that the facilitator (EC) would simply observe unless they became quiet, in which case a prompt would be provided. "Thinking aloud" sessions were audio- and video-recorded and transcribed using Zoom.

The remaining 7 participants preferred to complete CIS *Papillon Park* in their own time and were invited to provide qualitative feedback using a free text box in the online feedback questionnaire.

Quantitative Data Collection

After completing the CIS *Papillon Park*, participants were directed to complete the GUESS-18 questionnaire and the additional 2 items concerning the appropriateness of the tool for individuals with lived and living experiences of EDs and general mental health concerns (section S3.1 in Multimedia Appendix 1).

Evaluation Data Analysis

Qualitative Data Analysis

Transcripts were reviewed for accuracy and uploaded to NVivo 15 for analysis [141]. First author, EC, undertook deep familiarization with the data. Data were coded to first identify technical or usability issues that could be rapidly resolved by NSG (eg, statements concerning misunderstandings of game instructions). EC then conducted deductive and inductive cycles of TA [116]. The co-designed guiding principles were used as a coding framework for deductive TA, with statements coded for insights into the extent to which the new tool met these user requirements. Data were then revisited with an inductive lens, seeking further insights into user experiences that had not been captured during deductive analysis. Finally, EC and CM *reviewed* codes, initial themes, and interpretations for clarity and narrative consistency. Themes continued to be *refined* during the *write-up and reporting* phase.

Quantitative Data Analysis

GUESS-18 responses were scored using Microsoft Excel and analyzed and visualized in R Studio [142]. There were no missing data. Means and SDs were calculated for total user satisfaction and for each of the 9 subscales according to published guidelines [135,136]. Exploratory omnibus ANOVA tests were used to examine group differences in GUESS-18 overall and subscale satisfaction between the 3 groups of participants (ie, designers, newly recruited "thinking aloud" participants, and those who completed the games in their own time).

Data Integration

The integration of qualitative and quantitative feedback data was intended to provide greater value than each alone [143]. Qualitative evaluation using a psychometrically sound tool facilitates comparison with other serious games and gamified psychological assessments, which is challenging when using only qualitative data, but lacks depth, and does not distinguish between the 3 component games of the overall tool. Conversely, qualitative data allowed us to understand *why* users felt satisfied or dissatisfied with particular elements of their experiences, and the variability in their experiences between the 3 mini-games. To achieve these goals, we aimed to synthesize and interpret qualitative and quantitative data at individual, group, and sample

XSL•FO
RenderX

levels, and present an integrated narrative of our findings in the results section [137].

Ethical Considerations

Ethical approval for all research procedures was provided by Monash University Human Research Ethics Committee (reference 29393), and all research participants provided informed written consent for the data collection and analysis described herein. Data were deidentified to protect participant privacy and confidentiality. No participants can be identified by the information included within the main paper or supplementary file, where participants are referred to individually (eg, in quotations), pseudonyms have been used. Participants with LE were compensated Aus $60 (approximately US $44) for each focus group (or Aus $20 [approximately US $15] for Zoom make-up sessions) and Aus $40 (approximately US $29) for the evaluation phase.

Results

Ideation and Design Phase Results

Overview

In total, three overarching themes were defined with a total of 9 subthemes that describe guiding principles for redeveloping the CIS: (1) aesthetic appeal and a progressive story create an immersive user experience; (2) achieving individual and collaborative goals fosters player motivation and purpose; and (3) relatedness, variety, and autonomy: fulfilling key psychological needs enhances user engagement. The meanings of these themes and their subthemes are explained below, with illustrative quotes provided in Table 3.

XSL•FO
RenderX

Table . Summary of co-designed guiding principles and illustrative focus group quotes.

Theme and subtheme	Illustrative quotes
Aesthetic appeal and a progressive story create an immersive user experience	
1.1 An interactive journey	• "So, there's a narrative, overarching kind of structure that you have to follow, and the entire story is just the mission." [Ang] • "I like collecting things along the way … or like, just like interacting with objects in a way that doesn't necessarily add anything to your character or development, or anything, but just little interactions that are there." [Erin]
1.2 Whimsical worlds have broad appeal	• "There are a lot of like popular games that take a lot of elements of the real world, but then they adapt it into like their own art style, I guess, like aesthetic. It's just, very NICE to look at. And yeah, I guess the animations and the storyline, it's just very relaxing." [Georgie] • "I guess, I just find them very happy and appealing to look at … whimsical, is kind of the word that comes to mind.…. I guess it's a bit childish, but it's like happy childhood. It's sort of like happy childhood memories. Yeah, it's got that whimsical nature to it, but it still blends in a bit of reality." [Fiona] • "I think when I'm playing games, quite often, I would be doing it to kind of get out of the real world. I think a lot of people who just use games as like a form of escapism." [Chloe]
Achieving individual and collaborative goals fosters player motivation and purpose	
2.1 Growing and "leveling up"	• "I really like being able to level up and acquire certain skills." [Erin] • "With the experience, then you sort of level-up… you can purchase items that help you … or certain sorts of clothing, hairstyle, something like that." [Ang]
2.2 A prosocial purpose	• "For me, that's a quest … you find the person or the clues to save humanity." [Bethany] • "Oh yeah! Rescuing the towns people! That would be so cute!" [Fiona] • "I was thinking of growing something, potentially." [Dylan] • "Yeah, whether it's a garden or a forest. Just … more plant life, the better you do." [Dylan] • "I feel like it's all in a game. You know that this is virtual. It's not real to me. I think others probably feel differently though." [Ang]
2.3 Positive insight	• "I was thinking perhaps keeping it more towards, say, benefit versus less benefit as opposed to danger versus no danger." [Dylan] • "I like that it's not catastrophic, you know? You don't lose entirely." [Ang] • "Interpretation is more helpful. A leader board is a terrible idea." [Bethany] • "Because it just has that social comparison aspect." [Erin] • "Yeah, even though I'm trying, everyone else is doing so much better than I am." [Bethany]
Relatedness, variety, and autonomy: fulfilling key psychological needs enhances user engagement	
3.1 Batman needs his Alfred	• "You're Batman, and you need your Alfred." [Bethany] • "I think belonging to a group does enhance a game, whether it's a community or a gang or whatever. It creates more responsibility. And I really like to be able to get to know the people in your community or team, or whatever, and them all having their own little personalities and stories." [Erin] • "A diverse set of characters is more engaging, and each of the interactions adding to the storyline, adding details to this world. I feel that would make it more engaging." [Georgie]

XSL•FO
RenderX

Theme and subtheme	Illustrative quotes
3.2 Variety is the spice of game-life	• "I think, depending on how often in the game this is going to occur, [it's important] for it to not be the same every time …. I think I'd get a bit annoyed." [Erin] • "I like games with time limits …" [Chloe] • "Whoa, so stressful!" [Ang] • "Yes but keeps it really interesting." [Chloe] • "Where it's not too difficult where it's frustrating, but it's not too straightforward." [Georgie]
3.3 Choose your own adventure	• "I was thinking of a Harry Potter game I used to play when I was a kid, and you could, choose different wands. And that would give you different abilities." [Chloe] • "Yeah, Like different characters, different paths? Yeah. It's like the first game that I ever played was Pokémon. You choose the different sort of Pokémon, right? And then based on the different type, you have different abilities and so on." [Ang] • "I like changing the environment … in terms of customisation." [Bethany]
3.4 No trigger warnings needed	• "The main thing that I was thinking about was in some games you just get a little bit too much freedom with customizing your character. Most of the time people just end up creating, I guess what they wish they looked like. But then it just gets a bit triggering or problematic once you get to adjust heights or body shape and size and stuff. So, yeah, I feel too much customization of characters in games would be triggering." [Georgie] • "I think diversity in size, shape, all that - that's a big one. Size and shape in video games, there's not much diversity. So, I think that's really important." [Erin] • "I think there's going to be a lot less issues around inclusivity and stuff if you're just playing from behind the camera." [Erin] • "I think, if you're the one looking in, you've got less issues, with things like gender representation. If you're representing other people or characters, they need to be diverse." [Bethany]

Theme 1: Aesthetic Appeal and a Progressive Story Create an Immersive User Experience

Subtheme 1.1: An Interactive Journey

Participants described a preference for first-person game-play and a sense of advancement and forward momentum within a cohesive narrative structure. For example, the playing character would proceed through a journey or quest across a series of tasks, completing these as missions toward their overall goal. Participants also agreed that the playing experience would be improved by exploring varied environments as they progressed through the story.

Subtheme 1.2: Whimsical Worlds Have Broad Appeal

Participants described wanting the games to have an appealing art style, with characters and environments that are cartoonish, simple, and colorful, and a playing experience that is gentle and accessible. They consistently drew on examples such as Nintendo's *Super Mario* and *Animal Crossing*, and there was consensus that these features appeal to "gamers" and "nongamers" alike. Participants described a sense of escapism in these whimsical worlds as a key attraction to gaming. They also described the enjoyment of completing relatively simple or familiar tasks that have been rendered funny, quirky, surprising, or novel by the whimsical and cartoonish environment, or by the abilities (or lack thereof) of their playing character.

Theme 2: Achieving Individual and Collaborative Goals Fosters Player Motivation and Purpose

Subtheme 2.1: Growing and Leveling Up

Participants discussed the most meaningful goals and rewards to be gaining knowledge, skills, and expertise. These gains might contribute directly to the overall game goal, achieve personal growth, or be used to augment the character or their environment.

Subtheme 2.2: A Prosocial Purpose

Participants resonated with having an overall objective that helped others, although one participant felt this was less important. Participants agreed, however, that rewards should be nonmonetary, and that in-game "currency" should be instrumental to achieving their prosocial goal, rather than "capitalistic." Examples included rescuing townspeople, growing plant life, or taking care of realistic or mythical animals.

Subtheme 2.3: Positive Insight

Participants discussed that leaderboards and comparisons to other players' performance could be motivating; however, consensus was reached that feedback should avoid social comparison. The participants agreed that poor performance

XSL•FO
RenderX

should be "safe," such that no in-game characters would be harmed or imperiled if the player gained relatively little in-game currency or points. As much as possible, outcomes should be neutral or positive and avoid damage or significant losses, and feedback should be normalizing and supportive.

Theme 3: Relatedness, Variety, and Autonomy: Fulfilling Key Psychological Needs Enhances User Engagement

Subtheme 3.1: Batman Needs His Alfred

Participants felt games played within a mental health context should incorporate positive in-game relationships. One example was through a constant supporting presence of a sidekick, or as one participant stated, "*You're Batman, and you need your Alfred.*" In addition, participants felt the playing character could be part of a virtual team or be depicted engaging positively with nonplayable characters (NPCs) from the broader community. This subtheme, therefore, is closely related to pursuing a prosocial purpose.

Subtheme 3.2: Variety Is the Spice of Game Life

It was emphasized that incorporating as much variety as possible within the constraints of the task structure would be key to maintaining player motivation and would prevent the player experience from becoming monotonous. Participants also felt an appropriate level of difficulty and challenge to be important; while too little can be boring, too much becomes stressful and a barrier to engagement.

Subtheme 3.3: Choose Your Own Adventure

Participants requested the ability to make customizations and to interact with or construct the environment around them. These experiences were felt to create richness and immersion in games, as well as providing a sense of autonomy that fosters active engagement.

Subtheme 3.4: No Trigger-Warnings Needed

To maintain psychological safety, the participants agreed on the importance of avoiding the ability to customize or alter human forms and of diversity in the depiction of human and human-like characters. Avoiding stimuli or gameplay relating to food and eating, body image, alcohol, drugs or gambling, violence or crime, and gendered, racial, or cultural stereotypes was also discussed as critical for individuals who share their lived and living experiences.

In addition to the themes described above, the focus groups generated many specific ideas for each of the component games, which were summarized and communicated to the game developers (section S4 in Multimedia Appendix 1). Importantly, the focus group participants also evaluated their ideation and design phase experience positively (section S4.2 in Multimedia Appendix 1).

Production Phase Results

To achieve the co-designed themes while maintaining the validated structure of the original CIS, our game development partner produced the CIS *Papillon Park* with 3 component mini-games featuring a cohesive community garden theme. Cognitive Impulsivity is assessed as users proceed through *Horticulture Hero* (attentional control), *Fauna Finder* (reflection), and *Verdant Venture* (feedback monitoring or shifting), which can be presented in set or randomized order. Each game occurs within a unique garden environment and begins with a brief practice mode before the scored blocks (Figure 3).

Figure 3. Introductory screens for *CIS Papillon Park* component mini-games: Horticulture Hero (attentional control), Fauna Finder (reflection), and Verdant Venture (feedback monitoring/shifting).

The figure depicts 3 colorful cartoon images of a greenhouse workbench, each overlaid with 3 images from the mini-games, explaining their goals and response keys.

Users are led through the games by 2 virtual helpers—"Grandma Pixie" and "Winston" (Figure 4), and interact with diverse NPCs who reinforce their progress and the positive impact it has on the community. At the conclusion of each mini-game, users receive their total points and are offered a choice between 2 rewards to decorate the community garden. Their progress is visually depicted with their chosen reward and new growth.

The figure depicts an Australian ringtail possum wearing glasses and a yellow bow tie seated on a stool, alongside an older adult woman dressed in pink and leaning on a wooden walking stick. These virtual helpers provide instruction, performance feedback, and companionship to the user throughout *CIS Papillon Park*.

Table . Summary of thematic evaluations and illustrative quotes.

Theme and subtheme	Illustrative quotes
Aesthetic appeal and a progressive story create an immersive user experience	
1.1 An interactive journey	• "Overall, I quite liked the flow of the storyline and the characters that I interacted with…. It's a very well-developed experience." [Liza] • "I like that it's got a little ongoing story to kind of …. I feel like it like with that, and mixing things up, it kind of adds to that gamified element by like giving you something to work towards." [Jay]
1.2 Whimsical worlds have broad appeal	• "I found the graphics and background music/side effects of the game to be very calming and immersive." [Lily] • "I like the way that this is designed. I've done similar things to this before, where, um, I guess they're assessing a similar sort of thing where it's hit the space bar when a particular number comes up on screen. But I think the way that this is … visually it's a lot more ... interesting, which is nice. It's got nice bright colors, which makes it a little bit more fun to look at, versus your kind of black and white numbers on a screen." [Jay]
Achieving individual and collaborative goals fosters player motivation and purpose	
2.1 Growing and "leveling up"	• "You probably get a little better at this game as it goes on … as you get more familiar with it." [Tom] • "The 'practice' rounds of each game helped allay any anxiety I had about learning how to play the game and I found them all quite easy to pick up quickly." [Olivia] • "I would say that overall, it's an interestingly positive experience, because, firstly, it's not a steep learning curve. Not at all. I like and how simple it is, and how easy it is to pick up." [Ang] • "It did make me disheartened to not be able to figure out the pattern for this game and made me question whether I wasn't smart enough." [Millie]
2.2 A prosocial purpose	• "[The NPC's] were great. I think they were all very likable." [Jess] • "Maybe more people will come and visit and bring me [Winston] presents … I want that!" [Grace] • "I'm wondering if these random visitors are gonna come back into the game, - if they like if they play a role, or if they are just … there." [Erin] • "Grandmother's a bit patronizing, isn't she?" [Bethany]
2.3 Positive insight	• "The sound effects when I got answers right/wrong were very cute … and I felt a tinge of sadness when getting an answer wrong, but I didn't inherently feel upset for the rest of the game." [Liza] • "I wouldn't say it's easy not to beat yourself up about it …. but I like how low stakes this is." [Ang] • "I was left wondering how I had performed versus other people playing the game in this study." [Liza]
Relatedness, variety, and autonomy: fulfilling key psychological needs enhances user engagement	
3.1 Batman needs his Alfred	• "I think the art is a really good motivator because you get to see little Winston and Grandma Pixie … Who doesn't like a happy Winston?" [Alex] • "I like his happy sound … if you're happy, I'm happy." [Grace] • "That's three 200's in a row, Winston. I hope you're happy, little buddy." [Ang] • "I'm gonna end up in the negatives. Sorry, Winston." [Lily]

RenderX

Theme and subtheme	Illustrative quotes
3.2 Variety is the spice of game-life	• "The [horticulture hero] game was interesting and I liked that the plants changed each round." [Liza] • "It's nice to see the variety of points change this time" [Alex] • "I enjoyed the blurry animal guess game most - it wasn't the same choices repeated and it got you to engage cognitively with time urgency." [Millie] • "I feel like the whole design of this game is just to test my patience!" [Jess] • "[There were] too many rounds to make it to the next stage. It became quite tedious, boring and irritating." [Jo] • "If I was playing this game under normal circumstances, like at home, I might just turn it off, because it's really long." [Chloe]
3.3 Choose your own adventure	• "Oooh, there's a bird or a mushroom … I want the bird. (Gasps). It's a bird fountain! Oh my gosh that's so cool. OK, yes, I agree, wonderful choice, I know!" [Grace] • "That's cute … I like how you can customize it." [Erin] • "In the blurry game [Fauna Finder] … I felt I could actually engage and make a difference rather than something allocated/randomized." [Lexi] • "The first game was confusing as it was not clear what made each plant a successful choice [and why there wasn't 100 points, but only − 100, 50 and 200] and made me think the success was randomized like a gambling game rather than anything indicative of your own performance and choices." [Alex]
3.4 No trigger warnings needed	• "I really like the characters around here, because I can see that a lot of thought's gone into their design.... Very interesting gender-neutral choice." [Ang] • "It was nice that there was like a diverse range of different people that came in." [Fiona] • "The choice of animals - since you've got such realistic pictures - gorgeous for animal lovers, and they're not generally one's people get too icked out about - possibly the mice, but, like, if you were showing pictures of snakes, I wouldn't be able to play." [Bethany] • "I wonder what would happen to somebody who had a phobia of frogs." [Ang]

Theme 1: Aesthetic Appeal and a Progressive Story Create an Immersive User Experience

Subtheme 1.1: Interactive Journey

Perspectives concerning the game story, context, and environment were consistently positive. Participants enjoyed the overall story and community garden theme, and that each game took place within a different environment to provide variety and achieve the desired sense of progression.

Subtheme 1.2: Whimsical Worlds

All participants praised the art style and felt the visual and sound designs enhanced their playing experience. Participants described the designs as appealing, calm, and soothing, and as effectively "drawing players in." They felt these designs were key to maintaining their motivation and drew positive comparisons to standard cognitive assessments they had experienced.

Theme 2: Achieving Individual and Collaborative Goals Fosters Player Motivation and Purpose

Subtheme 2.1: Growing and "Leveling Up"

Participants described feeling that they were able to learn and improve their skills in positive terms. However, the degree to which participants endorsed this feeling varied across the 3 mini-games; the most positive statements related to Fauna Finder, which participants felt was more skill-based, and the more negative statements related to Verdant Venture, which participants tended to find frustrating.

Subtheme 2.2: A Prosocial Purpose

The community NPCs were found to be likable and appealing, and participants enjoyed seeing their achievements benefit Winston, their virtual companion. However, while some participants enjoyed interacting with the NPCs and learning that their performance was benefiting the community, others did not connect with this intended feature or found the NPC interactions to be protracted. Grandma Pixie's communication style also inspired some more polarized responses.

XSL•FO
RenderX

Subtheme 2.3: Positive Insight

Participants felt the game created a gentle, low-stakes environment that still engaged them emotionally and cognitively—enough to care about their performance, but not enough to feel stressed—and felt their interactions with Winston effectively supported this. Participants provided more mixed feedback relating to the lack of context for point totals; some participants wanted to understand their performance in comparison to other players or the maximum available, while others appreciated that this was not a feature.

Theme 3: Relatedness, Variety, and Autonomy: Fulfilling Key Psychological Needs Enhances User Engagement

Subtheme 3.1: Batman Needs His Alfred

All participants responded positively to Winston's companionship. Participants commented that they were motivated to perform on behalf of Winston, engaging emotionally with his audio and visual performance feedback.

Subtheme 3.2: Variety Is the Spice of Game-Life

Participants reported high enjoyment, engagement, and motivation when stimuli, responses, and rewards were varied, and when they felt their behavior was consequential. As with *Growing and leveling-up* above, these experiences varied across the mini-games, with participants typically finding Horticulture Hero to be easy but boring, Fauna Finder to be the most purposeful and engaging, and Verdant Venture to be the most difficult, random, and confusing. Moreover, 2 participants felt the game was overall too long.

Subtheme 3.3: Choose Your Own Adventure

Although opportunities for customization were limited, the ability to select from available rewards and to see those rewards depicted as garden decorations was appreciated and enhanced player engagement and fulfillment.

Subtheme 3.4: No Trigger Warnings Needed

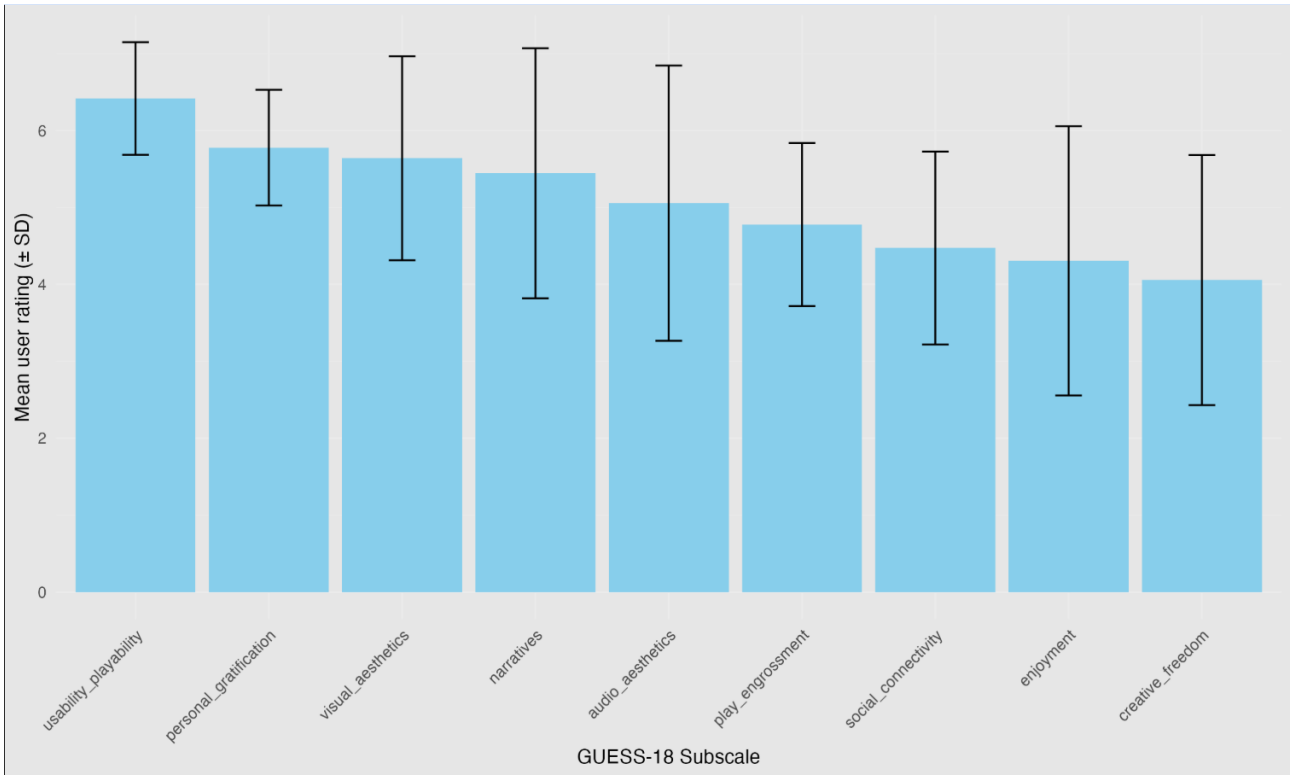
Finally, participants praised the diverse character depictions and "wholesome" gameplay features. They felt the production phase had been attentive to inclusivity and emotional safety, while also highlighting the need to consider individual sensitivities to the animals depicted in *Fauna Finder*.

Quantitative Outcomes

Evaluations of the games were overall positive, with a mean GUESS-18 composite score of 45.9 (SD=9.85; 72.9%, 57.3 - 88.5), and subscale scores ranging from 4.1 (neutral) for "Creative Freedom" to 6.4 (agree-to-strongly agree) for "Usability or Playability" (Table 5; Figure 5). There were no significant differences in mean composite or subscale scores between the groups of participants who were involved in the ideation and design phase, those who completed the "thinking aloud" evaluation over Zoom, and those who evaluated the games independently (Table 5).

Table . Game User Experience Satisfaction Scale, short version user satisfaction survey results.

Measure	All (n=18), mean (SD)	Designers (n=5), mean (SD)	Zoom (n=6), mean (SD)	Own time (n=7), mean (SD)	Group differences (ANOVA)[a]	
					F test (*df*)	*P* value
Composite score[b]	45.9 (9.85)	47.4 (4.98)	42.4 (10.38)	47.9 (12.25)	0.55 (2, 15)	.59
Subscale scores[c]						
Usability or playability	6.4 (0.73)	6.7 (0.27)	6.3 (0.76)	6.4 (0.94)	0.52 (2, 15)	.60
Personal gratification	5.8 (0.75)	5.8 (0.76)	5.7 (0.88)	5.9 (0.75)	0.10 (2, 15)	.91
Visual aesthetics	5.6 (1.33)	5.8 (0.57)	5.3 (1.40)	5.8 (1.73)	0.22 (2, 15)	.81
Narratives	5.4 (1.63)	6.1 (0.82)	5.1 (1.77)	5.3 (1.98)	0.56 (2, 15)	.58
Audio aesthetics	5.1 (1.79)	5.5 (1.70)	4.9 (1.69)	4.9 (2.14)	0.19 (2, 15)	.82
Play engrossment	4.8 (1.06)	5.0 (0.35)	4.3 (1.21)	5.1 (1.21)	1.14 (2, 15)	.35
Social connectivity	4.5 (1.25)	4.6 (0.96)	3.9 (1.46)	4.9 (1.25)	0.94 (2, 15)	.41
Enjoyment	4.3 (1.75)	4.2 (0.76)	3.3 (1.72)	5.3 (1.89)	2.62 (2, 15)	.11
Creative freedom	4.1 (1.63)	3.7 (1.44)	3.8 (1.29)	4.6 (2.05)	0.55 (2, 15)	.59



[a]Achieved power for 1-way omnibus ANOVA tests was calculated as 0.74 using G*Power 3.1 (α=.05, sample n=18, 3 groups, and average effect size of *F*=0.76).

[b]Composite scores range 9 - 63 with neutral midpoint 27.

[c]Subscale scores range 1 - 7 with neutral midpoint 4; higher scores indicate greater user satisfaction.

XSL•FO
RenderX

Figure 5. Game User Experience Satisfaction Scale, short version subscale ratings.

The figure presents a bar graph depicting GUESS-18 subscale ratings for the full evaluation sample (n=18). Bars indicate mean ratings for each subscale, and error bars indicate the SD, arranged from the subscale with the highest user satisfaction (usability or playability) to the lowest (creative freedom).

Ratings for the additional questionnaire items concerning *No Trigger Warnings Needed* produced an overall mean score of 5.72 (SD 1.22). Ratings differed significantly by group ($F_{2,15}$=7.64; P<.01) with significantly higher ratings in the 2 groups providing "thinking aloud" feedback than in the group playing in their own time (scoring and ANOVA outcomes for these items are provided in Table S3.4 in Multimedia Appendix 1).

Integration

Qualitative and quantitative evidence converged to allow us to understand which design features and gamification elements were most effective in facilitating long-term user motivation and engagement. Specifically, both qualitative and quantitative data demonstrated that the "wholesome" environment, cohesive and progressive story, attractive visuals, and appealing audio created a positive emotional user experience, which in turn facilitated immersion and enjoyment.

Qualitative evaluations also complemented quantitative data by allowing users to explain *why* particular subscales were rated higher or lower. For example, the inclusion of virtual helpers, practice rounds, retries, a progress bar, a timer or speed element, and visual depiction of achievements were key to user motivation and underpinned the high levels of usability or playability and personal gratification. Similarly, qualitative feedback explained that perceiving the themes defined during co-design concerning desires for autonomy (*choose your own adventure*) and variety (*variety is the spice of game life*) to be lacking resulted in the lowest GUESS ratings for the "enjoyment" and "creative freedom" subscales. Importantly, qualitative feedback showed users perceived the 3 mini-games that form the CIS *Papillon Park* to vary according to these characteristics, as well as their perceived level of difficulty, such that user motivation and engagement varied significantly between each mini-game. This variability had not been captured in the quantitative user satisfaction ratings.

Qualitative and quantitative evaluations diverged in relation to the GUESS-18 ratings for social connectivity and the overwhelmingly positive appraisals of Winston. Further analysis indicated that lower ratings for social connectivity were associated with qualitative feedback that NPC interactions, and the game overall, were too long.

Discussion

We aimed to redesign and evaluate the CIS, a validated gamified assessment battery of cognitive impulsivity, through a sequential mixed methods approach to user-centered co-design, agile game development, and user-centered evaluation [3,89,106]. We first defined LE user requirements, generating themes and subthemes that described overall guiding principles, and producing specific design ideas. The agile game development process resulted in a functioning suite of gamified assessments, the CIS *Papillon Park*, being deployed to secure Monash University servers. During LE evaluation, our qualitative analysis confirmed that the new tool largely met the co-designed user requirements. Quantitative ratings aligned closely, showing the CIS *Papillon Park* achieved strong overall user satisfaction according to the GUESS-18 composite scale, with strengths in usability, narrative, visual and audio aesthetics, and personal gratification.

XSL•FO
RenderX

Escapism into attractive virtual worlds featuring cohesive narrative storytelling and accessible gameplay, and a sense of personal growth and achievement, were identified as critical themes and key strengths of the gamified assessment tool produced in this study. Aesthetic and narrative characteristics are well-known to increase immersion and pleasure in gaming [144,145]. Furthermore, the gamification mechanisms we incorporated to foster personal accomplishment, including tasks with clear goals and rounds, points and performance feedback, in-game rewards, and visible depiction of achievements, are some of the most commonly used [59,65]. These characteristics were the most strongly endorsed in the qualitative and quantitative evaluations, confirming the new games to be broadly appealing and fulfilling, and reinforcing previous research demonstrating the value of aesthetics and gamification to user engagement and satisfaction with cognitive assessments [63,64,146]. These principles also align closely with the theoretical grounding of gamification [56,57,61], tapping into cognitive and emotional mechanisms to generate intrinsic motivation to engage with CIS *Papillon Park* [58,59]. In the context of cognitive assessments, engagement and intrinsic motivation serve critical instrumental purposes, encouraging uptake and continued, authentic effort, and thus valid assessment outcomes [45,46,62,66].

We also incorporated gamification elements that expand on those most used in mental health interventions, for example, the presence of virtual helpers [65]. Winston, Grandma Pixie, and the community NPCs reflected key ways in which our participants characterized mental health and positive functioning, including affirming interpersonal relationships and the pursuit of prosocial goals. Difficulties in these areas are well-documented features of EDs [147-152]. For example, socializing problems, social isolation, and loneliness have been shown to have a detrimental, bidirectional relationship with ED symptoms [152,153], while social connectedness may protect against ED onset and facilitate recovery [154-156]. As such, re-engaging with interpersonal relationships and meaningful life pursuits form common targets of harm reduction models of care and psychosocial recovery support for individuals living with EDs [157,158]. Within a gaming context, social interaction and collaboration toward mutual, prosocial goals are recognized as key not only to player engagement but also to realizing psychological benefits from gaming [58,59,66,159,160]. While real-time, multiplayer cooperation cannot readily be recreated within the context of cognitive assessment, evaluations suggested we had been successful in modeling meaningful collaboration and prosociality through reinforcing interactions with an endearing “side-kick,” although somewhat less successful in achieving this goal through interactions with members of a broader virtual community [161,162].

A key insight that emerged from the integration of qualitative and quantitative evaluation was the variability in user satisfaction between the 3 mini-games that form the CIS *Papillon Park* [143]. In total, 3 key elements distinguished user satisfaction—perceived autonomy and self-determination, variety, and level of difficulty. Our synthesized evaluation showed that gamification elements, including practice rounds, retries, a progress bar, and timer or speed, were key to achieving a level of difficulty that maximized user satisfaction [59,73]. Perceived lack of variety, autonomy, and creativity received lower quantitative ratings and inconsistent qualitative evaluations. These findings aligned closely with a previous study, where enjoyment helped people keep playing and maintained performance in easy games, while motivation facilitated performance and enjoyment in difficult games [163]. These findings reflect the inherent conflict between the repetition and standardization needed to achieve valid and reliable data in cognitive assessments, and user goals such as novelty and self-directed exploration that make games fun and engrossing, highlighting the difficulty of balancing the constraints of structured assessments with engaging game elements [62,63]. They also indicate that combining multiple gamification strategies, whereby elements enhance or compensate for one another, may be important in determining long-term user engagement [52,164].

User-centered co-design approaches are now commonly used to design mental health services and interventions leveraging web, mobile, and artificial intelligence technologies [48,74,78,99,100,165]. Less commonly, these approaches can be used to design and evaluate valid and reliable psychological assessment measures [42,88]. In developing the CIS *Papillon Park*, we took on board growing impetus to meaningfully incorporate LE perspectives throughout the research process [95,129]. Respectfully collaborating with individuals with lived and living experience in both design and evaluation is therefore a key strength of this study, underpinning its novel contribution to the field. Through evaluation, we were able to confirm user design priorities had been faithfully represented at all stages of the research process and were present in the final product [111,166]. Importantly, in addition to defining what to include in the new product, the co-designed guiding principles defined what *not* to include. It is important to note that some gamification elements might be harmful to certain populations, as exemplified by discussions concerning a leaderboard in this study [59]. Gamification is inherently experiential and subjective [54]; therefore, gamification and user-centered design work most effectively together, such that users define which gamification elements will be most safe and meaningful for them [167]. By following up on user-centered co-design with LE evaluations, we confirmed CIS *Papillon Park* maintained psychological safety for individuals with LEs of EDs and mental ill-health [168].

In terms of limitations, our co-design framework and qualitative methodologies meant we collaborated with relatively small groups of participants, and our quantitative evaluation analysis was somewhat underpowered. However, we nonetheless aimed that they would be representative of the target populations for the resulting assessment tool. We were therefore pleased to engage with groups that comprised varied current and historical experiences with disordered eating, that represented a broad range of experiences of commonly co-occurring mental ill-health, and that encompassed diverse identities and personal characteristics. These sentiments were shared by our participants, who endorsed the co-design groups and research processes as positive experiences, emphasizing their inclusivity [129,130]. This project was undertaken in Australia with

XSL•FO
RenderX

participants of White European, White North American, and Asian ancestry; thus, its findings may be less relevant in other cultures. Our methodology incorporated various forms of expertise to achieve a practical goal of reimagining an existing cognitive assessment tool [101,104,116,169]. As such, we incorporate key principles of qualitative research but depart from certain canonical aspects of "Big Q" approaches [115,122]. Further methodological limitations include the challenges of integrating user-centered co-design and agile development in a resource-limited context [89,92,105,106]. In terms of the quantitative results, our ANOVA analyses were slightly underpowered, such that there is an elevated risk that we failed to detect differences in user satisfaction between groups.

Ultimately, this project intends to enhance the impact and reach of the CIS by facilitating its potential for clinical translation and adoption by end users [170]. Validated tools with streamlined administration and analysis pipelines that are well-accepted by users are urgently needed to support current moves toward transdiagnostic, dimensional, and individualized care, and address the significant treatment gap for individuals living with EDs and mental ill-health [171-174]. Importantly, such individuals who are experiencing cognitive challenges as part of their symptom profile are eager for these issues to be addressed in treatment, yet feel these needs are rarely met [35,175,176], experiences that were highlighted in our focus group discussions. Including objective assessment of cognitive impulsivity in a clinical context may thus allow practitioners to identify individuals who would most benefit from targeted cognitive interventions or augmented treatments, and to achieve data-driven personalization of treatment approaches [177-179]. Next steps will therefore involve a detailed psychometric evaluation of the CIS "Papillon Park," confirming it maintains the properties of the CIS "Choices in the Wild West," before dissemination. Additional qualitative research is also planned, engaging clinicians and LE participants as key stakeholders to co-design feedback reports and implementation strategies.

The unique contributions of this study include effectively blending user-centered co-design, agile game development, and theory-based cognitive assessment and gamification to reimagine a validated assessment tool. By following up on LE co-design with qualitative and quantitative evaluations, we identified a combination of aesthetics, gamification elements, and accessible playing experiences that maximized user satisfaction, engagement, and motivation while prioritizing psychological safety. This underscores the importance of gamified assessments in the mental health field providing opportunities for users to experience satisfaction of psychological needs, including autonomy, personal achievement, and social support. By effectively engaging users, CIS *Papillon Park* therefore holds promise to facilitate valid and reliable assessment of cognitive impulsivity in individuals experiencing EDs and common co-occurring mental health symptoms. Incorporating well-accepted objective cognitive assessment tools in routine clinical care is needed to support the individualization and prioritization of interventions, and thus support treatment engagement and recovery for these underserved conditions.

Acknowledgments

The authors declare that no generative artificial intelligence tools were used during the conduct of this research, nor in the preparation of this manuscript.

The authors wish to thank Noble Steed Games for their expertise and creativity in producing Cognitive Impulsivity Suite "Papillon Park" and acknowledge Torus Games for the original Cognitive Impulsivity Suite "Choices in the Wild West," and for their contributions to the focus group co-design process. EC thanks Assistant Prof Trevor Chong and Dr Justin Mahlberg for their guidance and support, and Kayla Flannagan for her assistance with participant recruitment. Finally, we extend our gratitude to the participants of this study for generously sharing their time and perspectives.

Funding

EC is supported by an Australian Research Training Program scholarship and by a TranslatED scholarship from the Australia Eating Disorders Research and Translation Centre funded by the Commonwealth Department of Health under the National Leadership in Mental Health Program. AVG is funded by an Australian National Health and Medical Research Council Investigators (grant 2009464), and the Australia Eating Disorders Research and Translation Centre funded by the Commonwealth Department of Health.
